PROs are the most suitable method for assessing the patient's perspective of their lower urinary tract, vaginal and bowel symptoms [26]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last three ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this fifth ICI review, the ICIQ modular questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.

III. RECOMMENDED PRO QUESTIONNAIRES

Grades of Recommendation for Questionnaires 2012

As with previous Consultations, the Committee continues to use three grades of recommendation. However, we have added a + sign to indicate when published content validity is available for an instrument:

- Questionnaires were 'highly recommended' and given a **Grade A** if the Committee found "Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with persons with incontinence. **Grade A + indicates there is additional evidence of *published* content validity."**

- Questionnaires were "recommended" and given a **Grade B** if the Committee found "Published data

indicating that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability). **Grade B + indicates there is additional evidence of *published* content validity."**

- Questionnaires were considered to have "potential" and given **Grade C** if the Committee found "Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing. **Grade C + indicates there is additional evidence of *published* content validity."**

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire's potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

As decided in the Fourth Consultation the recommendation will be to preferably utilise questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A or A+ questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

Should none of the modular questionnaires be deemed appropriate for specific research or clinical purposes, ICI's recommendation is to use a Grade A+ or A questionnaire as previously recommended. When no suitable instrument exists a Grade B or C questionnaire, performing additional validation as indicated prior to use if feasible, should be used.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label 'with rigor' allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups (see below).

IV. INTERNATIONAL CONSULTATION ON INCONTINENCE MODULAR QUESTIONNAIRE (ICIQ): WHAT IS THE ICIQ?

The ICIQ modular questionnaire was developed to meet the need for a universally applicable standard guide for the selection of questionnaires for use in clinical practice and clinical research [27, 28]. The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaire discussed in this section. It was recognised at that time that there were many good validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

An international advisory board was established to continue the development of the modular ICI questionnaire outside the limits imposed by triennial convening of the ICI Committee. Early discussions with the advisory board resulted in the decision to expand the concept to include wider urinary symptoms, bowel symptoms and vaginal symptoms. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The members of the advisory board of the ICI can be seen on the ICIQ website at www.iciq.net. The ICIQ modular questionnaire was then established. Researchers who have developed questionnaires that they would like to be reviewed by the advisory board for inclusion should send the questionnaires and relevant publications to www.iciq.net. The project is a series of living documents that will be continually updated.

1. AIMS AND OBJECTIVES

The ICIQ's objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient's lives. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

- To recommend high quality self-completion questionnaires according to evidence of validation as stipulated by the three prior ICI Committees;
- To promote wider use of questionnaires to standardise assessment of lower urinary tract and pelvic dysfunction and its impact on patients' lives, in order to;
- Facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research.

The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed, the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire/s was acknowledged. Collaborative efforts to develop new questionnaires are welcome and encouraged.

The ICIQ's international nature requires that linguistically validated translations are available. More than 50 language versions of various modules have been validated to date, conducted according to established protocol.

Fourteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers are able to select module(s) to meet the particular requirements of their study or clinical practice. In order to simplify this selection process, modules have been categorised as shown in **Table 1**. It must be stressed that although multiple questionnaires can and probably should be used they must be used in the format in which they were originally designed and the questionnaires cannot be merged together.

In recent years, increasing advances have been made in the area of electronic documentation, particularly with regard to patient care. It is recognised that questionnaires requiring written completion by hand may lack versatility and therefore prevent uptake of the ICIQ, hampering

Table 1. The ICIQ Modular Structure

		RECOMMENDED MODULES	OPTIONAL MODULES	RECOMMENDED ADD-ON MODULES			
	CONDITION	Symptoms		HRQL	Generic HRGL	Sexual Matters	Post-treatment
Core modules	Urinary symptoms	Males: ICIQ-MLUTS Females: ICIQ-FLUTS	Males: ICIQ-MLUTS LF Females: ICIQ-FLUTS LF	ICIQ-LUTSqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	ICIQ-Satisfaction*
	Vaginal symptoms and sexual matters	ICIQ-VS		ICIQ-VSqol*	SF-12		
	Bowel symptoms and quality of life	ICIQ-B			SF-12	Males: ICIQ-Bsex* Females: ICIQ-Bsex*	
	Urinary Incontinence	ICIQ-UI Short Form	ICIQ-UI LF*	ICIQ-LUTSqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
	CONDITION	B) Specific patient groups		HRQL	Generic HRQL	Sexual Matters	Post-treatment
Specific patient groups	Nocturia	ICIQ-N		ICIQ-Nqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	ICIQ-Satisfaction*
	Overactive Bladder	ICIQ-OAB		ICIQ-OABqol	SF-12	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
	Neurogenic	ICIQ-Spinal Cord Disease*			SF-12		
	Long-term catheter users	ICIQ-LTC*			SF-12		
	Children	ICIQ-CLUTS*		ICIQ-CLUTS qol*			

Gray: In development; black: Grade A

attempts to promote standardisation of evaluation. Evaluations of electronic ICIQ modules are currently underway. Cognitive interviewing is being conducted among the potential populations of interest to ensure the appropriateness of these formats, for example, adults with varied lower urinary tract symptoms [11]. Quantitative comparison studies of equivalence are also planned to ensure the robustness of their measurement capabilities is not compromised.

In this chapter, questionnaires forming part of the ICIQ modular format are referred to as those preferred for usage. Although many of the modules are Grade A or A+ questionnaires, others are still under various phases of development and are graded appropriately. Questionnaires that are in early stages of development and have yet to reach Grade C are described as "in development". Where an ICIQ module is not available it is recommended that a Grade A or B or C questionnaire is used.

2. ICIQ MODULES

a) Core Modules

Questionnaires to assess the core symptoms and impact on health related quality of life (HRQL) of lower pelvic dysfunction are contained in this section, in addition to impact on sexual matters. Core modules (**Table 2**) provide evaluation of:

- Lower urinary tract symptoms
- Urinary incontinence
- Vaginal symptoms
- Bowel symptoms

Each symptom module is intended for the comprehensive yet succinct measurement of symptoms and associated 'bother'. The bother item attached to each symptom enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone. The HRQL questionnaires cover specific issues that are a consequence of symptoms, such as life limitations and emotional impact.

b) Specific Patient Group Modules

Questionnaires to assess specific conditions or symptom complexes such as nocturia and overactive bladder are contained in this section along with HRQL modules for these specific symptom complexes. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group making the items/questionnaire only utilisable in that population.

- Nocturia
- Overactive bladder
- Patients with spinal cord disease
- Patients using long term catheters
- Lower urinary tract symptoms in children

c) Optional Modules

This category lies within the core symptoms and includes lengthier questionnaires for more in-depth (maybe in-depth evaluation is more accurate) evaluation of lower pelvic dysfunction. Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.

- Lower urinary tract symptoms
- Urinary incontinence

d) Post-treatment Module

The ICIQ module for post-treatment satisfaction is in the early stages of development. Assessment of a patient's satisfaction with treatment (behavioural, surgical or medication) provides information on treatment impact on their condition and life and includes their perception of effectiveness, tolerability and convenience. It is not yet clear if satisfaction following treatment can be characterised by a set of common question items that are applicable to all lower pelvic health conditions. As with HRQL, there are generic and disease specific questionnaires that assess satisfaction. Ongoing studies will provide further evidence on which to make suggestions regarding post treatment evaluation but it is likely that this will encompass both generic and condition specific measures. Ultimately, the development of post treatment modules will also rely on advice from regulatory authorities (e.g. FDA, EMA) to ensure that measures capture a recognised multidimensionality of satisfaction.

3. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a symptom and HRQL module that match the intended purpose of a study in order to provide a comprehensive evaluation of these two perspectives. The extent of burden placed on the respondent and the study or clinical outcomes must be considered however and ultimately guide questionnaire selection. The characteristics of each module are summarised below, although more extensive information can be found on the project website, www.iciq.net. Modules currently under development are summarised in **Table 3**.

Table 2. ICIQ Module Description

Name	Scope of assessment	Domains	Items	Grade
ICIQ-MLUTS [29] (ICS*male*SF)	Male lower urinary tract symptoms and associated bother.	• Voiding • Incontinence • Individual items evaluating frequency and nocturia	13	A
ICIQ-FLUTS [30] (BFLUTS SF)	Female lower urinary tract symptoms and associated bother.	• Filling • Voiding • Incontinence	12	A
ICIQ-VS [31]	Vaginal symptoms including prolapsed and associated bother.	• Vaginal symptoms • Sexual matters • Quality of life	14	A
ICIQ-B [32, 33]	Bowel symptoms including anal incontinence and associated bother	• Bowel pattern • Bowel control • Quality of life	21	A+
ICIQ-UI Short Form [28]	Urinary incontinence.	• Urinary incontinence frequency, overall interference • Perceived cause of incontinence	4	A
ICIQ-LUTSqol[4, 34] (King'sHealth Questionnaire))	HRQL issues associated with urinary symptoms and associated bother.	• Life restrictions • Emotional aspects • Preventive measures	22	A+
ICIQ-MLUTSsex[35] (ICS*male*)	Male sexual matters associated with urinary symptoms and associated bother.	• Erection and ejaculation issues • Overall interference	4	A
ICIQ-FLUTSsex[36] (BFLUTS)	Female sexual matters associated with urinary symptoms and related bother.	• Pain and leakage with sexual intercourse • Overall interference	4	A
ICIQ-FLUTS Long Form (BFLUTS)	Detailed assessment of female lower urinary tract symptoms and associated bother.	• Varied lower urinary tract symptoms	18	A
ICIQ-MLUTS Long Form (ICS*male)*	Detailed assessment of male lower urinary tract symptoms and associated bother.	• Varied lower urinary tract symptoms	23	A
ICIQ-N	Comprehensive assessment of symptoms of nocturia and associated bother.	• Frequency • Nocturia.	2	A
ICIQ-OAB	Comprehensive assessment of symptoms of overactive bladder and associated bother.	• Frequency • Nocturia • Urgency • Urgency incontinence	4	A
ICIQ-OABqol (OAB-q) [5]	Detailed assessment of health-related quality of life issues associated with overactive bladder.	• Coping • Concern/Worry • Sleep • Social Interaction	25	A
ICIQ-Nqol (NQOL) [37, 38]	Detailed assessment of HRQL issues associated with nocturia.	• Issues associated with sleep disturbance • Life restrictions • Preventive measures	13	A+

Table 3. ICIQ Description of modules in Development.

Name	Purpose	Current status
ICIQ-CLUTS [39]	Assessment of urinary symptoms in children.	Validitytesting published awaiting reliability and responsiveness evaluation.
ICIQ-LTCqol	Assessment of HRQL associated with long term catheter use	Validity and reliability underway but yet to be published. Requires responsiveness evaluation.
ICIQ-Bladder diary [40]	Daily diary regarding bladder pattern including frequency, volume, intake and incontinence episodes.	Validity and reliability established. Requires responsiveness evaluation.
ICIQ-Spinal cord disease	Assessment of urinary symptoms and impact on HRQL associated with specific management **devices** and related bother.	Initial qualitative development completed. Requires quantitative evaluation.
ICIQ-VSqol	Detailed assessment of HRQL issues associated with vaginalsymptoms and related bother.	Initial qualitative development completed. Quantitative evaluation underway.
ICIQ-Satisfaction	Generic assessment of post-treatment satisfaction for lower pelvic dysfunction including surgical and conservative intervention.	Initial qualitative development completed. Quantitative evaluation underway.
eICIQ	Evaluation of altered administration of ICIQ modules.	Initial qualitative evaluation completed. Quantitative evaluation of psychometric equivalence underway.

4. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. More than 1200 requests for use of the various modules have been documented and over 180 published studies were identified up to March 2012. The most widely applied module is the ICIQ-UI Short Form, particularly to evaluate female urinary incontinence. Reports on further validation and translations of the ICIQ and related educational projects are growing in number. This is essential in order to achieve standardised evaluation of pelvic floor dysfunction, which is a primary aim of the initiative.

The ICIQ has also been applied to clinical and general practice settings, and has been adopted in national guidelines for the management of urinary incontinence in primary care by the Scottish Intercollegiate Guidelines Network (www.sign.ac.uk/pdf/sign79.pdf) and in a primary care resource pack by the British Society of Urogynaecology.

5. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a series of standardized questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. This assurance provides the user with confidence in the results obtained, which is important in clinical practice and research where treatment decisions or trial outcomes depend on this evidence. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires, thereby facilitating communication between clinicians and researchers and enable more widespread comparisons between different treatments and patient groups worldwide. Collaboration with the ICIQ is encouraged among clinicians and researchers in order to conduct further evaluation and provide further translations of ICIQ modules.

V. PATIENT-REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). This section and table series at the end of the chapter provides an overview and assessment of those measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. **Appendixed Tables 4 through 8** provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Please note, as instrument development and validation is an ongoing process, the tables below contain publications through August, 2011. As additional work may have been performed on an in-

strument, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study.

One trend that has become more apparent since the previous Consultations is the modification of more established urinary incontinence questionnaires for use in selected patient groups (e.g., pelvic organ prolapse; males; different cultural/language groups). When using a questionnaire in a patient group other than the group in which it was initially developed, cognitive interviews with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee's view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument's construct validity, reliability, and test-retest reliability, at a minimum, and sensitivity to change, in intervention studies.

For some of the more widely used instruments listed below, several modified, shortened versions have been published. Information regarding the modified versions is provided under the original source versions of the questionnaires, but the modified versions are evaluated and graded separately, based on the available information regarding their psychometric properties and performance.

1. HEALTH-RELATED QUALITY OF LIFE MEASURES

Health-related quality of life (HRQL) measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. UI is a symptomatic condition that has been shown to affect many aspects of a patient's life - physical, emotional, and social relations and cause concern and burden. As such, it is important to assess HRQL in clinical research and practice. **Appendixed Table 4** at the end of the chapter provides a quick overview of the variety of HRQL measures available and their validity and characteristics to determine which measure is suitable for your objectives.

2. PATIENT SATISFACTION AND GOAL ATTAINMENT SCALING

Patient satisfaction and Goal Attainment Scaling are two important but separate types of PROs that allow for individualised assessment of disease impact and treatment. Patient satisfaction is the subjective, individual evaluation of treatment effectiveness and/or the service provided by the healthcare system. Goal attainment scaling (GAS) is a method developed to ascertain individual patient treatment goals and using those to facilitate patient-provider interaction and tailor the treatment plan based on those individual's goals [41].

Measures of patient satisfaction can include evaluation of accessibility/convenience, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings and perceived quality/competence of health care personnel [42]. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance. As an outcomes measure, patient satisfaction allows health care providers to assess the appropriateness of treatment according to patient expectations. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing outcome among treatments with comparable efficacy [43].

Two patient satisfaction methods of promise with Grade B criteria are the BSW and OAB-S [44, 45]. Generally responsiveness cannot be assessed as there is no baseline assessment of patient satisfaction with treatment as no treatment has been given. **Appendixed Table 5** at the end of the chapter presents a summary of satisfaction instruments identified in UI, OAB and other LUTS.

GAS has been used to measure clinically important change in several therapeutic areas. Although it was originally developed to assess health outcomes in mental health settings, it has recently been expanded to include evaluations in urogynecology[46-50]. GAS has been linked to several possible benefits compared with traditional outcome measures, such as improved clarity concerning treatment objectives for both the healthcare provider and the patient, active involvement of the patient in problem-solving efforts, establishment of realistic patient and healthcare provider expectations of treatment, and increased motivation of patients toward improving their health condition [41]. The end result of GAS is to clarify patients' expectations for their treatment, document goal achievement, and eventually increase patient satisfaction and improve therapeutic outcomes.

One GAS instrument for lower urinary tract symptoms has been well-developed, the Self Assessment Goal Attainment (SAGA) questionnaire. The development and pilot testing of the SAGA questionnaire has been published [46]. SAGA was developed in 3 phases: (1) a preparatory phase in which preliminary information on goal setting and attainment was gathered; (2) a goal elicitation phase that included qualitative interviews with 41 patients with OAB symptoms and/or other LUTS; and (3) cog-

nitive debriefing interviews during which the draft questionnaire was administered to 11 patients with OAB and/or other LUTS. Numerous linguistically validated translations are available at: http://www.pfizerpatientreportedoutcomes.com [51].

3. SCREENING TOOLS

In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (**Appendixed Table 6**). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leiscester Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

4. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures that can be used to assess how bothered patients are by urinary symptoms are included in **Appendixed Table 7**. The Patient Perception of Bladder Condition [52] and the Urogenital Distress Inventory are the only Grade A recommend instrument.There are several Grade B and C measures which assess bother for incontinence and LUTS.

5. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as “the complaint of a sudden compelling desire to pass urine which is difficult to defer”[53]. Urgency is the hallmark symptom of OAB [54], thus assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency) [55, 56]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein[57] make a case for describing urgency as a “compelling desire to void in which patients fear leakage of urine” as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UUI (an event) rather than the strongest feeling of urgency (a sensation) itself. Several instruments have been developed to assess urinary urgency these are summarised in **Appendixed Table 8**.

VI.QUESTIONNAIRES TO ASSESS SYMPTOMS AND HEALTH-RELATED QUALITY OF LIFE IMPACT OF PELVIC ORGAN PROLAPSE

Many women with lower urinary tract and bowel symptoms have pelvic organ prolapse (POP). The clinical assessment, standardized measurement, conservative and surgical treatment of POP is covered in Chapters 5A and 15. Increasingly with new surgical techniques for the treatment of POP standardised objective and subjective assessments are required. This chapter will review the standardised symptom assessment tools for POP. These tools do not allow the clinical staging or planning of prolapse treatment, nor do they assess the correction of prolapse following conservative or surgical treatments. As with many of the other sections in this chapter, it is apparent that clinical conditions affect patients differently. Ultimately, the decision to seek and offer therapy for POP and the evaluation of its success will best be measured by the patient and not necessarily by the physician assessed clinical findings. Whilst not as advanced as the assessment tools to evaluate LUTS, there has been progress in the development of POP specific assessment tools since the last triennial ICI report.

It is important to remember that where specific problems of the patient with POP require assessment (e.g., lower urinary tract symptoms, sexual function) it may be preferable to use one of the questionnaires designed specifically for that purpose.

In general questionnaires for POP tend to focus more on the symptoms related to the lower bowel and prolapse probably because of the wider availability of questionnaires to assess LUTS. The broad three categories of instruments for POP are:

1. Presence of symptoms and their severity;

2. HRQL

3. sexual function.

As prolapse is almost always multidimensional, selecting questionnaires in the modular format of the ICIQ (see above) may well be preferable for many clinical and research applications

For POP, the Committee examined the quality of the psychometric evidence and only where published data were scientifically sound was the label ‘with rigor’ allowed. The Committee noted that this is a developing area and therefore three grades of recommendation were established (**Table 9**).

VII.QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQL IMPACT OF FAECAL INCONTINENCE

A range of PROs have been developed to identify the severity of anal (AI) or faecal incontinence (FI) and its impact on HRQL. By comparison with the last triennial review, questionnaires are now being incorporated into research trials on a more regular basis recognising the importance of capturing the patient's perspective. Less is reported regarding clinical assessment. Due to the close overlap between faecal incontinence and other pelvic floor disorders (in particular urinary incontinence), some of those questionnaires used for other pelvic disorders also include items to cover faecal incontinence. For similar reasons, items relating to faecal incontinence have often been included in questionnaires addressing general gastro-intestinal and colo-rectal function, as well as condition specific instruments in such areas as irritable bowel syndrome and inflammatory bowel disease, conditions which are commonplace in colorectal practice as well as in other specialties dealing with pelvic floor disorders [66, 67].It is also important to remember that the normal range of bowel function is broad, that bowel function may be highly variable within individuals without significant pathology. Consequently instruments in this field are likely to lack a degree of sensitivity or specificity for the specific bowel disorders such as IBS, IBD evacuation disorder and constipation.

Anal/faecal incontinence and bowel evacuation are intrinsically related to pelvic floor function and it may be inappropriate to consider bowel function purely in terms of continence and constipation. Evacuatory dysfunction may result from a variety of underlying pathologies including outlet obstruction, slow transit or other mechanical, pharmacological, metabolic, endocrine and neurogenic abnormalities [68]. Anal incontinence occurs in both sexes and it is unclear whether there is any difference between genders in terms of prevalence. Studies to date suggest that in different age groups prevalence varies, with unique risk factors attributable at these stages of life [69]. Symptoms are considered crucial to diagnosis as specific symptoms are thought to reflect the underlying pathophysiology [70]. Thus, urgency (the inability to defer defaecation) and urgency faecal incontinence are thought to indicate loss of voluntary control due to impaired external anal sphincter function, whereas passive faecalincontinence is thought to indicate impairment of the smooth muscle of the internal sphincter.

Table 9: Recommended questionnaires for the evaluation of symptoms and health-related quality of life impact of pelvic organ prolapse

Grade A (recommended)
Pelvic Floor Distress Inventory (PFDI) [58]
PelvicFloor Impact Questionnaire (PFIQ) [58]
Prolapse quality of life questionnaire P-QOL [59]
Grade B
The Australian Pelvic floor Questionnaire (APFQ) [60]
Pelvic floor symptom bother questionnaire (PFBQ) [61]
PelvicOrganProlapseUrinary incontinence Sexual questionnaire (PISQ) (PISQ-12) [62]
ICIQ vaginal symptoms questionnaire (ICIQ – VS) [62]
The electronic Personal Assessment Questionnaire – Pelvic Floor (ePAQ-PF) [63]
Grade C (with potential)
Pelvic Floor Dysfunction Questionnaire [64]
Danish Prolapse Questionnaire [65]

For AI/FI, the Committee examined the scope of available measures and quality of the psychometric evidence. While this remains a developing area, the publication of the ICIQ-B questionnaire for the assessment of anal incontinence and associated impact on quality of life means that a questionnaire is now available that reaches the highest level of recommendation, including the qualitative development phase [32, 33]. Further evaluation of existing measures such as the Faecal Incontinence Quality of Life index (FIQL) has also resulted in an improved grade of recommendation [71].

The grades of recommendation are as outlined in previous sections and below. **Table 10** summarises the questionnaires reviewed and grades of recommendation accordingly.

Appendixed **Tables 11 through 13** at the end of the chapter provide details of the specific psychometric properties and development of each questionnaire.

VIII. QUESTIONNAIRES TO ASSESS SEXUAL FUNCTION/SEXUAL HEALTH AND URINARY SYMPTOMS

Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health. A number have been specifically developed or adapted to examine sexual function in patients with pelvic floor disorders such as incontinence.

Table 10: Recommended questionnaires for the evaluation of symptoms and quality of life impact of faecal incontinence

Grade A+
ICIQ-B [32, 33]
Grade A
Faecal Incontinence Quality of Life Scale [71]
Birmingham Bowel and Urinary Symptom Questionnaire [72, 73]
Questionnaire for assessment of Faecal Incontinence and Constipation [74]
Grade B
Colorectal Functional Outcome Questionnaire [75]
Manchester Health Questionnaire [76]
Bowel Control Self Assessment Questionnaire [77]
Pelvic Floor Bother Questionnaire [61]
Elderly Bowel Symptom Questionnaire [78]
Faecal Incontinence and Constipation Assessment [79]
Grade C
Faecal Incontinence Questionnaire [80]
Ungraded (require formal validation, evidence of progress published)
Postpartum Flatal and Faecal Incontinence Quality of Life Scale [81]
Bowel Function Questionnaire [82]
Surgical Outcome Tool for Faecal Incontinence [83]

Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. The experienced clinician hopes to have an appreciation of the information required to make the correct diagnosis and institute appropriate treatment. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself.

Appendixed Table 14 at the chapter's end outlines a number of sexual health measures with a Grade A or B rating based on the criteria provided above. Three measures are of particular note, obtaining an A+ rating, having demonstrated not only reliability and validity but also that content was derived with patient input and responsiveness to treatment has been shown: GRISS [84], FSFI [85], and IIEF [86]. Most of the identified measures are self-reported, easy and quick to administer and many have various language versions available. The majority have also been previously used in incontinence populations. There are various others measures that would be given a rating of C (e.g., Sexual Behaviour Inventory [87, 88], McCoy Female Sexuality Questionnaire [89]), but given the breadth of measures available with an A or B rating, researchers are encouraged to use these for assessing sexual function/sexual quality of life. Specific choice of measure will be dependent on research hypothesis. For instance, if you wanted to assess impact of OAB on sexual function e.g. arousal in women then you would want to use the FSFI rather than the SQOL-F [90] because the FSFI has a specific arousal domain whereas the SQOL-F assesses sexual quality of life.

IX. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

1. OLDER PEOPLE

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since the elderly commonly have a number of associated comorbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance. Validated incontinence-specific PRO questionnaires, such as IIQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura assessed symptoms and HRQL in older people (men and women)

with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQL in elderly women [91].

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence. Two questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

a) The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. (1999) [92] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urgency incontinence. Cronbach's alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass coefficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

b) Caregivers

The Overactive Bladder Family Impact (OAB-FIM) scale was developed to assess the impact of OAB on family members of patients with OAB. This 19-item tool consists of 6 subscales [93]. Four subscales (Irritation, Activities, Travel, Concern) could be used for all family members; however 2 additional subscales (Sleep, Sex) should only be administered to spouses/significant others. The OAB-FIM was highly discriminating between OAB and control family members, with all OAB family members indicating significant impact (all $p<0.0001$). Internal consistency reliability (Cronbach's alpha >0.71) and 2-week test-retest reliability (intraclass correlation coefficients >0.73) were high for all subscales. Concurrent validity of the OAB-FIM was demonstrated through statistically significant ($p < 0.001$) Spearman correlations with the OAB-q (coefficients ranging from 0.35 to 0.58) and the PPBC (0.31 to 0.56). No differences were noted on the OAB-FIM by patient incontinence status (none, urge vs. mixed). OAB-FIM scores also discriminated by family member perceptions of OAB severity, particularly among the Irritation, Activities and Travel subscales. Correlational analyses among the OAB-FIM and relationship quality measures suggest that greater OAB symptom impact on the family member was associated with increased problems in the patient–family member relationship. The responsiveness of the OAB-FIM is yet to be assessed. This measure can be found at www.pfizerpatientreportedoutcomes.com.

2. CHILDREN

Some questionnaires have been developed specifically to address issues for children, particularly enuresis. See Chapter 9 (Children) and section on ICIQ modular questionnaire.

3. SPINAL CORD INJURED/NEUROLOGICAL IMPAIRMENT

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. This is an area where a small number of questionnaires are being developed with the Qualiveen being a notable exception (Also see section on the ICIQ questionnaire and below).

Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France [94]. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity [94]. Further validation of the Qualiveen has occurred in multiple sclerosis patients [95] and it has been translated and validated into English [96], German [97], and Portuguese [98]. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5 [99].

4. PROSTATE/BLADDER CANCER

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire [100, 101], Cancer Rehabilitation Evaluation System - Short Form (CARES-SF) [102], Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q) [103],PROSQOLI [104], Modified Southwest Oncology Group (SWOG) [105], Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P) [106],

Functional Assessment of Cancer Therapy Vanderviet Cystectomy Index (FACT-VCI) [107], EORTC metastatic prostate cancer [103], Changes in Urinary Function [108], Prostate-targeted Health Related Quality of Life [109]. While it is beyond the scope of this chapter to review and recommend PROs in this area, the principles and guidelines discussed herein apply to selecting a PRO related to prostate and bladder cancer.

5. LOWER URINARY TRACT SYMPTOMS/BENIGN PROSTATE DISEASE

Many questionnaires have been developed to assess LUTS and benign prostate disease; however, most do not contain a full evaluation of UI. Perhaps the most widely known urology PRO is the AUA Symptom Index [110], I-PSS (International Prostate Symptom Score) [110, 111]. The IPSS has been utilitised internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. Additional PRO measures for BPH are as follows: Patient-completed modification of the Boyarsky[112], BPH Impact Index [113], and BPH Health-related QoL survey [114].

6. SUMMARY

In summary, some general points to consider in selecting PRO measures for urology studies:

- Ensure that the PRO research questions and study endpoints are clearly defined. Determine the PROs that are most critical to assess and which are most likely to be affected by a particular condition and/or its treatment.
- Make good use of prior literature searches in identifying past research in the area(s) of interest, as well as in identifying the types of PRO measures other researchers have used in past work. This information can provide valuable information on how particular outcome measures have performed in previous populations, as well as provide additional information to assist in defining research questions/issues regarding the PRO components of any given study.
- Consider the characteristics of the population in selecting measures. For example, are the study subjects to be children or older adults, well educated vs. those with limited education, or persons with low literacy? Ensure that the mode of data collection is appropriate for use with the study population. Furthermore, do not assume that an instrument validated for use with Caucasian, middle-class individuals in the U.S. will be appropriate for use in other countries, and/or those of a lower socio-economic status or of different educational backgrounds. This chapter has indicated, where possible, the extent to which specific PRO measures have been validated, and used reliably with different populations.
- Use the questionnaires recommended in this chapter whenever possible. Do not “reinvent the wheel.” Developing new PROs is a time-consuming and complicated process. If a new scale needs to be developed, ensure that the guidelines proposed by the FDA and EMEA on developing PROs are followed and that the appropriate expertise in questionnaire development and psychometrics is available to your research team in order to guide the questionnaire development process.
- Know the strengths and weaknesses of different types of PRO measures. In general, generic measures are useful in providing information on multiple patient outcome dimensions that can be compared across different populations. They may lack sensitivity, however, in addressing concerns of specific patient populations (e.g., OAB, UI, faecal incontinence). Condition-specific instruments, in contrast, do address areas of function more specific to the condition, and tend to be more responsive to changes in clinic status, due to their increased specificity in addressing the conditions of their patient populations. Weaknesses of condition-specific instruments, however, are that they are often not appropriate for use with multiple populations, and cannot be used to make direct comparisons across different patient groups.
- Know how to score your selected PRO measures and how to interpret the scores. Specifically, ensure that the scoring method of a measure provides you with the information you need to answer your research question?
- Finally, train and certify your staff to administer PRO measures using either patient interview and/or self-administration techniques, depending on the method to be used in the study. The administration process needs to be standardised and completely similarly across all participants.

X. RECOMMENDATIONS FOR RESEARCH

1.The selection of a PRO questionnaire must reflect study purpose and objectives

2. Grade A recommended questionnaires should be used in all clinical trials evaluating treatments

3. The inclusion of the ICIQ modules is preferred in all studies to standardise outcome assessment

4. Continued PRO development, refinement, and use should accurately and adequately report on the methods, samples, statistical analyses and psychometric properties of questionnaires in scientific journals (i.e. validity, reliability and responsiveness), so the quality of each study can be assessed

Researchers are encouraged to use existing questionnaires and refine for specific populations when needed (e.g. frail elderly, children)

5.Researchers are encouraged to collaborative with the ICIQ project on the development and refinement of modules and translations.

Table 4: Health-related Quality of Life measures for Lower Urinary Tract Symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
BFLUTS (Bristol Female Lower Urinary Tract Symptoms Questionnaire). Currently the ICIQ-FLUTS (ICIQ-Female Lower Urinary Tract Symptoms); Grade A [30]	34-question tool used to assess female LUTS, particularly urinary incontinence, measure impact on quality of life and evaluate treatment outcome	Women, inconti-nence	√	√	√		√		None	www.iciq.net
Contilife® (Quality of Life Assessment Questionnaire Concerning Urinary Inconti-nence); Grade B [115]	28-intem tool used to assess the impact of urinary incontinence on HRQL. Originally developed in French and designed for women with UI (urge, stress and mixed UI)	Women, SUI	√	√ (ICC = 0.96)			√		√	www.proqolid.org
DAN-PSS-1(Danish Prostatic Symptom Score); Grade A [116]	15-item tool used to evaluate males with LUTS suggestive of uncomplicated BPH	Men, BPH	√	√	√		√			www.proqolid.org
EPIQ (Epidemiology of Prolapse and Incontinence Questionnaire); Grade B [117]	49-item tool developed and validated in English and Spanish to assess the presence or absence of AI, OAB, SUI, and pelvic organ prolapse in female population	women, PFD	√	√	√	√	√	√		contact developer
ICIQ-UI Short Form (International Consultation on Incontinence Questionnaire - Urinary Inconti-nence Short Form (ICIQ-UI Short Form); Grade A[28]	4-item tool used to assess the symptoms and impact of urinary incontinence in clinical practice and research	men and women, Urinary symptoms	√	√	√		√	√	√ (8 weeks)	www.proqolid.org

PFBQ (Pelvic Floor Bother Questionnaire); Grade B [61]	9-item global instrument used to assess female patients over the age of 18 years with symptoms of urinary incontinence, urinary urgency, and frequency, urge incontinence, faecal incontinence, obstructed defecation, dyspareunia and pelvic organ prolapse	Women, Urinary Inconti-nence, UUI, SUI	√	√	√	√		√		contact developer
SPI (Symptom Problem Index); Grade B [113]	7-item tool used to measure how troublesome the patients find their urinary symptoms	Male, BPH	√	√	√					www.proqolid.org
SSI and SII (Symptom Severity Index and Symptom Impact Index for stress incontinence in women); Grade B [155]	3-item tool used to measure stress incontinence severity and impact or bothersome of symptoms. This question-naire was developed and administered to women undergoing stress inconti-nence surgery	Women, SUI		√	√		√			www.proqolid.org
UI-4 (Urinary Incontinence -4 Questionnaire); Grade C [156]	4-item tool used to assess how patients are bothered by urinary incontinence	Women, UI					√			www.ncbi.nlm.nih.gov
UDI (UrogenitalDistres s Inventory); Grade A [119]	19-item tool used to asses symptom bother related to urinary incontinence. UDI is a complement to the IIQ	Women, UI, SUI	√	√	√		√	√		contact developer
UDI-6 (UrogenitalDistres s Inventory -6); Grade A [157]	6-item tool used to assess LUTS, including inconti-nence, in women.	Women	√	√	√	√	√	√	√	contact developer

Table 8: Urinary Urgency Measures for Lower Urinary Tract Symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
IUSS (Indevus Urgency Severity); Grade A [158]	Single-item tool used to quantify the level of urgency associated with each toilet void as measured during standard voiding diaries.	OAB with urgency inconti-nence, men and women		√		√	√	√	√ (12 Weeks)	contact developer
PPIUS (Patients' Perception of Intensity of Urgency Scale); Grade B [159]	Single-item tool used to assess female patient perception of urgency intensity in those women with UUI	Women, UUI		√					√	contact developer
SUIQ (Stress/Urge Incontinence Questionnaire); Grade B [160]	2-item tool used to differenti-ate between symptoms of stress and urge urinary incontinence	Women, UI		√			√			contact developer
U-IIQ (Urge Incontinence Impact Question-naire); Grade A [161]	32-item tool used to assess the interference of urine leakage and bladder problems Developed for use in patients with all types of incontinence.	MUI, UUI	√	√			√	√	√ (12Weeks)	contact developer
UPS (Urgency Perception Score); Grade B [162]	5-item OAB tool used for grading the urge to void and assessing the reason why individuals usually void	Men and women	√	√			√	√		contact developer
UPS (Urgency Perception Scale); Grade B [163]	Single-item tool used to assess the severity of urgency – whether or not urgency, the sudden and compelling desire to urinate should have a severity measure is debated.	OAB, men and women			√		√	√	√	contact developer

Table 8: Urinary Urgency Measures for Lower Urinary Tract Symptoms (continued)

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
UQ (Urgency Questionnaire); Grade B [154]	15-Likert Scale Item & 4-VAS tool used o assess the severity and impact of urinary urgency symptoms on HRQL. VAS scale is used to measure the impact of urinary urgency on overall HRQL, the severity, the intensity, and the discomfort of urgency.	Women, OAB	√	√	√		√	√	√ (10 Days)	contact developer
URIS-24 (Urge Impact Scale); Grade B [92]	24-item tool used to assess of the impact of the most common form of UI in older persons	Older persons, UI	√	√	√		√			contact developer
USIQ-QOL (Urgency Severity & Intensity Questionnaire: Symptom Severity); Grade B [164]	To measure severity impact from urinary urgency	Females, POP, UI	√			√		√		contact developer
USIQ-S (Urgency Severity & Intensity Questionnaire: Quality of Life); Grade B [164]	To measure quality of life impact from urinary urgency	Females, POP, UI	√ (Cronbach's Alpha = 0.85)			√		√		contact developer
USS (Urinary Sensation Scale); Grade B [165, 166]	5-point scale used to assess the impact of urgency with patients with OAB derivation from EMA's recommended 5-point scale	Urologists or urogy-necologists, Survey respondents with OAB symptoms	√ (Cronbach's Alpha = 0.85)		√		√	√	√	contact developer
UU Scale (10-item Scale to Measure Urinary Urgency); Grade A [167]	10-item tool use to measure urinary urgency	Men and women		√			√		√	contact developer
U-UDI (Urge-Urogenital distress inventory); Grade A [161]	9-item tool used to assess the extent to which the patient is bothered by the symptoms of urge urinary incontinence or mixed urinary incontinence with a primary urge component.	Men and women		√	√		√		√	www.mapi-institute.com

Table 11: Summary of PRO Measures for Faecal incontinence and other bowel symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsive-ness (Treatment Duration)	Psycho-metric Validation inOther Languages	Available Languages
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discri-minant			
Questionnaire for assessment of FI and constipation [74] **Grade A**	47-item general question-naire for constipation and anal incontinence, also including abdominal and urinary symptoms and medical history	Men and women		√		√			√	√	Contact www.iciq.net
Bowel function questionnaire [83] **Ungraded**	28-item bowel specific questionnaire including 10 anal incontinence-specific items	Men and women									
Faecal Incontinence Questionnaire [80] **Grade C**	63-item general questionnaire for bowel habits including faecal incontinence, also urinary symptoms and medical history	Men and women		√							
BBUSQ (Birmingham Bowel and Urinary Symptom Questionnaire [72, 73] **Grade A**	22-item questionnaire for bowel and urinary symptoms including 4 faecal incontinence-specific items	women	√	√		√			√		
FICA (Faecal incontinence and constipation assessment) [79] **Grade B**	98-item general questionnaire for constipation and faecal incontinence, also including abdominal and urinary symptoms and medical history	women		√		√					
PFBQ (Pelvic floor bother questionnaire) [61] **Grade B**	9-item symptom and bother questionnaire for pelvic floor disorders	women	√	√		√	√				

Table 12: Summary of PRO Measures for Faecal incontinence and HRQL associated specifically

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsive-ness (Treatment Duration)	Psycho-metric Validation inOther Languages	Available Languages
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discri-minant			
ICIQ-B [32, 33] **Grade A+**	19-item anal incontinence symptoms and HRQL questionnaire	Men and women	√	√	√	√	√		√	√	Contact www.iciq.net
FIQL (Faecal Incontinence Quality of life Index) [71] **Grade A**	29-item faecal incontinence HRQL questionnaire	Men and women	√	√			√		√	√	Contact author
MHQ (Manchester Health Question-naire) [76] **Grade B**	31-item anal incontinence HRQL questionnaire	Women	√	√			√				
Bowel control self-assessment questionnaire [77] **Grade B**	5-item faecal incontinence symptom and HRQL questionnaire	Men and women	√	√		√	√				

Table 13: Summary of PRO Measures for Faecal incontinence in specific patient groups

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsive-ness (Treatment Duration)	Psycho-metric Validation inOther Languages	Available Languages
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discri-minant			
Postpartum flatal and faecal inconti-nence quality of life scale [81] **Ungraded**	68-item anal incontinence HRQL questionnaire (adaptation of FIQL for postpartum females)	Women			√						
Surgical outcome tool for faecal incontinence[83] **Ungraded**	10-item anal incontinence symptoms and HRQL questionnaire for evaluation of incontinence surgery	Women									
COREFO (Colorec-tal functionalout-come question-naire) [75] **Grade B**	27-item anal incontinence symptom and HRQL questionnaire for evaluation of colorectal surgery	Men and women	√	√	√		√				
EBSQ (Elderly Bowel Symptom Questionnaire) [78] **Grade B**	56-item general questionnaire for gastrointestinal function including faecal incontinence, also including and medical history and HRQL	Men and women		√		√					

Table 14. Sexual Health and Quality of Life Measures

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
FSFI (Female Sexual Function Index); Grade B [85]	19-item tool used to assess the effects of incontinence on multiple dimensions of sexual function in sexually active, adult women	Women, OAB; SUI, MUI	√ (Cronbach's Alpha >/= 0.82)	√ (r = 0.79 - 0.86)				√		contact developer
ICIQ-VS (International Consultation on Incontinence Questionnaire -Vaginal Symp-toms); Grade B [31]	14-item tool used to assess effects of vaginal symptoms and associated sexual matter on sexual quality of life for sexually active females	Women	√ (Cronbach's Alpha = 0.81-0.88)	√	√			√ (all items except 'leakage during intercourse')		contact developer
PISQ (PelvicOrganProlapse/Urinary Incontinence Sexual Question-naire); Grade B [62]	31-item tool to assess sexual function after surgery in women with Pelvic Floor Dysfunction	Females with Pelvic Floor Dysfunc-tion	√ (Cronbach's Alpha = 0.85)	√ (k = 0.56 - 0.93)		√		√		contact developer
SFQ (SexualFunction Questionnaire); Grade C [168]	Generic Instrument used to assess the impact of OAB on sexual health/function in the male & female population	men& women with OAB								www.pfizerpatientreportedoutcomes.com
SQoL-F (Sexual Quality of Life–Female); Grade B [90]	To assess the impact of female sexual dysfunction on quality of life	women	√	√			√	√		www.pfizerpatientreportedoutcomes.com

I. INTRODUCTION

The first two reports of the International Consultation on Incontinence (ICI) contained chapters on 'Urodynamic Testing' [Homma 1999; Homma 2002]. Urodynamics is the umbrella term used to describe measurements of the function of the lower urinary tract. These measurements can be used in the management of urinary incontinence (UI). The third and the fourth report of the ICI expanded the topic to include physiological measurements of the lower gastrointestinal tract in relation with faecal (or anal) incontinence. Consequently, the chapters were named 'Dynamic Testing.'[Griffiths 2005].

In this fifth consultation, ICI 2012, we have further updated the evidence for the technical performance, clinical utility and responsiveness to treatment of dynamic testing. However faecal incontinence is discussed in a separate committee for this 2012 consultation. Diagnosis of faecal incontinence and its measurement techniques is therefore not included in this chapter. Consequently, the chapters' name is Urodynamic Testing. We have used the chapter on 'Dynamic Testing' from the previous (2009) consultation as a template for this report; retaining some of the original text and tables where there has been no change since the previous consultation [Rosier 2010; Rosier 2010; Rosier 2010]. Nevertheless the use of the previous chapter as a template, this chapter is updated with more than 200 new references and ±300 outdated references have been removed. With the aim to use the 'test of time' we have however usually not included references of publications less than one year before the consultation. Also discussions of tests that have been presented as 'new' in the previous years, without follow-up o manuscripts from other centres, and or without manuscripts that describe the clinical use in comparative studies, have been reduced in length.

Treatment of (stress) urinary incontinence (SUI) has changed considerably in the last decade and that has had its consequence on diagnostic testing. One of the effects has been that the paragraphs that discuss urethral pressures and or leak point pressures are reduced in length.

The primary aim of the chapter is to present what tests might be performed to elucidate the mechanism that causes UI in the individual, but a more predominant aim has been to make recommendations, and to give the strength of the recommendation (A to D), for what tests could or should be performed for certain groups of patients. Thus we present an overview of the best scientific evidence with regard to the role of urodynamic testing in clinical practice. On the basis of this, we provide recommendations for the current state of assessment of the patient with UI, and recommendations for future scientific evaluation of dynamic testing. We present the overview of scientific evidence in paragraphs, with conclusion(s) (with a level of evidence that follows the Modified Oxfort Scale) from this evidence for each paragraph. Following on from that, we present our graded recommendation(s) and where deemed useful some topics(s) for research. These items are highlighted in the text and are therefore also suitable for 'express reading'.

The chapter considers urodynamics for patients with signs and symptoms of urinary incontinence. The tests are described with the clinical perspective as well as with normal values and reliability of the measured parameters in mind, followed by reviews of the literature regarding clinical urodynamic evaluation of different patient groups with UI; women, men, children, neurogenic lower urinary tract dysfunction (NLUTD), and the frail elderly. Urodynamics of micturition problems is not addressed specifically and only described where deemed relevant, when a combination with symptoms and signs of UI is present. Each section concludes with the committee's recommendations.

A. URODYNAMICS

I. WHAT IS URODYNAMICS?

The term 'Urodynamic studies' (UDS) was defined by the International Continence Society (ICS) in 1988 as to 'involve the assessment of the function and dysfunction of the urinary tract by any appropriate method' [Abrams 1988; Schafer 2002]. The report in

2002 which revised the 1988 standard did not alter the definition of 'urodynamic studies' or 'urodynamics' but did include new definitions of 'urodynamic observations' [Abrams 2002]. Another update that adds specific terms for female pelvic floor dysfunction and -female- lower urinary tract dysfunction (LUTD) restates the 2002 ICS terminology report in a descriptive manner [Haylen 2010; Haylen 2010] and includes elements from the ICS good urodynamic practice report [Schafer 2002] as well.

The conventional experts view, endorsed in the previous standardisations and consultations, is that urodynamics is a series of more or less agreed-upon clinical tests, such as flow studies, filling cystometry, pressure-flow studies and urethral (closure) -function measurements. These measurements can be combined with simultaneous electromyography (EMG) recording and/or with imaging by either X-rays or ultrasound. Also implicitly agreed upon is that urodynamics is the way to determine, in an objective manner, which dysfunction causes people to have lower urinary tract symptoms (LUTS) and or signs of UI.

The attempt to gain understanding of an individual's lower urinary tract (LUT) functioning, on the basis of test observations, in relation to what is known about normal, or expected abnormal, physiology, is what constitutes urodynamics.

Urodynamic studies can answer questions such as: 'What is the cause, or causes of increased voiding frequency in this patient' as well as: 'Why does this patient have urinary incontinence?' These questions not only can be posed for individual patients but also can form part of clinical or laboratory research [Toh 2006; Nager 2009; Gordon 2001; Gomes 2004].

Conventionally, UDS involves the patient being connected to equipment in the laboratory in order to measure physiological parameters, such as pressures, inside the patient. The data is monitored while the test is being carried out and adjustments can be made to prevent or correct for technical problems and artefacts as they arise. Ambulatory urodynamics may be employed in an attempt to answer the clinical (or fundamental or scientific) question [Pannek 2008]. In ambulatory urodynamics, pressures and other physiological parameters from the patient are fed into a data logger and the patient is free to move about and carry out normal activities. The advantage is that such tests can last for many hours in more 'natural' circumstances for the patient but the disadvantage is that prevention of, and control for artefacts and also integration of patients' activity, sensations or perceptions is much more difficult. Videourodynamics (or ultrasound combined) is a technique to combine anatomical morphological information of the lower urinary tract with functional (pressure and flow) measurements.

II. WHAT SHOULD BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

It is frequently quoted that that the aim of urodynamic testing is 'to reproduce the patients' symptom(s)'. This committee has a view that the 'symptoms' here referred to are the patients' (or caregivers') way of expressing that she or he notices UI and/or any other sign (or presumed sign) of LUTD. No evidence exists about the incidence of the presentation of the specific symptom 'urinary incontinence' in a referred population without that being true. It is the committees' opinion that this incidence is however probably very, very low. It is therefore not the primary task to 'solely' confirm UI as a symptom but it is the doctors' task to 'translate' the sign and or symptoms into a clinical diagnosis that leads to an effective treatment.

Urodynamic testing should be applied to objectively measure and document the entire lower urinary tract function and or dysfunction when it can have therapeutic consequences, bearing the individual patients' symptoms, and all other relevant circumstances, in mind. Urodynamic testing can show signs such as (significant) residual urine or underactive detrusor which is often not specifically noticed by the patient, even when neurologically unaffected. Especially, but not uniquely in patients with relevant neurological abnormalities, upper urinary tract signs (dilatation) can exist or develop without any (new) symptom. Furthermore the patient can present with symptoms such as, 'urinary frequency', 'nocturia' or 'recurrent urinary tract infections', which are difficult or impossible to reproduce in the usual UDS- laboratory. The importance of urodynamic testing is thus to reproduce the dysfunction of the lower urinary tract and to determine the cause of the signs and or symptoms of urinary tract functional disease. The implicit consequence of this is also that ideally at least one complete filling (storage) and pressure-flow (voiding) cycle, that adequately represents the patients problem (e.g. with regard to volumes) including post voiding features, (residual urine, or after contraction) should be tested, analysed, and documented, even if only storage or voiding signs or symptoms have been expressed by the patient.

The role of urodynamic studies in broad clinical perspective can be:

a) to identify all factors that contribute to the LUT symptoms (e.g. urinary incontinence) and assess their relative importance;

b) to obtain information about all other aspects of LUT function or dysfunction whether or not expressed as a symptom or recognisable as a sign;

c) to allow a prediction of the possible consequences of LUT dysfunction for the upper urinary tract;

d) to allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment;

e) to confirm the effects of intervention or understand the mode of action of a particular type of treatment for a LUT dysfunction; especially a new and or experimental (pre-routine) one;

f) to understand the reasons for failure of previous treatments for urinary incontinence, or for LUT dysfunction in general (after unsatisfactory treatment).

Conclusion (level 1)

• Urodynamic testing in clinical practice is to evaluate a person's lower urinary tract function with at least one complete and representative filling-voiding-post voiding cycle by testing with relevant pressures and flowmetry. Urodynamic testing includes quality control, subsequent analysis, and documentation. Auxiliary testing of urethral (bladder outlet) closure function or simultaneous registration of pelvic floor muscle activity and or simultaneous addition of anatomical or morphological information with ultrasound, roentgen or other imaging can complete, or augment the value of, urodynamic testing for specific indications.

III. THE TESTS OF CONVENTIONAL URODYNAMICS

1. UROFLOWMETRY

This is the non-invasive measurement of urine flow rate. The patient voids into a flow meter in private ideally with a normal to strong (but not uncomfortable) desire to empty their bladder [Schafer 2002]. Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. After control for artefacts in automated calculations, the maximum flow rate, the volume voided and shape of the curve are usually the principal determinants of whether or not the patient is emptying their bladder in a normal way. If an abnormal voiding is obtained, it is good clinical practice to repeat the assessment to check that the result is reproduced, or not. Several factors, such as patient apprehension, can give an abnormal recording in patients who have no voiding difficulty. Asking the patient about what she or he thinks about the voiding; whether the voiding (including the volume) was an adequate representation of the real voiding (compare with voiding diary) and if necessary further explanation is absolutely relevant and must be regarded as standard (good urodynamic) practice. Repeating the assessment can eradicate the effect of such confounding factors and will confirm or refute the validity of earlier assessment(s). Unambiguous and careful instruction of the patient, privacy and a short meatus to flowmeter distance are all inherently relevant [Addla 2010].

2. FILLING CYTOMETRY

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a catheter being placed into the bladder, usually transurethrally, and another catheter being placed rectally or vaginally (or sometimes through an abdominal stoma) to measure abdominal pressure. Subtracting the abdominal pressure, indirectly measured via vagina, rectum or stoma, from the pressure measured inside the bladder (intravesical pressure) gives a representation of pressure changes due to the action of the detrusor smooth muscle or due to the (lack of) viscoelasticity of the bladder to volume change, measured and expressed as bladder compliance.

During this assessment, the bladder is usually filled with normal saline solution, or x-ray contrast solution in the case of videourodynamics, either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter if such is used to measure intravesical pressure. Usually the filling rate is much faster than physiological bladder filling so that, depending on the urodynamic capacity (and related to information from the voiding diary), the bladder is filled in about10 min.

The intravesical and abdominal pressure and the calculated ($p_{ves} - p_{pad}$) detrusor pressure are monitored as the bladder is filled and before the patient has been given 'permission to void'. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its capacity, its compliance (passive muscle adaptation to volume stretch and detrusor muscle relaxation) as distinct from the absence of (phasic) detrusor pressure rises. The filling (storage) phase of cystometry is the method of demonstrating urodynamic stress incontinence (USI) by means of coughing or straining, on request of the clinician [Ward 2008]. Good urodynamic practice demands that abdominal pressure, and intravesical pressure, as well as subtracted detrusor pressure are evaluated to diagnose urinary bladder storage function.

3. PRESSURE-FLOW STUDIES (VOIDING CYSTOMETRY)

This is a measurement of the mechanics of micturition. When the filling (storage) phase of cystometry is complete, the patient is given 'permission to void' and will empty their bladder on a flow meter whilst intravesical, abdominal and detrusor pressures are being recorded. The simultaneous measurement of flow rate and pressure enables voiding to be assessed and pressure flow analysis can help determine whether slow urine stream is due to bladder outlet obstruction (BOO) or to an underactive detrusor contraction or to a combination of those.

4. URETHRAL PRESSURE PROFILOMETRY

This is a test to estimate the urethra and the surrounding (muscle and other-) structures' ability to maintain the bladder outlet closed allowing the body system to contain urine within the bladder. By concept, a catheter is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). The pressure along the length of the urethra is measured and interpreted relative to the pressure inside the bladder (and or abdomen). The maximum pressure measured in the urethra is assumed to give an indication of the urethral closure function.

5. ABDOMINAL LEAK POINT PRESSURE

This is another concept to estimate the urethra's (bladder outlet's) ability to contain urine within the bladder. Intra -abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder gives an indication of the closure function of the urethra since higher closure pressures ('better function') require higher abdominal pressure increments to cause leakage.

IV. TECHNOLOGICAL INNOVATIONS IN URODYNAMICS

1. AIR-CHANGED CATHETERS FOR PRESSURE MEASUREMENT

Single-use, air-charged catheters have been developed and used for intravesical, intra-urethral and abdominal pressure measurement in urodynamics (T-Doc, Wenonah, NJ). Initial reports, presented at a meeting, from a female cadaver -study showed that these catheters gave more reproducible measurements of MUCP compared to micro tip catheters, water filled catheters and fibre-optic catheters [McKinney 2000]. In a clinical study in 2004 on 45 women, their performance has been shown to be comparable to micro transducers in the measurement of maximum urethral closures pressure and Valsalva leak point pressure (VLPP) [Pollak 2004]. However, the same study showed a difference in functional urethral length which was attributed to the different diameters of the two catheters. Following on from that, a randomised comparison of these air charged catheters with micro tip catheters, in another 64 women, showed that measured maximum urethral closure pressure (MUCP) and functional urethral length were equally reliable. However, the air-charged catheter showed a systematically higher reading causing the conclusion that they cannot be used interchangeably [Zehnder 2008]. The measurement of VLPP by Pollak et al [Pollak 2004] suggests that they can be used to measure intravesical pressure [White 2009; Zehnder 2008]. To compare the response of two disposable clinical catheter systems: water-filled and air-charged, to controlled pressure signals in a laboratory set-up to assess their similarities and differences in pressure transduction using a transient step test and a sinusoidal frequency sweep test, has been carried out. Water-filled catheters were reported to act as an under damped system, and sensitive to (motion) artefacts, whilst air-charged catheters acted as an over damped system, were less sensitive to artefacts and slower in response [Cooper 2011]. Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no hydrostatic pressure effect to account for, so that there is no need to position external sensors at the level of the symphysis pubis. There is also no need to flush the system through to exclude air; a process that is essential in a fluid-filled pressure-sensing environment. Also, there are no fluctuation artefacts in pressure produced when the patients move [Kim 2010]. However, although air-charged catheters may make urodynamics easier to set up, the conduct and interpretation of a urodynamic study still requires an experienced, appropriately trained practitioner.

Conclusions (level 3)

- Air-charged catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra.
- There have been no studies to show whether air-charged catheters provide a superior alternative to fluid-filled lines for measuring intravesical and intra-abdominal pressure in urodynamics.

Recommendation (grade C)

- Investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure in urodynamics are advised to check for themselves that they have an equivalent performance to their current system for measuring pressure.
- Investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure in urodynamics are advised to check for themselves how the performance of their system compares to the standard reference values for clinical relevant limits (of pressures obtained with the classical systems).

Topic for research

- A study to compare the performance of air-charged catheters with fluid-filled pressure lines in the measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry, to include 'fast' events such as coughing.

2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

Bladder sensation during urodynamics is usually recorded by the simple expedient of asking the patient to inform the investigator when they experience

different sensations. This is an ICS standardised, but subjective measurement which can be confounded by the investigators inadvertently distracting the patient whilst bladder filling is being carried out. Investigators can also bias the measurement by inadvertent prompting, or by causing too much 'concentration' and unrepresentative awareness of the patient [Frenkl 2011]. Bladder (filling) sensation has received increasing attention since (urinary) urgency and 'early' filling sensation are clinically important and some treatments are believed to or initiated to influence LUT sensation [Wachter 2011; Heeringa,R.2011].

A patient-activated, keypad 'urge score' device to measure sensations during bladder filling was introduced [Craggs 2005] to enable patient perceptions of bladder filling and the successive stages of increasing bladder sensation to be recorded without prompting or intervention by the investigator. The device provided reliable and repeatable measures of different bladder sensations. In a controlled setting with 11 healthy volunteers of both sexes, bladder sensations were recorded during non-invasive rapid bladder filling and related to bladder filling sensations during cystometry in the same healthy volunteers: bladder sensation was reported to be continuously incremental [Heeringa 2011].

Filling sensations during conventional urodynamics were marked on a body map in another prospective study. Results from this study suggested that women's bladder sensations vary in relation to their bladder condition and suggested that this may provide clinicians with relevant information about bladder (dys)-function adding to the usual history and clinical examination [Digesu 2009].

Daily life bladder sensation can be evaluated by sensation related bladder diary and during cystometric bladder filling. 185 women with SUI, OAB or mixed UI filled out a 3-day bladder diary grading bladder sensation and measuring voided volume at each micturition. During UDS reported filling sensations were noted. The end -cystometric volumes were significantly larger than the diary voided volumes for corresponding bladder sensations, and this in all groups, leading to conclusion that symptoms relate more to the diary. [Naoemova 2009]

Imaging studies with regard to brain activity during bladder filling and emptying were reviewed [Fowler 2001]. Research, that started 1996 has provided the in vivo evidence for the existing indirect -neuro anatomical- knowledge of the brain areas involved in lower urinary tract function control and modulation, but cannot yet be regarded as a replacement of cystometry

Many studies consistently show that the correlation between objective and subjective features of detrusor adaptation to volume increment, bladder proprioception and the subjective interpretation of filling is weak [Chung 2011; Meel 2011; Clemens 2011; Tsunoyama 2011; Coyne 2011; Deffontaines 2010; Honjo 2010]. In fact these observations also demonstrate that urodynamic testing is adding new and objective diagnostic information to what has been gathered with history, voiding diary and clinical investigation. Both, UDI as well as signs and symptoms, are relevant, in combination, to select further treatment.

Conclusion (level 3-4)

- On the basis of published results, a significant variation exists in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity, despite the standardisation of terms.
- Strategies to derive bladder filling sensation parameters in a more automated and objective way, have been published and show plausible and applicable results, however are not yet sufficiently tested with regard to reliability, relevance, investigator independency or test retest robustness.

Heart rate variability

The use of heart rate variability was studied during conventional cystometry [Mehnert 2009]. Heart rate variability was evaluated to serve as a monitor of the autonomic nervous system and an objective measure for bladder filling sensation. Heart rate variability showed to reflect sympathico -vagal balance and to correlate with bladder filling sensation in 11 healthy subjects.

Conclusions (level 3-4)

- Monocenter uncontrolled studies have provided evidence for an association of heart rate variability monitoring and urodynamic observations.
- None of the analysis or testing methods of the autonomic nerve system has, to date, shown any relevance for the diagnosis of lower urinary tract function or dysfunction in neurologically unaffected persons. No direct evidence exists for lower urinary tract dysfunction as a sign of – otherwise sub clinical- autonomic failure. No evidence exists that any analysis of autonomic function can be specific enough to monitor lower urinary tract function.

3. NON-INVASIVE PRESSURE (& FLOW) MEASUREMENTS

Over recent years, groups in UK and The Netherlands have been developing non-invasive techniques to measure pressure-flow in males. The UK group has developed a penile cuff device that was tested in various preclinical and clinical validation studies but has not been reported as a true replacement of pressure flow cystometry and has not been reported to be relevant for the diagnosis of UI [Griffiths 2002; Drinnan 2001; Griffiths 2005; Drin-

nan 2003; Clarkson 2008; Sajeel 2007; Harding,C. 2007]. The group in Rotterdam developed a condom catheter through which the patient voids into a urine flow meter. During flow, the stream is, via the condom episodically diverted to a transducer that records the bladder pressure at that time. Also this method has been carefully tested and compared with standard UDS [Pel 2002; Pel 2003; Huang 2004; van Mastrigt 2006].

Measurement of perineal noise during voiding as another way of non-invasively quantifying male BOO has been evaluated but the work has not yet progressed sufficiently beyond testing on models to determine the viability of this technique in vivo [Idzenga 2005; Idzenga 2006]. Both, noise analysis and condom pressure, have not demonstrated relevance for the diagnosis of (male) UI.

A subsequent technique, with automatic modulation of the flow rate by controlling pressure in a penile cuff, was recently introduced [Clarkson 2011] The prototype needs technical refinement but some feasibility has been shown in the determination of detrusor contraction properties in relation with the bladder outlet condition.

Transabdominal wall near-infrared spectroscopy was used to detect the haemodynamic changes that are associated with detrusor contractile activity. This has been demonstrable in a highly selective set of feasibility recordings and may lead the way for non invasive detection of detrusor activity [Farag 2011].

Conclusions (level 2)

- Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. None of these studies have however shown any applicability in the diagnosis of urinary incontinence.
- Near-infrared spectroscopy has in very selected recordings shown a relation with detrusor (over) activity and is reported to be applicable as a manner to detect detrusor overactivity.

Recommendation (grade B)

- The committee recommends that non-invasive measurements of bladder or detrusor 'voiding-pressure' are considered in order to evaluate voiding function in clinical experiments when the male patient is not required to undergo an invasive assessment of the storage function of the lower urinary tract.
- The committee does not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis urinary incontinence, or of lower urinary tract dysfunction.

4. URETHRAL RETRO-RESISTANCE PRESSURE

In the measurement of urethral retro-resistance pressure (URP), a small meatal plug is inserted just inside the female urethra and saline is pumped into the urethra until the pressure reaches the value sufficient to overcome the resistance offered by the urethra when the fluid flows into the bladder. The pressure required to achieve and maintain an open bladder outlet is taken to be a measure of urethral closure function. The basic principle behind the technique has its origins in 1923 when Bonney made an attempt to measure the efficiency of urethral closure [Bonney 1923]. In his first clinical paper, Slack et al studied 258 SUI women with the URP technique in comparison with MUCP and Valsalva leak point pressure (VLPP). They found that URP measurements correlated well with both standard assessments and found that only URP measurements correlated with UI severity [Slack 2004]. The URP, in a group of 61 women, without symptoms of UI and who had negative standing SUI -tests, was significantly higher than in a group of women with SUI who had been tested previously [Slack 2004]. This study also provided some test-retest data which showed that URP measurements were consistent in individuals.

Measurements of URP on 165 women with various urodynamic diagnoses were published subsequently [Digesu 2006]. Women with USI had significantly lower URP than women with competent urethral sphincters. Women with mixed urodynamic incontinence had values of URP intermediate between women with DO and those with USI. In the mixed symptoms group, URP mean values were not significantly different from those with DO and competent sphincters, or those with USI. The authors concluded that whilst there are significantly different URP measurements between women with DO and those with USI, the URP is not a diagnostic tool.

An analysis of URP in 48 women with clinically and urodynamically proven SUI (USI) without pelvic organ prolapse (POP) before and after anti-incontinence surgery (colposuspension n = 8, tension-free vaginal tape n = 6, tension-free transobturator tape n = 34) and another study to compare URP with 'established measures of incontinence severity' showed that preoperative URP did not correlate with SUI in all women, had no predictive value and did not correlate with the outcome of anti-incontinence surgery [Tunn 2007; Roderick 2009].

Conclusion (level 2/3)

- After positive first reports of urethral retro-resistance pressure measurements it was shown that this measurement does not give any better information about urethral closure function than the urethral pressure profile or valsalva leak point pressure.

Recommendation (grade B/C)

- The committee recommends that urethral retro-resistance pressure measurements are not used in clinical routine as an alternative to (cystometry or) urethral pressure measurements made with conventional urodynamic equipment to diagnose the type of (female) urinary incontinence.

5. URETHRAL PRESSURE REFLECTOMETRY

In 2005, Klarskov et al reported on an in vitro study of pressure reflectometry for the simultaneous measurement of cross-sectional area and pressure in a collapsible biological tube and subsequently the technique of urethral pressure reflectometry (UPR), to assess the female urethra, was presented in 2007. The team postulated that these parameters had the potential to provide more physiological information about the urethra than could be obtained from conventional urethral studies.

In the same year these investigators compared UPR with urethral pressure profilometry (UPP) in 143 women (105 patients and 38 healthy volunteers) [Klarskov 2007]. UPR was measured supine, both while relaxed and during 'squeeze', and while upright and relaxed, and compared with UPP using the perfusion technique, with the patient supine and relaxed. All measures were done twice to evaluate short-term reproducibility and 17 patients were assessed with both methods on two different days (long-term reproducibility). The authors showed that UPR measured the same pressure as UPP but the UPR was more reproducible. Subsequently UPR parameters of in 30 SUI women and 30 volunteers (23 'continent' and 7 'nearly continent') were reported and compared with UPP [Klarskov 2008].

Conclusion (level 3)

- Preclinical measurements of urethral pressure reflectometry opening pressure and cross sectional area ('dynamics') have provided some insight into urethral closure function and dynamics, but, as yet have no clinical relevance in the diagnosis of (female) urinary incontinence.

Recommendation (grade C)

- The committee recommends that urethral pressure reflectometry is not used in clinical practice for the diagnosis of urinary incontinence before clinical relevance, non inferiority and or superiority over current urodynamic tests has been demonstrated.

6. ULTRASOUND IMAGING

Imaging and ultrasound in relation to UI will be discussed in a separate chapter. We will only give a short summary of ultrasound in relation with urodynamic observations.

The measurement of detrusor wall thickness has been used in a number of studies as a screening test for DO or BOO with a variety of measurement techniques using transvaginal, transabdominal or transperineal ultrasound. Different protocols were used and measured different parts of the bladder for example the dome, the trigone or the anterior bladder wall. This has resulted in contradictory data. Some data showed a smaller bladder capacity in overactive bladder (OAB) wet or DO, and an association between increased detrusor wall thickness and DO on urodynamic testing. Also, observations of an association of ultrasound detrusor wall thickness and BOO have been reported. Most researchers conclude that overlap of the results and the relatively low predictive value should be improved before bladder wall thickness is used in clinical practice [Lekskulchai 2008; Kuo 2009; Panayi 2009; Panayi 2010; Oelke 2009; Chung 2010; Ozawa 2010; Kuhn 2010; Almeida 2011; Serati 2010].

Conclusion (level 3)

- There is some evidence that detrusor wall thickness is related to bladder outlet obstruction as well as to detrusor overactivity.
- There is no evidence that ultrasound detrusor wall thickness analysis can discriminate between detrusor overactivity and bladder outlet obstruction and a relatively low predictive value to discriminate from normal lower urinary tract function.
- There is a large overlap between normal and abnormal values in detrusor wall thickness and a lack of standardisation in ultrasound detrusor wall thickness measurement.

Recommendation (grade C)

- The committee recommends that ultrasound detrusor wall thickness is not used in routine clinical practice for the diagnosis of lower urinary tract function related to urinary incontinence.

B. URODYNAMICS: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE

I. REPRODUCIBILITY OF FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS

1. INTER-OBSERVER, TEST-RETEST AND PRACTICE VARIATION

When different investigators judge urodynamic traces together with written clinical information in women, there is agreement between them regarding the final clinical diagnosis in about 80% of cases. In other words there is, depending on the diagnosis, some disagreement in 20% of cases when urodynamics is judged in combination with clinical

parameters [Whiteside 2006]. A few studies have concluded that there is good short time inter and intra–rater reliability. In a single centre series of 621 urodynamic pressure flow tracings of female patients, small average differences between parameters were observed by various investigators, which was interpreted as good inter -observer agreement [Digesu 2003]. Inter-observer variability has also been tested in other ways. In a study where 4 experienced practitioners, evaluated 17 paediatric urodynamic datasets, they failed to agree on aspects of detrusor function, including DO, in a quarter of the cases [Venhola 2003]. This result is reminiscent of a similar study of the interpretation of urodynamic recordings of male voiding function [Kortmann 2000].

To determine the reproducibility of same session repeated UDS in women with symptoms of UI, 152 women presenting with symptoms of UI underwent standardised UDS, which consisted of free uroflowmetry and two filling cystometries and pressure-flow studies. Overall, reproducibility of the urodynamic parameters were good to excellent (ICC range: 0.72-0.93), except for the bladder volume at FSF (ICC = 0.46) and the maximum Watt's factor (ICC = 0.68). The bladder volume at FSF and the MCC were systematically higher in the second run (mean difference (95% CI) = -45 (-73; -37) and -3 (-15; 10), respectively). Reproducibility of the diagnosis SUI and/or DO were good to excellent (median ICC = 0.76, p= 0.68 and p = 1.00, respectively). Reproducibility of the volume and amplitude at DO, however, were only poor (ICC = 0.18 and 0.25, respectively). The authors of this study concluded that reproducibility of same session repeated –standardised-UDS, in women with symptoms of UI was good to excellent [Broekhuis 2010].

In a survey to determine the variation in urodynamic practices in the United Kingdom 100 questionnaires were sent to units known to be performing urodynamic investigations. There was a significant variation in practices with only 51% of units having a protocol for what tests should be performed, under what circumstances and how [Adekanmi 2002]. Standardisation of urodynamic variables may result in a greater consistency of diagnosis, allowing easier comparisons of treatment regimes and outcomes, and is the conclusion of studies and reviews of this kind [Zimmern 2006; Ellis-Jones 2006]. Standardisation, education and training as well as auditing and evaluation are reported to be relevant in this regard [Ellis-Jones 2006; Singh 2010; Moore 2011].

In a review to examine the influence of position during (filling) cystometry with regard to the sensitivity for DO, sixteen relevant studies with good consistency were analysed. All but two showed a clear influence, with a higher incidence of DO in the vertical position (sitting or standing) or onset of DO when changing to a vertical position. Performing the UDS in a supine position would have missed a large proportion of DO diagnoses, ranging from 33% to 100%. The authors noticed a substantial practice variation in position during urodynamic investigation and suggested standardisation was needed [Al-Hayek 2008].

Some suggested that these findings are caused by difficulties of interpretation, included movement artefacts, and also criticise over-dependence on patients for suitable data recording without a medical assistant. This presumed lack of reliability has lead to the study of the additional value and reliability of ambulatory UDS, as it may improve diagnostic sensitivity and maybe specificity. The additional diagnostic value of ambulatory UDS in patients with LUTS was compared with conventional UDS [Koeveringe 2010]. A retrospective study was done in 108 patients between 2002 and 2007. Ambulatory UDS was shown to be useful in patients with OAB, or in patients with UI that was not demonstrated during conventional UDS, but the study is difficult to extrapolate to real values of amended diagnostic capability.

2. SHORT-TERM (WITHIN-SESSION) REPRODUCIBILITY

A number of authors have investigated the within-session reproducibility of cystometric measurements. Because such measurements are conducted within a short period of time, the possibility that the first measurement influences the second, for example through a direct effect on the mechanical properties of the bladder (hysteresis and/or viscoelasticity), has to be considered.

30 healthy women with a mean age of 52 years, underwent 2 consecutive medium fill rate (50 mL/min) cystometries in a single session [Brostrom 2002]. The volumes at first desire to void (FDV) and normal desire to void (NDV) increased significantly from the first to the second measurement, by 34 and 51 mL respectively. The MCC showed no difference. The proportion of these healthy subjects who showed DO changed from 4/30 (13%) in the first cystometry to 1/30 (3%) in the second; statistically insignificant.

In a similar study [Mortensen 2002] of short-term repeatability in 31 female patients aged 14-74 years, two consecutive cystometries were performed with body temperature liquid at a rate of 50 mL/min. On the first cystometry, FDV occurred at a median volume of 112 mL (range 26-503 mL). The cystometric capacity had a median value of 150 mL, with a range from 39-633 mL. The volume at FDV increased by 46 mL from the first to the second cystometogram, while the MCC increased by 35 mL. These changes are similar to those seen in normal volunteers, but, as the authors point out, they are not clinically important because they are much smaller than the random variability within subjects, as measured by the 95% confidence limits of ±130 and ±106 mL respectively.

Chin-Peuckert et al [Chin 2003] examined the variability between two consecutive cystometries in 32 male and 34 female children with a mean age of 7. Most suffered from spinal dysraphism. A smaller number showed DO on the second study than on the first ($p< 0.05$), and similarly the volume at which DO was first observed was larger on the second study ($p<0.05$). Interestingly, these results are similar to those obtained in children without overt neuropathy [Griffiths].

Hess et al [Hess 2002] did not perform repeated cystometries, but first measured the bladder pressure 'as is' at whatever volume was in the bladder initially, in 21 men and 1 woman with 'neurogenic bladder'. They then drained the bladder and refilled to the same volume and again measured the pressure. The second 'cystometric' pressures were higher than the initial 'physiological' ones by approx 6 cm H_2O ($p = 0.01$), although strongly correlated.

In another study where fifty consecutive individuals with spinal cord injury had 2 trials (trial 1 and trial 2) of UDS done 5 minutes apart, differences in MCC, opening pressure, maximum detrusor pressure, volume (leaked) voided, and post void residual (PVR) volume were evaluated. The variation observed was ± 100-150 mL for the volume parameters and ±10-20 cm H_2O for the mentioned pressure parameters, all in both directions between 1st and 2nd [Chou 2006].

Sixty men with LUTS and 35 with NLUTD after spinal cord injury (SCI) were assessed, with symptom scores and uroflowmetry obtained and filling and pressure-flow cystometry carried out three times in succession. In men with LUTS, a significant decrease in the number and pressure of detrusor contractions in consecutive filling cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. In men with SCI, cystometric variables and DO remained consistent over sequential studies [Ockrim 2005].

Twenty asymptomatic women with a mean age of 42 years [30-55) agreed to undergo a urodynamic evaluation, repeated immediately without removing the catheters (a two-fill and void study) [Gupta 2004]. Sixteen women of this cohort returned for an identical assessment 1-5 months later. The short time variation was ± 5 mL/s for Q_{max} and ± 10 cm H_2O for $p_{det}Q_{max}$. Voided volume (VV) and first sensation of filling (FSF) differed ±50 mL in the test retest situation. The authors noted that the variation of parameters in these healthy women was larger than observed in other studies with patients.

3. INTERMEDIATE-TERM REPRODUCIBILITY

Homma et al [Homma 2000] found that, in 30 patients with DO, repeat cystometry carried out 2-4 weeks after initial testing showed a consistent shift towards normal. Bladder volumes increased by 10-13% ($p<0.01$), while DO disappeared in 10% of subjects and decreased in amplitude by an average of 18% in the remaining cases. The random variability of cystometric capacity was ± 57 mL (95% CI).

4. LONG-TERM REPRODUCIBILITY

10 healthy females (mean age 34 years), were investigated twice at an interval of 2 years in both, supine and sitting positions [Sorensen 1988]. FSF occurred at a mean volume of 378 mL supine and 354 mL sitting, with intra-subject variability over two years as quantified by the standard deviation (sd) of 76 and 100 mL (sd) respectively. MCC was 512 mL supine and 502 mL seated, with intra-subject sd of approximately 75 mL in both cases. Inter-subject sd's were a little larger: 76-144 mL. No significant differences in volumes or compliance over two years could be demonstrated.

Post hoc analysis of urodynamic (pressure flow) tests of male treated for LUTS with enlarged (unspecified) prostate and BOO (for a not specified proportion) showed test retest reproducibility to be good on the basis of parameter correlations, but without kappa or Bland and Altmann analysis [Kraus 2010].

A total of 48 children ±10 years were enrolled in a study to evaluate the influence of position during UDS in this patient group, with 60% neurologically affected. No difference was noted for maximum cystometric capacity, DLPP or pressure specific volumes at 20 and 30 cmH_2O between the supine and sitting positions. Statistically significant lower values were found for the volume of FSF and volume at which DO was first detected, with lesser difference for abdominal or Valsalva leak point pressure in the sitting position. Significant differences were also noted with position changes in regard to detection of DO and UI episodes, being more prevalent in the sitting position [Lorenzo 2007].

Summary

In patients and in healthy volunteers, if cystometry is repeated either during the same session or within about 4 weeks, the bladder volumes at which the various sensations are felt and the bladder capacity tends to increase by 30-50 mL, while the proportion of traces showing DO tends to fall. These systematic changes are fairly small in comparison with the random within-subject variability, which has an average range of about 50-60 mL.

Conclusions (level 2)

- A number of studies have reported test retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations; this can be regarded as the physiological variation of urodynamic testing.
- Various studies have demonstrated clinically relevant practice variation and inter-rater/observer variation.

Recommendations (grade B)

- The committee recommends that investigators and clinicians take into account the inherent physiological variability of urodynamic testing.
- The committee recommends investigators and clinicians evaluate the 'representativity' of the tests (which is an evaluation based on the patient's perception as to how well the tests have reproduced their usual lower urinary tract symptoms and function, helped e.g. by the voiding diary.) and the committee recommends that examiners strive towards maximal representativity.
- The committee recommends sitting position during cystometry, because that can increase sensitivity of the diagnosis of filling phase abnormalities.
- The committee recommends persistent attention to the standardisation of techniques, to education, and to practice quality evaluation, and consistency of interpretation of results, especially to reduce intra and inter-practice variation and inter–observer variability.

Topics for research

- The committee suggests further consideration of standardisation of urodynamic tests, procedures and evaluation, especially to reduce inter-practice variation.
- The committee suggests intensive dissemination of up-to-date standards and careful training of urodynamic investigators and suggests evaluation of the effect of these standards and training on health care quality.

5. REPRODUCIBILITY OF AMBULATORY URODYNAMICS

There is no published data on the reproducibility or test retest differences of ambulatory urodynamic studies. There is no report that evaluates the investigator dependency on the -post test- analysis of the recorded data.

II. CYSTOMETRY: NORMAL VALUES

1. NORMAL VALUES: FILLING CYSTOMETRY AND AMBULATORY URODYNAMICS

Normal values for cystometric variables are reported by a number of authors. A striking observation is that there is great inter-centre variability, even for tests in nominally similar persons or patients. There is no evidence from these studies that these variations are strongly associated with differences in filling rate, infusate temperature, or patient position. In addition to and referring to the previous consultations we report only the relatively recent studies on volumes, pressures, compliance, capacity and sensations.

Wyndaele et al [Wyndaele 2002] examined 50 volunteers; The bladder was filled at 30 mL/min with body temperature saline. For males (n=18; mean age 22 ± 3 years), FSF occurred at 222 mL ± 151 mL; FDV occurred at 325 mL ± 140 mL; and strong desire to void (SDV) occurred at 453 mL ± 94 mL, which was taken as maximum capacity. For females (n=32; mean age 21 ± 2 years) FSF occurred at 176 ± 96 mL; FDV at 272 mL ± 106 mL; and SDV at 429 mL ± 153 mL. DO was observed in 7/50 (14%) of these normal volunteers. The group also published a study with symptom free 'middle-aged' female volunteers. Of their volunteers, a substantial number were excluded because of asymptomatic abnormalities. The remaining had an average capacity during cystometry of 586 mL (sd 193 m) with 258 mL and 1092 mL as extremes [Pauwels 2004].

Twenty-four women without a history of frequent urgency and without DO (mean age 50.2 years, range 22-80 years), including 7 pre- (29.2 years), 7 peri- (48.8 years), and 10 postmenopausal (66.0 years) women were studied with uroflowmetry and video urodynamics to determine normative data for LUT function in asymptomatic continent women without DO across the age span. For all subjects, median maximum single VV in bladder diary was 500 mL and median MCC was 580 mL. SDV was reported at 287, 366, and 425 mL for pre-, peri-, and postmenopausal groups, respectively. The maximum flow rate was 25, 32, and 23 mL/sec in uroflowmetry and 23, 24, and 18 mL/sec during the pressure-flow study, respectively. Median PVR was below 20 mL in all groups. At maximum flow rate subjects voided with detrusor pressures of 29, 26, and 24 cm H_2O, respectively and MUCP was 94, 74, and 42 cm H_2O, respectively [Pfisterer 2007].

Thirty healthy males aged 21-32 years volunteered for an ambulatory urodynamic 24 h investigation, with a suprapubic catheter, to study natural fill urodynamics during normal and increased fluid intake. The recorded micturition data were: frequency (f), VV, voiding time, maximum flow rate (Q_{max}) and time to Q_{max}. The number of sensed and not-sensed detrusor contractions, and their duration and time in relation to voiding were also recorded. During the recording day, subjects were randomized to normal (30 mL/kg body weight per day) or larger (60 mL/kg body weight per day) fluid intake. There was a larger urine production and an increased voiding frequency in the fluid-loaded group ($p<0.0001$). The detrusor pressure ($pdetQ_{max}$) was significantly higher in the fluid-loaded group (73 cm H_2O, range 57-94) than in the normal fluid intake group (60 cm H_2O, range 45-86) ($p=0.003$). No other urodynamic data differed significantly between the two groups. Ambulatory urodynamics in normal young men showed a large inter -individual variation, detrusor contractions during filling were frequently recorded, and premicturition contractions were consistently found. The data found in this study were similar to

previous home flow recordings in the same group [Schmidt 2004].

In a retrospective study of 186 selected investigations the influence of urine production during filling cystometry on total bladder volume was observed. Mean filled volume (external infusion plus urine production) was 346 ± 152 mL, but mean real bladder capacity (VV + residual urine) was 391 ± 170 mL. In all patients, 14% extra urine was produced due to urine production (mean rate, 6.1 mL/min). In 42% of the investigations, the real bladder capacity was more than 110% of the infused volume. In 18% of the patients, the contribution of natural bladder filling was more than 25% of the infused volume [Heesakkers 2003].

Urodynamic tests were, in another study, conducted on 39 asymptomatic male volunteers with a mean age of 25.8 years (range 21 to 31) and mean weight of 75.5 kg (range 63 to 95) to examine the pressure-flow relationship and obtain evidence to support the hypothesis that fluid consumption has a role in detrusor voiding function. Volunteers were divided into 2 groups according to water consumption regimen of 30 mL/kg daily (17 patients, group 1) and 60 mL/kg daily (12, group 2). Bladder pressure was monitored via a suprapubic catheter and abdominal pressure was measured via a rectal balloon using an ambulatory system with an average duration of 20.5 hours. Doubling of water consumption increased urethral opening pressure from 51.2 ± 3.2 to 61.5 ± 5.1 cm. H_2O ($p<0.05$), maximum detrusor pressure from 58.9 ± 4.5 to 70.0 ± 6.2 cm. H_2O ($p<0.01$) and contractility from 15.4 ± 1.4 to 17.7 ± 1.4 W/m2. There were no significant differences due to water consumption in maximum flow rate (24.4 ± 1.4 to 25.2 ± 1.8 mL/s) or bladder capacity (286 ± 20 to 329 ± 15 mL) but a significant increase in the number of micturitions from 5.8 ± 0.5 to 9.8 ± 0.5 per day ($p<0.001$) proportional to water consumption [Schmidt 2002; Nager 2007].

2. COMPLIANCE

Compliance is the ratio of a change in volume measured relative to the corresponding change in pressure. Usually compliance is calculated over the change in volume from an empty bladder to that at MCC.

In 17 healthy subjects, using a filling rate of 35 mL/min,[Waalwijk 1992] the range of compliance values was very wide (range = 11-150 mL/cm H_2O; mean ± sd = 46 ± 40 mL/cm H_2O). Such a mean value implies only a small rise in pressure on filling (a few cm H_2O), consistent with having high compliance. Even higher values of compliance were reported by Hosker (range = 31-800 mL/cm H_2O; mean ± sd = 124± 150 mL/cm H_2O) in 72 healthy females (age 25-75 years) and these reproduced the wide range of values already published [Hosker 2004].

The results were comparable in elderly, peri and post menopausal women [Pfisterer 2007]. In another selected group of healthy middle aged, volunteers compliance was 'high' on average, however with a large variation [Pauwels 2004]. Similarly, Robertson showed that in 17 healthy male and female volunteers, the median detrusor pressure rise on conventional filling cystometry was 5 or 6 cm H_2O at filling rates of 50 and 100 mL/min respectively [Robertson 1999]. On ambulatory monitoring the median pressure rise was 0 cm H_2O however, a significantly smaller value.

Compliance cannot only be quantified in the units of mL/cmH_2O but also as a dimensionless number measured from empty to MCC. Compliance increases with age (because bladder capacity increases with age). This dimensionless value of compliance is to present a value that is independent of age (BUT not into old age). This is presented to be especially relevant in children when intra- and inter- individual test (retest) comparisons are made [Wahl 2004]. Consistently, among 22 healthy female volunteers, conventional cystometry and ambulatory study, performed in random order, showed a larger detrusor pressure rise on conventional filling as compared with ambulatory studies [Harlington 1996].

3. NORMAL SENSATIONS AND BLADDER CAPACITY

Earlier consultations have indicated the striking variability from centre to centre: FSV for example occurs at about 100 mL in one centre but at about 350 mL in another, a value large enough to provoke a strong desire to void in the first.

The bladder capacity is somewhat less variable from centre to centre, its mean varying from 340 to 570 mL. Apart from this inter-centre variability, the inter-subject variability of all the parameters is also substantial, with an sd of about 100 mL. Some of this variation represents genuine differences between subjects, but it should be noted that the within-subject variability is also quite large, in order of magnitude 50 mL.

As a rule of thumb in healthy adult subjects, and omitting some of the more inconsistent values, FSF occurs at about 170-200 mL, FDV or NDV (the ICS makes no distinction [Abrams 1988] at 250 mL, and strong desire to void at about 400 mL; MCC is about 480 mL. It is interesting that the mean VV on ambulatory monitoring falls between FSV (on cystometry) and FDV/NDV. Thus, in daily life, the bladder is usually emptied long before a strong or even a 'normal' desire to void would be felt on cystometry, although much more can be held if voiding has to be postponed. Correspondingly, there is a discrepancy in bladder capacity between daily life and urodynamic study, also depending on the method of measurement (uroflowmetry, voiding diary or cystometry) [Hertzberg 2003]. There is no evidence after the last

consultation to show that this inter investigator variability has decreased.

4. DETRUSOR (OVER-) ACTIVITY IN NORMAL SUBJECTS

DO is observed during conventional cystometry in up to 17% of asymptomatic subjects with a mean percentage of about 8%. The percentage is much higher, up to 69%, with ambulatory studies, although lower in other observations. DO can be observed during urodynamic testing, in healthy subjects (without the symptoms that are usually associated with OAB) which might also indicate that the observation of 'detrusor overactivity' should not always be interpreted as 'synonymous with pathology that demands treatment'. Nevertheless the false positive percentage remains unknown in those uncontrolled studies.

Conclusions (level 2)

- Various studies have been helpful in giving normal values and test retest variation of urodynamic parameters in healthy volunteers.
- There is some evidence that evaluation of filling sensation may be different between laboratories, (thus: 'may be observer dependent'), making data exchange as well as generalization and interpretation of published data difficult.

Recommendations (grade B)

- The committee recommends that investigators and clinicians bear in mind the results of urodynamic testing in healthy persons and to recognize 'normal' test-retest variation as well as the differences and/or variations between 'usual lower urinary tract behaviour', ambulatory monitoring and office urodynamic testing.
- The committee suggests that clinicians should be sufficiently aware of the normal variation, and normal values of lower urinary tract function and urodynamic studies.
- The committee recommends further standardisation and a practical objective means of recognizing and recording the parameters relevant to sensation during bladder filling.

5. INFLUENCE OF CATHETER ON VOIDING

A urodynamic database of 600 consecutive women referred for the evaluation of voiding symptoms was reviewed to examine the effect of a 7F transurethral catheter on flowrate. Before urodynamics, all patients voided privately using a standard toilet and free flow was recorded. Only 100 patients who voided similar volumes, varying by less than 20%, on the free flow, and pressure flow studies were included. In each VV category and urodynamic diagnosis, pressure-flow parameters were significantly different from the equivalent free flow parameters in all but 4 cases. Specifically the maximum flow rate was significantly less and flow time was significantly longer on pressure versus free flow studies (each $p<0.01$). An intermittent flow pattern was more common on pressure-flow, than in free flow measurements (43% versus 9%) [Groutz 2000].

Women between the ages of 30 and 70 years, without LUT complaints and without a history of surgery for UI, were recruited to prospectively examine the effect of a 6F urethral catheter on the urinary flow rate in healthy women without LUT symptoms. After a free flow rate, cystometry and pressure-flow studies were performed twice using a 6F urethral catheter. With a 6F urethral catheter in place, the women had a mean maximum flow rate of 16 mL/s on the first study and 15 mL/s on the second. A significant difference was demonstrated between the free and intubated maximum flow rates for both the first ($p = 0.0006$) and the second ($p = 0.0001$) study. No significant difference was detected between the two intubated maximum flow rates ($p = 0.262$) [Baseman 2002].

The impact of three different sized (4.5-, 6- and 7F) catheters on pressure-flow studies was studied in 60 women undergoing urodynamic evaluation for LUT symptoms, divided into two groups (A and B) of 30 women each. The patients underwent non-invasive free-flow uroflowmetry with determination of PVR. In group A the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 6F catheter once; in group B the two consecutive pressure-flow studies were performed using a 4.5F catheter once and a 7F catheter once. Free-flow rates were better with lesser residual. There was no significant difference in maximum flow rate, average flow rate and flow time between 4.5- and 6F catheter pressure-flow studies (A). However, there was a statistically significant difference between 4.5- and 7F pressure-flow studies (B) in those uroflowmetry parameters. Detrusor pressure at maximum flow ($p_{det}Q_{max}$) and maximum detrusor pressure ($p_{det\ max}$) in group A did not show statistically significant differences between 4.5- and 6F pressure-flow studies whereas in group B, $p_{det}Q_{max}$ and $p_{det\ max}$ were significantly different between 4.5- and 7F pressure-flow studies [Scaldazza 2005]. This more or less resembles the results in male patients, when a higher percentage of BOO shows that a 'mechanical' catheter effect is probably clinically relevant with catheters of 7F and larger [Zhao 2006; Trumbeckas 2006].

Conclusion (level 3):

- There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter.

Conclusion (level 4):

- It is also the opinion of the committee that single catheters 6-8F incorporating both a filling channel

and a pressure-sensing channel should be used for intravesical pressure measurement during cystometry (i.e. double lumen catheters in the case of using fluid filled pressure lines).

Recommendations (grade B)

- The committee recommends that investigators interpret pressure-flow voiding parameters and the subsequent post void residual together with the free flow (not catheterised, representative) voiding parameters.
- The committee recommends the 'standard' use of, as thin as possible, 'one-catheter-systems' (dual lumen if fluid filled) for filling and pressure recording during urodynamic testing.

III. REPRODUCIBILITY, RELIABILITY AND NORMAL VALUES OF URETHRAL PRESSURE MEASUREMENTS

1. NORMATIVE AND COMPARATIVE DATA FOR MAXIMUM URETHRAL CLOSURE PRESSURE

Tables in the previous consultations show that the between-centre variability in the values reported, with mean MUCP is large and that the between-subject differences, reported in most studies show a wide range. However in spite of this variability, the mean MUCP was consistently lower in patients with signs and symptoms of SUI than in non-SUI women. There is nevertheless so much overlap that MUCP cannot be regarded useful for diagnosis of SUI [Weber 2001].

Eighty primiparous women with self-reported new SUI, 9-12 months postpartum, were compared with 80 primiparous continent controls and 80 nulliparous continent controls to identify impairments specific to SUI. MUCP (± sd) in primiparous incontinent women (62.9 ± 25.2 cm H20) was lower than in primiparous continent women (83.9±21.0) who were similar to nulliparous women (90.3 ± 25.0). This lower MUCP followed by ultrasound assessment of bladder neck mobility on coughing was the measure most associated with de novo SUI after first vaginal birth [DeLancey 2007].

Studies providing normative data for men are scant, but there are some data on the UPP in normal males, however without any relevance for UI (neither for BOO or storage dysfunction) [Yalla; Abrams 1977].

2. RELIABILITY OF URETHRAL PRESSURE VARIABLES

In clinical practice, use of a fluid-perfusion technique to measure resting urethral pressure profile parameters such as MUCP yields an sd that ranges from 3.3 to 8.1 cm H_2O. On average, the sd is approximately 5 cm H_2O (95% confidence limits ± 10 cm H_2O) or ± 5%. With a micro tip transducer technique the sd varies between 3.3 and 16.5 cm of water, which means that the 95% confidence limits may be as large as ± 33 cm H_2O. The coefficient of variation when using the micro tip transducer technique has been reported to be 17% (95% confidence limits ± 34%). In one study using fluid perfusion the coefficient of variation of MUCP varied from 3% to 11% (95 % confidence limits 6% - 23%) [Toguri 1980].

Another, comparative study between fluid-filled and micro tip pressure transducers observed that MUCP obtained from the fluid-filled catheter was significantly higher than that obtained from the microtip catheter. However, the authors also concluded that the use of the double-lumen fluid-filled catheter for the measurement of MUCP can be considered a reliable technique since its reproducibility is as good as that of the micro tip catheter [Wang 2002].

A significant difference between MUCP values recorded by micro transducer versus fibre optic catheter systems has also been observed. Significantly lower mean MUCP's were recorded by the fibre optic system than by the micro transducer system. No significant difference was however observed between these two systems in the measurement of VLPP [Culligan 2001].

As mentioned above, the performance of air-charged catheters in measuring MUCP has been shown to be comparable to micro transducers in the measurement of maximum urethral closures pressure in a non-randomised study [Pollak 2004]. However, there was a difference in functional urethral length which was attributed to the different diameters of the two catheters.

In 2008, Zehnder et al carried out a randomised comparison of these air-charged catheters with micro tip catheters in 64 women and found that the air-charged catheter was as least as reliable as the micro tip for measuring both MUCP and functional urethral length. However, they found that the air-charged catheter gave a higher reading of both parameters compared to the micro tip device [Zehnder 2008].

3. AGING

It is well established that in women the UPP changes with age. A recent study of 255 women, ages 20-77 years, without DO, overt neuropathy or pelvic or UI surgery, confirmed that the MUCP is negatively associated with age ($r = -0.5$, $p < 0.0001$) [Schick 2003].

4. OTHER PARAMETERS AFFECTING THE MEASUREMENT OF URETHRAL CLOSURE PRESSURE

The 2002 ICS standardisation reports, relating to urethral closure pressures, discusses that the value of MUCP is not only dependent on the type of catheter

used but also its orientation within the urethra, the degree of bladder fullness and the position of the patient [Lose 2002]. There is no new evidence, nor evidence regarding newer techniques, that the intrinsic (urethral pressure) measuring quality has improved to a clinically relevant level with regard to sensitivity, specificity and reliability.

Conclusions (level 2)

- Various studies have shown considerable test-retest variation of all urethral pressure measurements or parameters.
- Various studies have shown that normal and pathological values of urethral pressure parameters are largely overlapping.
- Various studies have shown that urethral pressure(s) (parameters) are affected by age.
- Studies have shown that urethral pressures depend on patient position, volume of fluid in the bladder and position of the patient.
- Studies have shown that urethral pressures depend on the pressure recording catheter used and its orientation within the urethra.

Recommendations (grade B)

- The committee recommends that investigators and clinicians recognize the poor sensitivity and specificity of urethral pressure measurements and their 'normal' test retest variation.
- The committee does not recommend urethral pressure measurement as the only urodynamic test in patients with urinary incontinence either to confirm or to refute stress urinary incontinence.
- The committee recommends that the clinical relevance of urethral pressure measurements, if performed, is judged in relation to other urodynamic tests (such as cystometry) and to the clinical examination.

IV. LEAK POINT PRESSURE

1. INTRODUCTION

The detrusor pressure or the intravesical pressure (p_{det} or p_{ves}) at which involuntary expulsion of urine from the urethral meatus is observed is the LPP. The rise in bladder pressure causing leakage may originate either from the detrusor (caused for example by the filling of a low-compliance bladder) or from an increase in the abdominal pressure. Thus there are two different leak point pressures – the DLPP (DDLPP) and the abdominal LPP. The abdominal pressure increase during the latter is produced voluntarily by coughing (CLPP) or by Valsalva (VLPP).

LPP is not consistently defined throughout the reports in literature and we have not found any standardisation (report) of the technique. Any comparison of findings between studies is hindered by this.

The elements of CLPP or VLPP which could be standardised include: 1) the basic definition of LPP (baseline value of pressure; route of measurement – urethral, vaginal or rectal), 2) whether Valsalva or cough is used to produce leakage, 3) the technique to confirm urine loss, 4) location of catheter, and shift in location on cough or strain, 5) calibre of catheter (if transurethral) 6) type of pressure sensor 7) the volume in bladder, 8) the rate of prior bladder filling and 9) patient position [Weber 2001].

The same elements are relevant for DLPP except pressure measurement has to be from the bladder but could be through a suprapubic catheter.

2. RELIABILITY OF LEAK POINT PRESSURE MEASUREMENTS

a) Diagnosis

In a study that recruited 168 patients it was seen that women who demonstrate urodynamic SUI at lower bladder volumes do not report greater bother from the UI than women who leak at higher volumes. The authors concluded that leakage severity 'quantified' by this urodynamic method, is not an adequate reflection of UI related quality of life (QoI) and or subjective UI severity [Lowenstein 2007]. Another study confirms these observations [Albo 2007].

A total of 200 women with SUI were clinically evaluated and underwent urodynamic study to determine the correlation between VLPP and the UPP. A progressive correlation of VLPP with MUCP was found when UPP was performed at 50 mL ($r = 0.305$, $p<0.0001$), at 250 mL ($r = 0.483$, $p<0.0001$) and at maximum bladder filling ($r = 0.561$, $p<0.0001$). The authors concluded that there is a significant correlation between MUCP and VLPP [Almeida 2005]. Another prospective study in 109 patients assessed the relationship between CLPP and VLPP with SUI (n=61; 56%), DO (n=21; 19%) or a combination of these (n=27 25%). More women with SUI leaked during CLPP than during the VLPP; fewer women with DO leaked during CLPP and more during the VLPP [Sinha 2006]. LPP's are reported to be dependent on patient position; being lower in the standing position as compared to supine position [Nguyen 2002]. Another study with the goal of determining the effect of position on UPP seems to have been troubled by 'poor test retest reproducibility' in the standing position [Dorflinger 2002].

Two studies have been performed, one with 369 patients, including some without UI, and another study with 65 female patients with UI stratified into groups with various levels of LPP, various grades of urethral (hyper-)mobility, and various grades of UI severity. Both studies were unable to find strong 'urodynamic' discriminators for the type or the severity of UI

and concluded that all values overlapped. Patients with SUI can be characterised by LPP and change in the urethral angle and or mobility, although these variables have never resulted in define discrete classes [Fleischmann 2003; Schick 2004].

The results of these newer studies confirm the earlier conclusion in an expert review: 'It is not apparent that either LPP measurement or UPP can accurately predict which patients will achieve the best outcome of surgical treatment for SUI. Other parameters assessed during urodynamic evaluation might provide prognostic information regarding the risk of voiding dysfunction postoperatively and the possibility of persistent urgency-related leakage following surgery, though not directly predict cure' [Lemack 2004].

b) Treatment

Can any value of LPP (Valsalva or cough) and/or UPP help in the selection of treatment for patients with SUI? This question has been addressed by various investigators.

In a retrospective cohort analysis of 3-month outcomes in 145 subjects (TOT = 85; tension-free vaginal tape (TVT) = 60) it was observed that relative risk of postoperative urodynamic SUI, 3 months after surgery, in patients with a preoperative MUCP of ≤ 42 cmH_2O, was 5.89 (1.02 to 33.90, 95% confidence interval) when TOT was compared with TVT tape [Lemack 2004].

The value of urethral hypermobility, MUCP in the diagnosis of SUI was evaluated in 369 women with clinical symptoms suggestive of SUI without symptoms of detrusor overactivity. The cohort was divided into 2 groups according to continence or incontinence status. Continent and incontinent patients differed with regards to MUCP and hypermobility (each $p<0.0001$). Incontinent patients had a greater probability of a higher grade of each factor. MUCP was significantly lower in the incontinent group ($p<0.001$) [Schick 2004].

A prospective study assessed the difference in measured urethral function before and after TVT procedure. Twenty-three (65.7%) of 35 consecutive women had a preoperative diagnosis of intrinsic sphincter deficiency (ISD) as defined by MUCP < 20 cm H_2O and/or VLPP <60 cm H_2O. Subjective (Impact of Incontinence score and Urodynamic Distress Inventory) and objective success rates were 91% and 83%, respectively. The mean change in MUCP was -1.3 cm H_2O (95% CI -5.9, 3.3), whereas the pressure transmission ratio increased 15.7% (95% CI 5.0%, 26.3%). The mean decrease in straining urethral angle was 16.3 degrees (95% CI -23.9 degrees, -8.7 degrees). Cured subjects, demonstrating hypermobility preoperatively, continued to do so postoperatively. The effectiveness of the TVT did not appear to depend on a clinically significant change in the straining urethral angle. [Mutone 2001]

A total of 221 women 29 to 80 years old (mean age 55.2) were included in a later study to evaluate the outcome of the TVT procedure for SUI with low VLPP. Mean follow-up was 10.5 months (range 6 to 52). Patients were divided into 61 with low (<60 cm H_2O) and 160 with higher (>60 cm H_2O) VLPP. The overall cure rate was significantly lower in patients with low versus higher VLPP (82.0% versus 93.1%, $p = 0.013$). In women with low VLPP, multivariate analysis indicated that urgency symptoms and low MUCP were independent factors for treatment failure (OR 15.12, 95% CI 1.90 to 120.61, $p = 0.010$ and OR 0.92, 95% CI 0.86 to 0.99, $p = 0.018$, respectively). [Paick 2004]

174 consecutive patients who underwent a distal polypropylene sling procedure for the treatment of SUI were prospectively evaluated and reported in a slightly earlier study. The group was divided by VLPP into group 1: 60 patients who did not leak on urodynamics, group 2: 27 patients with VLPP > 80 cm H_2O, group 3: 71 patients with VLPP 30 to 80 cm H_2O and group 4: 16 patients with VLPP < 30 cm H_2O. Mean follow-up was 14.7 months (range 12 to 30) and mean patient age was 62 years (range 32 to 88). The groups were well matched before surgery with respect to age, number of previous surgeries, and severity of SUI symptoms and UUI. The percentage of patients who were cured or improved was similar among groups. After surgery there was no statistical difference among patient mean self-reported symptoms of or bother from SUI or UUI. The distal urethral polypropylene sling provides similar symptom improvement in all patients regardless of preoperative VLPP. LPP is helpful in the diagnosis of SUI but appears to be of minimal benefit in predicting the outcome of the distal urethral polypropylene sling procedure. [Rodriguez 2004]

A later study reported that neither MUCP nor LPP were good predictors of post-operative SUI but, because this was not the primary outcome measure of this study, there may not be adequate power to make this a definitive conclusion. [Paick 2007]

UDS which included CLPP and pressure flow studies that were performed twice at two visits 2 weeks apart were reported in a subsequent study to determine reproducibility in various diagnosis groups. Thirty-one women completed both visits, of those 14 had SUI in both sets of UDS, 11 had mixed UI result at UDS on both visits, six had SUI on one visit and mixed UI result in the other. The UDS variables of MCC and cough LPP have the most repeatability. Analysis in women with SUI alone compared to USI together with DO showed that the repeatability for pressure flow parameters and CLPP was better in women without DO, of which the CLPP was significantly different ($p = 0.036$). [Rahmanou 2008]

c) Within-patient variability

Sixty consecutive women with 'genuine' SUI underwent duplicate VLPP determinations by use of 8F

and 3F vesical and 8F vaginal catheters. Subjects also underwent a standard resting UPP, CLPP determinations, and pressure-flow micturition studies. Leakage was demonstrated on both Valsalva maneuvers in approximately 80% of subjects with both catheters and a high correlation between the test-retest VLPP within both catheters. The inter-catheter correlation between the 8F and 3F VLPP was significant but much weaker than the intra-catheter correlations; 8F VLPP's were significantly higher than 3F VLPP, although there were individual exceptions to this observation. The authors concluded in 1995 that VLPP technique must be precisely described, standardized, and validated before a technique can be advocated for clinical use. A later study to determine the quantitative and qualitative effects of patient position on coughing and VLPP in women with USI was done in 2002. Thirty-seven patients with genuine SUI and 4 with mixed incontinence underwent standardized UDS. LPP were performed using 8 Fr microtip catheters placed in the bladder and vagina at a bladder volume of 250 ml in the supine, semi recumbent and standing positions. UPP was performed in the semi recumbent position at similar bladder volume. The mean (+/- standard deviation) VLPP in the supine, semi recumbent and standing positions were 82 +/- 23, 73 +/- 24 and 63 +/- 22 cmH_2O, respectively ($p<0.001$). The mean (+/- standard deviation) CLPP also decreased as the patients were moved from the supine (98 +/- 29 cmH_2O) to the semi recumbent (88 +/- 24 cmH_2O) and standing positions (77 +/- 24 cmH_2O) ($p<0.001$). The correlation between LPP and MUCP was statistically significant and was dependent upon patient position and the provocative maneuver used. [Nguyen 2002]

The committee has found no reports on inter-observer variability.

Conclusions (level 2/3)

- Different definitions and techniques to determine (urine) leak point pressure exist.
- Various studies have demonstrated a weak association between abdominal leak point pressures and the patient experience of, or measured severity of bother, or amount of incontinence. It can be born in mind, in this regard, that one millilitre of fluid is already 20 drops and a 10cm diameter wet spot on a cotton cloth.
- Studies have shown that the 'isolated' parameters from abdominal leak point pressure measurements are not very helpful as predictors of success from surgery with either tension free vaginal tape or transobturator tape in patients with stress urinary incontinence.
- Studies have shown that different techniques and patient positions influence the results of leak point pressures determination.

Recommendations (grade B/C)

- The committee does not recommend abdominal leak point pressure measurement as a single urodynamic test in patients with urinary incontinence either to reject the diagnosis of stress urinary incontinence, or to select treatment.
- The committee recommends that the result of abdominal leak point pressure measurements, when performed on patients with urinary incontinence, should be judged in relation to other urodynamic tests such as cystometry and to the clinical examination.
- The committee considers detrusor leak point pressure in patients with neurogenic lower urinary tract dysfunction a relevant parameter. This is discussed in section III (neurogenic lower urinary tract dysfunction) and in section IV (patient evaluation: children).

V. DIAGNOSTIC PERFORMANCE OF FILLING CYSTOMETRY AND AMBULATORY MONITORING

1. SENSITIVITY AND SPECIFICITY OF FILLING CYSTROMETRY IN OVERACTIVE BLADDER SYNDROME

Earlier consultations [Homma 2002; Rosier 2010; Rosier 2010; Rosier 2010] have summarized scientific evidence for positive sensitivity, specificity and predictive value of symptoms for urodynamic SUI. Specificity, sensitivity and predictive value of symptoms were found to be less for DOI and also the association of 'mixed symptoms' of UI with UDS results was very low. We have found some additional studies and summarize the newest results.

a) Detrusor overactivity incontinence

The association of the results from UDS and symptoms assessment was summarized to be around 70% in the previous consultations; three more or less relevant studies are reported here predominantly reporting on patients with mixed symptoms of UI. It was noted in one study that some women with mixed symptoms of SUI and OAB reported worsening of their UI in a prospective trial, of duloxetine, used to improve urethral storage function. In this study, an assessment was made, as to whether pre-treatment pressure flow studies predicted which women with USI, in combination with DO(I) experienced increased leakage after treatment with duloxetine. All women included had mixed symptoms of UI with moderate or severe symptoms (bother) of SUI. Pressure flow studies of women who recorded a worsening of their UI were compared to those women who recorded no change or an improvement of their UI. The maximum or average flow rate, the bladder capacity, the detrusor pressure at maximum flow and volume voided showed no difference when the two

groups were compared. The pre-treatment voiding time was however longer in women who got worse following treatment with duloxetine. [Vella 2010]

The authors of another monocenter study in retrospection concluded that (semi-recumbent) UDS diagnoses of DO, and USI with DO are associated with significantly worse UI related bother and health related quality of life when compared to those with USI without OAB (or DO). [Haessler 2009]

The purpose of another study was to assess clinically relevant relationships between urinary diary and quality of life as well as to evaluate the reproducibility of validated questionnaires and urinary diaries in women with SUI as well as OAB symptoms of UI; a combination that is frequently, but imprecisely defined, named mixed UI. Forty-seven women with mixed symptoms of UI completed 7-day diaries, the Urinary Distress Inventory (UDI-6), Incontinence Impact Questionnaire, and the Medical, Epidemiological, and Social Aspects of Aging -questionnaire 2 weeks apart. The number of UU(I) episodes predicted UI severity on UDI-6 (R (2) = .38, p< .03). Except for the number of SUI episodes, diary variables and questionnaire responses were reproducible (range from Spearman's rho = .7 to rho = .96, p< .001). The 6 questions of the UDI-6 were concluded to adequately represent UI severity.

b) Detrusor overactivity alone

The sensitivity, specificity and predictive value of symptoms for the diagnosis of DO, was given in a review of papers quoted in the third ICI [Colli 2003] All authors of the various manuscripts and the reviewers have concluded, more or less strongly that the correlation between symptoms and DO is modest; underlining the necessity of urodynamic testing to obtain an objective diagnosis. Van Brummen et al [Brummen 2004] examined the sensitivity of DO, observed during conventional UDS, for UUI. They examined 95 women, with OAB, symptomatic SUI, and/or POP. Symptoms were assessed by a bladder diary and conventional filling cystometry was performed (sitting, fill rate 60 mL/min). Urinary frequency, urgency and UUI had similar associations with the cystometric observation of DO. Among patients with only one of these symptoms, DO was however not observed in 77-81%. In another study 171 women were recruited. The aim of this study was to develop a scoring system to discriminate between the symptoms of SUI and OAB. Physicians completed a specially developed questionnaire for all women complaining of LUTS. Women then underwent UDS. A scoring system based on the likelihood of each symptom for DO was developed using odds ratios and 95% confidence intervals (CI). This scoring system was subsequently used to discriminate those women with OAB from those with SUI. This scoring system had a sensitivity of 79%, a specificity of 78% and a positive predictive value of 73% to identify DO. Investigators suggested that the scoring system could be applicable in primary care to help discriminate between SUI (USI) and OAB (DO). [Vella 2008]

In a similar study, the accuracy of a UI questionnaire in the diagnosis of various types of UI was classified according to the results of multichannel UDS. Using a UI questionnaire consisting of 12 urinary symptoms questions, 129 women with symptoms of UI were interviewed. Of the 12 questions, only three questions (two SUI symptoms and one OAB symptom) were significantly associated with the diagnoses of (urodynamic) USI or DO. The sensitivity and specificity of the questions was relatively low leading to the author's conclusion that symptoms of UI were not sufficient to predict types of UI, and the suggestion that UDS is essential in the diagnosis and management of female UI. [Roongruangsilp 2005]

In a study to determine the prevalence and associations of 'sensory urgency' in comparison with DO 592 women, attending for an initial urogynaecological /urodynamic assessment, took part. The group was separated into those having 'sensory urgency'; OAB symptoms, without urodynamic DO, or those with DO. The only difference in the clinical profile between the groups was increased prevalence of the symptom of UUI. The authors concluded that sensory urgency and DO appear to be part of the same clinical spectrum of bladder dysfunction. [Haylen 2007]

To determine and compare the urodynamic characteristics in patients with OAB and patients with combined symptoms of OAB plus SUI (OAB+SUI), 120 patients (60 each in OAB and OAB+SUI groups) underwent detailed history, physical examination, complete UDS and 20-minute pad test. FDV, SDV, urgency, and the percentage of urodynamic SUI were greater in the OAB+SUI group; and functional urethral length, maximal urethral pressure and MUCP were significantly lower in the OAB-SUI group, than those in the OAB group (p<0.03). [Lin,L.Y. 2004]

c) Overactive bladder syndrome and detrusor overactivity

Many studies have been done to compare, more or less systematically retrieved, symptoms with the results of UDS. Apart from the fact that symptoms assessment varies between studies, (and UDS-techniques vary), the committee has stated in the introduction that it is highly unlikely that one subjective symptom (or a few symptoms) can be identical to the result of the UDS, which gives a broader view on the individual's LUT function. Nevertheless we report the recent studies in this regard.

Digesu et al [Digesu 2003] studied whether UDS is useful in the management **(Table1)** of women with symptoms of an overactive bladder (OAB). Women with LUTS and or UI were fully evaluated, with history,

urinary symptoms questionnaire, frequency-volume chart, vaginal examination, and UDS. Women with symptoms consistent with OAB (urinary frequency, urgency, and/or urge incontinence) were selected. Women with neurological disorders were excluded. A total of 4,500 women 22-73 years of age were studied. Only 843 women (18.7%) could be classified as having an OAB. Of these, 457 women (54.2%) had DO, whereas 386 women (45.8%) had no DO. Sixty-eight (8.1%) of the women studied had PVR greater than 100 mL. Of the 4,500 women studied, 1,641 (36.5%) had DO on UDS. Only 27.5% of these women (457 of 1,641) had OAB symptoms. False positive and false negative symptoms of 'OAB' were frequently noted and therefore the study concluded that OAB symptomatic diagnosis did not correlate with DO and that UDS remains mandatory for an exact diagnosis.

Table 1. Overactive bladder symptoms and detrusor overactivity, from [Digesu 2003]

	Detrusor overactivity	No detrusor overactivity	Totals
OAB symptoms	457	386	843
No OAB symptoms	1184	2473	3657
Totals	1641	2859	4500

Sekido et al [Sekido 2006] retrospectively reviewed the UDS of 50 adult patients (selected from a series of 137, referred with UI) with urinary urgency (12 males and 38 females) and looked into the correlation between bladder storage function (FSF, MCC, compliance and DO) versus OAB. 75% of male patients with OAB symptoms had DO in supine position and only 36.8% female patients.

Hyman et al [Hyman 2001] examined 160 men, mean age 61 + 15 years, without neuropathy but with symptoms 'suggestive of DO' . They observed DO in 68; a sensitivity of 43% for OAB symptoms. When there was UUI, then DO was seen more often than with symptoms of frequency, urgency, nocturia alone, suggesting a higher sensitivity for UUI.

In a retrospective study with 1,626 women with mixed (or 'combined') symptoms of UI were divided into stress predominant mixed urinary incontinence (MUI); urge predominant MUI; or equal severity of stress and urge MUI on the basis of the symptom scored most severe on the King's Health Questionnaire. [Digesu 2008] The frequency of different UDS diagnoses for the all women with MUI and in each of the above groups was calculated. Overall 3.338 women were studied. Of these 49% (1.626/3.338) reported MUI symptoms and were included. In this group 29% (464/1.626) had stress predominant MUI, 15% (248/1,626) had urge predominant MUI and 56% (912/1.626) had equal severity of urge and stress MUI. On UDI 42% (665/1,626) had pure USI, 25% (414/1.626) had pure DO, 18% (299/1.626) had both DO and USI and 15% (248/1.626) had UDS without abnormal filling phase. In those with stress predominant MUI, 82% had USI; in those with urge predominant MUI, 64% had DO. The UDS diagnoses were different for the different balance of symptoms (Chi2; $p< 0.05$). In women with equal severity of UUI and SUI, 46% had DO while 54% had UDS. The relative severity of MUI symptoms from the Questionnaire significantly distinguished between different UDS diagnoses in this evaluation that concluded that women with urge predominant MUI are more likely to have DO while those with stress predominant MUI are more likely to have USI.

In another study, 1457 adult males and females were retrospectively selected, based on OAB syndrome symptoms, to determine how well the symptoms of OAB syndrome correlated with urodynamic DO using ICS definitions. A better correlation in results between OAB symptoms and the urodynamic diagnosis of DO was observed in men than in women. Of men 69% and 44% of women with urgency (OAB dry) had DO, while 90% of men and 58% of women with urgency and UUI (or OAB wet) had DO. SUI seems to have accounted for the decreased rates in women since 87% of women with UUI also had the symptom of SUI. The ICS definition does not specify what constitutes abnormal voiding frequency. Analysis of results showed that increasing voiding frequency did not have any effect on increasing the accuracy of diagnosis of DO except in women with 10 or more daytime micturition episodes. The authors concluded that the bladder is a better and more reliable witness in men than in women. [Hashim 2006]

The association between urinary symptoms and the UDS diagnoses of DO and USI was calculated to describe the relationship between symptoms reported in a self-completed postal questionnaire, and urinary disorders based on UDS. The study population was selected from women aged 40 years or over living in the community, who responded to a postal questionnaire. Four hundred eighty-eight women completed UDS; 29.1% (142/488) were found to have DO (with and without leakage), 33.6% (164/488) USI, 20.7% (101/488) mixed diagnosis of incontinence, and 16.6% (81/488) no abnormality on filling cystometry. SUI and UUI were included in the risk model for USI. SUI reported monthly or more, was associated with more frequent diagnosis of USI, and UUI reported weekly or more, with less frequent diagnosis of USI (sensitivity: 76.9%; specificity: 56.3%; positive predictive value: 67.8%). Strong or overwhelming urgency, UI monthly or more, and nocturia once a night or more, were all significantly associated with an increased diagnosis of DO. Reporting of SUI monthly or more reduced the risk of DO (sensitivity 63.1%; specificity 65.1%; positive predictive value 63.1%). The conclusion was that a postal urinary symptoms questionnaire

was associated with UDS diagnosis with moderate accuracy and applicable. [Matharu 2005]

One hundred and fourteen women attending a tertiary urogynaecology clinic were included in a randomised crossover study to either an initial interview-assisted questionnaire in the clinic, with a follow up postal questionnaire, or an initial pre-outpatient questionnaire followed by an interview-assisted questionnaire at the clinic visit. Question responses were compared with urodynamic diagnoses. With the interview method, only severity of UI was significantly associated with DO ($p = 0.012$). With self-completion, severity of nocturia ($p< 0.05$), urgency ($p = 0.003$), UUI ($p = 0.003$), leakage without warning ($p = 0.035$) and incomplete voiding ($p = 0.01$) were significantly associated with DO. On interview, the symptom of SUI ($p = 0.002$) and use of pads ($p = 0.011$) were significantly associated with a diagnosis of USI. Severity of SUI ($p< 0.001$), frequency of leakage ($p = 0.004$), use of protection ($p< 0.018$), nocturnal incontinence ($p = 0.002$) and quantity of leakage ($p< 0.05$) on self-completion were strongly associated with diagnosed USI. There was no association between the symptoms of urgency or UUI, and USI. Concluded in this study was that no symptom had a high enough specificity and sensitivity to replace UDS in this postal questionnaire responses and had a better relationship with DO, for USI and for DO, than interview-assisted questionnaire responses. [Khan 2004]

The pattern of filling sensations was evaluated during standard UDS bladder filling in 75 patients who complained of UU(I) and showed DO, to evaluate whether a compelling desire to void is always perceived suddenly, or whether it can result from the gradual build-up of bladder-filling sensations. A compelling desire to void occurred suddenly, without a preceding sensation in 13% of the patients, at lower intravesical volumes, whereas 66% reported at least two normal preceding filling sensations before a compelling desire to void. The bladder volume at which the FSF was reported was not different regardless of whether it was described as a FSF , a FDV or a compelling desire to void ($p = 0.42$). The warning volumes were not different between patients with one or no filling sensation landmarks ($p = 0.7$), but they were significantly smaller than in patients with two or three filling sensations ($P = 0.85$). Compelling desire to void can occur suddenly if normal filling sensation is disturbed, but also gradually if the usual filling sensations are reported. In cases of disturbed filling sensation, the volume at compelling desire to void and the warning volume are significantly lower. [Wachter 2008]

To evaluate the reliability of spontaneously reported bladder sensations during real and faked cystometry in patients with non-neurogenic LUTD. In another study by the same researchers, fifty-nine patients with non-neurogenic LUTD were submitted to a real and a faked (no water infused) filling cystometry and were asked to describe all bladder-related sensations during the investigations. During the genuine cystometry, the expected pattern of filling sensations was reported by 88%. During the faked cystometry, not one of the patients reported the normal pattern of filling sensations. However, a minority of patients reported some sensation of bladder filling without actual bladder filling from the UDS equipment. The investigators concluded that patients with a non-neurogenic LUTD can reliably report bladder filling sensations during UDS. [Wachter 2008]

Five hundred and ninety-two women attending for an initial urogynaecological/urodynamic assessment were enrolled in a prospective study. Many signs symptoms and observations were reported but the reported prevalence of sensory urgency (defined as increased perceived bladder sensation during filling, a low FDV and low MCC in the absence of recorded urinary tract infection or DO) was 13%. The only differences in the clinical and UDS profiles of it and DO were reported as a significantly increased prevalence of the symptom of UUI and (by definition) the detrusor contractions during filling cystometry in women with DO. The authors concluded that ‘sensory urgency’ and DO appeared to be part one spectrum of LUT dysfunction. [Haylen 2007]

Fifty-eight patients with USI, 29 with DO, and 22 with both USI and DO were analysed in another monocenter cohort study. From 3-day hand-written and computer-analysed bladder diaries, average and maximum VV were calculated, and also voiding frequency and 24 hr urine production, as well as number, severity and type (whether accompanied by activity or urge) of UI -episodes, to compare frequency-volume and UI episode patterns in patients with USI and DO. Compared to the USI patients, the DO patients tended to have higher voiding frequency, lower VV, more urgency-related than activity-related leaks, smaller volume and equally frequent leaks and higher severity -scores for UI symptoms. The age- and volume-adjusted percentiles better separated the USI and DO groups’ frequency and volume measurements than did the raw measurements. Almost 60% of the USI patients had low VV measurements, high voiding frequency, and 40% had leaks with urgency sensations. A subgroup of 29 USI patients with ‘low’ (average volume <30th reference population percentile) VV measurements had high incidences of urgency and UUI. Reference population percentiles better separate the frequency /volume patterns of USI and DO than do the raw measurements. The investigators observed a substantial subgroup of patients with USI that had an OAB-like clinical picture, again suggesting that symptom assessment is important but not diagnostic with regard to the underlying LUTD. [Parsons 2007]

The UDS of women with DOI and USI, before

undergoing tension-free vaginal tape (TVT) surgery were retrospectively reviewed to determine if specific pre-operative urodynamic parameters could predict DO following TVT in patients with urodynamic mixed incontinence. Patients underwent clinical evaluation pre-operatively and those with persistent SUI after conservative treatments underwent TVT. Patients were re-assessed after at least 6 months post-operatively. Fifty-one women were reviewed. Forty-six of the 51 attended follow-up and 35/51 agreed to conventional urodynamic studies. Seventeen of the 35 reported OAB symptoms, and 18/35 were asymptomatic. Nineteen of the 35 women had DO and 16/35 had normal UDS. The median pre-operative opening detrusor pressure was higher in women with overactive bladder symptoms post-operatively. The median pre-operative opening detrusor pressure in women with DO post-operatively was 33.0 cmH_2O and the median pre-operative opening detrusor pressure in those with normal UDS post-operatively was 16 cmH_2O (15.0-23.0 cmH_2O $p< 0.05$ Mann-Whitney U-test). The investigators have concluded, in retrospect, that opening detrusor pressure before treatment is related to post-operative DO after TVT, in their series, but that higher numbers of patients are required to demonstrate the real predictive value of opening detrusor pressure. [Panayi 2009]

Conclusions (level 2)

- Many studies have shown the weak correlation between symptoms and the result of urodynamic investigation, especially filling cystometry, in patients with urinary incontinence.
- The committee concludes that the sensitivity and the specificity of the symptoms, when systematically assessed and voiding diary is included, is at best and in the 'most typical patients', around 60-70%, in comparison with the result of the objective results of urodynamic testing.
- The correlation of the symptom 'stress urinary incontinence' (expressed, or questioned) with the result of urodynamic investigation is somewhat better than the correlation of urgency or urgency urinary incontinence (expressed, or questioned) with urodynamic investigation.
- The committee concludes that especially when frequent voiding, urgency and/or urgency incontinence is part of the symptom complex of patients with incontinence, urodynamic investigation is of value to obtain an objective diagnosis, prior to invasive therapy.
- Taking into account the variation between various institutes and the test-retest variation, the committee considers it relevant that investigators and clinicians judge also how adequate the results of the performed tests represent the individual patients' symptoms.

Recommendations (grade B)

- The committee recommends urodynamic testing in patients with incontinence when an objective diagnosis is warranted. This is commonly the case when symptoms do not exclusively direct to stress incontinence, or when (for all types of incontinence) conservative measures have not been successful, or when relevant co morbidity exists or relevant previous surgery has been performed.
- The committee recommends interpretation of the results of the complete urodynamic testing in relation with the symptoms, signs, and the clinical (or other) examinations and with the voiding diary in all patients.

d) Distinguishing or defining characteristics of detrusor overactivity

Several groups have attempted to find characteristics of DO that may distinguish DO incontinence with different aetiologies, or DO incontinence of different severity.

One group [Flisser 2003; Romanzi 2001] examined 132 patients with OAB symptoms (with and without neurological disease) by videourodynamics. Based on the characteristics of their filling phase, patients were divided into 4 categories: type 1- no evidence of DO on videourodynamics; type 2 – DO present, and patient aware and able to abort them; type 3 – DO(I) present, patient aware and able to contract the sphincter (judged from the videourodynamics) but not to abort contractions; and type 4 – DO(I) present and patient unaware but unable to contract the sphincter or abort contractions. There was no significant relationship between the category and severity of symptoms as judged by voiding frequency, functional bladder capacity, or pad test. The authors concluded that the characteristics of the DO were not distinct enough to aid in differential diagnosis, but that the ability to abort DO and stop incontinent flow might have prognostic implications, especially for the response to behaviour modification, biofeedback training, and pelvic floor exercises.

Cucchi et al [Cucchi 2007] looked into detrusor contraction strength, detrusor contraction velocity and contraction sustainability. In this retrospective review, the authors separated male patients (without relevant neurological abnormalities) into three groups; Group 1 had DO, with urgency and UUI. Group 2 was similar to group 1 but did not have urgency before DO and Group 3 consists of 'normal' men. They found that detrusor contraction velocity was increased (or higher) in the group with urgency versus no urgency or normal, implying that this may be an underlying mechanism for urgency.

Defreitas and co-workers [Defreitas 2003] examined three groups of patients: group 1, men with LUTS and no known neurological condition for DO (n = 22); group 2, men with Parkinson's disease and

LUTS (n = 39); and group 3, women with Parkinson's disease and LUTS (n = 18). Patients with Parkinson's disease had a significantly lower median volume at first detrusor contraction than those with non-neurogenic DO. The percentage of group-1 patients with UUI was significantly lower than that found in the other two groups (9% versus 54% and 56%, p<0.001 and 0.002, respectively). No statistically significant correlation between the duration or severity of Parkinson's disease and urodynamic parameters was found. The distinction between Parkinson's disease proper and multiple system atrophy, which appears to be important with regard to bladder dysfunction,[Fowler 2001]was not made in this study.

In the study cited above,[Hyman 2001] 160 older men without neuropathy, but with symptoms 'suggestive of DO', were examined. DO was seen more often when there was UUI, than with symptoms of frequency, urgency and nocturia alone. The bladder volume at which DO was observed tended to be lower in those with UUI, frequency and urgency than in those without UUI (p = 0.07). The prevalence of DO was similar in men with and without BOO.

Ockrim at al [Ockrim 2005] compared the variability of DO in men with LUTS to that in men with SCI by sequentially repeating urodynamic studies three times. They observed a significant decrease in the number and amplitude of DO contractions in the 60 patients with non-neurogenic LUTS, whilst in the 35 SCI patients, the urodynamic variables remained the same over the subsequent studies.

The urodynamic characteristics of DO in women with multiple sclerosis (MS) (n = 54) were compared with the detrusor pressure 'pattern' found in women with LUTS and idiopathic DO (n = 42) in a retrospective study. Among other parameters, the amplitude of the first contraction, maximum detrusor contraction, and threshold volume for the first contraction were evaluated. The amplitude of the first contraction was statistically greater in the patients with MS and DO compared with patients with IDO (28.3 versus 20.5 cm H_2O, p = 0.003), as was the maximum detrusor contraction (46.4 versus 30.8 cm H_2O, p = 0.002). The threshold volume for DO was greater among patients with neurogenic DO (186.8 versus 150.5 mL, p = 0.037), which was likely to be secondary to the elevated PVR volume noted among patients with MS (p = 0.049). The authors concluded that additional investigation is required to determine whether these differences are due to neurogenic influences directly on the detrusor muscle through aberrant innervation or by other mechanisms. [Lemack 2006]

Miller et al [Miller 2002] suggested that functional bladder capacity was smaller in those with more severe incontinence as judged from the voiding diary in a study to evaluate quantification of DO.

Conclusions (level 2)

- Studies have not been able to show relevant differences in patterns or characteristics of detrusor overactivity whether the cause of overactivity is neurogenic or idiopathic.
- Various studies have not been unable to reliably quantify the severity of detrusor overactivity, in a clinically or scientifically applicable way.

Recommendation (grade C)

- The committee recommends that neither the cause (neurogenic or idiopathic) nor the severity of detrusor overactivity is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

Topics for research

- The committee recommends further evaluation and development of objective parameters for assessing the treatment outcome of detrusor overactivity.

e) Provocative manoeuvres

Some studies have shown that 50% of DO occurs during supine cystometry without provocation and that the remaining 50% is revealed by posture change, standing cystometry, on provocation by cough, or on catheter removal. [Turner Warwick 1979; Arnold 1974]

Awad and McGinis [Awad 1983] observed DO in 30% of female patients in the supine position versus 61% in the standing position. A systematic review of the literature by Al-Hayek et al [Al-Hayek 2008] concluded that supine cystometry failed to detect a significant percentage of patients with DO.

Webster et al [Webster 1984] concluded that in 52% of women with DO, provocation by fast filling in the standing position, with exercises such as coughing, was required to reveal it. Investigative technique, in particular the inflation of a balloon in the proximal urethra [Colstrup 1982] or the instructions given to the patient [Blaivas 2001], is also said to affect the frequency of the observation of DO.

Choe et al [Choe 1999] systematically examined which manoeuvres were most provocative of DO. In 134 women with symptomatic UUI they performed gas (CO2) cystometry. Six provocative manoeuvres were performed consecutively to evoke DO, including lying supine, rising to a seated position, walking toward the bathroom, hand washing, coughing and sitting on the toilet with instructions not to void. By filling to maximum capacity and performing these manoeuvres in 2 different orders, they were able to demonstrate DO in 76/134 subjects (67%). Sitting on a toilet with a full bladder and with the instruction not to void was the most provocative manoeuvre, responsible for revealing DO in 52 of the 76 (68%). Hand washing was a distant second, revealing overactivity in 15 of the 76 (20%). Other manoeuvres revealed very little DO.

An extreme provocative manoeuvre is the bladder cooling (ice water) test advocated by Geirsson et al. [Geirsson 1993]; The empty bladder is filled with water at a temperature of less than 10°C. This stimulates C-fibres that normally carry afferents from receptors sensitive to temperature and pain. In infants, stimulation of these receptors can initiate a detrusor contraction, but this response is normally lost at ages over 5 years. The bladder cooling test stimulated detrusor contraction (neurogenic DO) in 91-97% of patients with traumatic upper motor neuron lesion, but in only 47% of those with presumed idiopathic DO. Detrusor contraction was not observed in any patient with a lower motor neuron lesion or 'pure' (urodynamic) SUI. Thus the conclusion was that the bladder cooling test is highly sensitive for neurogenic DO, and highly specific for DO in general.

The bladder cooling reflex, elicited by the ice water test (IWT) was performed in patients with painful bladder syndrome (PBS, n = 17), idiopathic DO (IDO, n = 22), neurogenic DO, n = 4) and SUI (as controls, n = 21). The IWT was performed by intravesical instillation of cold saline (0 - 4 degrees C). A positive IWT was observed in IDO (27.3%) and neurogenic DO (100%) patients, but was negative in all PBS and all control patients. Thirteen (76.5%) PBS patients reported pain during the IWT, with significantly higher pain scores during ice water instillation compared to the baseline (p = 0.0002), or equivalent amount of bladder filling (100 mL) with saline at room temperature (p = 0.015). [Mukerji 2006]

A total of 114 patients over50 years, with an International Prostate Symptom Score (IPSS) >8 and QoL >2, were evaluated by UDS and IWT to investigate whether DO and/or the response to the IWT were related to night time urinary frequency. The DO-positive IWT responders had a significantly higher BOO-index than did the DO-positive IWT non-responders and the DO-negative IWT non-responders. The DO-positive IWT responders had significantly more frequent nocturia and smaller night time maximal and lesser VV than did the DO-negative IWT non-responders without any difference in the nocturnal VV. The patients with nocturia, two or more times, had a significantly larger nocturnal VV and smaller night time minimal VV than the patients with nocturia less than two times. The incidence of DO-positive IWT responders was significantly greater among the patients with nocturia three or more times than that among those with nocturia less than three times. The authors concluded that high grade BOO leads to development of C-fibre reflex activity. [Hirayama 2005]

Conclusions (level 2)

- A systematic review concludes that more detrusor overactivity is seen when the patient is in the sitting position during cystometry, when compared to the supine position.
- There is some evidence that moving to a toilet, and also hand washing, is strongly provocative of detrusor overactivity.
- Evidence suggests that ice water cystometry can be applied to elicit detrusor overactivity in patients with NLUTD and that a detrusor contraction during filling with ice water can be interpreted as a sign of pathologic (existing only in patients with relevant neurology) C-fibre reflex activity. It has however also been shown in this regard that false-negative tests do occur.

Recommendations (grade B)

- The committee recommends that the results of provocative cystometry are interpreted in the light of the patients' symptoms and to bear in mind whether the results obtained are representative.
- The committee recommends the performance of urodynamic investigation in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the better possibility of representative voiding and better patient comfort.
- The committee recommends that the position of the patient during filling cystometry is always taken into account because it can influence the demonstration of detrusor overactivity. Repeating the cystometry in a different position can be helpful when it is deemed clinically necessary.

2. AMBULATORY URODYNAMICS: SENSITIVITY AND SPECIFICITY

Ambulatory urodynamics is performed in an effort to capture more realistic or more physiological observations, especially of UI episodes. Thus, similar to provocative manoeuvres, it is an attempt to increase sensitivity by providing a longer time for DO to manifest itself. Strict protocols for the test (e.g. duration) and standards for systematic analysis are lacking. The authors of a review article [Cassidenti 1999] concluded that ambulatory monitoring detects UI better than conventional cystometry.

Radley et al. [Radley 2001] found that ambulatory monitoring revealed DO in 70/106 women with symptoms suggestive of DO (twice as many as conventional cystometry with provocation by hand washing), and that it detected DOI in 40 of the 70. The observation of DOI was correlated with symptom severity, but it was not clear how many women complaining of UUI showed DOI. Therefore the sensitivity observed in this study has remained unknown. The specificity of this method is at present not evaluated, and it is not very likely that therapy can be improved on the basis of (additional) ambulatory testing.

Conclusions (level 3)

- Studies have shown that ambulatory monitoring

is more sensitive to detrusor overactivity however the predictive value towards the selection (and outcome) of optimal treatment is still unknown.

Recommendation (grade A)

- The committee does not recommend ambulatory monitoring in the routine diagnosis of patients with urinary incontinence.

3. THE ADJUNCT USE OF IMAGING AND ELECTROMYOGRAPHY

Videourodynamics is an investigation where cystometry is carried out simultaneously with imaging (usually x-rays) of the lower urinary tract. This can be useful in the management of some patients; particularly children and patients with NLUTD and is briefly discussed in the relevant chapters. There is a fuller discussion of videourodynamics in the chapter on Imaging, Neurophysiology and other tests.

Another adjunct to cystometry is the simultaneous measurement of striated muscle activity using EMG. Most frequently this is used in the investigation of patients with NLUTD and often surface electrodes are placed on the perineum to detect (all - unspecific) striated muscle activity from pelvic floor muscles. Amongst other uses, failure of the urethra/pelvic floor to relax and pelvic floor voiding dysfunctions can theoretically be detected during voiding using this technique. Unfortunately, it is technically difficult to ensure a good quality EMG signal from the precise and relevant muscle(s) during this procedure and there have been no publications in at least the last 20 years investigating the benefits of combining EMG with cystometry.

VI. THERAPEUTIC PERFORMANCE OF FILLING CYTOMETRY AND AMBULATORY MONITORING

1. PREDICTION OF TREATMENT RESPONSE

a) Filling cystometry

The authors of a review of papers from 1980-2000 [Colli 2003] concluded that it is not possible to correlate the results of urodynamic tests with the effects of non-invasive therapy. Consistent with the table, Malone-Lee et al [Malone 2003] reported on 356 female patients with OAB symptoms. On urodynamics, 266 showed DO. There was no significant difference (between those with and without DO) in treatment outcome after 6-8 weeks of oxybutynin and bladder retraining.

On the other hand, previous reviews have concluded that women with UI and DO respond less well to surgery for SUI than those without DO. [Homma] Friis et al [Friis 1982] conducted a blinded prospective study to evaluate the usefulness of urodynamic examination compared to clinical diagnosis. The study showed that when urodynamic examination was added to the preoperative planning of treatment for female UI a more beneficial cure rate was found if the patient was treated in accordance with the urodynamic findings. However, the patient material is small and the power of the study is weak.

A retrospective study has shown that a careful minimal evaluation may be adequate to identify ISD, predict postoperative voiding difficulties and maximize surgical outcomes. [Thompson 2000] A Cochrane review concluded that current evidence is insufficient to demonstrate a clear improvement in clinical outcomes as a result of performing urodynamic studies. [Glazener 2002]

In men, fewer studies have been done. Golomb et al [Golomb 1999] examined whether preoperative urodynamic examination allows us to predict the risk of UI after radical prostatectomy. A small group of 20 patients underwent radical retropubic prostatectomy for prostate cancer. Urodynamics showed DO in 12/20 pre-operatively. 5 of these 12 suffered from UUI post-operatively. The positive predictive value of preoperative DO for post-operative UI was thus only 42%.

In a literature overview of the diagnostic and therapeutic value of urodynamic investigations in patients undergoing POP surgery, the reviewers found a large heterogeneity of results. 'Occult' SUI showed large variation between studies and de novo DO after TVT as adjunct to POP surgery was observed in inconsistent and unpredictable percentages. It was impossible to estimate the predictive value of urodynamic testing on the basis of this review and prospective studies were demanded. [Roovers 2007] A later clinical study confirmed this view. [Roovers 2007]

A study presented a decision-analytic model that evaluated the cost-effectiveness of basic office evaluation before surgery in women with POP and SUI symptoms and contrasted it with that of urodynamic testing. Costs were obtained from the Federal Register; effectiveness of treatment for UI was based on the published literature. The strategies of basic office evaluation and urodynamic testing had the same cure rate of UI (96%) after initial and secondary treatment. Under baseline assumptions incremental cost-effectiveness (cost for single extra cure of UI) of urodynamic testing was $328,601. According to sensitivity analyses, basic office evaluation was more cost-effective than urodynamic testing when the prevalence of pure DO was <8% or when the cost of urodynamic testing was >$103. The analysis concluded that urodynamic testing before surgery in women with POP and SUI symptoms is not cost-effective relative to basic office evaluation. [Weber 2000]

b) Ambulatory monitoring

Brown and Hilton [Brown 1999] used conventional

and ambulatory urodynamic monitoring to study the incidence of DO before and after colposuspension. They showed that preoperative ambulatory monitoring was unable significantly to predict which patients would suffer from urgency postoperatively, or even which women would demonstrate DO post-surgery. Another paper addressed specifically the effect on clinical management of doing ambulatory urodynamics. [Gorton 2000] In this retrospective chart review of 71 women, there were technical difficulties in 30/71 ambulatory studies although only 2 were not interpretable. 32/71 women showed DO and nearly all were treated with medication. Among the remainder without DO fewer received medication. However, fewer than half of those who received medication improved. The authors concluded that ambulatory urodynamics was not very helpful in deciding on management.

Conclusions (level 2/3)

- Various studies have shown that the result of urodynamic investigation does not perfectly predict the outcome of relevant treatment in all patients; either in patients with urodynamic detrusor overactivity or in patients with urodynamic stress incontinence and also not in patients with a 'double' urodynamic diagnosis.
- A retrospective study with subsequent health economic modelling has shown that in patients with 'pure symptoms of stress incontinence' urodynamic testing might not be cost effective.

Recommendations (grade B/C)

- The committee recommends that the result of urodynamic investigation is applied to 'optimize' treatment strategy without attributing perfect specificity to the result of treatment, in an individual patient.
- The committee recommends that the cost effectivity of urodynamic testing is taken into account when discussing the necessity of urodynamic investigation with the patient.

Topics for research

- The committee suggests that large multicentre ('national') prospective studies might be of help to better understand the cost-effectiveness of high quality urodynamic testing in health care quality for patients with incontinence.

C. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES

I. PATIENT EVALUATION: WOMEN

1. INTRODUCTION

The clinical evaluation of an incontinent woman is based on the combination of the medical history, physical examination and, when appropriate, selected urodynamic tests.

The patient's symptom SUI is clearly defined and the sign often can be objectively demonstrated as 'the observation of urine leakage from the urethra synchronous with exertion/effort, or sneezing or coughing'. Traditionally, cystometry with cough tests at representative volumes has been the core test for the urodynamic diagnosis of USI. Dynamic urethral closure pressure profilometry, leak point pressure testing and ambulatory urodynamics have been used to sub classify patients with USI.

In the previous report two expert reviews were cited which summarize the likelihood of correctly predicting the result of the UDS from symptoms and signs. [Harvey,M.A. 2001; Homma,Y. 2002] There have been further studies [Agur,W. 2009; Digesu, 2003], reporting that confirmation of USI in the group of patients with the sole symptom of SUI is observed in ±70-80% of the patients. However, patients with that 'sole symptom' were only a relatively small proportion of all reported and analysed cohorts. There have been 2 other studies highlighting the unpredictability and large variation of urodynamic diagnosis on the basis of symptoms in women [Mc Nanley, et al; Hameed, et al] An earlier study [van Waalwijk van Doorn,E.S. 1992] showed that, in a group of 154 females with both complaints and urodynamic demonstration of incontinence, the clinical observation of pure USI had a sensitivity and specificity of 90% and 65% respectively for the isolated symptom of SUI which would be challenged by these 2 further (retrospective) studies, both of which use a much larger data bases, one of over 6000 patients.

The objective information about LUT function adds to the diagnosis that is made on the basis of signs and symptoms. This addition can be of value for the professional when selecting a treatment to offer to the patient. However, it should be noted that besides their diagnostic potential, UDS can contribute qualitative and quantitative information about the underlying or coexisting pathophysiology that is valuable for the patient as well. One study did use a patient preference model to assess the utility of UDS in assessment. This study did highlight that whilst on QoL evaluation, UDS, by itself, did not lead to a better outcome, patient compliance with treatment was better in the group having UDS. Secondly far more women opted for UDS than was predicted. [Majumdar,A. 2010]

Malone Lee however, demonstrated that the presence or absence of DO in patients with symptoms OAB did not relate to outcome of anticholinergic treatment in a prospective randomised trial. [Malone-Lee,J.G. 2009] Likewise 2 studies have shown that symptoms reported during UDS vary between groups, and comparison of the results between groups may be difficult. [van Mastrigt,R. 2004; van Mastrigt,R. 2006]

The committee discusses in the following paragraphs the clinical application of UDS in patients with signs or symptoms of UI. Firstly women with SUI, followed by women with OAB with UUI.

2. STRESS URINARY INCONTINENCE

a) Urethral pressures and severity of stress urinary incontinence

There is no consensus on how to measure the severity of SUI clinically or urodynamically. Severity can be expressed on the basis of simple clinical measures such as questionnaires, or on a bladder diary or on pad weighing tests. A review concludes that static UPP parameters such as MUCP or cough profile parameters such as pressure transmission ratio cannot be used to characterize the severity of incontinence and suggested that abdominal LPP measurement might be a useful tool to quantify urethral dysfunction associated with SUI. [Weber,A.M. 2001]

However, other studies have found no correlation between leak point pressures and the severity of UI as measured by bladder diaries and QoL instruments. [Albo,M. 2007; Chen,C.C. 2008; Theofrastous,J.P. 1995; Nager,C.W. 2001] Leak point pressures are also limited as a diagnostic tool by the lack of standardisation of the technique. [Rodrigues,P. 2006]

A total of 221 women, 29 to 80 years old (mean age 55.2), were included in a prospective TVT treatment study, performed mostly using local anaesthesia with a mean follow-up of 10.5 months. Patients were divided into 61 with low (less than 60 cm H_2O) and 160 with higher (60 cm H_2O or greater) VLPP. The overall (subjective and stress test) cure rate was 10% lower in patients with low versus the patients with higher VLPP and, in women with low VLPP, but multivariate analysis indicated that symptoms of OAB, independent from low MUCP, were independent factors for treatment failure The authors concluded that women with urgency symptoms and or with low MUCP should be considered to be at higher risk for failure after the TVT procedure. [Paick,J.S. 2004] In another report the role of preoperative VLPP in predicting the outcome of the suburethral sling procedure for the treatment of SUI was prospectively evaluated in 174 consecutive patients with diverse grades of VLPP. The TVT provided similar symptom improvement in all the patients regardless of preoperative VLPP [Rodriguez,L.V. 2004] which was confirmed in a more recent study. [Costantini,E. 2008]

An expert review of the use of LPP testing and urethral pressure profilometry prior to surgical treatment for SUI, concluded that there remains no consistency as to whether this testing enhances surgical outcome of SUI treatments by improving case selection or altering the surgical approach based on study findings. The reviewer found little evidence to suggest that patients with more severe forms of USI on urodynamic testing fare more poorly after the most commonly offered surgical treatment than those with less severe forms. [Lemack,G.E. 2004] Subsequent studies and reviews have tried, without positive results, to identify ways in which UDS may predict voiding difficulties after suburethral tapes. [Mostafa, et al.; Murray,S. 2010]. However, the lack of (multicenter standardised) prospective evaluations has been implicated in the lack of progress on this topic. There is also a lack of knowledge with regard to subclasses of SUI and (types of) pelvic floor muscle exercises. [Herderschee,R. 2011]

Most retrospective monocenter studies show higher failure rates after surgery in women with low MUCP (≤ 20 cm H_2O) at MCC. [Weber,A.M. 2001; Miller,J.J. 2006; Guerette,N.L. 2008] However, other investigators have shown that a low MUCP is not an efficient predictor of surgical failure. [Homma,Y. 2002; Weber,A.M. 2001] In a recent prospective, randomised trial of women undergoing either Burch retropubic suspension or bladder neck slings, LPP's were not found to be predictive of surgical outcome for SUI. [Nager,C.W. 2008]

The value of urethral hypermobility, MUCP and urethral incompetence was analysed in a study with 369 women with symptoms suggestive of SUI, without symptoms of DO. Continent and incontinent patients differed with regards to urethral incompetence and hypermobility. Incontinent patients had a greater probability of a higher grade of each factor. Even after adjusting for the older age of incontinent patients by ANCOVA, MUCP was significantly lower in the incontinent group. The best univariate optimized cut-off point for discriminating continence from incontinence was obtained with urethral incompetence greater than grade I. [Schick,E. 2004]

In an attempt to define the urodynamic contraindications to Burch colposuspension, 79 patient's, eligible for continuous postoperative follow-up were enrolled in a prospective study. On post-hoc analysis, a VLPP level <60 cm H_2O was not found to represent an absolute contraindication to Burch colposuspension, provided that other parameters, such as MUCP and functional urethral length, are within acceptable ranges. [Bai,S.W. 2005]

From a total of 168 women, the 31% that demonstrated SUI at lower bladder volumes (100 mL) did not report greater bother from UI than the 35% women who leak at higher volumes (>400 mL). The Urogenital Distress Inventory, Incontinence Impact Questionnaire, and also the MUCP and VLPP were similar in the groups. Among the 116 patients who had a sling procedure, USI persistence did not differ according to the volume at which USI occurred preoperatively (p=0.72). The authors concluded that 'bladder volume when leaking' during a urodynamic study is not an adequate reflection of UI related QoL. [Lowenstein,L. 2007]

A review was done to highlight controversies, concerning the use of UDI prior to surgical treatment for SUI. The review focused on LPP testing and UPP. On the basis of the literature available at that time it was concluded that there remains no clear consensus as to whether UPP or V(A)LPP testing enhances surgical outcome of SUI treatments by improving case selection or altering the surgical approach based on study findings. Furthermore the author concluded that there was little evidence to suggest that patients with more severe symptoms of SUI by UPP or V(A)LPP testing fare more poorly after the most commonly offered surgical treatment than those with less severe forms. The third observation done in this review was that there are certain sub-populations of women who appear to be at higher risk of 'persistent urgency' and or of voiding dysfunction following incontinence surgery, and that UDI may aid in identifying this group. Overall was concluded that it is not apparent that either ALPP measurement or UPP can accurately predict which patients will achieve the best outcome of surgical treatment for SUI. The author suggested that other parameters assessed during UDI might provide prognostic information regarding the risk of voiding dysfunction postoperatively and the possibility of persistent urge-related leakage following surgery, though not directly predict cure. [Lemack,G.E. 2004]

Conclusions (level 2/3)

- Various studies have shown a weak association of incontinence severity with urethral function tests (leak point pressures and urethral closure pressures).
- Cohort studies have shown that incontinence volume and intravesical volume at leakages are poorly associated with symptoms severity and or with patients' quality of life.
- Studies have shown that urethral function tests (leak point pressures and urethral closure pressures) are of very little value in predicting the outcome of treatment with suburethral tapes.
- No studies have shown the relevance of urethral function tests (leak point pressures and urethral closure pressures) in predicting the outcome of non surgical or other treatments for stress urinary incontinence.

Recommendations (grade B/C)

- The committee recommends that urethral function measurements of leak point pressures and urethral closure pressures are not used as a single factor to grade the severity of incontinence.
- The committee does not recommend the use of contemporary urethral function tests to prediction the outcome of any surgical treatment for stress urinary incontinence.

Topics for research

- The committee suggests further studies with the aim of better understanding urethral closure function and dysfunction, in relation to the diverse treatments (especially conservative) of stress urinary incontinence.

b) Aspects of urodynamic studies relevant to therapy for stress urinary incontinence

In a systematic meta analysis (only) 129 (out of 6009) studies were relevant for inclusion using the Quality Assessment of Diagnostic Studies (QUADAS) tool to identify and synthesize studies of diagnostic processes of UI and to construct an economic model to examine the cost-effectiveness of simple, commonly used primary care tests. The diary appears to be the most cost-effective in the diagnosis of USI of the three primary care tests (diary, pad test and validated scales) used in addition to clinical history and clinical stress test. However, the meta-analysis also conceded that if a patient is to undergo an invasive urodynamic procedure, multichannel urodynamics is likely to give the most accurate result in a secondary care setting. [Martin,J.L. 2006] Two attempts to use artificial intelligence in UDS interpretation have been reported [Serati,M. 2011; Witjes,W l998], one reported neural networking and the second an automated analysis process of uroflow: neither was felt to be robust enough to improve diagnostic accuracy.

In 2006 in the UK, the National Institute of Health and Clinical Excellence (NICE) issued guidelines, on the basis of expert opinion collated by a modified Delphi process, that urodynamics was recommended before surgery for UI only if there is a clinical suspicion of DO or, if there has been previous surgery for SUI, or is anterior compartment POP or, if there are symptoms suggestive of voiding dysfunction [National Institute for Health and Clinical Excellence] and urodynamics was not routinely recommended for women before surgery for a 'clearly defined clinical diagnosis of SUI'. The evidence base for this recommendation has been disputed and is controversial and challenged and is now subject to several studies [Nager,C.W. 2008; Nager,C.W. 2001] and the reports of these are awaited. A study in 2008 by Agur et al casts doubt on the wisdom of the UK-NICE recommendation. [Agur,W. 2009] In their tertiary centre, patients are referred with lower urinary tract symptoms. A database of systematic analysis before UDS was used retrospectively to identify women aged 18-80 years who had UDS for UI over a 17-year period (1 January 1990 to 31 December 2006). The reliability of the patients' history in predicting 'pure' USI in patients with 'pure' SUI on the basis of the NICE criteria, was investigated. Only 324/6276 (5.2%) women had pure SUI; moreover, a quarter of those with pure SUI symptoms ultimately had urodynamic diagnoses other than USI, that could affect the outcome of continence surgery.

They concluded that only a small group of women fulfil the NICE criteria of pure SUI and it seems inevitable that even with these strict criteria, a woman could go forward to a surgical procedure with potentially important urodynamic findings unaddressed.

Conclusion (level 1)

- It is concluded in a model study, based on a selected retrospective cohort, that urodynamic testing is not cost effective in the primary health care setting for women with predominant stress incontinence symptoms.
- It shown that in the referred population, urodynamic investigation is the most accurate way to obtain an objective diagnosis in an individual patient with urinary incontinence symptoms.

Conclusion (level 3)

- It has been shown in retrospective and prospective cohort studies that symptoms of 'pure stress urinary incontinence' do not exclude other abnormalities of lower urinary tract function.

Recommendation (grade A)

- The committee recommends that the cost effectiveness of urodynamic testing is kept in mind when discussing 'cost and gain' of the various methods of diagnosis for urinary incontinence, in relation to the method of treatment.

Recommendation (grade B)

- The committee recommends urodynamic studies are carried out in all women prior to surgical intervention for stress urinary incontinence.

Topic for research

- The committee suggests that multicentre studies should address the question as to whether women with symptoms of 'pure' stress urinary incontinence are more at risk of failure from surgical treatment of their incontinence without pre-operative urodynamics, or have more adverse events following surgery without pre-operative urodynamics than women who have pre-operative urodynamic studies.
- The committee suggests that the balance of (over-) diagnosis (when urodynamic testing is used) versus (over–)treatment (with surgical interventions and risk of harm) carefully analysed in a prospective series of consecutive (otherwise unselected) referred women with incontinence.

c) Prediction of failure of surgery

Based on review of the available evidence it has been concluded that urethral pressure profilometry is not standardised, reproducible, or able to contribute to the differential diagnosis in women with SUI symptoms. [Weber,A.M. 2001] This review was done on studies of treatments done before suburethral tapes were widely used, but has been confirmed in the era of tapes. [Lemack,G.E. 2004]

Urethral retro-resistance pressure has also been studied as a potential predictor of surgical success. However, it has failed to show any predictive value for surgical success with colposuspension, retropubic suburethral slings and transobturator suburethral slings. [Tunn,R. 2007] This was underscored in a later manuscript. [Roderick,T. 2009]

Ward and colleagues carefully examined the impact of urodynamic testing on decision-making and treatment recommendations in incontinent women. They found that the probability that urodynamics would alter recommendations for medical treatments was 27% and 46% for surgical treatment. [Ward. 2002]. Johan [Johan, et al.] looked for similar effects with POP in 72 randomly selected cases. A total of 60% of the patients underwent preoperative UDS and 53% of the 43 women undergoing UDS had an abnormal result with POP reduction; 19% of these had pure SUI, and 30% had DO, either in isolation or in combination with SUI. The surgical management was altered in 7%, who had an additional continence procedure performed as a consequence of the UDS. UDS changed management in 33% patients and in 7% of patients, the surgical procedure was changed.

Conclusion (level 2)

- Leak point pressures are reported not to correlate with failure (or success) rates of colposuspensions, transobturator and retropubic suburethral, bone-anchored suburethral slings.

Conclusion (level 3)

- There is conflicting evidence that low urethral closure pressures are associated with poorer success rates of sub-urethral slings.
- It is the opinion of the committee that most evidence suggests now that urethral pressures (profile or leakpoint) are not relevant to predict the outcome of treatment in women with uncomplicated stress incontinence.

Recommendation (grade B/C)

- The committee recommends that measurements of urethral function (leak point pressures and urethral closure pressures) are not used to predict the likelihood of success after surgical treatment for women with uncomplicated primary stress incontinence.

d) Voiding difficulties after surgery

Surgery for SUI may lead to voiding difficulties. [Botros,S.M. 2007; Jarvis,G.J. 1994; Wang,A.C. 2003] One major problem is that many published studies do not use an unambiguous (urodynamic)

definition of voiding difficulties, BOO or underactive detrusor in women. Despite the 2002 ICS nomenclature this remains an area of contention because of the lack of specific numeric definitions or precise research on female pressure flow analysis. Various studies have presented a variety of parameters and cut-off values to define BOO [Bhatia,N.N. 1984; Iglesia,C.B. 1998; Lose,G. 1987; Gravina,G.L. 2007] or detrusor contraction or contractility. [Coolseat, et al.; Tan,T.L. 2003]

Furthermore, the ability of urodynamic analysis of voiding to predict difficulties after suburethral tapes is low. Shukla and colleagues found no urodynamic factors that were predictive of postoperative voiding difficulty following tension-free vaginal tape procedures in a multivariate regression analysis of 411 patients. [Shukla,A. 2007] This was confirmed in another large study. However patients considered 'at risk' (with 'abnormal UDS') were not enrolled for treatment in this study. [Lemack,G.E. 2008] However some investigators showed a significant relationship between flow rate values and the risk of voiding dysfunction and/or the need for clean intermittent (self-)catheterisation (CIC). [Dawson,T. 2007; Wheeler,T.L.,2nd 2008; Duckett,J.R. 2008]

Conclusion (level 3)

- Female voiding dysfunction is defined in many ways throughout the many publications and consistency in urodynamic analysis is lacking.
- Current test methods have not been unable to reliably predict which patients will develop voiding difficulties after surgery for stress urinary incontinence. In particular, normal urodynamic studies do not predict voiding difficulties after sub-urethral sling.
- However, flow rates, if abnormal, may be useful in predicting post-operative voiding dysfunction and retention following retropubic and transobturator suburethral slings.

Recommendation (grade C)

- The committee recommends that patients are informed that it is difficult to predict who will develop voiding difficulty following surgery for stress urinary incontinence.
- The committee recommends that patients with poor flow rates before (intended) surgery are informed that they have a higher likelihood of having voiding problems following suburethral sling placement for (urodynamic) stress urinary incontinence.

e) Postoperative urgency

The preoperative symptoms of UUI and urgency, and the UDS observation of DO, have each consistently been shown to be associated with poorer surgical outcome in patients with mixed UI. [Kulseng-Hanssen,S. 2008] Several studies where the amplitude of DO was graded have shown that the risk of persistent urgency was more closely associated with high-pressure DO (pdet ≥ 25 cm H_2O) than low-pressure DO. [Lose, G.1988; Pow-Sang,J.M. 1986; Lockhart, J.L.1984] Consequently it was suggested at that time that cystometry may allow a more precise selection of patients who respond to surgery despite DO with or without urgency symptoms. The success rate after anti-incontinence surgery in patients with low-pressure contractions are reported to be similar to the success rate in those without DO in a number of studies, [Lose, G. 224; Pow-Sang,J.M. 1986; Lockhart, J.L. 1984; Schrepferman,C.G. 2000] but the success rate in women with high-pressure DO is however reproted to be less than 50%. [561 Lose, G. 1988; Pow-Sang,J.M. 1986; Lockhart, J.L.1984; Schrepferman,C.G. 2000] On the other hand are reports that preoperative urgency symptoms resolve in a proportion of patients. [Nilsson,C.G. 2001; McGuire,E.J. 1980; Ward,K. 2002] Hypothetically, and suggested by some, surgical correction of the bladder outlet prevents ingress of urine into the proximal urethra which if it occurs, has been said to induce urgency or DO in some patients. [Jung,S.Y. 1999; Karlson,S.1953; McGuire,E.J. 1976]

De novo UUI has however also been reported to occur in 10-20% of patients after surgery. [Jarvis,G.J. 1994; Holmgren,C. 2007]

There is scant information on clinical or urodynamic risk factors; possibly the type of surgery plays a role. A recent retrospective trial suggested that the incidence of de novo UUI is higher in bladder neck slings than in retropubic suburethral slings which were also associated with more de novo UUI than transobturator suburethral slings. [Alperin,M. 2008; Botros,S.M. 2007] Another study showed that women with preoperative mixed symptoms of incontinence and DO, as well as women that used anticholinergics, had significantly worse outcome at 6 weeks. [Kenton,K. 2009] This observation was confirmed in a large longer term prospective follow-up study. [Lee,J.K. 2011]

Conclusions (level 2)

- Prospective studies have indicated that overactive bladder syndrome, mixed symptoms of incontinence and or detrusor overactivity during urodynamics at presentation have a negative effect on the outcome of (all available) surgical interventions for stress incontinence.
- Current test methods have been unable to reliably predict which patients will develop de-novo urinary urgency (overactive bladder syndrome) after surgery for stress urinary incontinence.
- Post hoc evidence suggests that procedures for the treatment of stress urinary incontinence which are more 'obstructing' produce a higher chance of de novo urinary urgency (OAB-syndrome).

Recommendation (grade B)

- The committee recommends that patients with stress urinary incontinence are informed that the chance of developing urinary urgency (overactive bladder -syndrome) following surgery is unpredictable.
- The committee recommends that patients are counselled before surgical intervention with regard to the possibility of a lesser success rate when OAB symptoms and or (urodynamic) signs of detrusor overactivity (or reduced compliance and or capacity) exist.

Topics for research

- The committee suggests further work to evaluate predictors of voiding difficulties or urinary urgency after contemporary (moderately invasive) treatments of stress urinary incontinence (e.g. transobturator or trans-vaginal tapes).
- The committee suggest that the hypothesis that suburethral tapes cure urgency, overactive bladder syndrome and or detrusor overactivity be challenged, in a properly designed prospective study.

f) The role of urodynamic studies in predicting occult stress urinary incontinence in women due to be treated for pelvic organ prolapse

Because 11 to 22% of continent women undergoing vaginal repair for a large cystocoele develop SUI following surgical repair [Beck,R.P. 1991; Borstad,E. 1989], it would be helpful to devise methods to evaluate patients who are at risk for this complication. [Ghoniem,G.M. 1994] Women with severe POP may develop urinary incontinence symptoms when the POP is reduced; this is frequently named 'occult' SUI. Voiding difficulty and BOO may coexist with occult SUI; all may be associated with POP, and all may be altered if the POP is reduced during UDS. The overall incidence of occult SUI was 25% when UDS was performed with and without pessary support of the bladder base during 'stress manoeuvres'. [Versi,E. 1998]. A special technique for reducing POP during multichannel urodynamics, revealed a 56% incidence of low-pressure urethra and an overall incidence of occult SUI of 83% in women with massive POP but without clinical UI. [Veronikis,D.K. 1997] More recently in 2008, the CARE trial in the United States examined 322 stress-continent women with stages II-IV POP who underwent standardised urodynamics. Five POP reduction methods were tested: two at each site and both were performed in each subject. Clinicians were masked to urodynamic results. At sacrocolpopexy, participants were randomised to Burch colposuspension or no Burch colposuspension (control). Preoperatively, only 12 of 313 (3.7%) subjects demonstrated USI without POP reduction. Women who demonstrated preoperative USI during POP reduction were more likely to report postoperative SUI, regardless of concomitant colposuspension. [Visco,A.G. 2008] Conventional urodynamic testing, including pessary testing, has been applied to initiate a plausible management strategy for patients with POP. [Smith,P.P. 2005; Ballert,K.N. 2009] Many studies emphasize the importance of urodynamic assessment with POP reduction to assess potential occult SUI and possibly DO. [Romanzi,L.J. 1999; Ghoniem,G.M. 1994; Versi,E. 1998; Weber,A.M. 2000; Marinkovic,S.P. 2004] However, although occult SUI is revealed in a high proportion of cases with severe POP, studies that assess reproducibility are lacking, inconclusive and or conflicting. [Bump,R.C. 1996; Colombo,M. 1997; Gordon,D. 1999; Heesakkers,J.P. 2005] Another study [Gravina 2007]concluded, on the basis of a mathematical model, that included DO, that urodynamic testing before a POP operation was not cost-effective if performed in all patients.

Conclusions (Evidence level 1)

- Various studies have shown that symptoms of stress urinary incontinence can appear after surgery for pelvic organ prolapse.
- There are a variety of methods to uncover 'occult stress urinary incontinence' in women with pelvic organ prolapse. In prospective studies. it is demonstrated that all have different sensitivities and specificities. Standardisation of these tests is necessary.

Recommendation (grade B)

- The committee recommends that patients with pelvic organ prolapse are informed about the relatively unpredictable chance of developing stress incontinence after surgery for pelvic organ prolapse.

3. URGENCY URINARY CONTINENCE

a) Pathophysiology and severity of urgency urinary incontinence

Urgency urinary incontinence (UUI) is the symptom, complaint, or sign of involuntary urine loss of urine associated with urgency. DO is the occurrence of involuntary detrusor contractions occurring during filling cystometry. Precise individual relationships between symptom severity and the various variables observed during urodynamic testing have not been established. Individual symptom severity is dependent on other factors besides lower urinary tract function, furthermore, urodynamic testing measures lower urinary tract function, in isolation from those factors. Studies have shown that symptoms and treatment result relate to Qol. [Kubota,Y. 2011; Payne,C.K. 2007]

As already indicated above, treatment and treatment response seem to depend relatively little on urodynamic measures, and also patients with OAB symptoms but without DO improve on antimuscarinergic treatment. [Malone-Lee,J.G. 2009]

Although urodynamic classification of UI type is related to adverse effects on QoL, no studies have

been successful in relating the quantified urodynamic abnormalities, when DO exists, to the symptom severity. [Duggan,P. 2011], although high scores on the urgency severity scale predict the finding of DO. [Chung,S.D. 2011] Urodynamic capacity, volume at first contraction, and or amplitude of the first, or highest contraction, are used as endpoints in treatment studies, and are, in those studies, observed to be altered in the direction of symptom improvement. (We refer to the treatment section for these observations.) A precise association between symptoms, symptom change and urodynamic findings can however not be deduced from this.

b) Prediction of treatment response

The positive predictive value of OAB (urgency usually accompanied by frequency and nocturia with or without UUI) for urodynamically determined DO is reported to be around 50%. [Digesu,G.A. 2003] On the other hand DO is reported in 10-69% of asymptomatic female volunteers, depending on the definition and type of cystometry. [van Waalwijk van Doorn,E.S. 1992; Heslington,K. 1996; Robertson,A.S. 1999; Homma,Y. 2002; Morgan, K; Turner-Warwick, et al 1979]

There are studies that show that, in patients with OAB, treatment response is not per se dependant on the observation of DO, however this does not make clear whether the urodynamics simply 'missed' the DO. It does also not exclude the necessity of urodynamics in the patients that has failed medical treatment which are the most common patients in referral clinics. [Saleem,A. 2010; Malone-Lee,J.G. 2009] Studies on voiding difficulties or de novo SUI or mixed incontinence (as a consequence of increased capacity because of treatment for UUI) have not been published.

Conclusions (level 2/3)

- Studies have not been able to show a strong association between overactive bladder symptoms and detrusor overactivity during urodynamic investigation.
- Various studies have directly or indirectly concluded that the individual prediction of the response to treatment for overactive bladder symptoms, on the basis of the characterization or quantification of detrusor overactivity during urodynamic investigation, is impossible.

Recommendation (grade B/C)

- The committee recommends that investigators and clinicians discuss with patients, with detrusor overactivity, that neither the quantity nor specific characteristics of detrusor overactivity predicts the response to any of the therapeutic approaches.

Topics for research

- The committee suggests further studies to find predictors of response on treatment for patients with overactive bladder syndrome.
- The committee suggests further studies to find urodynamic predictors of response for patients with overactive bladder without detrusor overactivity.

4. RECOMMENDATIONS FOR URODYNAMIC STUDIES IN WOMEN WITH URINARY INCONTINENCE

Recommendations for clinical practice:

1) The committee recommends non-invasive urodynamics (voiding and incontinence diary, PVR, and possibly uroflowmetry) for all patients with urinary incontinence.

2) The committee suggests that treatment, without invasive urodynamic testing, is offered in situations where the type of UI is clear, if the patient accepts the uncertainty margins of the diagnosis and there are no complicating factors. Furthermore the planned treatment should be not invasive and be simply reversible. The committee provides the following examples:

- Uncomplicated symptoms of stress urinary incontinence with normal bladder diary, normal flowmetry and without relevant post-void residual urine. (Symptomatic pure stress urinary incontinence with no symptoms or signs of voiding difficulties), for treatment with pelvic floor muscle training.
- Uncomplicated symptoms of urgency urinary incontinence, with a bladder diary in accordance with these symptoms, with normal flowmetry and without relevant post-void residual urine. (Symptomatic pure urge urinary incontinence with no symptoms or signs of voiding difficulties), for treatment by bladder training with or without combined pharmacotherapy.

3) The committee recommends that, whenever surgical intervention is planned, whenever there is doubt about the pathophysiology, or about whether the UI is uncomplicated or not, that invasive urodynamics should be performed in order to provide the knowledge on which rational treatment decisions and prognosis can be based. The committee also recommends urodynamics for patients that have had failed first therapies. The investigation should be tailored to the individual patient; typically this means that it will be a comprehensive examination of multiple aspects of storage and voiding function, and not just of the incontinence itself.

Recommendations for research:

1) The committee recommends research programs:

- to more clearly establish the technical and physiological basis of the urodynamic observations that are made in women with urinary incontinence

- to design and conduct randomised studies that may provide objective documentation of the utility of soundly based tests
- to conduct studies that may provide objective evidence of the utility of performing urodynamics in near-normal subjects and in defined patient groups

o note that the more complex and morbid the pathophysiological situation, the greater the differences between patients, and thus the more important it is to do urodynamics in order to obtain knowledge of what is to be treated

- to develop new tests, for example tests of urethral properties, which have a sound technical and physiological basis and lead to clinically relevant sub-classes of urinary incontinence

2) The committee recommends that no new therapy for urinary incontinence should be introduced without extensive urodynamic testing of all accessible aspects of its effect on lower urinary tract function and dysfunction.

II. PATIENT EVALUATION: MEN

1. INTRODUCTION

The incidence of UI in men is generally regarded as much lower than in women. The incidence of LUTS, in general, including OAB and symptoms suggestive of BOO in men however increase with age, as in women. [Kondo, et al.2002], although the QoL of women is more likely to be affected by OAB than men. Both men and women with bothersome OAB were significantly more likely to seek treatment, and to report the lowest levels of health related Qol. [Coyne,K.S. 2011]

In this section, the characteristic pathologies that lead to UI in men, rather than women, are discussed from the point of view of urodynamic testing. Although UI associated with, BOO (including BPO) or to prostatic surgery is most frequently encountered, other pathological conditions such as nocturnal enuresis and post-micturition dribbling are also clinically relevant (but not specific for) in men. [Kondo, et al.2002; Coyne,K.S. 2011] This section is organized according to the suspected origin or cause of UI or related LUTS, reflecting the diverse aetiologies responsible for incontinence in men.

2. URODYNAMIC TESTING OF DETRUSOR OVERACTIVITY AND OVERACTIVE BLADDER IN MEN

It has been estimated that 29.8 million adults aged >=40 years in the United States have bothersome OAB symptoms. The prevalence of OAB symptoms at least 'sometimes' was 27.2% in men and the prevalence of moderate/severe UI was 4.5%. [Coyne,K.S. 2011] The prevalence increased with age from 0.7% in 20 to 34 years old, to 16.0% in men 75 years old or older. [Markland,A.D. 2010] Storage LUTS was more prevalent than voiding or post-micturition LUTS in men (44.6%, 28.5%, 15.9%, respectively). The most prevalent LUTS was nocturia (36.6%). [Lee,Y.S. 2011] Significant negative correlation exists, between pre-treatment mean ICIQ-SF score and first sensation, and positive correlation between pre-treatment mean ICIQ-SF score and maximum detrusor pressure, were noted in a group of (male and female) patients taking pharmacotherapy for OAB. [Seckiner,I. 2007; Irwin,D.E. 2009] LUTS, OAB, UI, and LUTS/BOO are highly prevalent conditions, in men. [Irwin,D.E. 2009; Irwin,D.E. 2011] Treatment options for UI are rapidly expanding. Initial managements of LUTS including UI, include basic diagnostic tests to exclude an underlying disease or conditions such as UTI. In the EAU guideline the advised initial treatment is conservative (lifestyle interventions, physiotherapy, physical therapy, pharmacotherapy) and of empirical nature. [Thuroff,J.W. 2011]

In a systematic review on several longitudinal studies it was shown that OAB and UI symptom severity progresses dynamically over time, and may persist over long time periods for many individuals. [Irwin,D.E. 2010] The overall incidence of DO was 76.1% in male OAB patients, 63% of men with urgency (OAB dry) had DO, while 93% of men with urgency and urgency urinary incontinence (OAB wet) had DO. A better correlation in results between OAB symptoms and the urodynamic diagnosis of DO in men, than in women, was reported, more so in OAB wet than in OAB dry. [Al-Ghazo,M.A. 2011]. A high urgency severity score (USS) recorded in conjunction with a voiding diary, and OAB wet, were strongly associated with urodynamic DO. [Chung,S.D. 2011]

Detrusor contraction velocity is observed to be related to urgency, and urgency may have a role in enhancing and sustaining detrusor contractions in patients with DO. [Cucchi,A. 2007] First sensation ratio and bladder urgency velocity were statistically significantly correlated with the Urgency Perception Score. Urodynamic variables correlated with bladder sensation questionnaire scores and may be an objective method to assess sensory dysfunction. [Rapp,D.E. 2009] However among the 84 'BPH-DO' patients, 52 reported the symptom of urgency while 32 did not. Hypothetically, BPO patients with DO may neglect the symptom of urgency due to abnormal bladder sensation, or negate the symptom by subconscious sphincter contraction to abort the overactivity. [Tong,Y.C. 2007]

Reduced bladder sensation is defined as a bladder volume at first sensation >300 mL. Increased bladder sensation is defined as bladder volume at the first sensation <100 mL. Chronic post void residual and neuropathies are the most common cause of reduced (late) bladder sensation. In contrast, my-

elopathies are the most commonly reported cause of increased (early) bladder sensation and reduced capacity without DO. [Tsunoyama,K. 2011]

Idiopathic detrusor underactivity (DUA) is reported to result from two-stage development. [Cucchi,A. 2007] Patients with idiopathic DUA could be divided into group 1: low maximum possible detrusor contraction velocity, low isovolumic detrusor pressure and bladder emptying efficiency <67%; group 2: low maximum possible detrusor contraction velocity, low isovolumic detrusor pressure and bladder emptying efficiency >67%; and group 3: low maximum possible detrusor contraction velocity, normal isovolumic detrusor pressure and bladder emptying efficiency >67%. [Cucchi,A. 2009]

During filling cystometry, rectal contractions (RC) are frequently detected, the clinical significance of which has not been investigated, however reduced bladder compliance and bladder trabeculations were more common in patients with RC. The occurrence of RC correlated with the incidence of cerebrovascular accidents in males in a large monocenter retrospective cohort. [Cho,S.Y. 2010] Ambulatory urodynamics are complex but sensitive for the detection of DO, are prone to artefacts and time consuming. Therefore, the method is considered of best value when all other diagnostic means have failed. [Pannek,J. 2008]

Conclusions:

- Epidemiologic studies show that lower urinary tract symptoms in men >50 years of age are highly prevalent and that storage lower urinary tract symptoms are relatively more reported than voiding or postmicturition symptoms.
- Case series indicate, in male patients, that overactive bladder wet is associated with urodynamic DO. Overactive bladder dry symptoms might involve other lower urinary tract dysfunction or be the result of obstructed and or ineffective voiding.
- Guidelines suggest that the initial treatment for male lower urinary tract symptoms can be based on the predominant symptoms, without urodynamic testing.
- Guidelines recommend, on the basis of expert opinion, urodynamic testing when the initial management fails to resolve the storage lower urinary tract symptoms.

3. LOWER URINARY TRACT SYMPTOMS RELATED TO MALE LOWER URINARY TRACT DYSFUNCTION: DETRUSOR OVERACTIVITY AND BLADDER OUTLET OBSTRUCTION

Lower urinary tract dysfunction is as prevalent in elderly men as in women however urinary incontinence is less prevalent in elderly male, (without a history of relevant surgery) However if UI is present in men, urodynamics can be helpful. Coexistence of UI in men with BOO and DO increases with age and with the degree of BOO. [Oelke,M. 2008; Vesely,S. 2003] The prevalence of UI ranges from 11% to 34% among community-dwelling men aged ≥65 years. BPO-related incontinence may be related to progression of BPH, through BPE, or as a post surgical complication. [Han,E. 2007] Significantly more cases (14%) reported reduced sexual activity and decreased enjoyment of sexual activity because of LUTS in a large case control series of elderly men, and significantly fewer cases were satisfied with their sex lives compared with controls. [Irwin,D.E. 2008]

Among 1418 men investigated urodynamically (median age: 63 yr) 864 (60.9%), had DO. In univariate analysis, men with DO were significantly older, had larger prostates, and higher grades of BOO, higher storage IPSS sub scores, a lower VV at free uroflowmetry, and a lower bladder capacity at cystometry. In patients with 'clinical BPH', DO was independently associated with age and BOO. [Oelke,M. 2008]

LUTS in elderly men does not equate to BOO due to BPE, and, in particular, young men presenting with LUTS have a different prevalence of underlying aetiologies. Urodynamic studies are useful in the evaluation of this group of patients Abnormal UDS were noted in 36 (72%), including DO in 9 (18%), underactive detrusor / acontractility in 5 (10%) and BOO in 21 (42%). Fourteen (28%) had primary bladder neck dysfunction and five (10%) had BPO in a retrospective monocenter report of 50 men < 50 years. [Toh,K.L. 2006]

LUTS can result from a complex interplay of pathophysiological features that can include bladder dysfunction and BPO or poor relaxation of the urethral sphincter. About one third of men with LUTS who were older than 55 years of age had BPO. Patients younger than 55 years old with LUTS were more likely to have poor relaxation of the urethral sphincter. [Kuo,H.C. 2007] In a group of men with LUTS and small prostates (mean prostate volume was 29.2 +/- 7.2 mL and mean IPSS was 13.5 +/- 4.6) BOO was diagnosed in 42 (50.0%) patients, and underactive detrusor in 41 (48.8%) and DO in 28 (33.3%) were the other diagnoses. The results emphasize the value of urodynamics in this population, especially when invasive treatments are being considered. [Gomes,C.M. 2008]

Non-invasive investigations such as uroflowmetry and measurement of PVR are easy to perform, but, even in simple situations, can only give clues to the underlying pathology. Low Q_{max} on uroflowmetry cannot distinguish BOO from the poor detrusor contraction. [Chancellor,M.B. 1991] furthermore there is also a significant variation in Q_{max} in repeated tests. [Feneley,M.R. 1996] A recent study showed that the time to flow, while performing uroflowmetry, associates with the reported symptom of urinary hesitancy on IPSS. [Park,K.K. 2011] Relatively strong relationships were found between average flow rate and

flow time with scores of intermittency, weak stream and IPSS scores in elderly men with LUTS and a reduced flow rate. [Itoh,H. 2006]

Seki at al reported that DO, at initial evaluation, negatively affected outcome in a retrospective study of 384 patients who had undergone TURP for symptomatic benign prostatic enlargement. [Seki,N. 2006] In another study with patients with prostate carcinoma and symptoms, it was demonstrated that 95% of men who proceeded to TURP on the basis of urodynamic diagnosis, had improved flow rates at 12 months after palliative TURP. [Gnanapragasam,V.J. 2011] Monoski at al found, in 40 men who underwent photoselective laser vaporisation prostatectomy for 'BPH' and retention, that the presence of DO in patients on pre-surgery Urodynamics, is associated with significantly more storage symptoms, and are twice as likely to require anticholinergic treatment than the patient without DO. [Monoski,M.A. 2006]

After HoLEP, 29 patients (16.2%) had de novo UI, most of which resolved within 1-6 months; low MUCP at baseline urodynamics was found to be the independent urodynamic predictor of de novo UI after surgery, amongst others in a multivariate analysis. [Cho,M.C. 2011] UDS was used to assess the functional outcome following KTP -laser prostatectomy. All selected patients in this uncontrolled monocenter series (n=45) showed significant improvement in the IPSS in urodynamic pressure and flow. Detrusor contractility was not affected. [Hamann,M.F. 2008]

In an experts group discussion, it was concluded that UDS is indicated for the evaluation of effectiveness of new treatment modalities for elderly male patients. As in the existing guidelines, this expert group supports, on the basis of their expert opinion that UDS are not necessary before pelvic floor muscle training or medical treatment of LUTS/BPO or OAB. [Bosch,J.L. 2011]

Silodosin is evaluated to improve DO and BOO grade in patients with BPH and urodynamic testing showed objective improvement of voiding in a proportion of patients in a small monocenter study. [Yamanishi,T. 2010] In elderly male with OAB symptoms anticholinergics do not seem to influence effectivity of (urodynamic) voiding. [Ronchi,P. 2009]

The role of urodynamics and the finding of DO, in predicting continence outcome, after radical prostatectomy, still remains controversial. Aboseif et al compared 92 men with and without DO on pre-operative urodynamics before radical prostatectomy. They found, after one year, a significantly higher incidence of UI (39% v/s 3%) in patients with pre-operative DO compared to those without pre-operative DO. [Aboseif,S.R. 1994] On the other hand, Kleinhans et al concluded (44 patients) that preoperative DO did not correlate with post surgical UI eight months after radical prostatectomy. [Kleinhans 1999]

Conclusions:

- Various studies indicate that male lower urinary tract symptoms including incontinence may be due to detrusor dysfunction and or bladder outlet obstruction.
- Monocenter cohort observations demonstrate that detrusor overactivity and urethral sphincter dysfunction should also be considered in young men with lower urinary tract symptoms or men with a small prostate.
- Mono and multicenter cohorts show that although urodynamic studies do not unequivocally predict outcomes of pharmacological or surgical treatment, treatment results are however shown to be better predicted in patients who have had objective urodynamic tests.

Recommendations (grade C)

- Evidence that urodynamics improves outcome is limited, but nevertheless the committee recommends that all elderly male patients with incontinence should receive a complete urodynamic evaluation in order to understand the problem
- The committee recommends that clinical parameters are investigated which correlate with urodynamic results such as BOO or DO, in order to achieve better treatment outcome for LUTS in men, without invasive urodynamics.

4. POST-PROSTATECTOMY INCONTINENCE

a) General

After prostatectomy, a noticeable number of patients suffer from UI. The reported incidence following surgery varies widely and is believed to be related to patient age, pre-surgery lower urinary tract function, benign or malignant prostatic disease and the type of surgery and furthermore depends on the definition of incontinence that is applied. Approximately 10-14% of patients, suffer incontinence 2-5 years after radical prostatectomy. [Penson,D.F. 2005] A prospective survey study on 1201 patients and 625 partners, of outcome after treatment for prostate cancer, showed that UI was at its worst 2 months after surgery and then improved in most patients. Factors that were associated with worse UI were, older age, black race, and a high PSA score at diagnosis. Patients in the brachytherapy group reported significant deterioration in 'urinary irritation', symptoms suggestive of BOO and UI, compared with baseline. UI after brachytherapy was reported by 4 to 6% of patients at 1 to 2 years after treatment. [Sanda,M.G. 2008] Comparative studies indicate that UI is the most incident adverse effect of radical prostatectomy. [Wilt,T.J. 2008] Understanding of prostato-vesical anatomy and the pelvic floor, and meticulous surgical technique, are of importance in preventing UI.

Using accumulated data from 573 patients, reported in 8 articles from 1978 to 1997, which collated urodynamic evidence for UI following surgery for 'BPH' or prostatic cancer, it was suggested that the most common aetiology was isolated sphincter weakness, followed by sphincter weakness plus DO, and also DOI and or reduced compliance alone. Thus, a blanket assumption that there is a single cause of the UI would be wrong in two-thirds of men after radical prostatectomy. Furthermore also obstructed voiding is reported in these series. [Kondo, et al 2002; Porena,M. 2007; Ficazzola,M.A. 1998; Huckabay,C. 2005]

UI was more prevalent in men who were obese and physically inactive (59% UI) after prostatectomy. The best outcomes were in men without obesity and physically active (16% UI). Pre-prostatectomy physical activity and weight (BMI) may be important factors in UI after radical prostatectomy and the return of continence. [Wolin,K.Y. 2010]

Preoperative DO was not associated with worse post radical prostatectomy UI outcomes, or increased incidence of UI. Monocenter observations suggest that even if DO is present in men with USI after radical prostatectomy they may be considered for a male sling procedure. [Ballert,K.N. 2010]

Conclusions:

- Many case series show that sphincter weakness is the most common aetiology of male urinary incontinence after prostatectomy. However case series and reviews show that other lower urinary tract dysfunction besides sphincter incompetence plays an incident role in post prostatectomy urinary incontinence.
- Case cohorts indicate that detrusor overactivity before radical prostatectomy is not an important indicator for the postoperative incidence of urinary incontinence, or for the outcome from surgical interventions to treat the urinary incontinence.

b) Transurethral resection of the prostate and Open Prostatectomy for benign disease.

Approximately 1% of patients who have undergone TURP suffer from post-prostatectomy incontinence. [Mebust, et al 1989] Das and his co-investigators [Das,A. 2001] showed that the role of urodynamic investigation in preventing post-operative incontinence before laser resection of the prostate may be marginal. Another large monocenter study showed that the incidence of post laser-prostatectomy incontinence is less than 1%. [Krambeck,A.E. 2010] A systematic review and health technology assessment did not show differences in the incidence of incontinence following various more or less invasive (non medical) interventions for 'symptomatic BPH'. [Lourenco,T. 2008]

Kuo [Kuo,H.C. 2002] urodynamically evaluated 185 men aged from 55 to 91 with a mean of 75 years who had had variable LUTS after TURP which had been refractory to conventional treatments. He found that UI was present in 74 patients (40%) and that BOO and DO with impaired contractility (DHIC) were the most common findings associated with post-prostatectomy incontinence, followed by DO. Post-transurethral- prostatectomy incontinence is usually due to sphincter damage as a complication of prostatectomy, but may result from other causes, such as DO. Urodynamics showed no significant change in filling or voiding parameters when suburethral 'male'-slings were implanted. [Wadie,B.S. 2010]

After HoLEP, 29 patients (16.2%) had de novo UI, most of which resolved within 1-6 months; 11 had SUI, 12 had UUI, and the remaining 6 had mixed UI. A lower MUCP, on baseline urodynamics, was found to be the independent predictor of de novo UI after surgery. [Cho,M.C. 2011]

Conclusions:

- Case series have concluded that urinary incontinence after prostatectomy may be attributed to bladder storage dysfunction and can exist in association with (neo-bladder neck) bladder outlet obstruction although the most prevalent cause is a lesion of sphincteric function.
- Retrospective studies have shown that urodynamic tests cannot predict which patient will develop SUI or detrusor overactivity (with or without urgency incontinence) after surgical treatment for benign prostatic obstruction.
- Studies have shown that urodynamic tests can identify the aetiology(ies) of urinary incontinence (or other lower urinary tract dysfunction) after surgical treatment for benign prostatic obstruction, however the predictive value for the outcome of subsequent treatment is unknown.

Recommendation (grade C)

- The committee recommends urodynamic testing when elderly male patients have urinary incontinence after surgical treatment for benign prostatic obstruction if further surgical or invasive treatment is planned.

c) Radical Prostatectomy and Radiotherapy

Is (invasive) urodynamic investigation of incontinence after radical prostatectomy necessary?

Sphincter weakness, neo bladderneck outlet obstruction, DO and mixed incontinence are contributing to post-prostatectomy incontinence. [Kuo,H.C. 2002; McCallum,T.J. 2001] These parameters can be only identified by urodynamics, which is considered by most [Sakamoto,K. 2001; Gomha,M.A. 2002; Yurkanin,J.P. 2001], but not all [Hindley,R.G. 2001], to be one of the main tools for investigating

UI after radical prostatectomy. In brachytherapy for prostate cancer, urodynamics may have some value for predicting which men might develop acute urinary retention or might require CIC after treatment when the prostatic oedema has caused temporary retention. [Henderson,A. 2002] Castille et al prospectively assessed 229 men who were scheduled to undergo radical retropubic prostatectomy with preoperative urodynamics in an attempt to help physiotherapists predict postoperative incontinence. [Castille,Y. 2003] They observed that all men diagnosed as having DO or neo bladderneck outlet obstruction were incontinent 6 weeks after operation but had improved 4 months later. DO and neo bladderneck outlet obstruction were considered risk factors for postoperative incontinence.

Groutz et al [Groutz,A. 2000] found that USI was the most common urodynamic abnormality after radical prostatectomy (73 patients, 88%), followed by DO in 6, neo bladderneck outlet obstruction in 1 impaired detrusor contractility in 1, and normal findings in 2. Of 73 men diagnosed as having USI, 27 suffered from pure urodynamic USI, and the remaining 46 had concomitant bladder disorders such as impaired detrusor contractility (22 men), neo bladderneck outlet obstruction (14 men) or DO (10 men). Huckabay et al evaluated 60 men and found that twenty-four (40%) men had DO with 8 (13%) also having DOI. Only one patient had impaired bladder compliance. All men had USI, but 21 (35%) men demonstrated it only after removal of the (7F) urethral catheter. For men leaking with and without the urethral catheter, the respective abdominal LPP was significantly different, 86.3 and 67 cmH_2O, respectively. The men who leaked only in the absence of the urethral catheter had significantly higher abdominal LPP measurements. [Huckabay,C. 2005] Although SUI was one of the predominant symptoms of incontinence following radical prostatectomy, half of patients had USI together with UUI or decreased bladder compliance. Co-existing detrusor dysfunction had to be taken into consideration, as well as ISD, in order to properly treat persistent post-prostatectomy incontinence. [McCallum,T.J. 2001; 130 Lai,H.H. 2009] Male SUI is mainly caused by sphincter lesions after retropubic radical prostatectomy (RRP). After RRP, two-thirds were continent after 6 months, whereas one-third still suffered from incontinence. MUCP and FPL in the SUI was significantly lower in comparison with the continent group, accompanied by a characteristic UPP configuration. Postoperative urodynamics after 6 months may be predictive for persistent incontinence at the bladder, sphincter, and both. [Bentzon,D.N. 2009] Based on a study of 29 men with incontinence after radical prostatectomy, it was concluded that abdominal LPP is relatively poorly associated with incontinence severity and, therefore, has limited clinical value in the urodynamic evaluation of post-prostatectomy incontinence. [Twiss,C. 2005] Another study also investigated if abdominal LPP correlates with objective incontinence severity in patients suffering from post-prostatectomy SUI. There was only a weak inverse correlation between abdominal LPP and 24-hr pad weight which was not statistically significant. Age and time from prostatectomy did not significantly correlate with abdominal LPP. The abdominal LPP was considered a relatively poor predictor of incontinence severity and, therefore, has limited clinical value in the urodynamic evaluation of post-prostatectomy incontinence. [Twiss,C. 2005] Several robot-assisted radical prostatectomy (RARP) series have reviewed the impact of the initial learning curve on perioperative outcomes. Outcomes between groups (cases 1-300, 301-500, and 501-700) were compared. Continence rates improved from 75% to 93% for cases 501-700 (p<or= 0.05). Furthermore, significant improvement in continence rates between consecutive case groups was observed at all postoperative time points. [Frank,S.J. 2007]

Is (invasive) urodynamic investigation of incontinence after radiotherapy necessary?

There are few manuscripts reporting the effects of radiotherapy in those with prostatic cancer, and even fewer discussing the place of urodynamics. [Choo,R. 2002; Do,V. 2002] Henderson et al. [Henderson,A. 2002] assessed 100 patients with prostate cancer patients for brachytherapy with a minimum dose of 145 Gy. Prior to the treatment an unselected group of 57 of the 100 patients had been evaluated urodynamically. Patients with larger prostatic volumes (> 35 mL) and or with (UDS confirmed) BOO were more prone to problems after brachytherapy. The authors concluded that urodynamics might have a role in the selection of treatment for men with prostate cancer. Beekman et al found in 204 patients that high PVR (> 100 mL) is associated with slower resolution of voiding symptoms, prolonged (more than 3 days) catheter dependency, and increased post-brachytherapy surgical intervention for BOO. [Beekman,M. 2005] Also Wehle et al suggested that the combination of urinary flow rate, prostate volume, postvoid residual urinary volume, combined with the American Urological Association symptom score helped to identify patients with underlying voiding dysfunction. Urinary flow rate was a statistically significant predictor of genitourinary tract morbidity after brachytherapy for localised prostate adenocarcinoma. [Wehle,M.J. 2004]

Men after brachytherapy were, in a monocenter retrospective cohort, reported to have a relatively high incidence of DO, prostatic and urethral strictures and prostatic urethral stones. [Blaivas,J.G. 2006] A survey amongst 625 (responding) patients that assed the Qol following radical prostatectomy, high dose external beam radiation therapy and brachytherapy iodine implantation as monotherapies for localized prostate cancer showed that a better rate of urinary continence was maintained in those who underwent radiation based therapies. Better bowel function, lesser sexual function and

less urinary irritation was reported in those who underwent surgery. [Frank,S.J. 2007]

Conclusions:

- Case series and reviews show that the main cause of urinary incontinence after RRP is sphincter weakness and that detrusor overactivity contributes in only a small proportion of those patients.
- Case cohorts show that higher maximal urethral closure pressures or abdominal leak point pressures, indicating greater urethral sphincter resistance is not of utmost clinical relevance
- UI after RRP will improve with time. A study concluded that postoperative urethral pressure profile after 6 months may be predictive for persistent incontinence.

d) Artificial urinary sphincter and male sling

Gomha and Boone [Gomha,M.A. 2002] treated 86 patients who were incontinent following prostatectomy with implantation of an artificial urinary sphincter (AUS)and assessed whether or not prior radiation affected surgical outcomes in those who had or had not had radiotherapy. Urodynamic study prior to artificial sphincter implantation revealed that DO was much more prevalent in group with radiation (26%) than in group without radiation (5%). In spite of this, post-operative urgency with or without urgency incontinence was found in similar proportions of the 2 groups, and similar proportions wore 0 to 1 pad a day to protect against their incontinence. They concluded that the pre-operative urodynamic finding of DO did not predict outcome in this group. Similarly, Thiel and co-workers retrospectively reviewed 86 patients and concluded that patients with post radical prostatectomy USI, plus DO, low compliance, or decreased MCC and FSF have identical outcomes after AUS implantation to those just with USI. [Thiel,D.D. 2007]

The presence of adverse preoperative UDS features as: poor bladder compliance <10 mL/cm, the presence of DO, early sensation of bladder filling at <75 mL, an early FDV at <125 mL, reduced MCC of <200 mL, low abdominal LPP of <30 cm H(2)O, low peak flow of <10 mL/s, low detrusor pressure at peak flow of <10 cm, or a bladder contractility index of <100, did not negatively affect either the post-AUS daily pad use or the continence rate after AUS implantation in patients with post (radical) prostatectomy UI. [Lai,H.H. 2009]

Recent publications on the male suburethral sling show good continence cure rates in post prostatecomy cohorts. A monocenter retrospective study reported that, when post-hoc criteria are applied, cure rates were lower in men that used more pads before sling implant. [Bochove-Overgaauw,D.M. 2011] Also, Ullrich & Comiter evaluated 22 patients urodynamically, at a mean of 25 months after a male sling procedure, and found that patients with postoperative retrograde leak point pressure < 50 cm H_2O and DO were seen to be associated with failure. [Ullrich,N.F. 2004] The trans obturator -tape (TOT) for treatment of post-radical prostatectomy UI, was shown to be effective and well accepted by patients. The mean MUCP improved, which associated with cure, and a majority of patients in a small (n=20) uncontrolled single centre cohort was satisfied. [Rehder,P. 2007] At 12-month follow-up of this treatment, with a larger group of patients (n=118), 73.7% of the men were cured and using significantly less pads, 16.9% were improved, and 9.3% were still incontinent. The detrusor voiding pressure, postvoid residual urine volume and maximal flow rates remained unchanged, while the VLPP improved significantly). [Rehder,P. 2010]

A concern of any procedure in treating men with UI after radical prostatectomy is whether the treatment induces obstruction and causes retention. A study to evaluate this with regard to the 'male sling' questioned whether this treatment eliminates UI without affecting the voiding .The VLPP improved significantly and the detrusor voiding pressure, PVR volume, and maximal and average flow rates remained relatively unchanged. At 3 and 6 months postoperatively, the Incontinence Quality of Life scores had improved significantly compared with the preoperative scores with a reduction in pad-use (from 5 to 1) and urine loss (780g before and 70g after). [Davies,T.O. 2009]

These studies confirm the earlier observations, that the fixed urethral resistance of the perineal male sling for the treatment of (post RRP) SUI in male patients, did not cause BOO or cause de novo voiding dysfunction. Average maximum flow rate did not change significantly nor was there a significant change in detrusor pressure at maximum flow rate, but the pad use, LPP and UI scores were significantly improved after sling surgery. [Ullrich,N.F. 2004]

Conclusions:

- Studies have not consistently concluded that urodynamic variables provide predictive value for treatment in male post prostatectomy incontinence.
- There is weak evidence to support urodynamic evaluation (for patients with a large prostate) before radiotherapy for cancer of the prostate.
- Studies have shown that urodynamic tests are needed to identify the aetiology of urinary tract dysfunction after surgical or radiotherapy treatment of prostatic carcinoma. However the predictive value of urodynamics for the effect of subsequent treatment is unknown.
- Leak point pressures and urethral pressures, measured in their various ways, are consistently reported to be improved after anti -incontinence treatment using different surgical techniques, and

their improvement is associated with cure or reduction of incontinence volume and or pads use.

- Most single centre reports conclude that urodynamic variables, used to evaluate voiding, do not show clinically significant change after suburethral sling procedures or artificial urinary sphincter implantation.

Recommendations (grade B)

- The committee recognised that urodynamic testing for incontinence after radical prostatectomy is not particularly important for the diagnosis of sphincter dysfunction (stress urinary incontinence) in patients with post prostatectomy incontinence. However, the committee recommends that urodynamic testing is considered in patients where other dysfunctions of the lower urinary tract (obstructed voiding, significantly reduced bladder compliance and or detrusor overactivity) cannot be excluded on the basis of signs and symptoms.

Topics for research

- The committee suggests research to find predictors for lower urinary tract dysfunction after treatment for benign prostatic obstruction or for prostatic carcinoma.
- The committee suggests research to improve the prediction of success (whether or not on the basis of urodynamic testing) of treatment for lower urinary tract problems that may follow treatment of benign prostatic obstruction or prostatic carcinoma.

5. NEUROLOGICAL LESIONS RELATED TO MALE INCONTINENCE

Several ailments or pathological conditions have been reported to be closely associated with incontinence, e.g., neurological diseases, prior radiotherapy, neurogenic DO, diminished bladder compliance, nocturnal enuresis, post-micturition dribble and terminal dribbling. [Kondo, et al.] A history of prostatectomy as well as the existence of BPE in combination with one of the here before mentioned conditions may be a diagnostic challenge. Nocturia has a variety of potential causes and was shown to have high impact on bother score, strong associations with poor health and other LUTS. Nocturnal polyuria (NP) is a predominant cause of nocturia. Principal causes for nocturia were global polyuria in 17%, NP in 33% and small functional capacity <250 mL in 16.2%; 21.2% had mixed forms of NP and reduced bladder capacity and 12.6% suffered from other causes. [Klingler,H.C. 2009]

a) Nocturnal enuresis

Nocturnal enuresis in adult males is rather rare. Sakamoto and Blaivas reported, in a tertiary care practice, important interesting observations based on data of over 3000 patients referred for the evaluation of LUTS. [Sakamoto,K. 2001] They found that 8 of 3277 patients (0.02%) had adult onset nocturnal enuresis without daytime enuresis. All these patients were male, with a mean age of 63 years (48 to 80 years) and all suffered from BOO with mean maximum urinary flow rate 8.5 mL/s, mean IPSS 12.6, and mean PVR urine 350 mL (50 to 489 mL). The authors identified hydronephrosis in 5 of the 8 patients, a bladder diverticulum in 3/8, vesico-ureteric reflux in 4/8 and low bladder compliance in 4/8. Five of the 8 underwent TURP resulting in improved symptoms. Thus BOO is one of the distinct pathologies that can provoke nocturnal enuresis with variable LUTS, but it is not the only pathological factor. For example, Hunsballe [Hunsballe,J.M. 2000] found more delta activity in electroencephalography among adult primary enuretics compared to normal controls. Therefore, invasive urodynamics may be justified in such patients, because it is the only way of reliably identifying BOO.

Nocturnal enuresis plagues nearly 28% of patients with a neobladder. Indeed, 25 of 30 patients (83%) who underwent the Stanford pouch ileal bladder had nocturnal enuresis 1 year later. [Uygur,M.C. 2000] Patients older than 65 years are at greater risk because of the physiological increase in LUTD nocturnal diuresis associated with aging. An orthotopic neobladder produces variable LUTD including both failure to empty the bladder and failure to store urine. The urodynamic behaviour depends on the type, length, and configuration of the bowel segment used. [Steers,W.D. 2000] There may be overdistension, elevated PVR, lack of sensation, reduced MUCP, or more frequent and higher-pressure DO. [El Bahnasawy,M.S. 2000] The intestinal overactivity in a neobladder resembles bowel peristalsis. [Sakakibara,R. 2007]

El-Bahnasawy et al studied urodynamically 50 enuretic men at least 1 year after a radical cystoprostatectomy and ileal neobladder and compared them to 17 men with only occasional enuresis and 50 men without enuresis after similar surgery. Both enuretic groups had significantly higher residual urine volumes, higher pressures at mid-capacity and at maximum enterocystometric capacity, higher amplitude of contractions and lower compliance than continent men. Men with occasional enuresis also had a significantly higher frequency and duration of DO contractions and lower maximum urinary flow rates than continent men. [el-Bahnasawy,M.S. 2005]

Urodynamic investigation is important to establish the diagnosis and select treatment, although one group suggested that nocturnal enuresis or nocturia could be simply alleviated by waking up at least twice per night to void. [Uygur,M.C. 2000]

Conclusions

- Epidemiology shows that non- urologic causes for nocturia are prevalent and nocturnal polyuria can

be diagnosed with a 24 h frequency-volume chart.

- Urodynamic studies in elderly men indicate however that detrusor overactivity and/or bladder outlet obstruction with ineffective voiding may play a role in a proportion of patients with nocturnal enuresis.
- New onset, night time incontinence, in an elderly male, warrants urgent urodynamic pressure-flow analysis.

b) Stroke

Stroke is a common and well-known cause of enuresis and LUTD in the older population. The predominant symptoms are urinary frequency, urgency and UUI (including night-time incontinence) while DO is the most common finding on urodynamics. [Marinkovic,S.P. 2001] In patients after a stroke, incontinence (or LUTD in general) is a serious threat for Qol. [Edwards,D.F. 2006] Post-stroke UI is a predictor of greater mortality at 1 week, 6 months and 12 months after stroke. However, patients who regain normal bladder control in the first week have a comparable prognosis as the patients who do not have micturition disturbances following stroke. [Rotar,M. 2011]

Because DO in male stroke patients with LUTD is prevalent, conservative or pharmacologic treatment is often instituted without prior urodynamic investigation. An expert summary of the literature suggested that the size and the site of the stroke does have an influence on urological findings. [Badlani,G.et al] Experts agree that simple tests such as uroflowmetry and, especially, PVR urine assessment (by ultrasound) are however useful, since elevated residual urine is to be expected in a significant proportion of these patients, and its evaluation can improve caregiving and Qol. [Chan,H. 1997; Teng,C.H. 2005] Cystometry has limited value: the prevalence of DO in older people is quite high even in the absence of stroke (perhaps 10% in women and 25 to 35% in men). Therefore the observation of DO alone may not be helpful although the finding of other LUTD, such as obstructed voiding, is.

The prevalence for isolated UI, on admission, was 12.4%, for isolated faecal incontinence 7.6% and for double incontinence 33%. At discharge, the prevalence had decreased, to 8.1% for isolated UI, 4.9 % for isolated faecal incontinence and 15.1% for double incontinence. Double incontinence was more prevalent than isolated incontinence in patients after stroke during post-acute rehabilitation. [Kovindha,A. 2009]

Evaluation of the stroke type may be helpful in the determination of the type of urinary dysfunction and in deciding the appropriate bladder management: the ischemic group was reported to have DO (70.7%), underactive detrusor (29.3%), and hemorrhagic group has DO in 34.6%, and underactive detrusor in 65.4%. (P = 0.003). [Han,E. 2007]

In patients with stroke and voiding dysfunctions, UDI can be performed to identify the presence of BOO or dysfunctional voiding. Voiding dysfunction is also a significant problem in patients with head injury. NDO is seen in patients with injuries above the pontine micturition centre. The voiding abnormality has good prognosis and resolves spontaneously. [Singhania,P. 2010] Among the 36 patients with stroke and DO, 25 patients (62.5%) had DO without sphincter dyssynergy and 11 (27.5%) had DO with sphincter dyssynergy. UDS is a useful tool to assess and manage the bladder following stroke with UI. No significant correlation was found between UDS findings and site of (stroke) lesion in a retrospective single institute study with 18 women and 22 men. [Gupta,A. 2009] In a urodynamic study of bladder dysfunction in idiopathic normal pressure hydrocephalus (iNPH), LUTS were seen in 93% of the patients, with storage symptoms (93%) being more common than voiding symptoms (71%); and urinary urgency (overactive bladder) (64%) frequency (64%) being more common than UI (57%). Although the majority of patients had normal bladder volume at the first sensation (mean 134 mL), bladder capacity was small (mean 200 mL) and DO was seen in 95% of patients. [Sakakibara,R. 2001]

Conclusion:

- Detrusor overactivity and or underactive detrusor can be present in patients with stroke or other neurological lesion.
- In ambulatory male patients, after stroke, with voiding dysfunctions, careful urodynamic study can be offered to identify the presence of detrusor overactivity, or static (BPO) or dynamic (dyssynergic) bladder outlet obstruction.

c) Parkinson's disease

Parkinsonian diseases are known to significantly influence bladder function (see section D.V.6). LUTS may be the first sign, especially nocturia in male patients. Large capacity bladder (when discovered during urodynamic testing for LUTS) may also be a sign of Parkinsonism. [Purohit,R.S. 2008; Williams,D.R. 2009; Blackett,H. 2009; Cheon,S.M. 2008] DOI is common in male patients with Parkinsonism [Defreitas,G.A. 2003], but urodynamic findings differ in different diseases of this group. [Sakakibara,R. 2001] Defreitas et al carried out a retrospective review of the urodynamic results in men with DO due to BOO (22 patients) and compared them to men (39 patients) and women (18 patients) with Parkinson's disease. Patients with Parkinson's disease had a significantly lower median volume at first detrusor contraction than those with non-neurogenic DO. The percentage of urgency incontinence was significantly lower in patients without Parkinson's disease than in men and women with it (9.1% versus 53.8% and 55.6%). No statistically significant correlation between the duration or the severity

of Parkinson's disease and UDS parameters was found. [Defreitas,G.A. 2003] The most prevailing urinary symptom in Idiopathic Parkinson's Disease was nocturia (77.5%) followed by urgency (36.7%) and frequency (32.6%). Urodynamic tests revealed neurogenic DO in 33 patients (67.3%), underactive detrusor in 6 patients (12.2%), and 10 (20.4%) patients with normal detrusor function. However, no significant correlations between any of the urodynamic parameters and disease severity was found. The urinary (storage) symptoms manifested urodynamically as neurogenic DO are more common in IPD patients than voiding symptoms. [Ragab,M.M. 2011]

Urinary dysfunction, manifested primarily as storage disorders with subclinical voiding disorders and normal anal-sphincter electromyography, occurs in early and untreated PD patients. Urodynamic studies showed abnormal findings in the storage phase in 84%, with DO and increased bladder sensation without DO in 58.0% and 12.0% of patients, respectively. In the voiding phase, underactive detrusor, impaired urethral relaxation such as detrusor sphincter dyssynergia, and BOO were present in 50.0%, 8.0% and 16% of patients, respectively. In patients with both storage and voiding phase abnormalities, DO plus underactive detrusor was the most common finding. [Uchiyama,T. 2011]

One study investigated the LUTS and urodynamic and cystometric findings in PD, dementia with Lewy bodies (DLB), and Alzheimer disease (AD). Urgency and urgency incontinence suggest DO, which was more prevalent in dementia with Lewy bodies than in PD and Alzheimer disease, whereas mean VV, free flow, MCC, and detrusor pressure were similar in the groups; DO was seen in 92% of the patients with DLB, 46% of the patients with PD, and 40% of the patients with AD. [Ransmayr,G.N. 2008]

Conclusions:

- Detrusor overactivity and detrusor underactivity, with or without urethral sphincter dyssynergia, are commonly found in male patients with Parkinson's disease.
- Bladder outlet obstruction is not related to Parkinson's disease. For male patients with Parkinson's disease and voiding dysfunction, urodynamic testing is recommended to select appropriate treatment strategy.

d) Diabetes Mellitus (DM)

Men with DM and LUTS can present with varied urodynamic findings, apart from the classic sensory or motor cystopathy. Urodynamic studies showed delayed first sensation (>250 mL), increased capacity (>600 mL) underactive detrusor, DO, high postvoid residual urine volume (more than one third of capacity), and BOO (Abrams-Griffiths number >40) in 23.1%, 25.0%, 78.8%, 38.5%, 65.4%, and 28.8% of the men, respectively. [Bansal,R. 2011] Kebapci re-evaluated the urodynamic findings of LUTD in type 2 diabetic patients describing patient characteristics and concomitant chronic complications: LUTDD was present in 74.07% of men. The group defined 'diabetic cystopathy' as diminished sensation of filling and significant postvoid residual and observed that in 50% of their patients, also BOO, (25%) and DO (in 25%) were observed. 'Diabetic cystopathy' (in this specific definition was the most frequent finding. Ageing, duration of diabetes, worse metabolic control, PVR >100 mL, cardiac, oesophageal and gastric parasympathetic autonomic neuropathies, retinopathy, and microalbuminuria provided a means to predict LUTD, and select patients for urodynamics. [Kebapci,N. 2007]

It was observed in a monocenter retrospective case control study that patients with DM who undergo radical cystoprostatectomy take longer to regain daytime and, even more so, night time continence than non diabetic patients. [Kessler,T.M. 2008]

There is a relatively low prevalence of BOO in diabetic patients with prostate enlargement and LUTS. Of the 50 patients in the study, 23 (46%) had BOO. There was no correlation between the IPSS, uroflowmetry, post-voiding residual urine or prostate volume and the presence of BOO ($p > 0.05$). Non-invasive tests did not allow the identification of LUTD and only urodynamic evaluation is able to determine symptom aetiology. [Dib,P.T. 2008]

Conclusions:

- Clinical cohort studies show that men with diabetes and lower urinary tract symptoms can present with a variety of urodynamic findings, including detrusor overactivity, underactive detrusor and bladder outlet obstruction.
- Uncontrolled cohort studies indicate that non-invasive tests are less sensitive to relevant abnormalities in comparison with urodynamic evaluation and investigators have concluded that urodynamic investigation is necessary when lower urinary tract symptoms arise in patients with diabetes mellitus.

e) Recommendations for urodynamic investigation for men suffering from nocturnal enuresis, stroke, Parkinson's disease or DM

Conclusions (level of evidence 2/3)

- Nocturnal enuresis in adult males is rare but problematic, and it is associated with many possible aetiologies.
- Nocturia, nocturnal enuresis or lower urinary tract symptoms may be the first, or an early sign, of Parkinsonism in elderly male patients.
- Lower urinary tract dysfunction in patients with Parkinsonism can be the result of detrusor overactivity, (benign prostatic) bladder outlet obstruction,

dyssynergic voiding or post void residual urine or any combination thereof.

Recommendations (grade B/C)

- The committee recommends that urodynamic evaluation should be conducted in all cases of nocturnal enuresis in adult males
- The committee recommends that urodynamic evaluation should be performed in patients with Parkinsonism. There should be flowmetry and postvoid residual assessment in all cases and invasive testing when abnormalities are observed in flowmetry and postvoid residual assessment.
- The committee suggests that investigators should be alert for large capacity bladder and/or underactive detrusor (or large residual without significant bladder outlet obstruction) as an early sign of Parkinson's disease.

III. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

1. INTRODUCTION

Neurogenic LUTD is not precisely defined. The International Continence Society has defined 'neurogenic detrusor overactivity' (NDO): 'when there is a relevant neurological condition'. [Abrams,P. 2002] The specificity and sensitivity of signs and symptoms to confirm a relevant neurological condition are unknown, which is more or less acknowledged in the ICS standard above. However, for some of the urodynamic outcomes, also mentioned in this standard, a confirmation of 'clinically normal neurology' is required. In a recent EAU guideline the term 'neurogenic LUTD' is referred to as 'secondary to confirmed pathology of the nervous supply' and a precise description of the advised neurourological examination is provided. [Stohrer,M. 2009] Neurogenic incontinence may be described by terms such as, 'Reflex' or 'overflow incontinence'. These terms are not currently recommended by the International Continence Society nor used in the EAU guideline but they will also be discussed below, together with other relevant topics for this group of patients which are not covered elsewhere in this chapter.

2. WHAT IS USUALLY EVALUATED?

Because not all patients with neurogenic conditions develop LUTS or have abnormal urodynamic findings, a specific understanding of the dysfunction in each individual is a prerequisite for the correct choice of therapy. The aim of the diagnostic tests is to describe the (dys)function of the bladder, the urethra and the pelvic floor, their coordination during filling and voiding, and their influence on other conditions (e.g. autonomic dysreflexia) or organ systems (e.g. renal function).

Except in a few diseases where empirical, conservative therapy can safely be instituted, or where LUT dysfunction is predictable (e.g. post-stroke), urodynamic investigation is usually deemed to be required on the basis of clinical practice guidelines and expert reviews. Urodynamics is advised to provide the understanding of the situation on which rational treatment must be based. Even when empirical therapy is instituted without urodynamics, experts' opinion usually agrees on the basis of good clinical practice which is that the patient must be carefully monitored to determine whether and when urodynamics is needed. [Stohrer,M. 2009; McGuire,E.J. 2010]

A large proportion of patients with neurological conditions show anatomical abnormalities that involve the LUT, especially those born with abnormal neurology (MMC-see in children section of this chapter), and do have congenital relevant 'end organ (LUT)-sequelae' that can be demonstrated by imaging. Videourodynamics is the test of choice usually advised on the basis of expert opinion when relevant anatomical information is needed and relevant to establish treatment. [Stohrer,M. 2009]

3. SPECIAL TESTS

In patients with spinal cord injury (as a result of a trauma in later life) the detrusor and its innervation can be assumed to have developed normally (unless there was a positive history of urologic or other relevant abnormalities), before the injury. [Yoo,P.B. 2011; Kennelly, M.J. 2010]. Also, it has e.g. been shown that urethral sphincter relaxation in persons with dyssynergic activity can be improved or normalized. [Huang,Y.H. 2008]

Ice water (bladder cooling) test is sometimes used in an attempt to identify neurogenic DO (see section C.V.1.e: provocative manoeuvres) or to demonstrate the integrity of the detrusor muscle function and or its innervation. The clinical relevance of the ice water test is however undetermined and in patients with high level spinal cord injury the test can cause autonomic dysreflexia. [Chancellor,M.B. 1998; Huwyler,M. 2007]

One channel cystometry is reported to be feasible and reliable because patients with complete spinal cord injury usually do not generate much (abdominal or other) muscle activity below the lesion level and intravesical pressure adequately represents detrusor (relaxation or) activity. [Wyndaele,J.J. 2009]

4. NEUROGENIC DETRUSOR OVERACTIVITY INCONTINENCE

DO in association with neurological disease, may lead to UI. Observed during urodynamics, this type of incontinence is termed neurogenic DOI. The corresponding clinical sign or symptom is however variable: if the DO is accompanied by sensation (desire to void) it might be termed UUI; frequently however any sensation is absent, and so the term urgency in-

continence is an incorrect description of the situation. For this reason the term 'reflex incontinence' was introduced [Abrams 1988], implying uncontrolled emptying of the bladder without sensation. This term is no longer recommended. [Abrams 2002]

When a selection of symptomatic patients with NDO was analysed retrospectively, it was observed that patients with incomplete lesions had similar amplitudes of detrusor contraction and that also leakpoint pressures did not differ from patients with complete lesions. The authors consider it therefore relevant to perform UDS in patients with incontinence who have incomplete SCI. [Moslavac,S. 2008]

5. DETRUSOR-SPHINCTER DYSSYNERGIA

Neurogenic DO is often accompanied by detrusor-sphincter dyssynergia: a neurogenically determined failure of pontine coordination of detrusor and bladder outlet. In DSD the failure of the urethral sphincter and or the pelvic floor to relax completely and sustained, when the detrusor contracts, causes a dynamic type of BOO which may not only prevent complete bladder emptying, but can also lead to chronic and or intermittent high detrusor pressures, during bladder filling and or attempted voiding or incontinence. If high intra -detrusor pressures are present for prolonged periods in daily life, renal function is endangered (see the following subsection on 'overflow incontinence').

6. LEAKAGE ASSOCIATED WITH CHRONICRESIDUAL/ RETENTION OF URINE ('OVERFLOW INCONTINENCE')

'Overflow incontinence' is another term that is no longer recommended. [Abrams 1988] It meant continuous or intermittent (-stress 'like') leakage from a constantly overdistended bladder. [Abrams 1988] However neither what constitutes 'overdistended' nor the cause of the leakage are defined by the term 'overflow incontinence'. The presenting symptom is usually characterised by small amounts of incontinence, exacerbated by increased abdominal pressure, together with an inability to empty the bladder by voiding. Whilst incontinence appears as a problem of lower urinary tract storage function, 'overflow incontinence' originates from a dysfunction of voiding. Overflow incontinence can exist in combination with BPE and BOO but also exists in conditions with relevant neurologic pathology. Incontinence due to neurogenic underactive detrusor (or acontractility) or DSD, with incomplete emptying, and neurogenic incomplete voiding with incontinence, are clinical (urodynamic) descriptions and have not been officially defined.

During urodynamics a frequent observation is of a bladder with low compliance and little or no detrusor activity; as the bladder is filled, the detrusor pressure rises because of the poor compliance, until it reaches a value sufficient to overcome urethral resistance and open the urethral sphincter; dribbling leakage then ensues. Clinically, the most important variable is usually reported to be the detrusor pressure at which leakage occurs, the detrusor leak point pressure (DLPP). If this pressure is elevated, and if similar pressures are attained during continual leakage in daily life, then renal function is endangered because the constantly high detrusor pressure hinders outflow of urine from the ureters into the bladder. Conventionally, DLPP's of 40 cm H_2O or more are believed to be unacceptable. There is evidence (mostly from paediatric studies with children with meningomyelocele) that upper urinary-tract deterioration is more probable when DLPP is elevated above that 40cmH_2O. [McGuire,E.J. 1996; Tanaka,H. 1999; Kurzrock,E.A. 1998] However, the evidence for a cut-off at 40 cm H_2O seems less clear and an expert opinion appears to introduce 'as low as reasonably achievable' and a 'safe' detrusor pressure of below 20 cmH_2O, over the entire 'daily' volume range, when CIC is part of the treatment, is advised. [McGuire,E.J. 2010]

7. REPRODUCIBILITY AND RELIABILITY OF TESTS

Since many patients with NLUTD have severe subpontine neuropathy, the influence of the emotional (limbic) nervous system on lower-tract function is reduced or eliminated; thus, urodynamic observations may be less influenced by the test circumstances than those made in individuals with an intact nervous system. Nevertheless, the test conditions (e.g. the rate of filling the bladder) do influence the results, and should be chosen carefully. [Homma et al 2002] Some advocate ambulatory monitoring to reduce the variability of filling cystometry. [Pannek,J. 2009] However, tests of longer duration with natural filling, did not relevantly assist in the diagnosis and selection of treatment in patients with SCI in a monocenter prospective comparison. [Martens,F.M. 2010]

8. DOES URODYNAMIC TESTING HELP TO SELECT (OPTIMAL) TREATMENT?

The aims of therapy for NLUTD are to achieve the most physiological filling and voiding conditions possible, as well as a management situation acceptable to the patient in daily life. Long periods of elevated detrusor pressure during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk. [McGuire,E.J. 1996; Tanaka,H. 1999; Kurzrock,E.A. 1998]. The primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling, [Stohrer, 1994; Rivas, D.A. 1995; McGuire,E.J. 2010] achieve continence, and to manage incomplete emptying due to (medically induced) underactive detrusor or detrusor acontractility, with CIC. [Stohrer,M. 2009]

Adequate management depends on whether the detrusor is overactive or has reduced compliance, and only urodynamic testing can answer those questions unequivocally. Timely and adequate diag-

nosis is of paramount importance for the patient's Quol, as well as for safety. [Bomalaski,M.D. 1995; Cardenas,D.D. 1995] There is expert agreement that urodynamic investigation is essential to monitor the effects of any treatment and in the follow up of any sequelae of the disease and its management. Urodynamics is certainly needed to document the effects of new treatments or management strategies for patients with NLUTD. But changes in urodynamics do not always relate to clinically relevant improvements in these patients. [Huwyler,M. 2007; Pannek,J. 2009; Kabay,S.C. 2008] A retrospective study shows with 80 SCI patients and a minimum follow-up of 5 years, that it is possible to manage continence and preserve (100% of) upper tracts with ultrasound monitoring of the kidneys and repeated UDS. [Nosseir,M. 2007] Another retrospective observation indicates, in a series of 200 children with various types of NLUTD, that the intensity (frequency) of urodynamic follow up can be adapted according to the estimation of the risk for upper tact deterioration on the basis of urodynamic parameters achieved at a baseline. [Wang,Q.W. 2006]

Conclusions (level 3)

- There is expert agreement on the basis of a large number of case series that urodynamic testing is of great relevance to establish the management and to achieve the best long term clinical outcome in patients with neurogenic lower urinary tract dysfunction.
- On the basis of expert opinion, videourodynamics is necessary when anatomical information is deemed clinically relevant.
- Case series indicate that it is possible to monitor patients without anatomic abnormalities of the lower urinary tract (especially adult age spinal cord injury) with cystometry and ultrasound of the upper tract.
- No specific reports about the optimal frequency and techniques of follow –up urodynamics in patients with neurogenic lower urinary tract dysfunction exist
- No conclusive evidence exists about the predictive value towards (the outcome of) treatment with regard to ice water testing, or of ambulatory monitoring of patients with neurogenic lower urinary tract dysfunction.
- Some evidence from centres of excellence indicates that 'simple, one channel, cystometry' is feasible and reliable in the monitoring (follow-up) of a selected group of patients with complete spinal cord injury.

Recommendations (grade B/C)

- The committee recommends that patients with signs and symptoms of dysfunction of the lower urinary tract and relevant neurological abnormalities should receive urodynamic evaluation (including filling and voiding cystometry), if initial treatment will be affected as a consequence of the urodynamic diagnosis, or if 'simple' first line diagnosis and management have been unsuccessful.
- The committee recommends that at least at a baseline, to establish the state and function of the lower tract in patients with neurogenic lower urinary tract dysfunction, videourodynamic evaluation is indicated if relevant anatomical abnormalities are to be expected.
- The committee recommends that the frequency of testing and the techniques applied in the follow – up of patients with neurogenic lower urinary tract dysfunction be critically analysed and optimised, and to develop guideline recommendations on the basis of those analyses.
- The committee recommends that urodynamic testing in patients with neurogenic lower urinary tract dysfunction is done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

Recommendations for research:

- Comprehensive urodynamic testing should remain an integral part of the evaluation of new therapies and management strategies for neurogenic lower urinary tract dysfunction whether conservative, medical or surgical. The first goal of this should be to monitor the safety of the (developed) approach for the patient and the secondary goals of this urodynamic testing should be the efficacy outcomes (preferably on predefined urodynamic criteria).
- Specific urodynamic diagnosis categories and diagnostic techniques need to be developed to quantify detrusor sphincter dyssynergia and neurogenic underactive detrusor.

IV. PATIENT EVALUATION: CHILDREN

1. INTRODUCTION

The indications for urodynamic evaluation in children are usually neurological, anatomical and or functional abnormalities, with the types of studies to be performed being based on the presumed underlying pathological conditions rather than on the presenting symptoms.

Many of the conditions for which urodynamics is employed in children involve anatomical and or neurological abnormalities, in which LUT dysfunction is variable, and may be multifaceted and unpredictable on the basis of clinical signs and symptoms. UI in children is relatively more frequently seen (compared

to adults), and in combination with other lower urinary tract (or lower bowel or pelvic floor) dysfunctions. On the other hand, urinary continence (and lower urinary tract function) are the result of a normal maturation process that can be delayed in some, and 'cure' (or 'resolve') without requiring medical intervention. Urodynamic testing is used to establish as clearly as possible the baseline situation where needed, so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment. The result of urodynamic testing will, however, not necessarily be the only deciding factor in this regard. Perhaps more clearly than in any other patient group, the aim of urodynamic studies in children is to provide objective knowledge about LUT function and dysfunction as well as to provide understanding to the care-giver and to the patient (and her or his parents). More extensively than in other ages, non-invasive urodynamic techniques are initially explored, not only because they are easier accepted and better applicable for children, but also to have comparable parameters during follow-up, and to exactly identify those children and clinical conditions that will benefit from further invasive exams. Essential are a meticulous and complete history, physical examination including clinical neurological testing and assessment by voiding diaries. Furthermore, initial ultrasonographic measures of bladder volume and wall thickness have been reported more and more as a useful tool in selecting who will need invasive testing. [Bower,W.F. 2010; Drzewiecki,B.A. 2011]

2. NEUROGENIC BLADDER DYSFUNCTION

a) Myelodysplasia

For the last 20 years, initial urodynamic studies, very early in the neonatal period, have been recommended for children with myelodysplasia, the basis being that they help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture. [Sidi,A.A. 1986] DO on cystometry, underactive detrusor during voiding, detrusor-sphincter dyssynergia (usually established on the basis of surface EMG), DLPP, and PVR are the key elements of a detailed urodynamic study that need to be considered. [McGuire,E.J. 1981; Bauer,S.B. 1984]

In an exhaustive review of the efficacy and reliability of urodynamic studies in newborns with myelodysplasia [McLellan 2003], of 24 studies analysed, 13 focused on EMG activity of the striated urethral sphincter or pelvic floor, 7 on bladder compliance and 2 on cystometric technique. Twenty-one studies had level of evidence 4, 2 had level 3 and one level 1 study was found. Nine of the 24 studies were performed at international sites and the remainder within the United States. The urodynamic patterns of normal detrusor function (66%), acontractile detrusor (33%), DO (57%), and detrusor compliance, as well as detrusor-sphincter dyssynergia (21%), DSD (37%) and sphincter denervation (60%) were similar, with little variability across comparable studies.

Van Meel et al have shown that repeating the IWT will increase its positivity. Combining the IWT and electrical perception threshold (EPT) will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurological cause of the dysfunction in children with idiopathic DO. In those with negative IWT's, the EPT's were significantly different between the neurological and not neurological patients, independent of the number of IWT's done. [Meel 2007]

Bladder capacity was studied in a group of 506 myelodysplastic children [Palmer 1997] and found to conform to the formula: capacity in mL = 24.5 x (age in years) + 62. This formula for the increase in bladder size with age is 20% less steep than published age-related bladder capacities in neurologically unaffected children (e.g. 30 x age + 30). [Starfield 1967; Koff 1983] However, those children who did not have DO had a bladder capacity similar to normals. Because neurological impairment affects detrusor compliance, cystometric filling rate also influenced the measured capacity and compliance as noted in 3 studies that addressed this issue. [Palmer 1997; Kaefer 1997; Landau 1994] The lower the filling rate the greater the compliance and the larger the capacity.

Bladder augmentation alone without simultaneous anti-reflux repair is usually considered sufficient for the resolution of pre-existing vesico-ureteral reflux in children with NLUTD. Cystometry can be used to evaluate the effect of this treatment. A retrospective study by Juhasz et al in 2008 suggested that diverse GI segments used for augmentation had identical effects on the urodynamic results and the resolution of vesico-ureteric reflux. [Juhas 2008]

Several studies that evaluated the urodynamic result of bladder augmentation have been published. Significant increase in bladder capacity and compliance were achieved and maintained in the long term. [Lima 2008] A recent small mono-centre study, showed that preoperative urodynamics has some predictive value on the outcome of augmentation towards the relief of vesico-ureteric reflux in those children. [Soygur 2010] Follow up of affected children after early childhood is relevant, and urodynamic testing forms the basis for (surgical) management. [Almodhen 2007] A 20 years follow-up of 52 children demonstrates also that the early urodynamic diagnosis has been an adequate basis for the management of children with meningomyelocele in a single centre of excellence. [Thoru 2011]

Rendeli et al retrospectively assessed the usefulness of urodynamic testing to determine the optimal timing of neurosurgery and to evaluate the evolution of bladder function in children with lipomeningocele. All patients underwent urodynamic testing

preoperatively and during extended follow up (mean 6.5 years, range 3 to 12). At the latest follow up, 65% of patients in the youngest group had improved urodynamic parameters compared to 33% of those 12 to 36 months old and 28% of those older than 36 months. Urodynamic evaluation and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord. [Rendeli 2007] A recent retrospective mono-centre study confirmed that urodynamic testing is relevant towards the outcome of neurosurgical interventions. [Maher 2009]

Six studies evaluated the relationship between level of the neurological lesion (on clinical examination) and LUT function, but none could predict a specific urodynamic pattern based on the level of the lesion. Sacral level lesions can be associated with an upper motor neuron urinary tract 'urodynamic pattern' just as readily as the expected lower motor neuron findings. [Dator 1992] Similar findings have been noted for children with thoracic or high lumbar level lesions where the incidence of sacral reflex sparing is 54%. [Pontari 1995]

Approximately 90% of children born with meningomyelocele will have a normal upper urinary tract at birth. Over time, many children who have not received proactive urological care develop upper and/or LUT deterioration. The deterioration is an acquired phenomenon secondary to the development or progression of various LUT hostility factors such as DO, reduced bladder compliance, detrusor-sphincter dyssynergia and/or high LPP. [Sidi 1986; Bauer 1984; Wang 2006] Despite the fact that only one study was at level 1, all urodynamic studies corroborated their reliability by reporting that the prediction of upper urinary tract deterioration on the basis of urodynamic testing is possible with 90% accuracy.

In 2006, Wang et al calculated a urodynamic risk score including a DLPP of >40 cmH_2O, a bladder compliance of <9 mL/cmH_2O and evidence of acontractile detrusor. They postulated that the selective use of urodynamic variables might be valuable for predicting the risk of upper urinary tract dilatation in children with neurogenic bladder-sphincter (or LUT) dysfunction. They found that decreased bladder compliance, increased DLPP and acontractile detrusor are the main urodynamic risk factors, and they reciprocally increase the occurrence and grades of upper urinary tract dilatation. The grades of renal dilatation are compatible with increases in relative unsafe cystometric capacity and the calculated urodynamic risk score. [Wang 2006] Severe bladder trabeculation in incontinent children with NLUTD is reported to be associated with BOO. [Khoury 2008]

Monocenter studies suggest that prevention of high bladder filling pressure (before upper tract dilatation is observed) is necessary and feasible even before any urodynamic diagnosis. [Dik 2006; Hopps 2003; Obara 2003; Jong 2008] However not all authors consider that prophylactic (high pressure prevention) treatment is beneficial, but all recommend periodic cystometry when new onset hydronephrosis, vesico-ureteric reflux or UI develops, the latter in children on a continence program already (i.e. CIC and/or drug therapy). [Bauer 1985; Geranio 1988] When new onset UI, not related to urinary infection, nor easily treated by increasing current treatment regimens occurs, one study has shown that repetition of cystometry, urethral pressure profilometry, and EMG measurements, is helpful in management. [Teichman 1994]

When incontinence develops in spite of strict adherence to bladder and bowel continence programs, or when changes occur in leg function or sensation, or when the child experiences back pain or increasing scoliosis, a change in neurological impairment might be expected. 4 studies, noted that a considerable number of myelodysplastic children (40% to 61%) regardless of their neurological level have progressive neurological deficits as they grow up and reach puberty. [Dator 1992; Spindel 1987; Lais 1993; Tarcan 2001] Two of these studies noted changes particularly early in infancy, while a third study noted changes throughout childhood. Most clinicians agree that myelodysplasia is a dynamic disease process which changes as the child grows and that warrants constant vigilance of both the neurological picture and lower urinary tract function.

In 2006, Schulte-Baukloh et al evaluated prospectively the efficacy and tolerability of propiverine for treating neurogenic DO in children and showed that urodynamic testing has been relevant to evaluate the treatment. [Schulte 2006] This was recently confirmed in a longer follow up with urodynamic evaluation as an outcome. [Schulte 2011]

Renal transplantation in patients with myelodysplasia is a challenging issue. Persistent LUT dysfunction carries increased risks for the grafted kidney. Recent publications suggested that renal transplantation is a safe and effective treatment modality in patient with myelodysplasia when objective analysis of LUT function is done and the results are taken into account properly. Some series show cohorts where videourodynamic tests were performed on all patients preoperatively as well as postoperatively. Augmentation cystoplasty has been reported to be required in a proportion of children to achieve a low-pressure reservoir with adequate capacity [Ali-El-Dein 2004; Bilg 2008; Luke 2003] to optimize the LUT for transplantation.

b) Occult spinal dysraphism

Several series characterising the preoperative urodynamic evaluation of children with occult spinal dysraphisms have documented abnormalities in striated urethral sphincter function (denervation and/or detrusor-sphincter dyssynergia) in 20 - 35%

of babies under 2 years of age with normal neurological examinations; thus emphasising the need for urodynamic testing in these children. [Keating 1988; Yip 1985; Satar 1997; Torre 2002; Hsie 2006; Kumar 2008] Six reports in older children revealed a greater correlation (70 – 90%) between an abnormal neurological examination and the likelihood of finding an abnormality on urodynamics. [Keating 1988; Hsie 2006; Kumar 2008; Satar 1995; Kondo 1986] A few studies demonstrated that between 10% and 20% of patients experience a loss in function immediately postoperatively (most of whom had abnormal LUT function preoperatively), and a variable number, usually inversely related to age, have improved sacral cord function on postoperative assessment 3 or more months after surgery. [Keating 1988; Satar 1997; Satar 1995; Kondo 1986; Fone 1997] Two studies, both retrospective, revealed an efficacious response in EMG activity, with stabilisation or improvement in up to 60%, on postoperative urodynamic assessment when the dysraphic state was corrected before 2 years of age. [Keating 1988; Satar 1995] When children were first operated on after 2 years of age, 2 urodynamic reports documented an additional 25 to 35% with progressive changes in urethral sphincter function with axial growth, very few of whom had a detectable change on physical examination. [Yip 1985; Satar 1995]

In a small prospective study in 2008, it was observed that children with meningomyelocele, as compared to closed dysraphism, tended to have more bladder dysfunction as exemplified on clinical history and urodynamic assessment. The authors concluded that a urodynamic study before neurosurgical intervention helped to identify the severity of bladder dysfunction in clinically overt cases and also identified LUTD in clinically silent cases. Evaluation after operation tended to show better outcome in children with closed dysraphism. The study also identifies deterioration in some patients with seeming clinical improvement. [Kumar 2008]

In 2007, Abrahamson et al studied the urodynamic findings in a consecutively treated population of children with meningomyelocele after untethering of the spinal cord. Severe bladder dysfunction, moderate dysfunction and mild dysfunction were defined preoperatively. After untethering, 35% of the patients experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. [Abrahamsson 2007; Snodgrass 2010]

Conclusions (level 2/3)

- Retrospective and prospective studies have shown that the urodynamic diagnosis of (neurogenic) detrusor overactivity and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms.
- Many retrospective and prospective studies have shown that regularly repeated urodynamic testing in patients (children) with meningomyelocele or (occult) spinal dysraphism reveals clinical relevant results with regard to management and surgical or medical treatment.
- On the basis of expert opinion, videourodynamic testing is preferable above urodynamic testing without video, however the exact advantage (e.g. in repeated investigation) is not substantiated.
- Various studies have shown that lower urinary tract function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth)
- No studies have been published that are a help to determine the optimum of timing and frequency of urodynamic follow-up.

Recommendations (grade B/C)

- Comprehensive urodynamic testing is advised in all patients with myelodysplasia or (occult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood.
- On indication, unscheduled urodynamic testing should be considered when relevant (lower body half and or urinary tract) clinical (or neurologic) signs or symptoms arise or when significant (surgical or medical) treatment changes have been instigated.

Recommendations (grade C)

- The advantages and disadvantages of the addition of video (x-ray) to urodynamic testing should be considered in children with myelodysplasia or (occult) spinal dysraphism on an individual basis.
- Timing and technique of urodynamic testing in patients with myelodysplasia or (occult) spinal dysraphism must be selected on an individual basis.
- To help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture, initial urodynamic studies, very early in the neonatal period, are recommended for children with myelodysplasia or (occult) spinal dysraphism.
- The committee recommends on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with urinary tract function in children with myelodysplasia or (occult) spinal dysraphism (see also the chapter on faecal incontinence).

c) Sacral agenesis

Sacral agenesis, absence of the lowermost vertebral bony segments, is a lesion that can be missed in infancy because of its sometimes subtle clinical

manifestations, with generally no loss of lower extremity motor and sensory function, and the non-progressive nature of its pathophysiology. [Guzman 1983; Borrelli 1985] Urinary and/or faecal incontinence usually manifests at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. In 8 reports that provided enough data, urodynamic studies had been 90% accurate in delineating the neurological deficit, which cannot be predicted by the level of absent vertebrae. [Jabokson 1985; Gotoh 1991; Saito 1991; Boemers 1996; Boemers 1994; Boemers 1994; Wilmshurst 1999; Mosiello 2003; Taskinen 2002] These studies reveal that between 30 and 40% of these patients have an upper motor neuron type lesion with DO and an intact but dyssynergic sphincter, while 25 to 50% have signs of a lower motor neuron deficit with acontractile detrusor and denervation in the sphincter, and 15 to 20% have normal LUT function. [Guzman 1983; Jabokson 1985] Tethered cord occurs in children without sacral anomalies as well as in those with low anorectal malformation (ARM).

Mosiello et al [Mosiello 2003] recommend evaluation of all patients that have sacral agenesis with MRI, and this necessity has been confirmed by others, who found the extension of the sacral defect as a prognostic factor for retethering. [Kim 2010] When MRI shows sacral or spinal cord anomalies, UDS should be considered, preceded by neurological exam and considering neurophysiological testing (evoked potential testing) The authors of this and subsequent studies recommend a non-invasive evaluation for all other children, and urodynamics when NLUTD is suspected. [Borg 2009] It is presumed that the neurological deficit associated with this entity is fixed because no study showed any progression of the neurological disorder with increasing age.

Conclusions (level 3)

- Case series have shown that urodynamic evaluation of lower urinary tract function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction.
- It is shown that approximately one third of children with anorectal anomalies have spinal dysraphism and/or tethered spinal cord associated with urodynamically demonstrable neurogenic lower urinary tract dysfunction .

Recommendations (grade C)

- Clinicians should consider urodynamic testing in children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma
- Clinicians must consider that in children with lower urinary tract dysfunction, otherwise clinically silent sacral agenesis can exist.

d) Spinal cord injury

The scarcity and variability of spinal cord injuries in children makes it difficult to propose any one treatment program unless the specific type of LUT function is known on the basis of urodynamic testing. [Chou 2006; Generao 2004; Silveri 2006] Even if the individual regains the ability to void spontaneously and empty his/her bladder, it is imperative to know the detrusor filling and emptying (detrusor) pressures. Even if the child is continent on CIC, it is important to measure detrusor compliance in order to determine the potential risk for vesico-ureteric reflux and hydroureteronephrosis. [Pannek 1997] Four studies extol the need for urodynamic studies once spinal shock from the initial injury wears off, to determine the presence of low filling and voiding pressures and the ability for complete emptying, for the reasons cited above. [Decter 1993; Kim 1998; Fanciullacci 1988; Iwatsubo 1985] All studies are monocenter, retrospective and use historical controls for comparison.

In the presence of elevated urodynamic filling and voiding pressures, a 30% incidence of upper urinary tract deterioration can be expected. [Kurzrock 1998] Effective voiding with pressures below 40 cm H_2O in the absence of detrusor-sphincter dyssynergia ensures a stable upper urinary tract. [Fanciullacci 1988] Urodynamic monitoring has been demonstrated to be relevant in the follow up and prevention of upper tract deterioration in a retrospective cohort study. [Generao 2004] In another study on 17 children aged 6 months-18 years with cervical (4), thoracic (8) and lumbar (5) SCI, all but one showed DO on first evaluation, which was changed to an acontractile and or compliant detrusor pattern by medical treatment; 7 had increased bladder capacity and 8 decreased DLPP at follow-up; only 2/17 developed minor UUT impairment. [Silveri 2006] A cauda equina injury usually leads to a lower motor neuron type of deficit of the striated sphincter that may not require any treatment to prevent upper tract damage because the bladder empties readily at low pressure, but it probably necessitates medical and/or surgical therapy to achieve continence. Urodynamic studies are invaluable to efficaciously manage any spinal cord lesion related LUT dysfunction, in order to maintain a healthy upper urinary tract and long-term survival with minimal morbidity. [Kim 1998; Watanabe 1996]

Urodynamic studies, undertaken no earlier than 6 weeks after injury, allow for the manifestation of the extent of the neurologic injury. [Iwatsubo 1985] Periodic urodynamic reassessment is appropriate up to 2 years after injury, due to the potential for changes during that time. Further urodynamic follow up is ‘standard’ as in adult patients. [Nosseir 2007]

Conclusion (level 2/3)

- Retrospective studies have shown that urody-

namic testing of all children with spinal cord injury is relevant.

- Retrospective studies have shown that urodynamic testing of children with spinal cord injury results in diagnoses and treatment similar to adults with spinal cord injury.

Recommendations (grade C)

- The committee recommends that urodynamic testing in children with spinal cord injury is planned on an individual basis, but no earlier than 6 weeks after injury.

e) Cerebral palsy

Only a few published studies describe the urodynamic findings in children with cerebral palsy. [Decter 1987; Mayo 1992; Reid 1993; Yokoyama 1989] The vast majority of the children with cerebral palsy tend to gain normal lower urinary tract function, but often at an age that is later than expected for normal individuals. [Decter 1987] Any incontinence is usually secondary to urinary urgency from DO. [Reid 1993] A meta-analysis of urodynamic studies performed in children with either persistent incontinence despite frequent toileting, or urinary tract infection, revealed either normal function (15%) or DO (73%; 85 of 117 patients);[Decter 1987; Mayo 1992; Reid 1993] detrusor sphincter dyssynergia is very rarely observed during voiding (5%; 12 of 249 patients). [Dator 1992; Mayo 1992; Yokoyama 1989] In some recent studies, detrusor-sphincter dyssynergia was present in higher prevalence then earlier reports (11% / 5%). [Karaman 2005; Bross 2007] Normal function was less prevalent (only 15%) in the more recent case series. [Bross 2007; Silva 2009]

Therefore, it has been suggested on the basis of expert opinion that cystometry and sphincter EMG are to be considered, but only when frequent toileting or anticholinergic therapy fails to control incontinent episodes, the child develops urinary infection from ineffective voiding, or when ultrasonography reveals hydronephrosis.

However, videourodynamic assessment can be considered in all patients with infantile cerebral palsy. The decision should not be based on clinical symptoms because at least half of the children with spastic cerebral palsy have clinically silent bladder dysfunction. 100% of children had clinical improvement postoperatively (selective dorsal rhizotomy), 71% who were incontinent preoperatively became continent and none had deterioration on urodynamics. [Bross 2007; Houle 1998; Farmer 2007] There is a spectrum of clinical and urodynamic LUT function in children with cerebral palsy: 77% void spontaneously but do have UI. Incontinent children have a lower age-related bladder capacity, as shown both in slow fill water cystometry study [Richardson 2009] and in a noninvasive evaluation (flowmetry plus PVR), showing a significant difference between observed and expected bladder capacity. [Ersoz 2009]

Conclusion (level 3)

- Some studies (with historical/ literature -control groups) have shown that clinically unexpected lower urinary tract dysfunction – predominantly dysfunctional voiding and lower bladder capacity - can occur in children with cerebral palsy.

Recommendations (grade C)

- Clinicians should carefully evaluate voiding in children with cerebral palsy and should consider complete urodynamic testing when dysfunction is suspected
- Urodynamic testing is to be considered in all patients with spastic cerebral palsy. Undiagnosed and untreated patient's bladder dysfunction remains pathological and potentially dangerous, and may damage the upper urinary tract.

f) Tumours

LUTD exists after sacrococcygeal teratoma resection and recently again it was, on the basis of a monocenter cohort, proposed that urodynamic testing is necessary for those children. [Mosiello 2003; Ozkan 2006; Berger 2011]

A recent study showed that children with central nervous tumours can have urodynamic abnormalities, whether the tumour is in the spinal cord or not. On the basis of this, a monocenter and selected cohort study concluded that a child with a CNS tumour regardless of location needed urological and urodynamic testing. [Nguyen 2010]

Conclusion (level 3)

- It was shown in monocenter cohorts that urodynamic testing is relevant after resection of a sacrococcygeal teratoma.
- A study showed that all children with central nervous system tumours can have lower urinary tract dysfunction regardless of the location of the tumour.

3. ANORECTAL MALFORMATION OR IMPERFORATE ANUS

Imperforate anus is classified as high, intermediate or low depending on whether or not the rectum ends above, at, or below the levator ani muscle. In the past, imperforate anus repair for high lesions frequently resulted in urinary (stress-) incontinence due to a pudendal nerve injury that often occurs from a perineal approach to bringing the rectum down to the anal verge. [Pena 1986] With the advent of the posterior sagittal anoplasty this complication has been eliminated as a cause for subsequent UI, although bladder neck incompetence may be a consequence of extensive mobilisation of the sigmoid colon which helps transfer the rectum to its final location. However,

reports of spinal MRI's reveal a 35% incidence of distal spinal cord abnormalities in children with an imperforate anus. [Barnes 1986; Greenfield 1991; Kakizaki 1994]

Wetting after definitive repair is reported to be the possible result of stress incontinence through ineffective emptying ('overflow incontinence') and underactive or acontractile detrusor rather than sphincter injury. In 2005, Shimada et al reported on the reconstruction of cloacal anomalies in a consecutive series of 11 girls. The main clinical characteristic of bladder dysfunction was a failure to empty. [Shimada 2005] They could not define the precise aetiology, but iatrogenic injury from extensive dissection can lead to the higher risks of peripheral nerve damage.

In 2004, Warne et al prospectively studied the effect of surgical reconstruction by posterior sagittal approach and total urogenital mobilisation in either causing or worsening bladder dysfunction in new patients with cloacal anomalies. A comparable group of patients with ARM were studied as comparative controls to assess the effect of posterior sagittal approach without urogenital surgery. Natural filling urodynamics via a suprapubic catheter showed that bladder dysfunction was present in 9 of 10 patients with cloacal anomalies and in 12 of 20 patients with ARM. After surgery there was significant deterioration (frequently a change to underactive detrusor) in bladder function in half of the cloacal group and in 1 of 20 patients with ARM. Patients with cloacal malformation have a high incidence of innate LUTD and surgical reconstruction can cause further deterioration particularly in the group that needs extensive intrapelvic mobilization. Urodynamic assessment is required to evaluate LUTD in these patients. [Warne 2004] In 2006, a prospective study reported on children with ARM, prior to and following definitive procedure, using urodynamic evaluation. Among these 19 children, 13 underwent re-evaluation after definitive surgery for ARM. Only 9 of the 19 patients had normal urodynamics pre-operatively and post-operatively, and the LUT function of 3 patients was found to be worsened postoperatively. [Kumar 2006]

Mosiello et al recommends evaluation of all patients with ARM using MRI. When MRI shows sacral or spinal cord anomalies, urodynamics should be performed. They recommend a non-invasive evaluation for all other children and urodynamics when NLUTD is suspected. [Mosiello 2003]

NLUTD occurs in 50% of those with ARM. [Kumar 2006; Boemers 1996] The prevalence of spinal dysraphism and/or tethered cord in patients with ARM is 32-34%, independently from the severity of ARM and a variable proportion (40-60%) of those patients who have tethered cord needed untethering. [Kim 2010; Suppiej 2009]

The reliability and reproducibility of these findings among the various studies analysed confers an important role for videourodynamic studies as an integral part of the evaluation and management of these children: it has diagnostic accuracy; it provides arguments to consider treatment of any intraspinal (neural) abnormality to improve the child's chances of achieving urinary and faecal continence. Urodynamic testing is also considered useful as a basis for future comparison, if LUTD should subsequently become a problem in children not undergoing early spinal cord exploration.

The VATER or VACTERL association is a group of diverse abnormalities that include Vertebral bony, Anal atresia, Cardiac, Tracheo-Esophageal fistula, Renal and Limb anomalies. [Cardenas 1995] Imperforate anus may occur as an isolated lesion or in conjunction with this association. Spinal cord pathology occurs in 38% of cases producing a picture of upper and/or lower motor neuron deficits to the LUT. [Boemers 1996; Greenfield 1991; Emir 1998; Capitanucci 1996; De Gennaro, M. 1994] By combining the incidences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of LUTD to as high as 76% (38 of 50 children). [Boemers 1996; Emir 1998; Capitanucci 1996] When the rectum ends above the levator ani muscle there is a much greater chance of LUTD than when it ends below the pelvic floor [Mosiello 2003; Emir 1998] and the older the child is at the time of urodynamic assessment the more likely he/she is to have abnormal LUT function. [De Gennaro,M. 1994; Capitanucci,M.L. 1996]

Conclusions (level 3)

- Various studies have shown that a significant proportion of children with an anorectal malformation has primary or secondary dysfunction of the lower urinary tract, lower urinary tract innervation abnormalities or pelvic floor dysfunction.

Recommendations (grade C)

- Clinicians should consider urodynamic testing in children with imperforate anus when clinical signs of lower urinary tract dysfunction exist.
- Clinicians should consider urodynamic testing in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological abnormalities exist, before and or after reconstructive surgery independent of (the existence of) lower urinary tract symptoms.

4. ANATOMIC ABNORMALITIES

The use of urodynamics for evaluating anatomic lesions that affect the lower and, consequently, the upper urinary tract in children is still somewhat controversial. Essentially, the evidence consists of uncontrolled case series and expert opinions although many clinicians now feel its usefulness is beyond question.

a) Posterior urethral valves

Nowhere is the above controversy more obvious

than in boys with posterior urethral valves. [Bauer 1979; Mitchell 1982; Glassberg 2001] Prior to the ready availability of urodynamics, persistent upper urinary tract dilation was managed with bladder neck resection and/or striated urethral sphincter resection. By demonstrating the presence of DO or secondary underactive detrusor, urodynamic studies have helped explain the findings of hydroureteronephrosis that many of the children exhibited over time despite adequate valve ablation. These studies changed the focus from increased bladder outlet resistance to altered bladder function as the aetiology of the longer term sequelae.

There are only a few urodynamic reports prior to valve ablation. In one, DO was seen in 60%, poor compliance in 10% and normal function in 30%. [Kim 1997] In the other, all 46 patients had 'bladder hypercontracility' (obsolete term, used in the manuscript) and comparable high maximum voiding detrusor pressures. At the end of follow -up (mean 4.5 years) in this second study, no patient in group 1 (22 patients who underwent simultaneous valve ablation and bladder neck incision at the 6 o'clock position) had 'bladder hypercontractility' or DO, and the mean maximum voiding detrusor pressure was 53 ± 15 cm H_2O. In comparison, 9 patients in group 2 (24 patients who underwent simple valve ablation) had 'bladder hypercontractility', 6 had DO and the mean maximum voiding detrusor pressure was 87 ± 45 cm H_2O ($p<0.01$). [Kajbafzadeh 2007] Another study compared urodynamic patterns before and after valve ablation, and within 15 days following ablation and at one year of life. At presentation, median cystometric bladder capacity was 22 mL (5 to 125) and maximum voiding pressure was 112 cm H_2O (40 to 331. No significant differences were found before and after ablation. Voiding pressures had significantly decreased ($p=0.01$) and bladder capacity had increased ($p<0.001$) at 1-year follow-up. [Taskinen 2009] Comparing the patterns found in other series of infants, voiding pressures in infants with posterior urethral valves are as high but not higher.

In a series of urodynamic studies after valve ablation, the type of bladder function observed, correlates with the time elapsed from surgery; DO is the predominant pattern initially [Bauer 1979] but changes are noted in both DO and compliance over time. [Holmdahl 1995; Holmdahl 1996; De Gennaro,M. 1996; De Gennaro,M. 2000; Donohoe 2004] In 2005, a series of 30 patients showed DO with single or multiple detrusor contractions in 60 %, and small capacity, reduced bladder compliance in 40%. [Puri 2005]

Myogenic failure, in conjunction with increasing capacity and poor emptying, are primarily a later phenomenon, and are most likely to be secondary to increased urine production and decreased frequency of voiding with advancing age. [Holmdahl 1996] Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor 'decompensation' and/or secondary bladder neck outlet obstruction leading to obstructive voiding and finally underactive detrusor or acontractility. [Androulakakis 2005] Vesico-ureteric reflux was initially, in a small and selected series, most commonly noted in boys with DO, whereas hydronephrosis is most frequently seen with a poorly compliant bladder, [Peters 1990; Ghanem 2004] while in a recent study patient with and without reflux had similar voiding pressures. The persistence of upper urinary tract changes is related to the bladder's unresponsiveness to medical therapy for the DO and/or for detrusor underactivity (usually clean intermittent (self-) catheterisation). However, it is possible that this condition is secondary to sufficiently infrequent voiding in the face of increased urine production. BOO from a secondary hypertrophied bladder neck can also occur, requiring further intervention. [Kajbafzadeh 2007] Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on urodynamic evaluation; persistent poor compliance, high detrusor pressures, BOO and or chronic failure of the detrusor to adequately contract during voiding with increased PVR are the most likely causes of deterioration. [Bauer 1979; Mitchell 1982; Holmdahl 1995; Holmdahl 1996; Peters 1990; Lopez 2002; Ansari 2010] Most probably, the extended use of antenatal diagnosis could select a 'new generation' of valve patients, who undergo proper early ablation of the obstructing valves allowing normal cycling, which helps 'bladder healing'. Youssinf, comparing a group of 16 children who underwent valve ablation as newborns and a group of 16 boys observed after age 1 year, showed that post-void residual urine and vesicoureteral reflux improved in a higher percentage in those early treated. [Youssif 2009]

b) Bladder exstrophy and persistent Cloacal anomalies

Once the exstrophied bladder is closed it may be difficult to manage persistent UI, upper urinary tract dilation or vesico-ureteric reflux. Whether to further improve continence function and whether to perform augmentation cystoplasty for a small capacity, poorly compliant bladder are challenging questions. In addition, as more children undergo complete primary repair of the exstrophic bladder in the neonatal period, the most accurate assessment of bladder function is by urodynamics. Only a few studies report the change in LUT function following bladder neck reconstruction in patients with persistent incontinence; 20% show DO preoperatively versus 37% postoperatively, and compliance worsens in up to 50% after surgery. [Hollowell 1993; Diamond 1999; Burki 2006; Caione 2005] No studies are extant that have correlated incontinence with bladder capacity, compliance, DO and/or LPP. [Gargollo,P.C. 2008; Kajbafzadeh 2008; Camanni 2009]

c) Ectopic ureterocele

Urodynamic studies in babies with an ectopic ureterocele have shown that LUT function may be altered in as many as half the affected patients; 2 reports revealed that between 55 and 70% had a larger than normal capacity bladder for age with high compliance, and poor bladder emptying due to underactive detrusor. [Abrahamsson 1998; Sherman 2003] In another multicentre analysis of 616 children with a variety of ureterocele types, investigators found only a 6% incidence of bladder dysfunction (all in children with an ectopic ureterocele) consisting of primarily DO; less than 1% had poor bladder emptying whereas the remainder had normal bladder storage function and complete emptying. [Holmes 2002] In a recent study in 2007, voiding dysfunction was suspected in 23% of patients. [Shimada 2007] UI and/or infection following surgical incision or excision of a ureterocele is likely to be secondary to the obstructive effects of the ureterocele directly on the bladder outlet and not to any surgical complication. [Holmes 2002; Sherman 2003; Abrahamsson 1998] Patients undergoing bilateral ectopic ureterocele repair are at increased risk for postoperative voiding dysfunction. Whether this risk is present preoperatively or is a result of a trigonal lesion is unclear. Recently, there is an increasing agreement in favour of conservative management of paediatric duplex system ureteroceles, by mean of simple endoscopic puncture followed by close surveillance: reflux can resolve spontaneously in a significant number of patients, and bladder function should be conserved. [Matsui,F. 2009; Jesus 2011]

d) Vesicoureteral reflux

It had been shown that vesico-ureteric reflux may be a secondary phenomenon resulting from DO and not a primary anatomic abnormality at the ureterovesical junction in a significant proportion of children. [Koff 1979; Griffiths 1987; Sillen 1996; Greenfield 2000; Capitanucci 2000; Podesta 2004] There is growing evidence that DO may lead to vesico-ureteric reflux in a marginally competent ureterovesical junction mechanism. [Khoury 2008; Chandra 1996; Chandra 2000] This DO may be a natural phenomenon in the infant bladder, especially in boys, due to the presence of higher voiding pressures [Podesta 2004; Webster 1984; Sillen 1992; Sillen 1996; Yeung 1997; Bachelard 1999] and/or a learned dysfunction in older children who try to withhold voiding throughout the day. [Greenfield 2000] Several investigators have shown that DO tends to resolve with increasing age [Chandra 1996; Sillen 1996; Nielsen 1989; Sjostrom 2009], also showing, in a longitudinal study, that changes occur between the first and second year of life in children with dilating reflux, going from an immature pattern, with high pressure levels, to a high capacity bladder with incomplete voiding. [Sjostrom 2009]

The bladder pressure at the onset of vesico-ureteric reflux, as determined by nuclear cystometrography, is a significant independent predictor of vesico-ureteric reflux resolution in children. The pressure at the onset of vesico-ureteric reflux was also highly predictive of spontaneous resolution ($p = 0.0005$). Vesico-ureteric reflux occurring at greater pressures was more likely to resolve spontaneously, independent of the vesico-ureteric reflux grade or bladder volume at the onset of vesico-ureteric reflux. [Arendonk 2007] The degree of renal scarring ($p=0.018$) and the degree of reflux ($p=0.038$) were found associated with the detrusor pressure with highest detrusor pressure in the group with 'urge syndrome'. [Acar 2009] In addition to grade of reflux, bladder volume relative to predicted bladder capacity, at the onset of vesico-ureteric reflux, appears to provide additional prognostic information regarding the likelihood of spontaneous resolution of primary vesico-ureteric reflux. [McMillan,Z.M. 2006] Large bladder capacity and high compliance correlated with 'passive' reflux, while reflux during micturition correlated with low bladder capacity: the first pattern showed a lower resolution rate within the third year of life, in a longitudinal study by videocystometry. [Wahll,L. 2009]

Despite this finding, there is ample evidence in 4 studies to show that treating the DO and/or voiding dysfunction with anticholinergic agents leads to a faster rate of resolution of vesico-ureteric reflux (63 - 92% within 1 year) [Homsy 1985; Scholtmeijer 1994; Batista 1997] than it might when the child is treated only with antibiotics to prevent recurrent infection (resolution rate 25 - 54%). [Seruca 1989; Ural 2008]

In this setting, history-taking about voiding habits [Gool 1992], and urodynamics with cystometry and uroflowmetry to confirm the abnormal bladder and possibly sphincter function, become paramount, rather than just treating the child with antibiotics and getting yearly voiding or nuclear cystograms. Urodynamic studies have confirmed the presence of DO and/or high voiding pressures in at least half the babies studied with high grades of vesico-ureteric reflux, whereas only 38% had totally normal function. [Webster 1984; Bachelard 1999; Yeung 1998; Bachelard 1998; Sillen 1999; Ural 2008] Upper urinary tract damage is more apt to occur in children with abnormal bladder function as reported in 4 retrospective reviews. [Nielsen 1989; Scholtmeijer 1994; Sillen 1999; Leonardo 2007]

In 2006, videourodynamic studies were performed in 40 patients. LUTD was present in 76% of the children, with DO in 73% of the children with vesico-ureteric reflux, in 63% of the children with UI, in 77% of the children with episodic urinary tract infection, and in all of the children with diurnal enuresis. Compared to children without LUTD, the voiding pressure was significantly higher in children with dysfunctional voiding (with vesico-ureteric reflux, 61 ± 30 vs. 25 ± 16 cm H_2O, $p = 0.004$; without VUR, 53 ± 24 vs. 25 ± 16 cm H_2O, $p = 0.010$). [Kuo 2006] In the 5 patients

who had post-treatment urodynamic studies, biofeedback pelvic floor muscle training and treatment with antimuscarinics effectively decreased detrusor pressure, increased bladder capacity and maximum flow rate, and reduced the grade of VUR. In children with recurrent or persistent urinary tract infection, meticulous assessment of signs and symptoms is reported to have a ± 70-80% association with the result of invasive UDS. [Ramamurthy 2010]

Special attention should be given to secondary causes of vesicoureteral reflux such as primary bladderneck dysfunction (reported to be an underdiagnosed entity in those children), since conventional treatment will most likely fail if these conditions are not addressed which was shown to be relevant in a randomized trial. [Kajbafzadeh 2010; Glassberg 2010]

Many clinicians treating patients with vesico-ureteric reflux, advocate urodynamics to assess the LUT in children with high grade vesico-ureteric reflux, especially for those patients that have incontinence, renal damage, or who are about to undergo surgery for vesico-ureteric reflux. [Scholtmeijer 1994; Moran 2004; Musquera 2004; Fotter 2005; Kajbafzadeh 2010] Precise urodynamic (pressure flow) criteria for outlet conditions in children are however still undefined.

e) Urethral stricture

Urethral stricture disease in boys is rare, usually arising from a previously unsuspected straddle injury. Uroflowmetry can accurately predict the presence of a urethral stricture in 88% of affected males. [Martin 1995] The significantly decreased quotient of Q_{max} at greater and at smaller VV's was suggested to be useful to demonstrate a mild BOO. [Szabó 1996] An occult urethral obstruction develops in some asymptomatic children after hypospadias repair and uroflowmetry can be helpful [Orkiszewski 2004; Kaya 2007], as showed by significantly different pre- and post-meatotomy findings of Q_{max} (p=0.001), voiding times (p=0.03) and curve morphology. [VanderBrink 2008]

Periodic urinary flow rates, analysing the maximum flow rate in relation to volume voided, may alert the clinician to early signs of renarrowing but efficacy of periodic flow rates has not been corroborated. [Bukurov 1992] Uroflowmetry should be integral in the management of urethral stricture and complete urodynamic investigation is repeatedly required after treating traumatic rupture of the posterior urethra. [Otgun 2006]

Conclusions (level 3)

- Many case series have demonstrated frequent urodynamic abnormalities, predominantly detrusor overactivity and reduced bladder compliance or large capacity bladder with impaired filling sensation, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesico-ureteric reflux or bladder exstrophy.
- Proper urodynamic assessment has shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities.
- The use of urodynamic studies has aided in an objective measurement of success or failure of treatments for these abnormalities.

Recommendations (grade C)

- Clinicians should consider complete urodynamic testing of the filling and voiding function, at least once, in children with posterior urethral valves, urethral stricture, ectopic ureterocele, vesico-ureteric reflux or bladder extrophy.
- Clinicians should consider regular uroflowmetry and postvoid residual urine assessment in the follow-up and further management of children with posterior urethral valves, urethral stricture ectopic ureterocele, vesico-ureteric reflux or bladder exstrophy.

5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT

When assessing functional disorders involving the LUT in children, one must take into account the dynamics of the maturing nervous system, learned habits of elimination for bladder and bowel function and social influences that might modulate the child's behaviour in a negative or in a positive manner. [Yeats 1976; MacKeith 1973]

a) Diurnal incontinence

Urodynamics has a limited place in diurnal (day and night) incontinence. This condition is not considered worrisome before age 5 or 6. When older, most children without an (until then unsuspected) anatomic or neurological lesion should be dry. [Bellman 1966; Neveus 2006] UI in children can have many causes and history and clinical investigation are very important in this regard. UI can also coincide with dysfunctional voiding and or bowel elimination problems. [O'Regan 1985; Koff 1998] Treating these elimination dysfunctions with behavioural modification, biofeedback training, drug therapy or CIC [Pohl 2002] and/or antibiotics to prevent further urinary infection is necessary before considering urodynamics. [McKenna 1999] Uroflowmetry with a PVR urine determination and cystometry are however indicated; especially if the incontinence persists despite medical therapy. A monocenter study reports that children with chronic constipation as the predominant symptom can also have unrecognized LUT problems. [Kasirga 2006]

In one study of girls with recurrent infection without vesico-ureteric reflux two distinct patterns of dysfunction emerged in 80% of those studied, either DO with a normal urinary flow pattern and complete emptying, or a normal detrusor with an intermittent flow pattern and incomplete emptying. [Borer 1999] In boys

with persistent day and night time incontinence, UDS is warranted to determine the presence of different forms of LUTD that may be contributing to the symptoms. [Ramakrishnan 2008; Yeung 2004]

Faecal incontinence in the absence of any anatomical or neurological deficit often affects LUT function and contributes to UI in a number of ways. Constipation and faecal impaction have been shown to cause DO and a reduced functional bladder capacity. [Kasirga 2006] Understanding and eliminating this possible aetiology can normalise LUT function. There is no need for urodynamic testing, before starting treatment for faecal impaction, in these cases. [O'Regan 1985]

Persistent daytime and night-time incontinence in the absence of urinary infection and a normal bladder and bowel emptying regimen warrants cystometry, pressure-flow studies and a urinary flow rate. A meta-analysis, over 20 years, of 460 children with daytime incontinence evaluated with urodynamic studies reveals DO in 57% (261 of 460), dysfunctional voiding (failure to relax the sphincter mechanism) in 22% (34 of 152) and normal findings in only 14% (64 of 460). [Webster 1984; Hanna 1981; Borzyskowski 1987; Rodriguez 1989] Many of those studies use terms that are outdated now and those should be replaced ('transformed' where possible) with the new. [Neveus 2006] In recent studies, dysfunctional voiding was present in 76% of 40 children with DO. [Kuo 2006; Zajaczkowska 2004] These findings are not gender-specific but are age-dependent, with most children outgrowing the abnormal findings by puberty. [Borzyskowski 1987] It is presumed that normal children, without day or night-time wetting, do not have a pronounced degree of DO or dyssynergia but the evidence for this is lacking due to the paucity of studies in normal children.

Urodynamic testing has clearly improved our understanding of the aetiology of diurnal incontinence but no study has shown that urodynamic characterisation of any abnormality has improved the efficiency of treatment for these children.

b) Enuresis (nocturnal)

Night-time wetting (enuresis) is a condition that is common in children aged 5 years but which improves with time, so that less than 15% of pubertal boys and 5% of pubertal girls continue to be affected. [Fergusson 1986] Multiple causes for the persistent wetting, ranging from genetic factors, to maturational delays, to sleep disturbances, to social causes, to attention deficit disorders, to bladder and urethral dysfunction, to excess fluid intake, to abnormal vasopressin secretion and/or to constipation, have been implicated. [O'Regan 1985; Hoebeke 1995; Hjalmas 1997; Chandra 1998; Neveus 2006] Although in various cultures there may be social and familial pressures to resolve the condition before puberty, in western societies it is generally not necessary to conduct urodynamics until adolescence, to determine why the wetting has not abated. Urodynamic testing in 615 enuretic children, with and without daytime symptoms, has identified DO in 61%. [Mayo 1990; Medel 1998; Hellerstein 2003] In a prospective study, bladder volume and wall thickness index was calculated based on ultrasound studies. The index was measured by dividing maximum bladder volume by mean bladder thickness. Bladder volume was expressed (normalized) as percentage by dividing the patients measured bladder capacity by expected bladder capacity and subsequently the detrusor was classified as thick (index:< 70), normal (70 to 130) or thin (>130). Of the patients with an index of less than 70: 96% exhibited DO on cystometry. [Yeung 2004; Sreedhar 2008] In another prospective study, 116 children with primary enuresis were evaluated and urodynamic abnormalities were seen in 80/116 (69%) patients namely DO 50/116 (43%), small bladder capacity 20/116 (17%), large bladder capacity 4/116 (3%), decreased bladder compliance 3/116 (3%) and detrusor sphincter dyssynergia 3/116 (3%). The combination of abnormal micturition history with daytime urinary urgency or frequency, or dysfunctional voiding symptoms like squatting and/or abnormal voiding charts, predicted abnormal results of urodynamics correctly, with a sensitivity of 81% and specificity of 86%. [Sehgal 2007] However, other studies state that urodynamic diagnoses are more distinctive than symptom complexes for LUTD in children. [Glassberg 2010]

When the children are divided into those with day and night-time incontinence (non monosymptomatic) versus those with just nocturnal wetting (monosymptomatic), the incidence of DO decreases from 64% to 35% in the latter group. [Medel 1998] In another prospective study comparing enuretics to age-matched non-enuretic controls, bladder capacity at night (enuretic capacity) was significantly less in those who wet versus those who did not. [Kawauchi 2003] Although the authors did not speculate on aetiology they felt that enuretics were less able to hold their urination than non-enuretics. Management should be directed at improving the child's ability to withhold urination. Treating the non monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) with low recidivism rates when based on the findings of urodynamic testing. [Porter 1995; Kosar 1999; Neveus 2010; Hoebeke 2010; Abidari 2002]

Conclusions (level 2/3)

- Various studies show that treatment for children with functional incontinence (and of the, frequently associated, bowel elimination problems) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with postvoid urine assessment.
- Various studies, reviews and guidelines agree on the relevance of urodynamic testing in children

with incontinence and nocturnal enuresis resistant to initial (conservative) treatment.

Recommendations (grade B/C)

- The committee recommends uroflowmetry and postvoid residual urine assessment (until -for the individual child- representative values are obtained) as 'urodynamic'-screening and evaluation in all children with lower urinary tract symptoms, urinary incontinence and or with nocturnal enuresis resistant to first line therapy.
- The committee suggests urologic signs and symptoms assessment in children with chronic constipation.
- The committee recommends complete urodynamic testing in children with urinary incontinence and or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

Suggestion for research

- The committee suggests that further integrated approaches to the diagnosis (and management) of children with anorectal (elimination) dysfunction, in combination with lower urinary tract dysfunction are undertaken.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

Often, differences in urodynamic parameters exist from one study to another, or one year to the next. Chou et al provided reference ranges for 'normal' variability in urodynamic parameters that can be considered as 'no real change' from one study to the next. It was a retrospective chart review. Fifty consecutive individuals with spinal cord injury had 2 trials of urodynamic studies done 5 minutes apart. They established percentile ranges. Knowing these ranges of variability can be helpful in determining whether differences between filling trial 1 and filling trial 2 in a single study, or year-to-year changes in urodynamic studies, are significant or simply the normal variability of the urodynamic study. [Chou 2006]

'Functional' bladder capacity (as derived from the voiding diary, without the first voiding in the morning) is presented as a relevant parameter for the clinician in the International Childrens' Continence Society definitions. [Neveus 2010] To assess the voiding phase, pressure flow studies are performed immediately after filling cystometry. Available reports on detrusor pressure during voiding in symptom free children is reported to give a wide range; between ± 50-60 cmH_2O in one study [Wen 2007] and ±100cmH_2O in another [Yeung 1995]

A rate of filling resulting in 10% increment of the expected bladder volume per minute, has been recommended in children to determine detrusor compliance and functional bladder volume accurately and standardised. [Hoebeke 1998] Some investigators advocate that infants should be assessed with much lower rates of filling or with natural filling cystometry. [Yeung 1998; Sillen 1999] Several studies do show lower detrusor pressure increases under natural filling versus even slow filling rates during cystometry. [Norgaard 1995; Landau 1994; Kaefer 1997] Even though the practicality of time management plays a role in a busy urodynamic laboratory, it is essential to perform urodynamic testing in a way that reveals what one considers clinically important information. One study in particular [Kaefer 1997; Landau 1994] demonstrated that the intravesical pressure was lower when it was measured initially by catheterisation (before emptying the bladder) and then compared to the pressure at the same volume during the subsequent cystometogram. Except for determining bladder volumes at specific pressures, [Landau 1994] no study has shown that these differences are crucial in the management of children with LUTD. One study looked at the effect of the temperature of the instillate (25° versus 37.5°C) on measured detrusor pressures and found no significant differences in compliance. [Chin 2003] Van Meel et al have shown that repeating the IWT will increase its positivity. [Meel 2007]

The smallest dual-channel urethral catheter available should be used in children for the same reasons as specified for adults, although the measuring lumen must be large enough to measure pressures in a technically adequate manner. Although urethral catheters of moderate size (8F) do not always obstruct the urethra in girls [Griffiths 1982] or produce higher than the normal voiding pressures, as measured with suprapubic tubes, it is prudent to employ the smallest calibre catheters that are practical when doing a cystometogram that measures filling as well as voiding pressures. For very young infants it may be better to insert a suprapubic catheter placed under anaesthesia the day before the test to make the subsequent investigations more accurate [Yeung 1999; Yeung 1999] but this has not been assessed with any precision. Furthermore, precise standards for pressure-flow analysis in boys or girls, or for grading of BOO 'resistance', have not been published. The precise association and or prevalence of obstructed voiding with incontinence is therefore also unknown.

Most children can undergo urodynamic studies without pre-medication; only the most agitated may require some degree of sedation [Bozkurt 1996] and it does not appear to have a significant effect on the outcome of the testing. Even then, children should not be so heavily sedated that they cannot void around the catheter. However, there are no studies that show a difference in bladder filling pressure (whether related to compliance or to DO) in awake versus anaesthetised children.

In the previous consultation the recommendation was made that children should receive comprehensive urodynamic testing in a laboratory that is specialised in paediatric urodynamic testing with appropriately trained personnel. [Ramamurthy 2010; Bael 2009; Uluocak 2009]

Conclusions (level 3/4)

- The committee concludes (on the basis of various studies to determine normal and test retest values for urodynamic testing in children) that within the limits also provided for adults, urodynamic testing in children is reliable and reproducible.
- Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values cannot be given and the influence of the transurethral catheter size on voiding is unknown.
- The committee concludes that standards for pressure flow analysis in children are lacking.

Recommendations (grade C)

- The committee recommends that the specific demands of children, physically as well as psychologically are taken into account, before urodynamic testing is carried out as well as during the testing. The committee advises specialised workers, units and equipment to ensure this.
- The committee recommends that invasive diagnostic tests should be done if indicated by the results of non-invasive procedures and should be done only when the outcome will or can alter management.
- The committee recommends that clinicians take into account the variability and test retest differences of urodynamic testing in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child's behaviour, and the implications for the results of the tests.

Suggestion for research

- The committee suggests to elaborate on standardisation of evaluations to judge how the 'laboratory' circumstances have influenced the child's behaviour, with the aim to better include how well the urodynamic tests have represented the actual dysfunction, in the evaluation of the test.

V. PATIENT EVALUATION: FRAIL ELDERLY

1. INTRODUCTION

Frail older patients are poorly represented in all studies, but especially in those involving invasive interventions or medications, By definition, they suffer from multiple impairments (e.g. poor mobility, cognitive impairment, renal failure) or disease conditions (heart failure, multiple medications). [Fairhall,N. 2011; Fried,L.P. 2001; Inouye,S.K. 2007] Such individuals are at risk of admission to hospital or a care home. [Hrisanfow,E. 2011] Older people age at different rates, with some developing a clinically recognised pattern of frailty characterised by impairments in a number of functions including a greater risk of developing incontinence. [Ferrucci,L. 2004; Baltes,P.B. 2003; Hirayama,F. 2008] However usually the multimorbidity excludes them from research trials, which limits appropriate continence care. [Narayanan,S. 2007; Ferrucci,L. 2004] Elderly patients should however not be considered differently from younger subjects simply because of their chronological age. LUTS, especially storage ones, showed age-related alterations in the two sexes in the absence of any overt underlying disease, and bladder function in both sexes may be subject to a gender-independent aging process. [Araki,I. 2003] UDI findings in the (frail) elderly tend to demonstrate DO [Jones,K.W. 1985; Resnick,N.M. 1989], even in individuals that do not spontaneously report symptoms or bother. There may also be a reduction in bladder capacity, urinary flow rate and detrusor contractility. [Homma,Y. 1994] Because of these age dependent changes, the utility of UDI has to be judged against this specific background in the elderly where diagnosis and treatment of specific conditions is strongly dependent on and related to frailty by itself. [Homma,Y. 1994] These features need to be born in mind when considering the contributors to, and investigation of, incontinence. Limitations to care may also be appropriate in a frail older person who is nearing the end of their life. [Gillick,M. 2001] The invasive nature of conventional UDI becomes a relatively more important factor in the old or frail elderly, who may be more vulnerable to any intervention than younger people. For example, one study [Okorocha,I. 2002] showed that there was a significant association between age and the presence of asymptomatic bacteriuria before cystometry and between the bacteriuria and urgency (without DO) on cystometry. Asymptomatic bacteriuria did not influence the UDI outcome except in patients with urgency (without DO); and the authors recommended that screening and treatment be considered individually in older women who are being investigated for storage symptoms.

Given the multifactorial nature of incontinence in the elderly [Miller,K.L. 2002] and the fact that there may exist easily reversible causes or contributory factors relatively more frequently in these patients, it is suggested repeatedly that screening for contributing factors in the 'vulnerable elderly' is very relevant. [Resnick, 1984; Bing,M.H. 2007; Gibbs,C.F. 2007; Fonda, 522]

UDI is reserved for patients in whom conservative management and medical management, direct or

indirectly aimed at lower urinary tract improvement, has failed or has proved inadequate, and in whom more intensive or invasive therapy is being considered. Also in the elderly, there is a given group of patients who desire further attempts to correct or manage the incontinence, and who therefore need a detailed and objective diagnosis. [Sims,J. 2011] Improvements in the structure and process of 'continence care' for the elderly has resulted in improved patient reported (Quol) outcomes, and the structure presented by a geriatrics (ambulatory) clinic may serve as an example of care quality improvement. [Min,L.C. 2011] Certainly assessment of persistent LUTD and UI is of relevance in the elderly after urological interventions, however UDI diagnosis is rarely mentioned in the follow-up of persons with 'failed' interventions. [Shikanov,S. 2010; Namiki,S. 2009; Poulakis,V. 2007]

The place of UDI in the frail elderly with incontinence is not precisely established, given that the number of studies seeking to establish its clinical utility is even smaller than in younger adults: there is very little objective evidence for or against clinical UDI in this population group. However, the same principles apply as those in younger age groups, namely that UDI should only be done if it is going to affect the management of the patient and that conservative and medical therapy has failed with the patient desiring further treatment. [Abrams,P. 2009] A recent review, on the basis of a RAND procedure, to search for health care quality indicators underpins that UDI 'should be performed' in the workup of vulnerably elders when surgical intervention is considered. [Fung,C.H. 2007]

The changes in function that occur with age, not only in the LUT, but also in the neural system that controls it (or fails to control it), may all have impact on urological problems. UDI research studies, to establish what these changes are, how they are related to other aging associated changes, and how the changes might be reversed, are needed. [Inouye,S.K. 2007]

Overactive bladder syndrome is frequently diagnosed in the elderly and in the frail elderly and medical (pharmacological) treatment seems plausible for elderly, with extrapolated evidence from younger patients. In non-systematic reviews on pharmacotherapy UDS do not play an important role to initiate treatment for overactive bladder syndrome in the frail elderly. [Kraus,S.R. 2010; Staskin,D.R. 2005; Wagg,A.S. 2007]

2. ROUTINE EVALUATION

Among the frail elderly, incontinence is the paramount troublesome symptom, in both men and women, with a steeply rising incidence after age 80. [Hunskaar, S 2002] The type of incontinence appears to be predominantly urgency. [Hunskaar,S. 2002] Mixed symptoms of incontinence are the commonest in women [Valentini,F.A. 2010] SUI is relatively uncommon in men of any age (except post radical prostatectomy) and it seems to become gradually less common in women after the age of about 50, [604 Hunskaar 2002] or is reported with a range of incidences, [Wennberg,A.L. 2009] for reasons that are incompletely understood.

a) Urinary urgency incontinence

The symptoms of UUI are frequently the result of DO. Thus one possible reason to perform UDI might be to identify DO. The relevant test is filling cystometry. There are reasons to question whether this is the best approach because in straightforward symptoms of urinary urgency incontinence in the elderly, DO is highly probable, and it is considered possible to initiate pharmacological or behavioural therapy without a very significant possibility of harm. [Kraus,S.R. 2010; Staskin,D.R. 2005] On the other hand: DO is only one of the contributors to the symptoms of urinary urgency incontinence [Miller 2002; Griffiths 1996], and non voiding detrusor overactivity is believed to exist in (older) people who are apparently free of (bothersome) bladder symptoms. However, if making the diagnosis of DOI is essential, it is necessary to demonstrate leakage caused by an involuntary detrusor contraction.

Reduced bladder sensation or 'awareness' may lead to very little warning of impending leakage, and it is believed to have a neurological (cerebral) in the elderly with LUT symptoms. [Griffiths,D. 1998; Griffiths,D.J. 2002]

In symptomatic elderly people, UUI frequently coexists with incomplete bladder emptying. Among men who have not had prostate surgery, BPO is a frequent contributor to incomplete emptying. However, if there is no BOO, particularly in women, in whom the incidence of BOO is very low, incomplete emptying is usually a sign of impaired bladder contractility, termed by the ICS as underactive detrusor. The UDI abnormality underlying UUI with incomplete emptying (assuming no BOO) has also been named 'DHIC'. [Resnick,N.M. 1987] Its significance is that the standard pharmacological treatment of UUI – with antimuscarinics – may worsen bladder emptying and possibly lead to urinary tract infection, or even make the incontinence worse. However, on the other hand, if the patient has large residuals, then treatment with CIC may be considered indicated and therefore combining that with antimuscarinic therapy is an option, although such a combination can be problematic in frail elderly patients.

In frail elderly women, DO is reported to be the commonest UDI diagnosis in a large retrospective series of referred elderly women. Intrinsic sphincter deficiency, underactive detrusor and reduced bladder compliance [Valentini,F.A. 2010] were also prevalent in this series. Population surveys with symptoms questionnaires (without UDI's) confirm this pattern in various countries and care-

settings. [Burti,J.S. 2012; Malmsten,U.G. 2010; Kwong,P.W. 2010; Chen,Y.M. 2009; Verdejo,C. 2007; Sexton,C.C. 2011]

Simple cystometry:

Some report that UDI's in the elderly can be done by 'simple cystometry', if cystometry is indicated and no equipment or referral is available. [Wall,L.L. 1994] The procedure applies a large open syringe attached to a single-lumen catheter, steri1e water or saline and a tape measure. Fluid is infused by gravity and LUT function can be semi quantified at the bedside and may be applicable for disabled patients. [Sutherst,J.R. 1984; Sand,P.K. 1991; Ouslander,J. 1988; Dennis,P.J. 1991; Fonda,D. 1993; Galarneau,L. 2003] Simple cystometry, as compared with multichannel cystometry, has a specificity of 75-79% and a sensitivity of 75-88% for the observation of DO in those studies [Fonda,D 1993; Ouslander,J. 1988], and is improved by combining it with simpler tests [Sutherst,J.R. 1984; Ouslander,J. 1988] such as a clinical stress test. [Resnick,N.M. 1996] However, the clinical significance of these findings is limited because DO is found in up to 50% of symptom-free elderly while DOI is the most likely finding in incontinent frail elderly in any case. [Resnick,N.M. 1987; Resnick,N.M. 1989; Griffiths,D.J. 1992] Furthermore 'detrusor hyperactivity (2010: 'DO') with impaired contractility' (DHIC) [Resnick,N.M. 1989] is reported to be a common abnormality observed in the frail elderly population with incontinence and cannot be diagnosed with simple cystometry. [Resnick,N.M. 1987; Resnick,N.M. 1989] A total of 185 patients who had persistent LUTS after TURP were enrolled in one study, and the results revealed that a normal videourodynamic tracing was found in 9%, pure DO in 10%, 'low detrusor contractility' in 19%, DHIC in 14%, poor relaxation of the urethral sphincter in 19%, and recurrent or remaining BOO in 28%. [Kuo 2002] Single-channel cystometry is less sensitive for detecting low-pressure detrusor contractions than multichannel recording [Resnick,N.M. 1996] and if a detrusor contraction coincides with a cough, the leakage might be wrongly regarded as the sign of a positive stress test.

b) Stress urinary incontinence

Among older men, SUI is almost entirely confined to post radical prostatectomy patients (see section D.II, Patient evaluation: Men). Among elderly women, pure SUI seems to be rare. UDI testing usually follows the methods used in younger women. Frequently, it is difficult to perform a 'typical' examination because the patient is not able to produce a strong cough or valsalva in the upright position. On the other hand, it may be just such factors that make SUI less common in this population or of lesser relevance in this group.

3. EVIDENCE FOR REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC TEST IN THE GERIATRIC OR FRAIL ELDERLY POPULATION

There is little published evidence about reproducibility and reliability in this patient population. Two groups have recently examined specific aspects of geriatric urodynamics which have some bearing on this topic. There is a little earlier evidence on the reproducibility of some parameters.

a) Filling cystometry

One group[Goode,P.S. 2002] sought UDI changes associated with behavioural and drug treatment of UUI in 105 ambulatory, non-demented, community-dwelling women, of mean age 67 years (range 55-91). Although oxybutynin and behavioural treatment were both effective, the authors were unable to demonstrate that the improvement in incontinence was related to the UDI changes observed, probably because of diverse UDI diagnoses at inclusion, as well as the variability of the UDI outcome. (See sections C.I and C.II).

b) Post-void residual urine

Residual urine is believed to depend on the presence of BOO (in men) as well as underactive detrusor. [Abrams, P 2001] Thus, in a man, the presence of substantial residual urine (> 100 mL), in the absence of a large prostate, and or severe BOO, suggests that the increased residual urine is mainly due to a reduction in detrusor contractility. [Rosier,P.F. 1996] There may be a clinically relevant age-dependent decrease in contractility in both sexes. [Abarbanel,J. 2007; Abdul-Rahman,A. 2010]

Post void residual urine varies in a given individual and can wax and wane over time. Significant daily variations have been observed in elderly patients of both sexes, with larger residuals (up to 40% greater) being measured in the early morning. Similar changes have been described in patients with BOO or underactive detrusor. [Bristow,S.E. 1996; Thind,P. 1995] Residual urine is an unspecific sign of dysfunction and also no clear predictor of deterioration of residual urine volume or of complete urinary retention has been identified in general, however prostatic obstruction is an undisputed prevalent cause of urinary retention in elderly male.

c) Pressure-flow studies

Another group retrospectively analysed UDI data on 84 females 53 years old or older, with UUI, who received either a titrated dose of antimuscarinic medication or placebo in a controlled trial. [Tan,T.L. 2003] The detrusor muscle is believed to deteriorate in function as a result of aging, by diverse investigators and since antimuscarinic treatment might affect detrusor voiding function urodynamics is applied to

monitor this. Driving a contraction to its maximum load (and zero contraction velocity) is a manner to evaluate muscle force, and stop-flow test is the practical way to do this. Three different variations of the stop test were therefore compared to analyse detrusor voiding contraction before and on treatment in this study. The voluntary stop test yielded isovolumetric detrusor pressure values inconsistent with the other 2 tests. The mechanical and continuous occlusion tests gave very similar results that were highly correlated with one another. Treatment with oxybutynin decreased isovolumetric contraction pressure only statistically significant for the continuous occlusion test. The authors concluded that voluntary stop test should not be used to evaluate detrusor contraction power, but that occlusion stop test can be of relevance to evaluate the effect of treatments that affect detrusor voiding contraction in the elderly.

4. EVIDENCE THAT PERFORMING URODYNAMIC TESTING IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION

Few relevant studies have been published in this population. One publication assessed the results of TVT for the treatment of SUI in 76 consecutive women more than 70 years old (median age 76 years). 31% (24/76) of the patients had OAB symptoms and 4 (3%) had proven DO. [Sevestre 2003]. All patients had preoperative multichannel UDI evaluation however the technique applied was very imprecisely described. At a mean follow up of 25 months, 67% of the patients were cured. Preoperative urgency symptoms were cured in 46% of the group. Among the failures, 14 (18%) had UUI, while 'de novo' urgency without incontinence was noted in 21%. Pre-operative UDI was not able to predict the outcome of a popular SUI procedure in older women in this monocenter uncontrolled cohort. It does show that post-operative difficulties may be due to urgency and UUI, however, symptoms are not a good 'predictor' of UDI diagnosis, and therefore pre-operative urodynamics in women undergoing SUI surgery is valuable in helping to counsel patients especially if they have signs or symptoms of OAB.

5. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED

a) Post-void residual urine

Based on the above, there is general agreement that, certainly in the elderly, PVR urine measurement is indicated before treatment of incontinence either with anticholinergic medication or by SUI surgery. A consistently large residual urine certainly is a reason for caution, and careful monitoring of bladder emptying, and may be a relative contra¬indication to such treatment. [Thuroff,J.W. 2011]

b) Uroflowmetry

Uroflowmetry is a simple and non-invasive test. A normal uroflow without much residual urine probably rules out significant BOO or underactive detrusor, but this finding is unusual in the elderly. Conversely, a poor uroflow is common in the elderly irrespective of sex, and although it cannot distinguish between BOO and underactive detrusor, in either case there is a relative contraindication to anticholinergic therapy. Consequently, uroflowmetry (with residual urine measurement) may be a useful screening tool prior to instituting therapy. However, interestingly, in a retrospective study of hundred women tested, the first free flow was not interpretable in 44% but interpretable in 91% on the second free flow. [Valentini,F.A. 2010] This confirms the usefulness of performing at least two free flows on patients. [Reynard 1996]

c) Pressure-flow studies

In male patients with cognitive impairments or Parkinson's disease or multiple system atrophy (MSA), is sometimes unclear whether the incontinence is due to BPO or to the cerebral changes. There is weak evidence to suggest that prostatectomy may improve the continence if UDS shows 'severe' BOO. [Gormley,E.A. 1993] If BOO is equivocal or absent, then there is little point in performing surgery in an attempt to alleviate the signs and symptoms. After screening with uroflowmetry and residual urine measurement, pressure-flow studies may be indicated in older men in whom BOO cannot be ruled out and surgery is at least contemplated.

6. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS

Various papers have examined the urodynamics of Parkinson's and related diseases. Parkinson's and related diseases as well as dementia's are prevalently associated with aging as are prostatic obstruction, detrusor and pelvic floor muscle degeneration and deterioration sensomotoric functions. UDS can be of relevance to determine the most important cause of the LUTS in the elderly, where central nervous system disease is a frequently occurring comorbidity and clinical signs and symptoms are regularly more difficult to obtain.

a) Parkinson's Disease

One group [Defreitas 2003] found that men with presumed BOO related LUTS were less likely to have DOI on UDI's than men or women with Parkinson's disease. DO associated with Parkinson's disease occurred at smaller bladder volumes than DO in BOO-related DO, although this finding was more pronounced in women than in men. The duration and severity of Parkinson's disease were reported not be related to the UDI abnormalities in this study.

Another group [Sakakibara 2001] found that the majority of patients with Parkinson's disease (72%) or MSA (100%) had symptoms of LUTD. DO was more common in Parkinson's disease. DSD was seen only in MSA. BOO (> 40) was more common in Parkinson's disease than in MSA. A detrusor underactivity was less common in Parkinson's disease than in MSA and PVR (> 100 mL) was only present in (47% of) patients with MSA.

Conclusions (Level 3-4)

- There is direct and indirect evidence that urinary incontinence in the (frail) elderly often has diverse and or multiple coexisting factors.
- Apart from general health, mobility, neurological diseases and medications, the lower urinary tract is directly affected by aging of the detrusor, and can be both overactive during storage as well as underactive during voiding,) and aging of the outlet; prostate, and pelvic floor muscle function.
- In common with all patients, but maybe even more relevant; symptoms are not synonymous to the abnormalities that can be measured with urodynamic studies
- Every test or procedure can cause harm in the (vulnerable) elderly but there is no published evidence that invasive urodynamic studies causes significantly more harm in the elderly.
- Simple bedside urodynamic testing has an inherent unreliability, and it is unclear whether the risk of misdiagnosis outweighs the 'simplicity' over conventional urodynamic studies.
- Especially, but not exclusively, male patients, with central neurological disease, can have urologic disease (e.g. prostatic obstruction) as a cause for incontinence or other lower urinary tract dysfunction.

Recommendations (grade C)

- As urinary incontinence in frail elderly people may be the result of a number of contributory factors, many of which are reversible by simple measures, such patients should be first evaluated by a clinician skilled in the care of older people before any invasive investigations or more potentially harmful medications are given.
- Post-void residual urine measurement by a non-invasive method is recommended before institution of pharmacological or surgical treatment of incontinence. It should be repeated to monitor the effect of such treatment
- Uroflowmetry should used to screen for voiding abnormalities prior to invasive treatment in the elderly.
- Filling cystometry, as a single investigation, has limited value in this patient population. 'Simple cystometry' is not recommended
- Simple cystometry can be used as a 'screening test' for non- invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management. However, the low specificity and sensitivity towards complete urodynamic studies diagnosis must be taken into account.
- The committee recommends offering comprehensive urodynamic testing to all elderly, with due consideration of any co morbidity, that have not responded to management of relevant contributing factors, and or behavioural or pharmacological therapy, and in whom further invasive therapy is considered.
- The committee recommends that comprehensive urodynamic testing be performed in centres with a special interest in incontinence in the frail elderly, by trained and certified staff who frequently perform urodynamic testing of patients referred with suspected lower urinary tract dysfunction
- To maintain adequate urodynamic expertise in this difficult-to-examine patient population, and to provide a background of 'regular' patients against whom specific patients can be judged, it is essential that such centres examine substantial numbers of frail elderly patients

Topics for research

- Study of biological mechanisms of continence and incontinence in the frail elderly, especially those related to supraspinal control or lack thereof.
- Development and testing of treatments specific to the frail elderly with incontinence.
- Establishment of the reproducibility and reliability of urodynamic measurements in the frail elderly.
- Investigation of the associations of defecation and faecal loading or impaction of the bowel on detrusor contraction, incontinence and other lower urinary tract problems (e.g. UTI), as well as investigation of the management of combined faecal and urinary incontinence.
- Further investigation of the (cause of, and optimal management of) clinically observed association of DO and underactive detrusor during voiding (and post void residuals) in the (frail) elderly.

A. INTRODUCTION

The Committee was given the task of updating the evidence on imaging, neurophysiological testing and other tests in the field of urinary and anal incontinence. The Medline, Embase and Cochrane databases were searched for the relative subjects from January 2008 and February 2012. All references obtained from the database search were screened for relevance, full text papers were obtained and reference list were used as additional source of evidence when appropriate.

The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and Pad test) in the paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

The following keywords were used for the difference subjects:

- Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2004 to 2008.
- Neurophysiology: clinical neurophysiology, conventional urodynamics, neurourology, urinary dysfunction.
- Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, tissue analysis were used.

Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. The first draft of the chapter was reviewed by all committee members, the final draft was then edited first by the Committee Chair and then by the book Editors.

Diagnostic techniques were evaulated with reference to the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit. The level of evidence was graded taking into consideration that imaging, neurophysiological testing and the other tests pertain to the area of "diagnosis" and the quality of the published papers is graded according to the criteria specific for this area. Areas of future research were identified.

Notwithstanding the large body of evidence research on imaging in anal and urinary incontinence, its clinical benefit remains questionable. Test-retest, intraobserver and interobserver accuracy are often provided for diagnostic tests although diagnostic accuracy is sometimes difficult to calculate. When ultrasound is used to measure bladder volume, catheterisation can be used as a reference standard and accuracy can be easily calculated but when sphincter volume is calculated with ultrasonography, there is no solid reference standard except another imaging technique (e.g.: MRI) and the validity of the measurement is tested against another weak test such as Valsalva Leak Point pressure of maximum urethral pressure profile. Imaging can either be performed to better understand the pathophysiology of incontinence and pelvic organ prolapse and it may be of importance although no immediate clinical benefit is evident (e.g.: calculation of sphincter volume with ultrasound). It can be performed as a diagnostic test in patients undergoing surgery so that quantification of the clinical benefit requires complex clinical trials (e.g.: MR imaging of pelvic organ prolapse in patient undergoing prolapse repair) in which different reference standards can be used (e.g.: physical examination or anatomic finding during surgery). Although imaging can sometimes offer a better understanding of the anatomy underlying the condition (e.g.: presence of an enterocele) the clinical benefit of this additional information may not be observed in all patients.

Although imaging is clearly a difficult area for research, the consensus regarding introduction of a

diagnostic test into our daily practise must rely on the evidence of clinical benefit in terms of safety, outcome or cost-benefit ratio.

Imaging studies belong to the area of diagnostic studies, they should follow the suggestions of the STARD initiative and they differ substantially from other types of clinical trials (Bossuyt 2003). The aim of clinical studies of diagnostic tests should be to provide information regarding the diagnostic accuracy of the proposed test although, this is not always possible.

A few considerations regarding the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarised herewith.

Imaging of parameters with known prognostic value (e.g. PVR)

- The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocele imaging) and should be solved using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition.
- When the imaging is quantitative, accuracy versus the gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensitivity, specificity, positive and negative predictive value, accuracy, inter-rater and intrarater variablity).
- Once validity has been proven, one can assume that the predictive value of the imaging study is equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)

- When the imaging is qualitative (eg: intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.
- Once validity is proved, the prognostic value for patient management should be investigated.
- Confirmation of the proposed imaging study by independent groups is required ideally for both validity and prognostic value or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

B. IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

This is a very wide area that often requires a multiprofessional and muldisciplinary approach. The patient population is quite heterogenous including children, female and male subjects suffering congenital malformation of the genital and urinary tract, neurogenic disorders, iatrogenic conditions and traumatic lesions. Clinical guidelines always refer to the so called “standard patient” but the majority of subjects referred to secondary and tertiary referral centres cannot be defined as such and their management sometimes requires deviation from guidelines recommendations. The large variability and the uniqueness of the observed cases may justify the adoption of a knowledge-based management in the absence of proven clinical benefit. Research on imaging of urinary incontinence and genital prolapse remains very active. Although all guidelines recommend not to use imaging in the evaluation of the standard patient, many clinicians believe this is an ideal adjunct to physical examination in evaluating the anatomical condition of the individual subject.

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extraurethral [1]. This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, LUTD causing UI, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplatic children and then considered to apply in all neurogenic patients [2] and automatically transferred to male and female patients with or without neurogenic problems; the value of 40 cmH2O of bladder pressure as threshold value at which the UUT is at risk should therefore used with caution. In male patients, chronic retention of urine can be associated with UI and lead to chronic renal failure. In women, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis [3] (**Figure B 1 a,b**).

I. IMAGING OF THE UPPER URINARY TRACT

1. INDICATIONS

Generally speaking, there is no need for upper tract imaging in patients with UI unless any of the

Figure B 1-a: Procidentia uteri

Figure B 1-b: IVU: bilateral hydronephrosis. Left kidney is in sacral ectopia.

previously described conditions is suspected or diagnosed. In children with extraurethral incontinence imaging of the UUT helps to identify the underlying cause.

The objectives of UUT in the incontinent patient are as follows:

1. Evaluation of the upper urinary tract when the presence of an ectopic ureter or ureterovaginal fistula are suspected.
2. Evaluation of the kidneys whenever UI is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders)
3. Exclusion of hydronephrosis in cases of UI associated with severe uterine prolapse (**Figure B 2 a,b,c,d**).

2. TECHNIQUES

Upper tract imaging modalities include intra-venous urogram (IVU), ultrasound sonography (USS), computerised tomography (CT scan), magnetic resonance imaging (MRI), and isotope scanning. No data regarding reproducibility, specificity, sensitivity, positive and negative predictive value in relation with the diagnosis and management of UI are available. The choice of the imaging modality also depends on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS are preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

a) Ultrasonography

USS is the gold standard technique for primary imaging of the upper urinary tract because of the relatively low cost of the equipment and the examination, its wide availability, the lack of any exposure to ionising radiation. Renal USS is independent on kidney function and provides a good evaluation of kidney morphology. Concomitant renal disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with LUTD, the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. Although, no strict correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage [4]. In children, kidneys with a pelvic diameter >20 mm are considered to be at risk for deterioration and require intervention [5]. Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient [6]. Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral reflux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

b) Intravenous Urography

IVU is the original radiographic examination of the upper urinary tract which allows evaluation of upper urinary tract anatomy and function. Successful examination is dependent upon adequate renal capacity to concentrate urine and the examination is currently contraindicate when creatinine levels exceed 2.0 mg/dL [7] because of the possible increased toxicity of the contrast medium and the lack of concentration of the contrast agent by the impaired kidneys. While the former can be taken care of by adequate hydration of the patient, the poor concentration

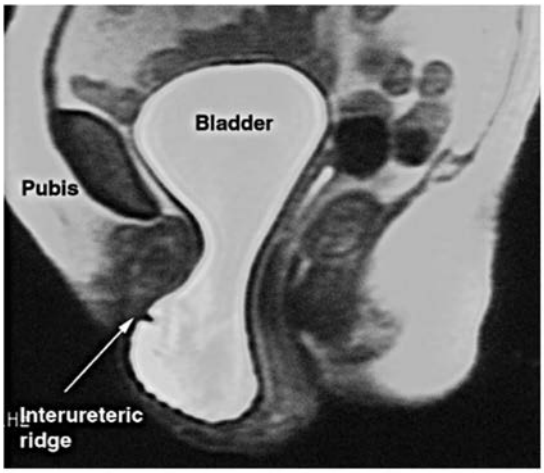

Figure B 2-a: MRI: complete urogenital prolapse

Figure B 2-b: MRI: ureteral dilation

Figure B 2-c: MRI: ureteral dilation

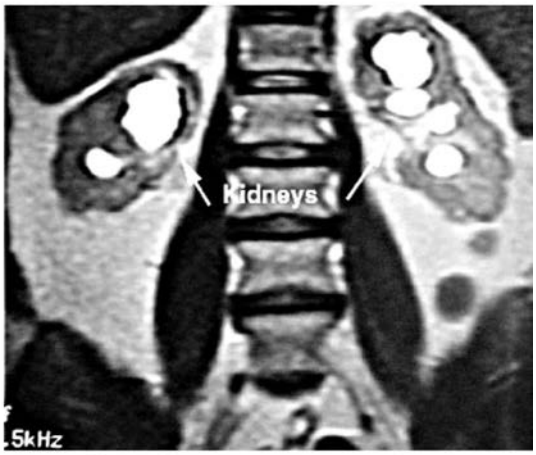

Figure B 2-d: MRI bilateral hydronephrosis

capacity of an impaired kidney limits the possibility to delineate the collecting system. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumours may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system [8-10]. In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI (**Figure B 3 a,b**) or isotope scanning should be considered [11-13]. IVU is the appropriate first imaging study when uretero-vaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropyelocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases [14, 15]. Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

c) Computerised tomography

High quality information of the upper urinary tract anatomy can be obtained using multidetector helical CT scans and 3D reconstruction software. Differently from IVU which only acquires images in the antero-posterior or oblique CT acquires images in the axial plane. Pictures can then be reconstructed in 2D along any plane or in 3D whenever required. CT scan can be used irrespective of renal function when no iodinated contrast medium is used. Whenever hydronephrosis is present, urine can be used to delineate the collecting system reducing the need for contrast agents. In general, intravenous contrast medium is required to highlight specific anatomic characteristics. CT scan is often used after a first line evaluation with USS and it has replaced IVU almost entirely. Sev-

Figure B 3-a : MRI diagnosis of ureteral ectopia

Figure B 3-b: MRI diagnosis of ureteral ectopia:

eral authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, despite a normal IVU and ultrasound [16]. In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

d) Magnetic resonance imaging

MRI shares some of the advantages of CT over IVU in the evaluation of the upper urinary tracts. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the upper urinary tract remains dependent upon renal function and concerns about its nephrotoxicity have been recently raised [17]. The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydronephrosis and urinary tract anomalies as an alternative to IVU. The use of MRI in the diagnosis of ectopic ureter has recently been described [18-20].

e) Isotopes

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques.

Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radionucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system [21, 22]. Diuresis renography with bladder drainage is recommended when obstructive uropathy is suspected [23]. Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys [24].

f) Conclusions

Imaging of the UUT is rarely required in LUTD unless the condition originates from a malformation, a traumatic or a iatrogenic problem of the UUT. More rarely a condition of the LUT may endanger renal function, the preservation of which is required to guarantee a normal life expectancy in patients with LUTD.

g) Consensus Statement

o Imaging of the UUT is NOT indicated in the evaluation of non-neurogenic stress, urgency or mixed UI. [**Level of Evidence 3, Grade of Recommendation C**]

o Imaging of the UUT is indicated in cases of:

a) neurogenic UI with high risk of renal damage (due to high detrusor pressure, e.g. myelodysplasia, spinal cord injury, and low compliance bladders) [**Level of Evidence 3, Grade of Recommendation C**]

b) chronic retention with UI [**Level of Evidence 3, Grade of Recommendation C**]

c) untreated severe POP [**Level of Evidence 3, Grade of Recommendation C**]

d) suspicion of extra-urethral UI by upper tract anomaly [**Level of Evidence 3, Grade of Recommendation C**]

o The choice of the imaging techniques and their sequence depend on the clinical question and their availability. The least invasive techniques should be preferred and should precede the more invasive, also taking into consideration cost effectiveness. [**Level of Evidence 3, Grade of Recommendation C**]

h) Suggested Research Areas

o Prevalence of upper tract deterioration in various UI populations

o Natural history of upper tract damage

o Relation between upper tract dilation, renal damage and bladder function

II. IMAGING OF THE LOWER URINARY TRACT

The use of imaging of the LUT in patients with UI dates back 40 years, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old their clinical value remains at best, unclear.

1. X-RAY IMAGING

Voiding cystourethrogram (VUCG) was the mainstay of x-ray imaging of the LUT but it has been replaced almost entirely by USS because of its ease of use, low cost and availability. While CT has not gained acceptance because of the exposure of ionising radiations, MRI took the lead as the most promising imaging modality because it offered a comprehensive view of the pelvis and enabled visualisation of the position of visceral organ in relation to bony reference points. 3- and 4D USS recently offered volume acquisition with limitations in terms of the volume that can be acquired. Continuous technical development in imaging technology and techniques made this research area particularly interesting.

In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction separating the bladder neck from benign prostatic obstruction although it may play a role in the management of post-prostatectomy incontinence [1]. In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals [2]. The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for reflux [3].

Positive-pressure urethrography has been used for the diagnosis of female urethral diverticula, it was shown to be more sensitive than voiding cystourethrography [4-6] although MRI is the gold standard for the diagnosis of diverticula and planning surgical repair [7, 8].

The rationale for imaging studies of the lower urinary tract in this field derives from the hypothesis that stress UI is caused by urethral hypermobility. This was the theoretical base of the classification of UI published by Green in 1968 and then modified by Blaivas and Olsson in 1998 [9, 10]. Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and imaging techniques aiming at measuring bladder neck displacement during straining have been abandoned. The same applies to outcome research in urinary incontinence where surgery that limits bladder neck displacement does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suites and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The possibility of imaging what was usually perceived during physical examination such as bladder neck mobility or POP increased the usefulness of USS. Research in the field of MRI first looked into the possibility of fast dynamic acquisition to image the displacement of visceral organs during effort to better qualify POP and then moved into morphological imaging of the pelvic organs muscular support to investigate the physiopathology of genital prolapse.

a) Female Cystourethrography

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering UI to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflux, diverticula, fistula, stones and tumours. In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction [1, 11].

The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals [2]. In a study comparing cystourethrography with direct radionuclide voiding cystography and voiding urosonography with contrast medium, voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive [12].

1. Background

History and methodology of cystourethrography in females had been reviewed by Olesen [6]. The technique is now over 70 years old. Voiding cys-

tourethrography with lateral projection was first done by Mikulicz-Radecki in 1931 [13]. The use of a metallic bead chain to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum [14, 15]. In an attempt to combine qualitative and quantitative information regarding the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the nineteen sixties and seventies [16-20].

2. Methodology (projection, positioning and exposures)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and therefore many impair the quality of the examination [13]. Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures [**Figure B 4**]. The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements [21, 22]. However, in VCUG the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g.: coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of short duration and difficult to catch on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively [13]. Squeezing can demonstrate pelvic floor awareness and contraction [23].

3. Combined imaging and urodynamics

Videourodynamics has been by some regarded as the “gold standard” in the evaluation of LUTD [23]. Reproducibility of the combined examination has not been assessed and further the radiation dose has to be considered [15, 20, 24-26]. One study has attempted to compare videourodynamics with saline cystometry [23]. Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamics first. The degree of bladder descent noted on screening was greater than on clinical ex-

Figure B 4:VCUG with digital substraction (courtesy of Dr Carbone, Rome, Italy)

amination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux [1, 11, 14]. Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important to ensure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states [13, 18, 27, 28].

Patients with Parkinson's disease and multiple system atrophy are best evaluated by videourodynamics and sphincter motor unit potential analyses to identify characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open bladder neck at rest and detrusor-external sphincter dyssinergia [29]. Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflux, widening bladder neck and proximal urethra. Narrowing at the level of the membranous urethra can suggest, the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder [also known as the Hinman syndrome]) even in the absence of neurogenic symptoms and signs [30-32]. Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamics have been considered essential. Additionally, children with non-neurogenic voiding dysfunction are found to have a number of abnormalities with videourodynamics [33, 34]. Indications for videourodynamics include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

4. Normal and defective bladder support

The whole issue about the clinical value of VCUG is about the role of defective bladder support in the pathophysiology of SUI in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was inherent to the classification of SUI and the concept that impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains regarding the concept of urethral hypermobility in a modern view of female SUI and this contributed to the decreasing use of VCUG in the evaluation of a standard female patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck **Figure B 5a**. During voiding (**Figure B 5b**) the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone. Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone [35]. Cut off values were usually 115° or more [36, 37];
2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle

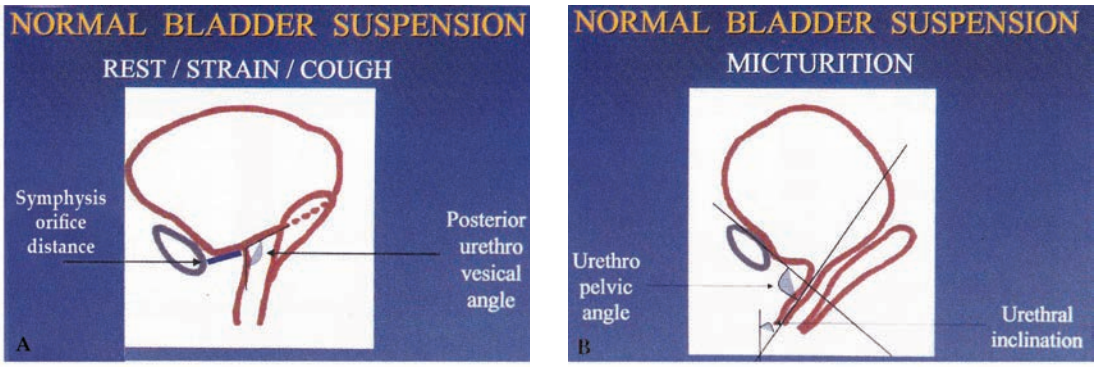

Figure B5: Female Cysto-urethrography 1a: normal appearance on couching, straining and squeezing b: normal appearance on voiding

also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively [37];

3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normal subjects the mean UP is about 95° and the cut off point for bladder descent are values below 70° [13];
4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descent [13];
5. The urethral axis at rest (UAR) and during straining (UAS) (**Figure B 6**) Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovesical junction or a point posterior to that) are important qualitative parameters estimated on straining films [36].

Anterior bladder suspension defects or bladder base insufficiency (BBI) (**Figure B 7**) is defined as SO < 20 mm with a normally positioned vagina

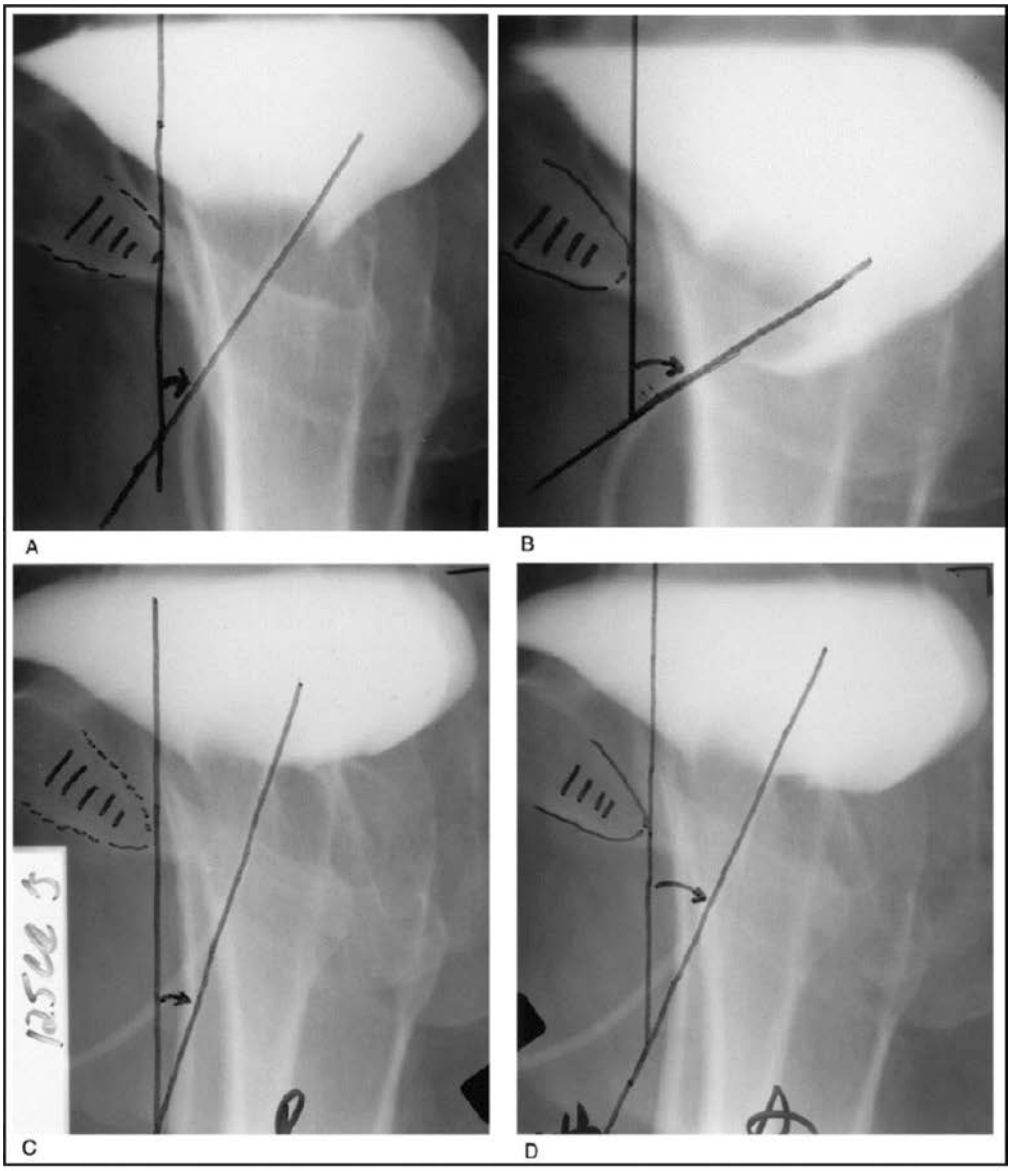

Figure B 6:Example of standing, lateral views on VCUG with 125 mL of contrast within the bladder. (A) Preoperative UAR. (B) Preoperative UAS. (C) Postoperative UAR. (D) Postoperative UAS. The urethral angle is calculated from a reference line drawn through the inferior portion of the pubic symphysis.

at rest, during coughing or micturition and/or funnelling of the bladder base at rest or with coughing. BBI can be graded 1-3, which corresponds to Green's type I descent [13, 38]. The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects (**Figure B 8** are defined as a posterior-inferior bladder displacement and a UP of less than 70° [13]. It corresponds to Gruen's type II [39]. Sometimes (**Figure B 9**) only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R2= 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for SUI, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure [39]. A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system increases when measurements are performed in a more upright position [39].

5. Reproducibility

The observer variation has been evaluated in four university uro-gynecological units (**Table 1**) [23, 36, 40, 41]. The inter-observer agreement was 43-79% and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests [42].

6. Accuracy for the diagnosis of SUI and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. One has to consider that sensitivity and specificity depend on intrinsic factors such as reproducibility (as measured by

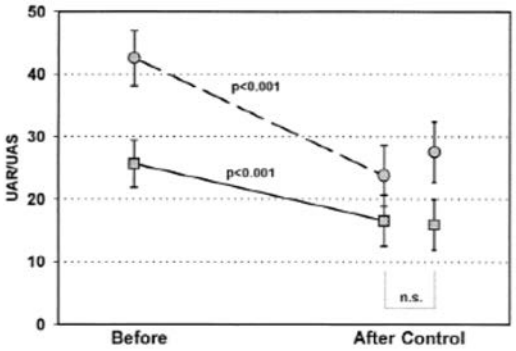

Figure B 9:Mean 6 95% confidence interval for UAR (squares) and UAS (circles) before and after surgical correction compared with age-matched controls. Difference from "before" to "after" was significant for both surgical groups; difference between "after" and "control" was not significant.

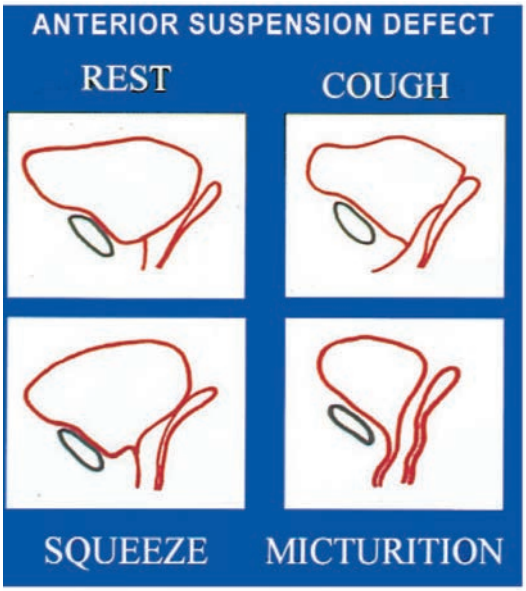

Figure B 7: Female Cysto-urethrography. Anterior bladder suspension defect

Figure B 8: Female Cysto-urethrography. Posterior bladder suspension defect

Table 1: Inter- and intra-observer variation (agreement) on cystourethrography in females with urinary incontinence.

Type of examination, patients and observers	Inter-observer variation	Intra-observer variation
Bead-chain [1] stress & urgency incontinence n°92 3 observers on 5 landmarks	45.8-80.7 %	
VCCU [2] stress incontinence n° 52 1 observer on type of descent	79% 95% c.l. 65-89	
VCCU [3] stress incontinence n° 29 2 observers on type of descent	70% 95% c.l. 75-89	53% 95% c.l. 27-78
VCCU [4] n° 93 stress & urgency incontinence 6 observers on type of descent	43-60% kappa 20-39%	72-99% kappa 57-98%
VCUG [5] Stress incontinence n° 11 2 observers on urethral angle shift from rest to straining	r = 0.83 (p=0.001) for UAR r = 0.82 (p=0.002) for UAS	

intraobserver and interobserver variation) and extrinsic ones such as the characteristic of the patient cohort used to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the 'so called' index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately the diagnosis of SUI is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and also adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult [42].

No consensus has been reached in the peer-review literature as to the lack of discriminant value of VCUG between SUI and continence, the majority of published papers are consistently negative although new promising data have been published [37, 39, 43-45]. The specificity of 5 radiological parameters on static bead chain VCUG was 44-76% and the sensitivity 53-100% [45, 46]. Neither was the degree of SUI correlated with the type or degree of suspension defects [23, 40, 47]. The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colpo-cystourethrography [38, 48]. In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained [45]. Evaluation of the urethral angle at rest and during stress in controls and in patients with SUI and various grades of anterior vaginal prolapse show a significant relationship between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; r2= 0.28). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6 ° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed changes were found to be statistically significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VUCG): UAR and UAS decreased from 48.1° ± 16.5 ° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis

while similar values were found after surgery (**Figure B 10**). This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height (LATH), obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change of LATH values was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively [p<0.001]).

These are the first data supporting the used of standing VCUG as an outcome measured, previous peer-review papers suggested the inability of its technique to distinguish postoperative failures from success [13, 23, 42, 44, 46, 49-52].

7. Comparison of cystourethrography and ultrasonography

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship between X-ray and USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal USS and voiding colpo-cystourethrography has been compared with perineal USS [46, 47, 53, 54]. The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because imaging can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction [11]. Simple and extensive funnelling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies [30].

8. Comparison of cystourethrography and MRI

The introduction of MRI in the assessment of the LUT required adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpocystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension [55, 56]. Although there is an obvious concern about the fact that dynamic MRI

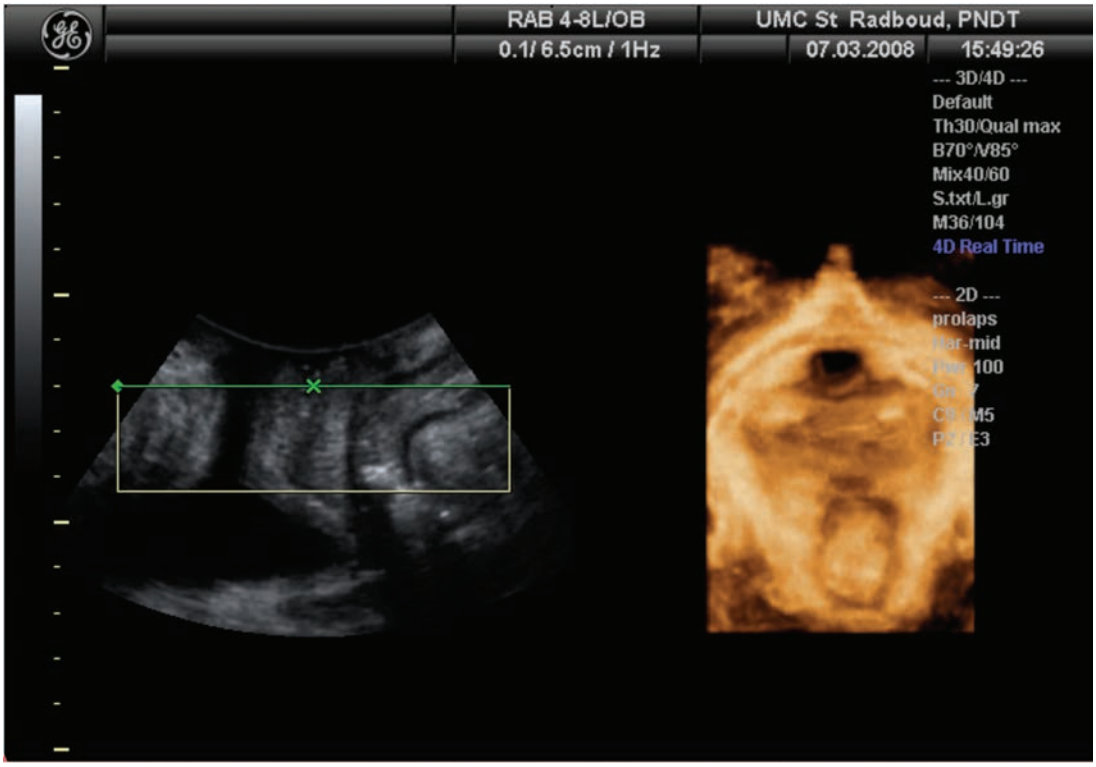

Figure B 10: Perineal midsagittal two-dimensional view and three-dimensional rendered image. Normal anatomy.

imaging is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colpocystourethrography did not showed any significant difference [56].

9. Conclusions

VUCG does not have a major role in the evaluation of the standard female patient with UI confirmatory results on the clinical utility of measuring urethral angle and cystocele height in patients with UI and POP who are scheduled for surgery still missing. Defective bladder support can be diagnosed on VCUG with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency.

10. Consensus Statement

- o Cystourethrography is NOT indicated in primary uncomplicated stress, urge or mixed female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].
- o Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence [Level of Evidence 3, Grade of Recommendation C].

11. Suggested Research Areas

- o Variation of VCUG parameters in patients with SUI +/- ISD and prognostic value for surgical repair.
- o VCUG in re-do surgery for SUI

2. ULTRASONOGRAPHY

Ultrasonography has been used in the evaluation of urinary incontinence as early as 1980 [1]. Over the past three decades the quality of the ultrasound image and its processing has improved beyond what could have been imagined during the 70's. Various new developments, such as the use of contrast medium, colour Doppler, 360 degree transducers and three- and four dimensional imaging have been introduced and have led to more widespread use of ultrasonography in the evaluation of the lower urinary tract and pelvic floor disorders.

A number of studies have reported good correlations between ultrasonography and x-ray in the evaluation of urinary incontinence [2-9] Schenck et al 2011. In particular, the position of the bladder neck at rest and during Valsalva [10] manoeuvre has frequently been compared, and all authors agree on a good correlation. Some authors even found better accuracy for ultrasound [5], especially in obese women [2]. Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination and it is also more acceptable to patients because of the lack of for radiation exposure. However ultrasound itself produces problems by needing to be in direct contact with the patient even during dynamic manoeuvres and the resolution is dependent on the frequency of the probe used. The higher the ultrasound frequency, the better the resolution but there is reduced penetration into the tissues.

a) Types Of Ultrasonography

Different imaging approaches have been used, such as abdominal, transvaginal, transrectal, perineal and transurethral. Synonyms for the perineal approach are transperineal, introital, labial or translabial access, all use a similar method and there does not appear to be a substantive difference between these terms, a common agreed term needs to be decided upon.

Abdominal ultrasonography is generally not considered to be helpful in pelvic floor and urethral imaging because of the acoustic shadow caused by the pubic bones particularly in the obese patient [1]. All approaches in ultrasound have a problem of distorting the tissue being imaged due to compression. With vaginal ultrasonography this risk is probably highest [11], although this has also been denied [12]. Most recent studies report on perineal ultrasonography that allows the visualisation of all three compartments in one image but again compression of the urethra may occur and imaging is impaired with vaginal prolapse or gas in the rectum. The development of three-dimensional ultrasonographic systems has brought increased accuracy to measuring volumes of irregular structures as well as reconstructed images from novel directions and allowing pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 [13]; the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (**Figure B 10**) (see figure in this document). These three two dimensional planes are at orthogonal to each other being the sagittal, coronal and axial planes. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility of reviewing the acquired images from any investigator and the ability to analyse the acquired volume through any plane (similar to CT scans or MRI) (**Figure B11**). This means that the levator ani muscle can be easily visualised. However interest has focused on the absence of the pelvic floor being imaged and a defect being implied. Ultrasound produces images by being reflected by a tissue. These reflective surfaces produce images of great clarity and resolution which are independent

Figure B 11: Perineal midsagittal two-dimensional view. Normal anatomy of the levator ani muscle.

of the ultrasonic frequency. However once the tissue is perpendicular to the direction of travel of the ultrasound waves then axial resolution is effective, this limits the accuracy and the ability for tissues to be imaged. This highlights the importance of testing all ultrasound imaging modalities against a gold standard such as cadaveric dissection or comparing with another medium such as MRI or CT. Four-dimensional imaging involves a volume of tissue being continuously scanned, this inevitably involves a time delay and cannot be "real-time" but incorporates the enormous improvement in speed of three-dimensional systems over the last few years and it makes three-dimensional assessment of the dynamic relation of the pelvic organs on Valsalva manoeuvre and pelvic floor contraction possible.

b) Standardisation

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures below **(Figure B 12a**) [14] whereas others prefer presentation of the cranial parts above (**Figure B 12b**) [15]. All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognisable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position (**Figure B 13)**. Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre [16]. Only a few studies have been performed in the standing position [17]. There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder [18, 19]. Attempts to standardise Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted [12,20]. In one study [17], a peak flow meter has been used, where women were asked to "huff" maximally and to reach the same force during a number of "huffs". It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre [21]. Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been documented and is one of the reasons for the lack of standardisation [21].

c) The Urethra And Bladder Neck

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure

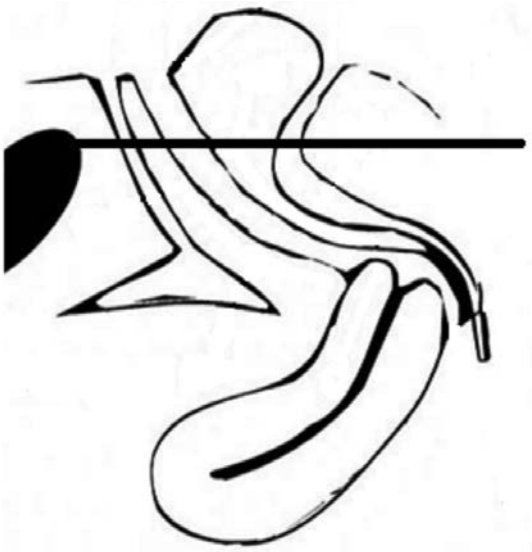

Figure B 12-a: Perineal midsagittal two-dimensional ultrasound view on three compartments and horizontal reference line according to Dietz.

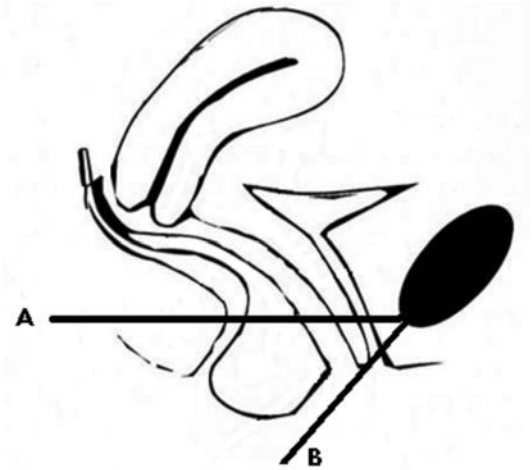

Figure B 12-b: Perineal midsagittal two-dimensional ultrasound view on three compartments and reference lines according to Tunn and Schaer.
A= horizontal reference line
B= central line of the symphysis as reference line for bladder neck descent

becomes hypoechoic. These same structures will become hyperechoic, however, when the fibres are located perpendicular to the beam. Ultrasonography may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner mucosal layer of the urethra will appear hypoechoic (**Figure B10**), these structures cannot be distinguished from each other on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechoic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechoic circular structure in the axial plane as seen on three-dimensional ultrasonography [22,23]. The rhabdosphincter has been found to be thinner dorsally [13], and both ventrally and dorsally [24] by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally [25]. These differences may be due to the approach used to image the structures as well as types of probes applied but this has not been addressed in any study to date.

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated [15, 25, 26]. Intra-urethral ultrasonography has been used for this purpose although complete imaging of the lateral parts of the sphincter are difficult due to the higher frequencies emitted by these probes [27], others have used two- or three-dimensional ultrasonography of the urethra [13, 22, 24, 28,].

Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach [24, 29]. Ultrasound measurement of the female urethra has been found to be reproducible [13, 22]. Sphincter volume may differ significantly when 2D or 3D imaging is used [22]. Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers [28]. A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported [13]; correlations with the urethral pressure profile

Figure B 13: Perineal ultrasound examination in the supine position.

(UPP) have been found [23, 25, 26, 28] but these data could not be reproduced [30]. Ultrasonography imaging during micturition has been explored with the aid of a remote control systems [31]. The use of intra-urethral ultrasonography with rotating probes (360°) has been proposed by various authors although no particular advantages over perineal US could be identified and incomplete imaging appears to be a problem due to the high ultrasound frequency emitted [27, 32-35].

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al. [36, 37].

d) Bladder Neck

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catheterisation (**Figure B 10**). Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (**Figure B 14**). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction away from the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation or bladder neck mobility. Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle. A number of studies have validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported although the clinical value of such measurements is still elusive [4, 12, 38-40]. Normal values of bladder neck mobility have not been defined, since there is a great range in mobility even in young nulliparous women. In one study amongst nulliparous continent women of approximately 20 years of age, the bladder neck descent varied between 1mm and 40mm [41].

Others [38] found an average descent of 15 mm on Valsalva manoeuvre and 8 mm on a cough. Brandt et al. have found an average bladder neck descent of only 5 mm in 16 year old girls [42]. Racial differences have been demonstrated, with white women having greater bladder neck mobility compared with black women [43]. Genetic determination of bladder neck mobility has been suggested [44]. Numerous studies have found greater bladder neck mobility in parous compared with nulliparous women [12, 30, 45-47]. Bladder neck hypermobility, however defined, is considered to be related to stress urinary incontinence [15, 30]. A large number of studies have correlated ultrasonographic findings with urodynamic parameters [47-56]). Specificity and

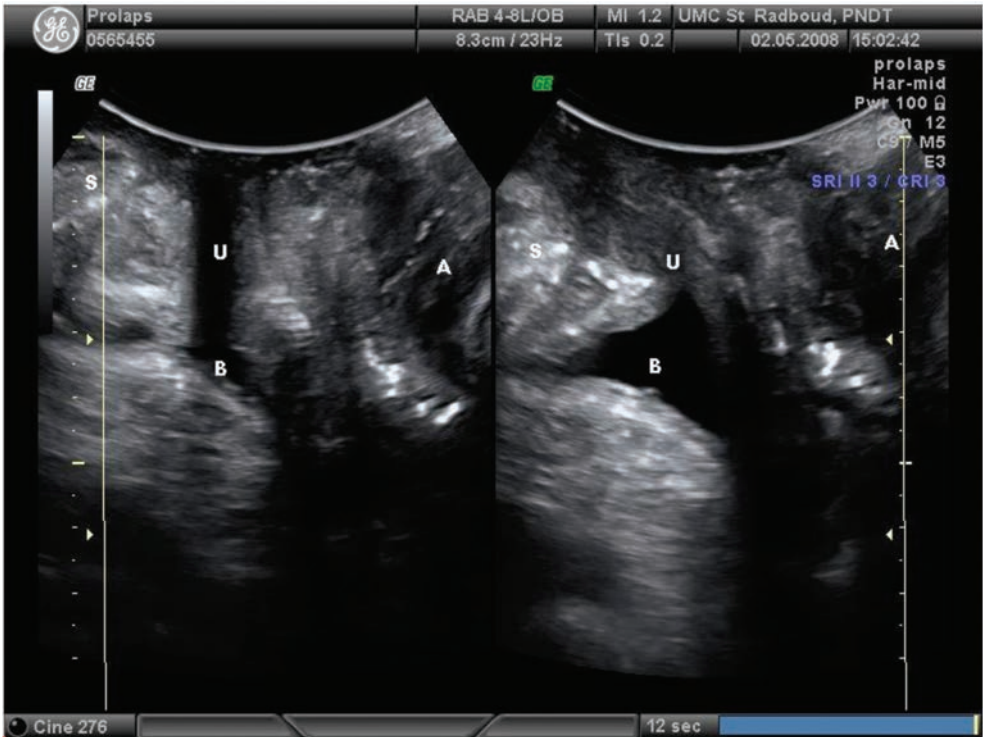

Figure B 14: Perineal midsagittal two-dimensional view at rest and on Valsalva manoeuvre. Bladder neck descent. (S= symphysis pubis; U= urethra; B= bladder; A= anal canal.)

sensitivity of ultrasonography for the diagnosis of stress incontinence were 83 and 68% in one study [50] and 92 and 96% in another study [57]. There is one study which has used ultrasound of the bladder neck movement on coughing and Valsalva as a marker with patients undergoing pelvic floor exercises. In this study the response to treatment was not associated with changes to the bladder neck mobility [58] underlining this is probably an associated phenomenon and not the cause for stress urinary incontinence.

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They were able to demonstrate that the variations in urethral pressure were caused by the activity of the urethral sphincter as well the pelvic floor muscles [59]. The contractions from the urethral sphincter during acute stress events such as coughing are thought to be due to fast contractions. Some studies have used ultrasonography in an attempt to optimise patient management, but despite the abundant literature on the use of ultrasonography in the investigation of women with urinary incontinence, disappointedly, a clinical advantage in terms of patient outcome has not been reported until now [60, 61].

Urethral funnelling can be observed on ultrasonography (**Figure B 15**) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well [62-64]. In a study on stress incontinent women, funnelling was found to be present in nearly all women [63, 65]. Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra [66, 67]. Colour Doppler has, furthermore, been used to visualise the periurethral vasculature in nulliparous women [68] and differences have been described between continent and incontinent women [69, 70] and before and after oestrogen supplementation in postmenopausal women. Doppler velocimetry has recently been used in a study on the vascularisation of the levator ani musculature and a correlation has been found between the absence of an end-diastolic flow and the presence of stress urinary incontinence [71]. The blood flow around the urethra and bladder has been studied with Doppler before and after insertion of tension free vaginal tape and the transobturator tape. The blood flow decreases only after insertion of the tensional free vaginal tape whereas the blood flow was unchanged after insertion of the transobturator tape which may relate to the direction of urethral compression [72].

e) Determination of the Post Void Residual Urine and Bladder Wall Thickness

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine [73-77]. Ultrasonographic data have been compared with residual volumes obtained by in and out catheterisation under ultrasound control and were found satisfactory. However, Khan et al. have

Figure B 15: Perineal midsagittal two-dimensional view. Urethral funnelling.

challenged the methodology of these studies and have found deficiencies in all reports on the topic [78]. A simple formula often used is [Height * Width* Depth](cm) * 0.7= Volume (ml) in which the factor 0.7 is the correction for the non circular shape of the bladder. Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and have been found to be more accurate than standard ultrasound measurements, furthermore they can be used by health care providers with no training in ultrasound imaging[79]. These machines are widely used and are, in general, experienced as reliable enough for clinical use, however, in the case of ascites [80] or an ovarian cyst [81] for example, the estimated urinary volumes can be incorrect, and in post partum women.

Recently the normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml [74]. Ultrasound measurement of bladder wall thickness (BWT) and ultrasound estimated bladder weight (UEBW). Ultrasound measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children [82]. More recently, BWT has been used to predict the outcome of children with primary nocturnal enuresis [82-84]. BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia [85]. Measurement of BWT was also proposed to diagnose bladder dysfunction (detrusor over activity and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infection [86, 87]. Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided [88].

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 +/- 1.1 mm and 3.0 +/- 1.0 mm, respectively were reported by Hackenberg and co-workers [89]. Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) [90]. A small increase of detrusor hypertrophy with age has been reported in both genders [89]. In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS [91, 92].

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A significant difference was shown in patients with DO and USI (6.7 +/- 0.6 versus 3.5 +/- 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively [93]. In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrography or ambulatory urodynamics [94]. In 2002, the same group showed no overlap in the 95% confidence intervals of BWT was shown in patients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO [95]. In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT [96]. Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound estimated bladder weight from three-dimensional ultrasound. An average value of 42 +/- 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder volumes (200 to 400 ml) [97].

Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited. Although data published in the peer review literature on this subject are quite consistent, two discordant papers were recently published from Australia. Blatt and co-worker showed uniform values of BWT measured using an abdominal approach among men and women with non-neurogenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction, this may reflect the thinning of the bladder wall with increasing bladder volume [98, 99, 100]. A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO [101] which could be due to the fact that translabial ultrasound is unreliable [102].

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Ultrasound measurement of BWT and UEBW is an interesting alternative approach that may avoid invasive urodynamics in some patients. [103]. The reduction in bladder wall thickness has been found after the relief of bladder outlet obstruction [104]. The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS [105] and in the evaluation of bladder response to pharmacological treatment [106].

f) Pelvic Floor Muscles

Ultrasonography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound **(Figure B 16**) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze [16, 107] but also the dimensions of the genital hiatus or the posterior anorectal angle can serve this purpose [108]. Comparison with traditional measurements of pelvic floor muscle strength has been performed [107], and good correlations with palpation and perineometry have been found [109, 110]. Ultrasonography has been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre have been found with training [111]. Another research group has reported that the thickness of pelvic floor muscles increased after training [112]. A number of studies have assessed healthy female volunteers to establish normal values [41, 112], and one study has specifically compared elite athletes with normal volunteers [113]. Measurements of the levator ani muscle, with the use of two-dimensional imaging, has been recently described, and although direct comparisons to three dimensional ultrasonography are lacking, the acquired data were comparable [114]. However one study has compared three-dimensional ultrasound of the levator ani hiatus at rest and during contraction in a number of different groups of women with prolapse, urodynamic stress incontinence and asymptomatic women suggesting that these measurements are not sensitive enough to discriminate between different groups [115].

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women with a visual feedback of their exercise [16, 116]. In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography to observe bladder neck movement [16]. This does not appear to produce better outcomes of changes with pelvic floor physiotherapy [117]. The contraction of the pelvic floor muscle just before and

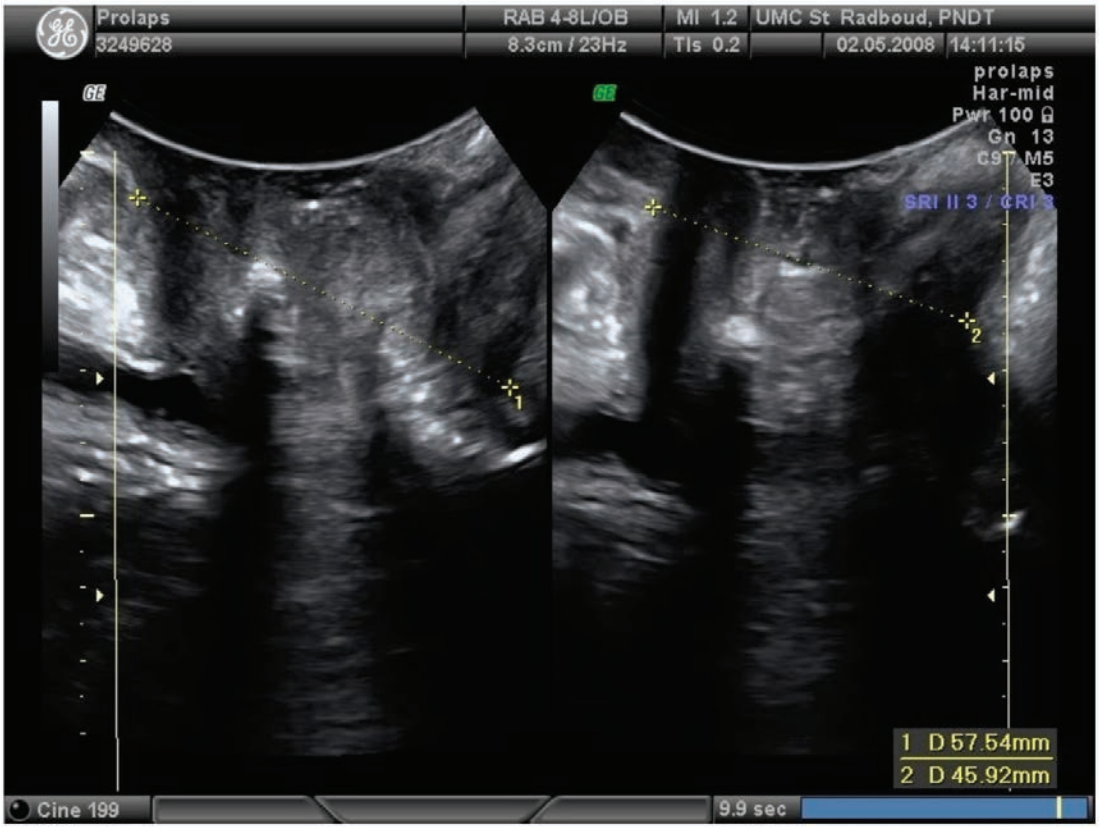

Figure B 16: Perineal midsagittal two-dimensional view at rest and on contraction. Levator contraction with ventro-cranial displacement of the urethra.
Measurement of minimal dimension of genital hiatus (from symphysis pubis to levator ani muscle)

during a cough, “the knack”, can also be visualized [118]. It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (**Figure 17**) [114]. Most studies, however, have used three-dimensional perineal ultrasonography for this purpose [17, 108, 113, 119, 120]. The thickness of the muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test retest and inter observer characteristics [17]. There is a learning curve to measurement of the levator ani hiatus needing over ten sets of scans to perform the measurement. However measurements of the pubic arch were not accurate suggesting that measurements of levator avulsion may require more training [121].

The pelvic floor muscles were found thinner in women with pelvic organ prolapse [15, 114, 122] and with urinary incontinence [123], whereas their genital hiatus was found larger [124] interestingly this finding does not produce a significantly reduced maximal voluntary contraction even with pubovisceral muscle defects [125]. Well trained women have thicker pelvic floor muscles compared with controls [113], and Chinese women had thinner muscles compared with Caucasian women [120]. In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index [120]. Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressure measurements [126, 127]. A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction [128]. Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction [129]). Others [130] have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles.

1. Levator Trauma

Using three dimensional transperineal ultrasound avulsion of the levator ani muscle from the symphysis pubis has been described in up to 36% of parous women [131]. The integrity of the attachment of the pelvic floor muscle to the symphysis pubis can be visualised (**Figure B 11 and B 18a**).

A systematic review of diagnosing pubovisceral avulsions on ultrasound and MRI has been published which showed an association with pelvic organ prolapse and recurrence after surgery. However there was no association between pubovisceral avulsions and urinary symptoms or anorectal dysfunction [132]. This is similar to results from MRI studies, where it has been shown that the risk of pelvic organ prolapse further increases when the levator injury goes together with vaginal architectural distortion [133, 134].

Although these defects have recently been identified during labour, it is not known whether there is any reasonable (preventive) treatment for these women [135, 136]. There is an increase of the occurrence of levator muscle trauma with maternal age at first delivery [137]. There was a strong correlation between the presence of levator muscle avulsion and poorer muscle strength [138]. It has, however, been shown that the correlation between the clinical assessment (palpation of the muscle) and three-dimensional ultrasonographic assessment of muscular defects was only poor [139], as well as the inter-observer repeatability of the palpation of defects [140]. A quantification method for levator muscle defects on ultrasonography (tomographic ultrasound imaging) (**Figure B 18a and b**) has been described [119]. Another parameter, which has been found to be related to the severity of pelvic organ prolapse, was the size of the inner circumference at minimal hiatal

Figure B 17: Intravaginal 360 degree ultrasound imaging.
Levator ani muscle, urethra and anal sphincter complex.

Figure B 18-b: Tomographic ultrasound imaging in oblique axial plane. Bilateral avulsion of the levator ani muscle from the symphysis pubis.

dimension of the levator ani muscle on Valsalva manoeuvre [114, 119, 135]. The area of the levator hiatus on Valsalva manoeuvre ranges from 6 to 36 cm2 in nulliparous women, with an outlier of almost 50 cm2 in a young nulliparous athlete [113, 124]. An area of more than 30 cm2, 35 cm2 and 40 cm2 on Valsalva manoeuvre has been described as mild, moderate and severe ballooning of the genital hiatus respectively (**Figure B 19**) [141]. The assessment of the levator hiatus has been shown to be a reproducible measurement [17, 131], whereas the reproducibility was less for muscle diameter measurements [17, 108, 124].

Comparisons of the hiatal diameters and hiatal area as measured by three-dimensional ultrasonography and MRI revealed good correlations, especially for the measurements at rest. The correlation for hiatal diameter at Valsalva manoeuvre was lower, which is most likely due to the difficulty to reach the correct plane of the levator ani muscle on MRI [142]. However at rest using MRI to alter the angle of acquisition plane has been shown to change the area of the levator hiatus by 10% [143]. This has been supported by subsequent papers showing a good inter and intra-observer relationship when measuring the levator hiatus with ultrasound and MRI [144] and even with interdisciplinary readers [145] though the later group did find only fair agreement when measuring the anorectal angle with ultrasound. The width of the levator ani hiatus on 3D transperineal ultrasound has been found to wider in black women than white women and the urethral sphincter volumes were significantly larger in black women than white women [146].

The presence and clinical relevance of paravaginal defects represent a controversial issue amongst urogynaecologists, and there is a lack of scientific proof for the concept. In a study by Reisinger et al., an echogenic layer in the lower anterior vagina, which was thought to be a part of the endopelvic fascia, could be identified reproducibly in nulliparous and parous women by transrectal three-dimensional ultrasonography [147]. According to more recent insights, however, previously described paravaginal defects with loss of the H-shape of the vagina in the axial plane on three-dimensional ultrasonography [138, 148, 149] are likely to represent the detachment of the levator ani muscle from the symphysis pubis [150]. However in a study comparing ultrasound and MRI to assess levator avulsion there was only a moderate correlation with ultrasound showing a higher

Figure B 19: Perineal three-dimensional rendered image. Ballooning of the genital hiatus

number of complete avulsions and MRI showing a higher number of partial avulsions [151]. In an attempt to increase validity of the levator avulsion diagnosis minimum criteria have been set [152], but even with these more stringent rules two out of three normal women were considered false positives where they were thought to have full avulsions. It is important to note that MRI studies tend to find thinning or aplasia rather than avulsion perhaps indicating that transperineal ultrasound may not have the resolution to visualise very thin levator ani muscles [153].

g) Pelvic Organ Prolapse

In cases of mild and moderate pelvic organ prolapse, perineal ultrasonography can be used, for the investigation of the prolapse. Ultrasonography should, however, only be used in addition to the patients history and clinical examination. In cases of severe pelvic organ prolapse, ultrasonographic assessment is not possible due to transducer dislocation by the prolapse. The ultrasonographic imaging of the anterior compartment (i.e. bladder, bladder neck and urethra) is the easiest to perform, and the majority of scientific studies deal with this compartment (**Figure B20**).

Correlations with clinical examination [154, 155] are also highest for this compartment. Reproducibility of ultrasonographic imaging of prolapse in the anterior compartment were shown to be good [155]. This reproducibility has not been studied for the other two compartments until now.

In studies amongst 83 and 117 women with the uterus in situ, the uterus could be visualized on perineal ultrasonography in 82% and 97% of cases, respectively (**Figure B 21**) [155, 156].

A number of studies have focused on the posterior compartment [157-165]). The distinction between enterocele (**Figure B 22**) and rectocele (**Figure B 23**) is known to be difficult on clinical assessment. In these cases, two-dimensional ultrasonographic imaging in the midsagittal plane can be helpful. The ultrasonographic visualisation of an enterocele has been confirmed with defaecography as well as intraoperative findings [157]. It has not been shown, until now, however, whether this extra ultrasonographic investigation indeed leads to superior clinical outcomes of prolapse surgery. Interestingly anterior compartment prolapse is related to levator ani area whereas posterior compartment prolapse is not as well as prolapse symptoms not being associated with levator ani hiatus area [166].

In a study on ultrasonography of the posterior compartment a differentiation between true rectocele, enterocele and perineal hypermobility has been made [160]. Intussusception can also be visual-

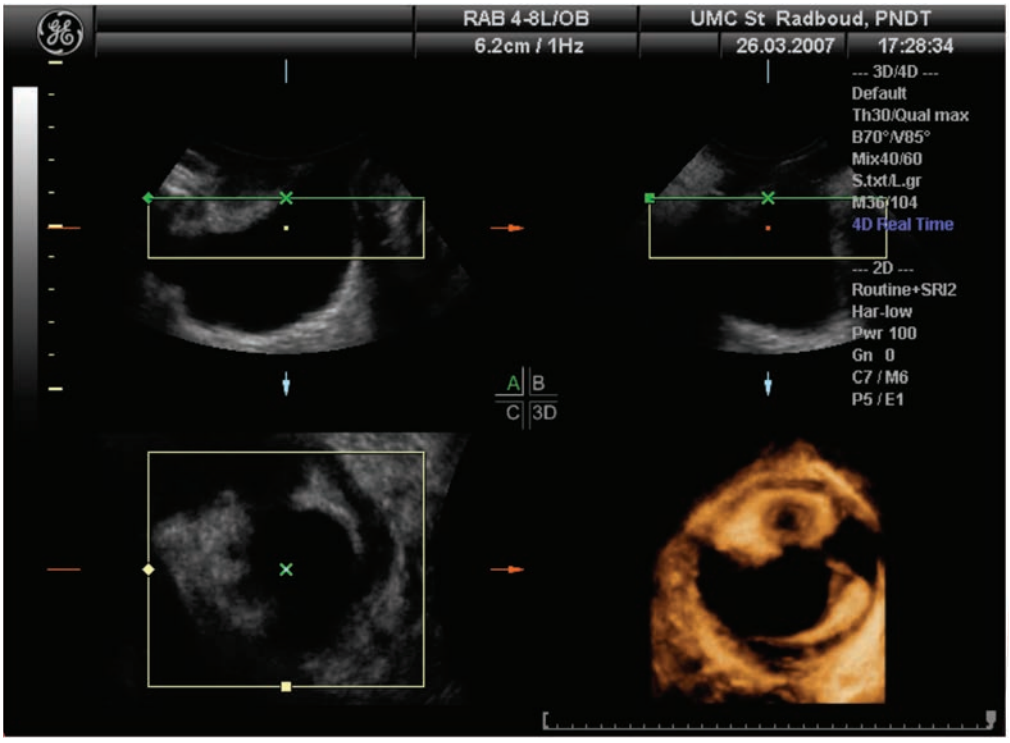

Figure B 20: Perineal midsagittal [left upper], coronal [right upper] and axial [left lower] two-dimensional view and three-dimensional rendered image [right lower].
Cystocele.

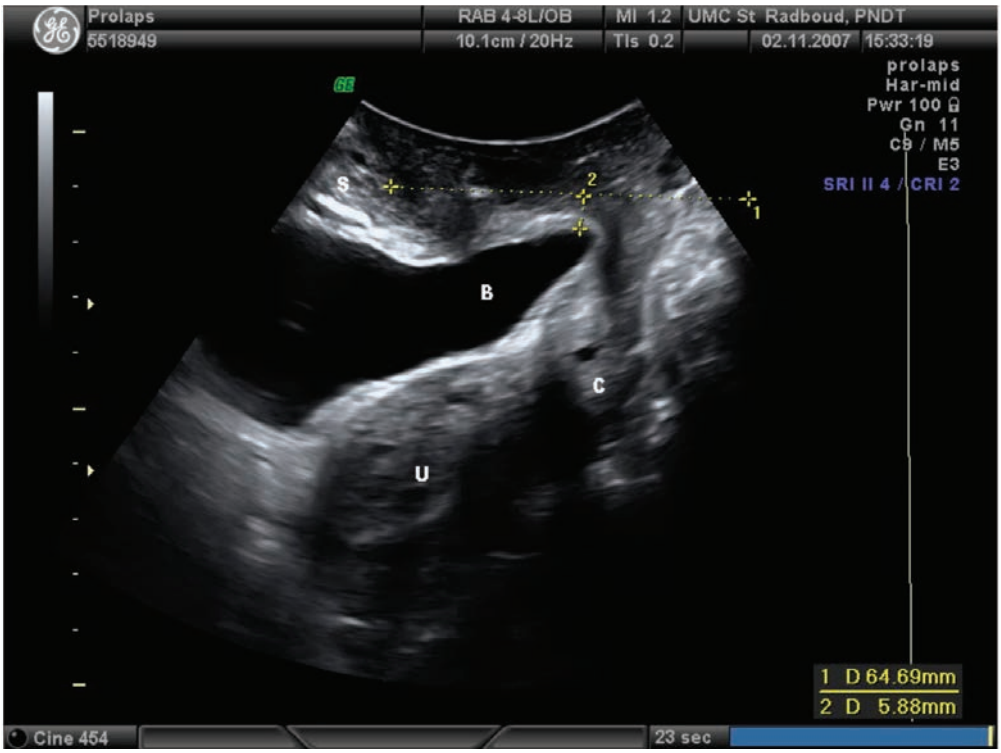

Figure B 21: Perineal midsagittal two-dimensional view. Cystocele and descending uterus. (S= symphysis pubis; B= bladder; U= Uterus; C= cervix.)

Figure B 22: Perineal midsagittal two-dimensional view and three-dimensional rendered image. Enterocele. (S= symphysis pubis; B= bladder; E= enterocele; R= rectum; A= anal canal.)

ised on ultrasonography [167]. Perineal hypermobility and an enterocele was seen as a descent of the rectovaginal septum or abdominal contents on Valsalva manoeuvre respectively, below a horizontal line through the inferior margin of the sympysis pubis (see below for more information on these measurements). Ultrasonographic staging was significantly correlated with clinical staging and the presence of symptoms of obstructed defaecation [15, 161]. In one third of the patients with clinically diagnosed rectocele, however, no ultrasonographic abnormality could be found. As far as interrater reliability was concerned, two expert ultrasonographists have reached moderate to good interrater reliability for the detection of a rectovaginal septum defect, descent of rectal ampulla, and the depth and width of a rectocele [160]. In one study, rectocele and perineal hypermobility were present in nulliparous women in 12 and 13% respectively the significance of these findings has not yet been determined [162]. The posterior anorectal angle, which is the angle between the anal canal and the posterior rectal wall, can be measured at rest and under dynamic circumstances such as straining and squeezing. A number of studies have compared these findings with defaecography and found in general a good correlation [164, 165, 168] but one study found poor inter-rater reliability [146].

1. Quantitative Assessment Of Pelvic Organ Prolapse

In the quantitative assessment of prolapse in the various compartments, a reference line, such as the hymen in POPQ, is needed. For ultrasonography, a horizontal line drawn from the inferior margin of the symphysis pubis is the most widely used reference line for this purpose. A disadvantage of this line is that there is only one fixed point through which the reference line can be drawn and the horizontal line may change with the rotation of a handheld transducer.

The effect of rotation is obviously increased with increasing distance from the fixed point, and consequently there is greatest error in the posterior compartment [155]. Although this problem has been overcome in research settings with the use of motion tracking systems, at the moment this is not a realistic option for routine use in clinical practice [169]. For quantitative assessment of rectoceles, the depths of the rectocele as measured in relation to a line through the anterior anal canal, may be more useful as compared with the descent in relation to the horizontal reference line [170].

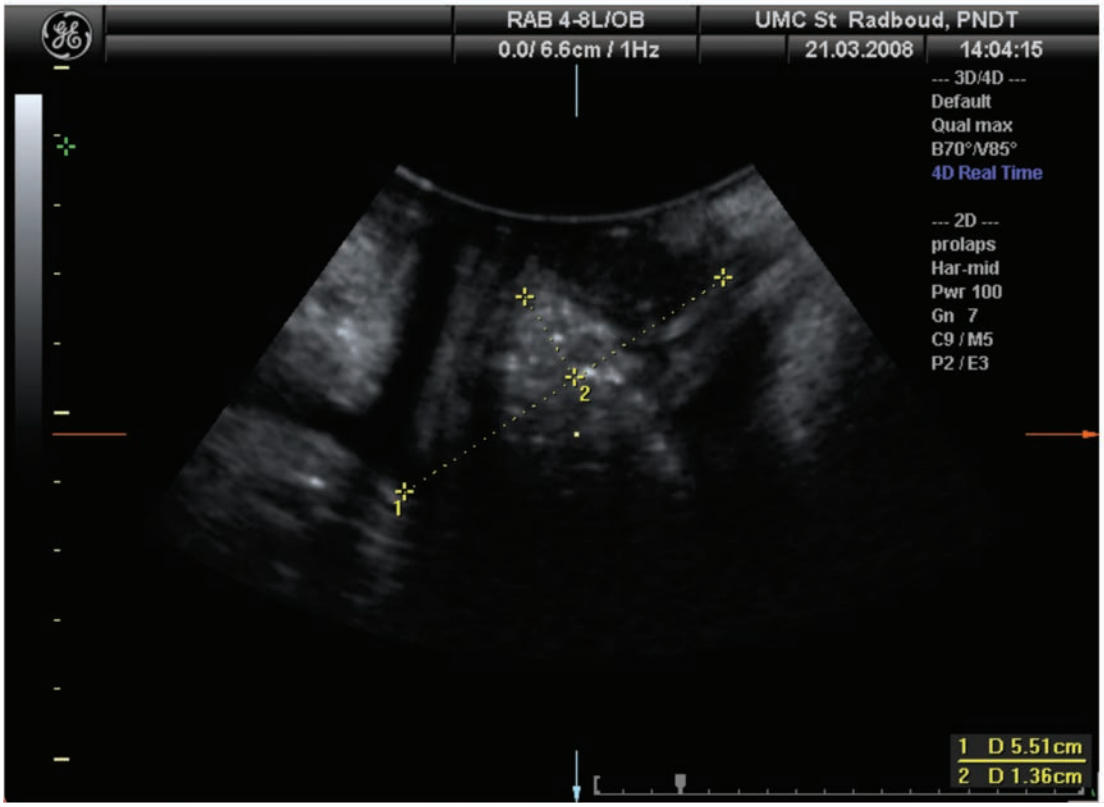

Figure B 23: Perineal midsagittal two-dimensional view.
Measurement of the depth of the rectocele, perpendicular to a straight line through the anterior border of the anal sphincter complex, i.e. 14 mm.

Since pelvic organ prolapse can be visualised well with the use of ultrasonography, it raises the question whether this assessment modality is superior to others, such as clinical examination. In a recent study on the relationship between prolapse symptoms and the most dependent point of the prolapse on POPQ and on ultrasonographic assessment, POPQ performed better in the prediction of prolapse symptoms with increasing stages of prolapse [170]. This finding has been replicated in all compartment underlining the superiority of clinical assessment over ultrasound [171]. In a previous study, where only women with a single compartment prolapse were studied, the area under the receiver operating curve was, however, as good as 0.86 and 0.82 for the anterior and posterior compartment respectively [172]. In both studies the cut-off value for symptomatic prolapse averaged 15 mm below the horizontal reference line through the symphysis pubis. Larger anterior vaginal wall prolapses do have larger levator ani hiatuses and are more likely to have avulsions (69% compared with 35%) [173].

As far as dynamic MRI and X-ray defecography are concerned, there are only a few studies available as yet, on comparisons with ultrasonography. For enterocele detection in women with obstructed defaecation, perineal ultrasonography has been compared with X-ray defaecography, but not with the clinical findings [164]. In the women in whom enterocele had been detected by either method, the enterocele was detected by both ultrasonography and X-ray in 71% of women. In this study, perineal ultrasonography showed more severe stages of enterocele compared with X-ray defaecography. In another recent study from a different research group, X-ray defaecography has been compared with perineal ultrasonography using a vaginal probe in women with impairment of the posterior pelvic floor. Good to excellent concordance has been found for the assessment of the anorectal angle, rectocele and intussusception. The authors claimed, however, that rectoceles with a depth less then 20 mm could not be detected on ultrasonography [159], which is discordant with most other publications on the topic and as well as the authors' experience.

h) Ultrasonography In Relation To Pregnancy And Delivery

Vaginal delivery is commonly accepted as the major risk factor for the development of pelvic organ prolapse later in life. In nulligravid women, there is a wide variation in pelvic organ descent for all three compartments [128, 156, 174-176]. In a study of 169 women who underwent ultrasonography during and after pregnancy, a significant increase in pelvic organ mobility (downwards displacement) was found in all three compartments [177]. The increase in mobility was significantly correlated with the length of second stage of labour and the mode of delivery. The greatest mobility was found in women who underwent an operative vaginal delivery, but no association was found with the gestation at delivery, length of the first stage of labour and birth weight, although birth weight reached borderline significance. In a similar study, focussing on the posterior compartment in 52 nulliparous pregnant women, 8 women developed de novo true rectoceles, and the descent of the rectovaginal septum increased with 22 mm for the entire group, which was statistically significant [178]. On the other hand, in a study amongst 207 women, of whom half of the women had a clinically diagnosed rectocele, no relation has been found with (vaginal) parity, and only a weak correlation has been found with age for a posterior vaginal wall prolapse as assessed with ultrasonography [160]. This suggests that the effect of vaginal parity on pelvic organ descent, is most evident in the anterior and central compartments, and may have another pathophysiology compared with the posterior compartment [177]).

Concerning bladder neck descent, it has been shown that the first delivery caused the most marked changes compared with the subsequent deliveries, with the most marked changes with forceps delivery [179].This is supported by two different research groups, who have reported that an increased antenatal ultrasonographic bladder neck descent was associated with normal vaginal delivery [180, 181]. Furthermore, vaginal delivery was strongly associated with a larger, and more distensible antenatal levator hiatus [180]. The underlying reason remains hypothetical, but more antenatal laxity of the structures may allow for a smoother delivery. Women with increased bladder neck mobility, however, also have an increased risk of de novo urinary incontinence post partum [20] but this outcome can be halved by antenatal pelvic floor exercises [182]. Avulsion of the levator ani muscle from the symphysis pubis, as outline above, is typically found in vaginally parous women only (**Figure B 18b**) [131, 183, 184]. It has, furthermore, been shown that a higher maternal age at first vaginal delivery is strongly related to an increased risk of these avulsions [131, 184]. Mode of delivery has a strong association with the incidence of levator ani injury such that vaginal delivery 15.4% are affected, 33.3% after ventouse delivery and 71.4% after a forceps delivery but there were no levator injuries detected in the Caesarean section group [185], similar findings have been reported by other groups [186-189]. The timing of the levator ani damage appears to be as the head crowns [190]. The levator ani hiatus has been reported as enlarging after vaginal delivery [191, 192] and this enlargement being maintained for up to three years later [193] but other groups have not found it enlarged nine months after delivery compared with antenatal measurements. However forceps delivery did lead to long term enlargement of the levator ani hiatus [194]. The risk of levator ani avulsions increased with enlarged head circumference and prolonged second stage in labour [195].

i) Pelvic Floor Surgery

Ultrasonography has been used during anti incontinence surgery with the aim of obtaining optimal results from surgery, for example during Burch colposuspension [196, 197]. On an individual basis, the bladder neck was lifted between 1 mm and 10 mm. The authors have obtained excellent results with a 94% continence rate after 1 year, but unfortunately no control group was incorporated in the study. Levator ani avulsions have been found to be associated with persistent vaginal prolapse even after attempted surgical repair [198].

1. Slings and Meshes

Monofilament meshes, for example polypropylene meshes, are easier to visualise on ultrasonography compared with multifilament meshes, such as IVS [199]. Ultrasonography has been widely used to localise the exact position of tension free midurethral tapes (**Figure B 24**) [180, 200-203]. The tape is generally easily visible as an hyperechogenic structure under the urethra and is easy to recognise, which contrasts with the poor images of polypropylene on MRI [204]. Exact midurethral position of the tape is not essential for proper function [205]. Despite the fact that the tape was located in the midurethra in only two-third of cases, this had no relation to postoperative continence status [206]. During Valsalva manoeuvre, the tape moves in a semicircle movement around the inferior margin of the symphysis pubis [207]. This results in a position closer to the symphysis, which consequently leads to a certain degree of mechanical compression during Valsalva manoeuvre. Another mechanism of action is kinking of the urethra around the tape [208]. A number of studies have looked at transobturator tape and compared these with retropubic tapes [199, 209-212]. Two studies could not detect any differences between the two types of tape [199, 212], whereas in the other two studies [209, 211], subtle differences with no apparent clinical consequences were found.

Imaging both tension-free and transobturator tape procedures during straining show a reduction in the diameter of the hypoechoic urethral core and the diameter became significantly smaller only in the successful procedures [213] and a reduction in the symphysis pubis to tape distance led to continence [214]. Other authors have suggested optimal positions of the tape being between the distal third and middle of the urethra with a tape-urethral distance of 2mm, greater than 3.9mm distance led to failure of the procedure. The tape to urethral distance can be reliably assessed using 4D ultrasound [215]. Midurethral tapes impinging on the urethra has been reported as being associated with voiding difficulty and the “V” shape of

Figure B 24: Perineal three-dimensional rendered image. Polypropylene mesh (TVT-O) after one-sided incision of the tape.

the tape was the same regardless of the insertion method (ie TOT compared to TVT) [216]. Tapes sited around the midurethra resulted in a reduction in flow rate compared with a distal tape position under the urethra which did not change flow rates [217] and this positional information has been used to determine the management of de novo symptoms after surgery [218].

The bladder neck is displaced during insertion of a midurethral by using a rigid guide during insertion of a tension-free vaginal tape. Ultrasound has been used to determine that the bladder neck is moved by 1.4cm by this technique [219]. Recently, ultrasonographic localization of polypropylene mesh as used in prolapse surgery has been described (**Figures B 25 and B 26**) [220]. These meshes are usually easily visible on ultrasonography. It appears that the ultrasonographic appearance of the mesh is significantly shorter and narrower than the size at implantation within six weeks of the procedure [221]. It is unclear whether this is due to shrinkage of the mesh or represents difficulties in visualising the full extent of the implanted mesh. The failure of mesh to support vaginal prolapse was associated with mesh shrinkage [222, 223].

The differentiation between recurrent herniation and the detachment of the mesh arms from the pelvic sidewall for example, will aid in the better understanding of the mode of action of these meshes [224].

2. Bulking Agents / Injectables

Periuretral bulking agents/injectables, such as microparticulate silicone (Macroplastique), various gels (e.g. Durasphere), and collagen, can be visualised by imaging techniques. For MRI, an overview of appearances of periurethral bulking agents is already available [225]. On ultrasonography, the injectables appear hypoechoic after injection, and become more hyperechoic over time due to dehydrogenation. Good intra-observer variability of repeated measurements of periurethral collagen volumes have been found [226].

The location in relation to the bladder neck and a circumferential distribution of collagen injectables around the urethra, as well as the height and volumes of the injected periurethral collagen bumps, were associated with the treatment success of periurethral bulking agents [226-228]. Although the volume range was wide, a collagen volume of 2.8 cc on three dimensional ultrasonography has been assessed as optimum volume from a continence point of view. Poon et al. have published a decision tree, in which a combination of the patients´ symptoms after collagen injection and the configuration and volume of the periurethral collagen on three-

Figure B 25: Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior vaginal wall (Prolift anterior).

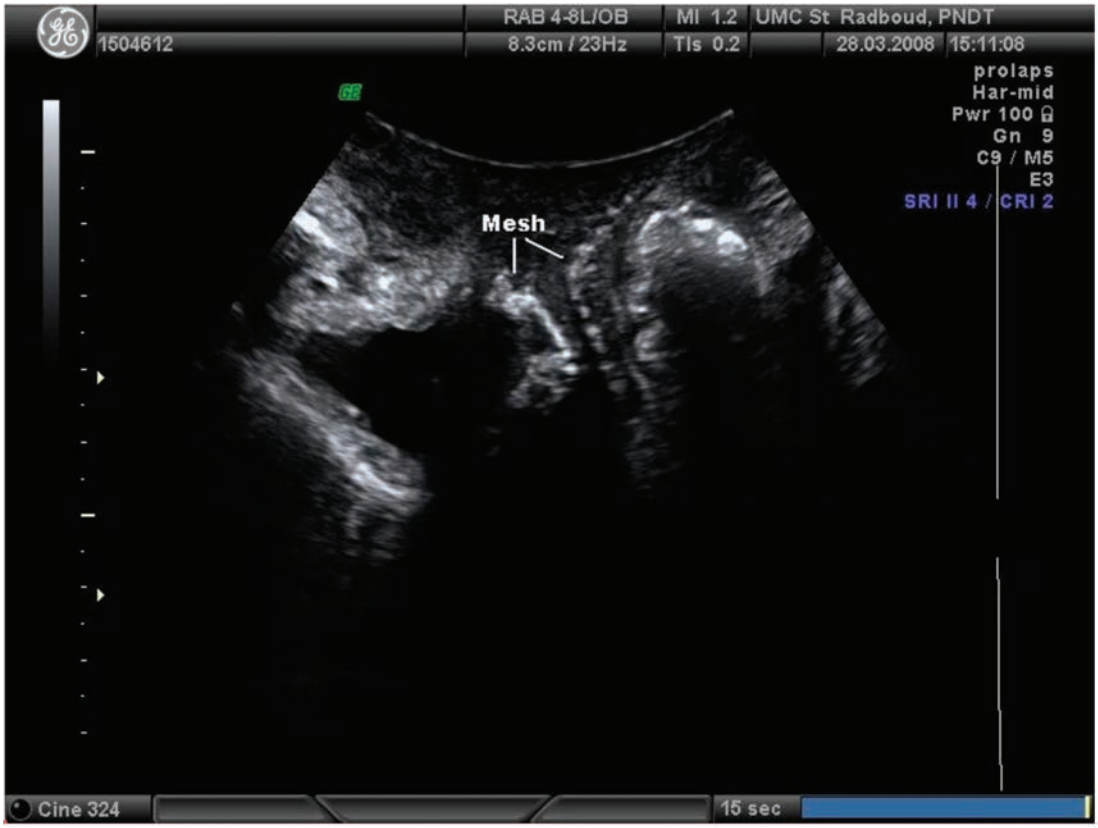

Figure B 26: Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior and posterior vaginal wall (Prolift).

dimensional ultrasonography, assist in the decision for further treatment of women with intrinsic sphincter deficiency [226]. In this algorithm, women with asymmetric deposition and/or low collagen volumes were offered further treatment with injectables as this is associated with failure [229].

Ultrasonography has not only been used for follow-up, but also during placement of periurethral injections. Transurethral ultrasonography-guided injection of autologous stem cells has been used in women and men with stress urinary incontinence. The technique allowed precise injection of the myoblasts directly into the rhabdosphincter, and was more effective in the resolution of incontinence compared with urethroscopic guided collagen injectables in the submucosa in a randomized controlled trial [230, 231]. The use of stem cells in the management of urinary incontinence is of great interest although the subject remains controversial and confirmatory studies are eagerly awaited.

j) Conclusions

Research in US imaging of the pelvic floor has flourished over the last decade although the clinical benefit of it remains uncertain. Standardisation of imaging techniques and terminology are eagerly awaited. Imaging of pelvic floor muscle in relation to POP is a promising area because of the possible insight into the pathophysiology of the condition and treatment outcome. Research suffers from a lack of coordination among different research groups and a more structured approach to research on imaging of UI and POP is advisable.

k) Consensus Statement

- Ultrasound is not recommended in the primary evaluation of patients with urinary incontinence and/or pelvic organ prolapse (rectal prolapse is dealt with in a different section). [**Level of evidence 3, Grade of recommendation C**]
- Ultasound is an optional test in the evaluation of patients with complex or recurrent urinary incontinence and/or pelvic organ prolapse. [**Level of evidence 3, Grade of recommendation C**]

l) Future Research Areas

- Standardisation of terminology of pelvic floor US imaging
- Internal and external validity of techniques of pelvic floor imaging
- Confirmatory studies to validate previously published evidence on imaging of UI and POP

o Accuracy of US diagnosis of levator ani injury

o Prognostic value of preoperative US imaging and outcome of POP surgery

o Health technology assessment of pelvic floor imaging in the management of UI and POP.

3. MRI (THE EVOLVING ROLE OF MRI IN THE ASSESSMENT OF THE FEMALE PELVIC FLOOR).

The role of magnetic resonance imaging (MRI) in evaluating pelvic floor disorders has been established in recent years and continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MR can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MR imaging, equipment and software have significantly improved image quality and now MRI provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to see how this imaging might result in a better understanding of these diseases and improve their diagnosis and management.

Although women might present with symptoms isolated to one of the pelvic compartments, they often have concomitant defects in other compartments or pelvic structures. In these women, imaging can provide information to extend what can be determined on physical examination [1]. Furthermore, surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and inadequate diagnosis and staging of pelvic floor deformation and dysfunction [2]. Accurate diagnosis of coexisting abnormalities is therefore essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical examination, the sensitivity and specificity of the pelvic examination in diagnosing various forms of pelvic floor prolapse is low [3] [4] [5]. Ultrasound and fluoroscopy have been used to improve diagnosis [6] [7] and the role of MRI in pelvic floor dysfunction is rapidly developing. A recent systematic review suggests that prolapse assessment on dynamic MR imaging may be useful in the posterior compartment, although clinical assessment and dynamic MR imaging seem interchangeable in the anterior and central compartment [8].

There is now a robust literature indicating that MRI provides detailed images of bladder neck and urethral mobility, rectocele, cystocele, enterocele and uterine prolapse, in a single non-invasive study without exposing the patient to ionizing radiation [9] [10] [11] [12] [13] [14] [15] [16] [17] [18]. MRI also provides a multiplanar thorough evaluation of pelvic organs including the uterus, ovaries, ureters, kidneys, and levator muscles, as well as the urethra, that is unavailable by any other imaging modality [11] [13] [14] [15] [16] [17] [19] [20]. MRI can identify ureteral obstruction, hydronephrosis, and uterine and ovarian pathology. In addition, MRI remains the study of choice for the evaluation of urethral diverticuli.

The following measurements using MRI in urogynecology and female urology have been highlighted in the recent IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction [21]:

(a) Bladder neck and cervical descent/mobility:

- Position of bladder neck and cervix at rest and on Valsalva.
- Pubo-coccygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers they should be clearly described.

(b) Intercurrent pelvic pathology: For example, fibroids, ovarian pathology.

(c) Uterine version: Anteverted or retroverted; flexion at the isthmus.

(d) Bladder abnormalities: For example, tumor; foreign body.

(e) Urethral abnormality: For example, diverticulum.

(f) Postoperative findings: For example, bladder neck mobility.

(g) Pelvic floor measurements/levator defects: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.

(h) Descent of pelvic organs.

This article is an update to the ICI article on the role of MRI in assessing the female pelvic floor [2009] and provides a current review of where we are in evaluating the role of MRI in understanding the causes and treatment of pelvic organ prolapse.

a) Technique

The evolution of MRI is partly due to new hardware implementation (3Tesla magnets, large magnet sections and opne magnets) but largely to software development in the sense on new sequences that open novel possibilities in the field of functional and dynamic imaging.

1. Conventional MRI

Standard MRI consists of two dimensional image acquisitions. Usually conventional T1 images and spin echo T2 weighted images are obtained. Proton density T2 weighted scans provide excellent soft-tissue definition [**Figure B 27**]. However, the long imaging time of conventional MRI hampers its ability to evaluate the movement of organs that are characteristic of POP.

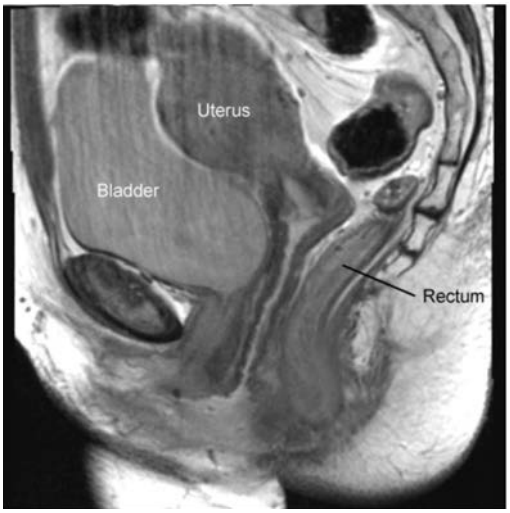

Figure B 27: Sagittal mid pelvic section showing anatomical detail visible in static images made with Proton Density sequence.

2. Ultra Fast Image Acquisition And Mr Sequences

Pelvic organ movement during Valsalva is identifiable using very fast single-shot MR sequences and the technical aspects have been summarised in our prior report [**Figure B 28**] (ICI 2009). [15] [16] [22] [23]. These sequential images are obtained approximately once per second, either as a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. Most pelvic floor details can be seen without the need for bowel preparation, premedication, instrumentation or contrast medium but often, especially with MR defaecography, ultrasound gel or other suitable agents are used to enhance visibility of the rectum and vagina. The MRI torso coil is centered at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spin echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnoea with the patient relaxed and during various degrees of progressive abdominal straining.

Since the time of the last report, continued development of techniques have occurred to allow visualisation of the dynamics of pelvic organ during increases in abdominal pressure. Steady-state free precession gradient-echo imaging provides an alternative T2-like imaging contrast (T2- and T1-weighted imaging) with robust signal and a rapid acquisition time of less than 1 second, thereby permitting near real-time continuous imaging. This is an improvement on the HASTE approach that requires 1–2 seconds between acquisitions to allow T1 recovery; therefore, real-time imaging is not possible. Comparisons of the degree of POP shown on dynamic true fast imaging with steady-state precession (FISP) versus HASTE sequences in symptomatic patients reveal a greater degree of prolapse in all three compartments with a dynamic true FISP sequence. Near real-time continuous imaging with a dynamic true FISP sequence may therefore be useful to evaluate pelvic floor dysfunction in addition to dynamic multiplanar HASTE sequences [24).

During a typical study of pelvic organ movement two sets of images are obtained. The first set consists of static sagittal and para-sagittal images covering the pelvis from left to right sidewall. These images are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor [15] [16] [22] [23]. The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated [25] [26]. The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds.

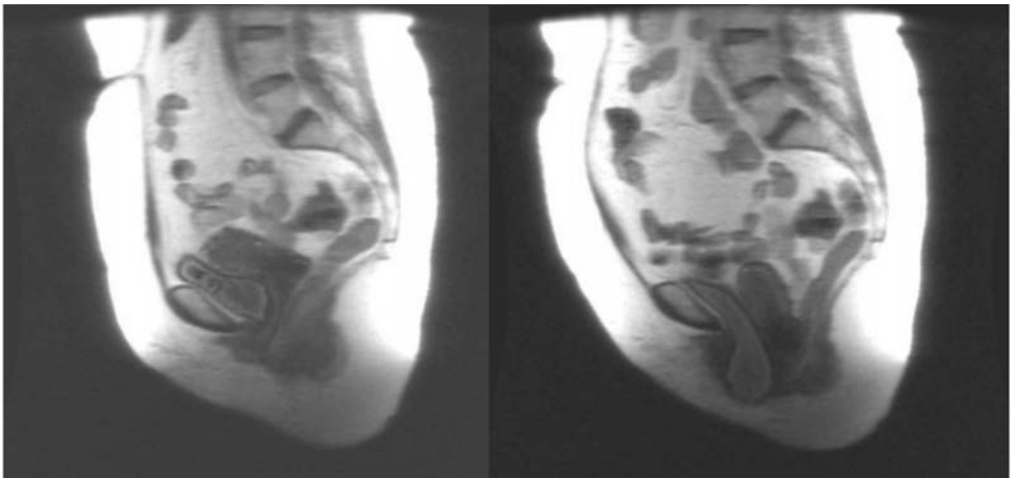

Figure B 28: The rest and strain image taken from a mid-sagittal dynamic MR sequence revealing cystocele and uterine descent using SSFSE sequence.

The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse. Images can then be looped for viewing on a digital station as a cine stack.

Dynamic MRI allows detection of POP that may not be evident on conventional static sequences, as it permits both structural and functional evaluation. For example, in women with lower urinary tract symptoms evaluation of the urethra may be of added value. [27] There has been further clarification of how the conduct of the examination can affect what is seen. For example, the first time a woman performs a Valsalva maneuver, she may not get the prolapse to protrude to its maximal extent. Tumbarello et al [28] found that 40% of women have a greater than 2cm increase in prolapse size from their first to third Valsalva attempt and 95% of women extend their prolapse further with a third Valsalva. They concluded that, as with clinical examination, several attempts may be required to have maximal anterior compartment prolapse present during dynamic MRI of the pelvic floor. Delancey et al evaluated whether the use of a speculum blade modifies the evaluation of pelvic organ prolapse (POP) as assessed by dynamic MRI. Twenty-seven women with POP Quantification (POPQ) stage II or greater, scheduled for POP surgery, were evaluated using MRI. The procedure was repeated using the posterior blade of a standard plastic Grave's speculum to successively retract the anterior and posterior vaginal walls. Standard POPQ was 15% stage II (n =4), 59% stage III (n =16) and 26% stage IV (n =7). The use of a blade evidenced hidden pelvic prolapsed compartments in 59% (n =16) of cases. For 48% of patients (n =13), the variation of the leading edge of at least one additional prolapsed compartment was diagnosed as more than 20 mm. In this series, the use of a speculum blade during dynamic MRI modified the POP evaluation in a large proportion of patients with POP stage > or =II [29].

3. THREE DIMENSIONAL MRI

The nature of MRI technique where a series of parallel images are made allows them to represent a 3D block of tissue. Three dimensional (3-D) MRI provides precise detail of the bony and muscular pelvic structures (**Figure B 29**) so that 3D models can be constructed based on these detailed images. In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be seen. Fielding et al. made 3D models of the pelvic viscera and supporting muscles and bones with the marching-cubes algorithm and a surface-rendering method in nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform [25]. They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovesical angle of 143.5°. In addition, these 3D models made from multi-slice scans during a maximal Valsalva have allowed direct measurements of changes in the relationship between the vagina and pelvic walls.

3D MRI enables evaluation of paravaginal defects, apical descent and vaginal widening. Larson et al [30] studied the relative contributions of "midline defects" (widening of the vagina) and "paravaginal defects" (separation of the lateral vagina from the pelvic sidewall) in women with anterior prolapse using 3D MRI models of the anterior vaginal wall and found that changes in lateral anterior vaginal wall were considerably greater than changes in vaginal width in cases vs controls. These "paravaginal defects" were also highly correlated with apical descent.

The geometry of the arcus tendineus fascia pelvis (ATFP) and arcus tendineus levator ani (ATLA) in women with unilateral levator ani muscle defects and associated "architectural distortion" has been studied using 3D MRI. In those women, the ventral arcus anatomy is significantly altered in the presence of levator defects as well as architectural distortion, resulting in change of the supportive force direction along the lateral anterior vaginal wall, thus increasing the risk for anterior vaginal wall prolapse. [31]

a) Normal Pelvic Floor Functional Anatomy

Understanding how the pelvic floor works: one of the great challenge for every surgeon and physician involved in the management of disorders involving muscle, fascias and viscera on this complex area of the human body. Anatomical description of pelvic floor muscles at autopsy does not always reveal their function and the reasons of their dysfunction that not necessarily derive from anatomical changes but also from derangement of their networking. The variable weight of these two components may explain the variable outcome of conservative and invasive management in the individual subject. MRI offers a unique opportunity to investigate the pelvis

Figure B 29: Pelvic Organs as seen from caudal on a three-dimensional reconstruction from Magnetic resonance images. Copyright Mosby Inc.

a single functional unit and to investigate the relative contribute of its different parts and sections.

1. MR IMAGING OF NORMAL PELVIC SUPPORT STRUCTURES

MRI studies of normal subjects have improved our understanding of normal pelvic anatomy, its variations [25] [26] [32] as well as anatomic changes in pelvic floor dysfunction [20] [33] [34].

In the supine position the female pelvic floor is dome shaped at rest [34] [35]. During voluntary pelvic floor contractions the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens.

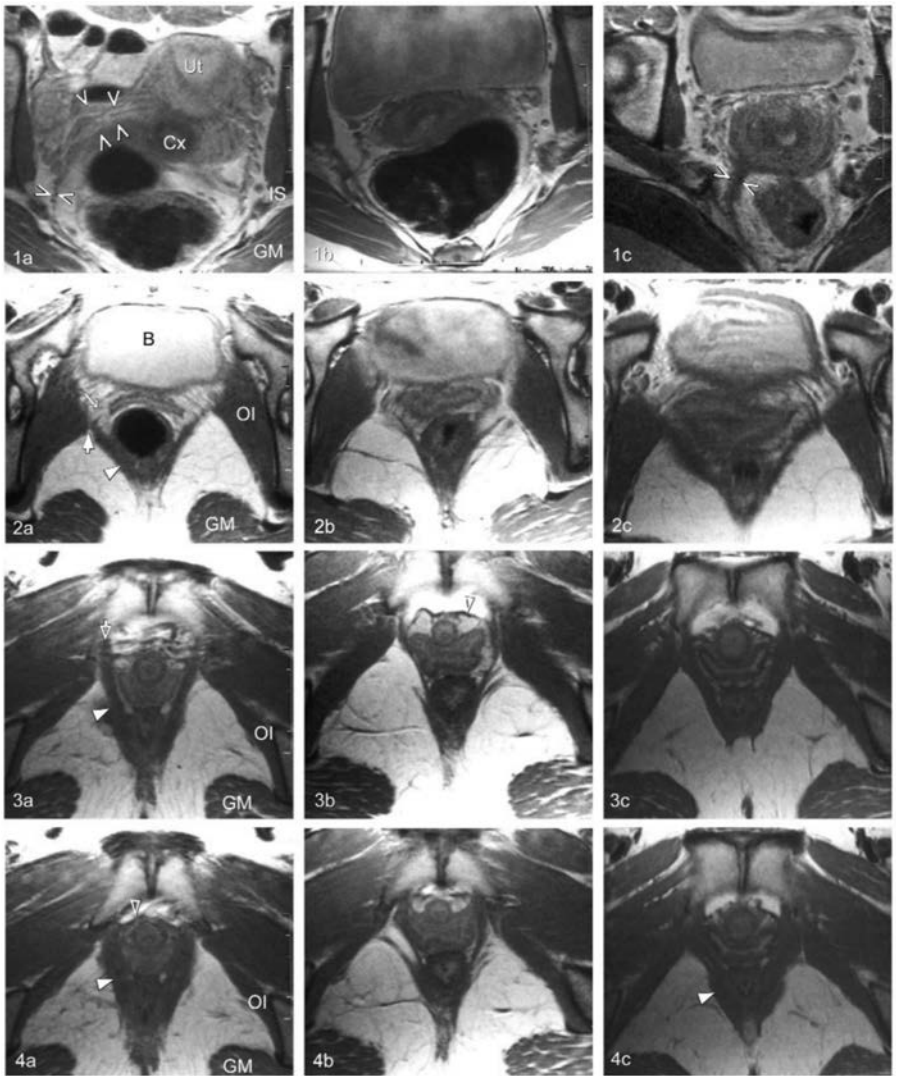

Figure B 30 : Axial images according , in 22-year-o ld (1a-4a), 24-year-old (1b-4b), and 34- year-old (1c-4c) nulliparous women without urogynecologic problems. 1a-c, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in 1c. GM, Gluteus maximus muscle. 2a-c, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. 3a-c, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in 3b. Vessels (white gap) are visualized between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. 4a-c, At level of middle urethra, pubovesicalis muscle is seen as shown in 4a (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in 4a and 4c). [123]

With MRI the specific structures are identified and their normal variations described **[Figure B 30**]. Tan [33] demonstrated the anatomy of the female pelvic floor with MRI. The pelvic and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments, and the zonal anatomy of the urethra. The MRI findings in volunteers correlated with the endovaginal MR findings and gross anatomy in cadavers. Chou [36] studied the urethral support structures relative to the arcuate pubic ligament including the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. Tunn et al [37] showed that 2- to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features in continent nulliparous women with normal pelvic organ support and urodynamics. The uterosacral ligaments also exhibit greater anatomic variation than their name would imply [38].

More recently, characteristic anatomic features of the posterior compartment and perineal body have been studied with MR cross-sectional anatomy and can be further elucidated and integrated with 3-D anatomy. In nulliparous asymptomatic women the posterior compartment's upper, mid, and lower segments are best visualised in MRI in the axial plane. It is bounded inferiorly by the perineal body, ventrally by the posterior vaginal wall, and dorsally by the levator ani muscles and coccyx. In the upper portion, the compartment is bordered laterally by the uterosacral ligaments, whereas in the middle portion, there is more direct contact with the lateral levator ani muscles. In the lower portion, the contact becomes obliterated because the vagina and levator ani muscles become fused to each another and to the perineal body [39]. (**Figure B 31**). The perineal body anatomy has been possible to study using 2mm MR images. Visualisation of perineal body anatomy in living women and development of 3-D models enhanced our understanding of its 3 different regions: superficial, mid, and deep [40]. The three distinct perineal body regions are [1] a superficial region at the level of the vestibular bulb, [2] a midregion at the proximal end of the superficial transverse perineal muscle, and [3] a deep region at the level of the midurethra and puborectalis muscle. Structures are best visualised on axial scans, whereas craniocaudal relationships are appreciated on sagittal scans. In the superficial portion at the level of the vestibular bulb (VB), the bulbospongiosus (BS) inserts into the lateral margins of the perineal body, whereas the superficial transverse perineal muscle (STP) and external anal sphincter (EAS) traverse the region. In the perineal body's midregion at the proximal end of the superficial transverse perineal muscle, the puboperinealis muscle inserts into the lateral margins of the perineal body and in some individuals can be seen to cross the midline. This region also contains the distal internal anal sphincter. The puboanalis muscle is also visible as it inserts in the intersphincteric groove between internal and external anal sphincters. The puboanalis muscle and internal anal sphincter extend into the perineal body's most deep region at the level of the midurethra. Here the pubovaginalis muscle also becomes visible as it fuses with the vaginal side wall, sending fibers posteriorly to the perineal body. In this location, the longitudinal muscle of the rectum may be visible in the midline. The puborectalis muscle forms a loop behind the rectum at this level but

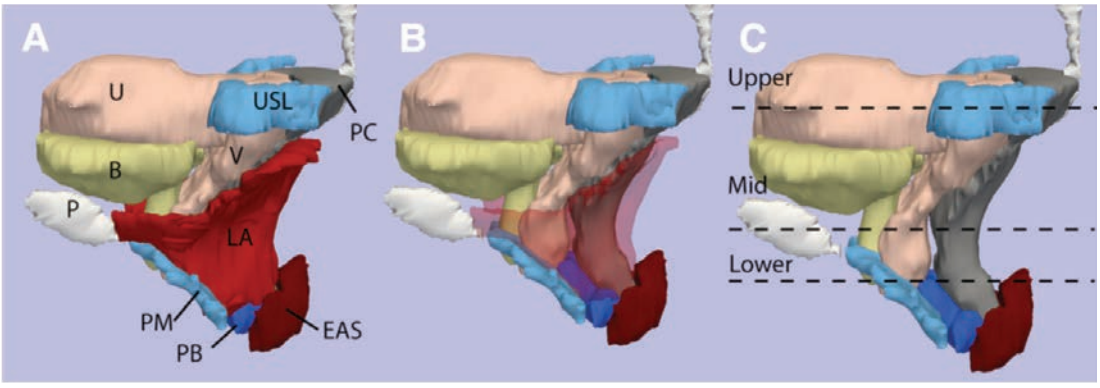

Figure B 31: The outline of the midsagittal pubic bone (P) is shown. The bladder (B) is yellow; the uterus (U) and vagina (V) are pink; the uterosacral ligament (USL) and perineal membrane (PM) are turquoise blue; the levator ani muscle (LA) is red; the perineal body (PB) is royal blue; the external anal sphincter (EAS) is dark red; and the posterior compartment (PC) is gray. Figure B 32: 3D Model of the perineal body [40]

does not contribute fibres to the perineal body. (**Figures B 32-33**)

One of the key anatomical contributions MRI has made to the understanding of normal pelvic floor structure, regards the ability to make images of a wide variety of normal living women. The pelvic floor is greatly distorted in cadavers due to loss of muscle tone and pressures during embalming. Otcenasek et al have used MR images of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal 3-D model that displays the features of pelvic floor anatomy (**Figure B 34**) [41].

2) Levator ani muscle functional anatomy

Evidence from MR and CT images in volunteers and cadavers shows that the anterior transverse portion of the levator muscle is basin-shaped; the middle transverse portion funnel-shaped, while the posterior transverse portion dome-shaped. The puborectalis appears u-shaped outside the vertical portion [42]. On MR images of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), puborectal and iliococcygeal portions of the levator ani muscle muscles in women with normal pelvic support, the puborectal muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum in the axial plane. The course of the puboperineal muscle near the perineal body is also seen best in the axial plane. The coronal view is

perpendicular to the fiber direction of the puborectal and pubovisceral muscles and shows them as "clusters" of muscle on either side of the vagina. The sagittal plane consistently demonstrates the puborectal muscle passing dorsal to the rectum to form a sling that can be seen as a "bump". This plane is also parallel to the pubovisceral muscle fiber direction and shows the puboperineal muscle [43]. (**Figure B 35**).

b) Pathophysiology of pelvic floor disorders

1. Levator ani defects

One of the major contributions of MRI to understanding the cause of pelvic floor dysfunction came from its documentation. LA injury seen after vaginal birth is highly associated with POP. In [44] a case-control study with group matching for age, race, and hysterectomy status, women with prolapse (cases) were compared to those with normal support (controls). Major defects were those that lost more than 50% of the muscle bulk. Cases were more likely to have major levator ani defects than controls (55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) (**Figure B 36-37**). Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons). This confirmed earlier uncontrolled observations with ultrasound [45].

It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured, while that of muscle bulk, with the capability of the muscle

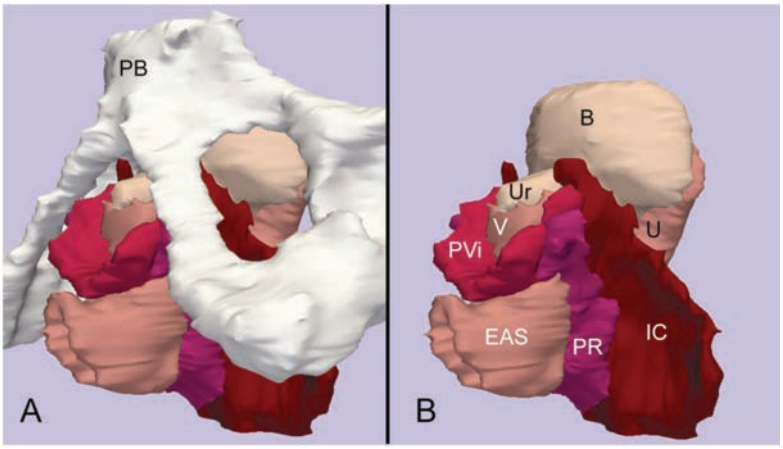

Figure B 35: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. The pubovaginal, puboperineal, and puboanal muscles are all combined into a single structure, the pubovisceral muscle. Inferior, left 3-quarter view. B. The same model without the pubic bone. to close the hiatus. Hoyte et al [46] examined 10 women with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm3 (P <0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P <0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P =0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P =0.003), and levator shape (90%, 40%, and 20% dome shaped; P <0.005). Subsequently, using a novel thickness mapping [47], they found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status [48]. Using muscle cross-sections from 3-D reconstructions they found that women with visible levator ani defects on MR have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating a compensatory hypertrophy in this area. Furthermore, after controlling for prolapse, women with levator defects appear to have a more caudal location of their perineal structures and larger hiatuses at rest, maximum contraction, and maximum Valsalva manoeuvre [49].

Among women with POP, those with major LAD appear less likely to experience stress incontinence when “coughing, laughing, or sneezing” (odds ratio (OR) 0.27) and when “twisting, reaching, lifting, or bending over” (OR 0.26) than women with normal muscles. They are less likely to have obstructive symptoms characterized by assuming an “unusual toileting position” or “changing positions...to start or complete urination” (OR 0.27). Women with minor LAD appear more likely to experience stress incontinence with exercise (OR 3.1) and urge incontinence (OR 4.0) than those with normal muscles. Lower urinary tract symptoms are therefore less common among women with prolapse and major levator ani defects and more common among those with minor defects [50]. This may be explained by the fact that the women with major LA defects have larger prolapses than those who do not have major LA defects. It is a clinical observation that prolapse often reduces the occurrence of stress incontinence (urethral kinking?) and this hypothesis is consistent with the observations mentioned above.

2. Identifying the injury zone within the levator ani muscle most often involved by injury

MRI based 3D models show that in women with bilateral puborectal muscle avulsion after vaginal delivery, the damage affects the pubic origin of the muscle. This structural change alters the support to the whole endopelvic fascia and destabilizes both the anterior and the posterior vaginal walls [51]. In women with significant muscle on one side and damaged muscle in the same individual [52] the injury involves the muscle’s origin from the posterior pubic bone. (**Figure B 38**) Distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle is observed in 50% of women. The defect is right sided in 71% of patients. The average difference of the amount of muscle lost in these types of injury between the normal side and the defective side is up to 81% at locations nearest the pubic origin [53]. Almost all of the volume difference (13.7%, P=0.0004) is attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle.

3. Changes in the hiatus size and levator plate angle with prolapse

The levator ani muscle’s constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes to the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) which is presumed to be influenced by muscle action. Hsu and colleagues [54] studied 68 women with pelvic organ prolapse and 74 normal controls. During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm). Increases in levator plate angle were correlated with increased levator hiatus length (r = 0.42) and perineal body location (r =0.51). The bladder neck descent at straining is also correlated with the levator plate angle at rest, hiatus length at rest and at straining [55]. Uterine cervix descent at straining is correlated with increased hiatus length and width at straining, and greater levator plate angle (p=0.007) at straining. Paradoxically anterior rectal bulging at straining is inversely correlated with the hiatus width at rest (p = 0.04).

Perineal descent and localised outward bulging of the levator ani during Valsalva was evaluated by Gearhart and colleagues [56]. In this study, dynamic MRI of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernia. Patients with POP, fecal and/or urinary incontinence, or chronic constipation were evaluated. Fifteen percent of patients (12/80) had unilateral (n = 8) or bilateral (n = 4) levator ani hernias on MRI. Perineal descent on physical examination was associated with a levator ani hernia in nine patients.

4. MRI and the bony pelvis

Studies of the bony pelvis dimensions and their associations with POP, levator ani defects and stress in-

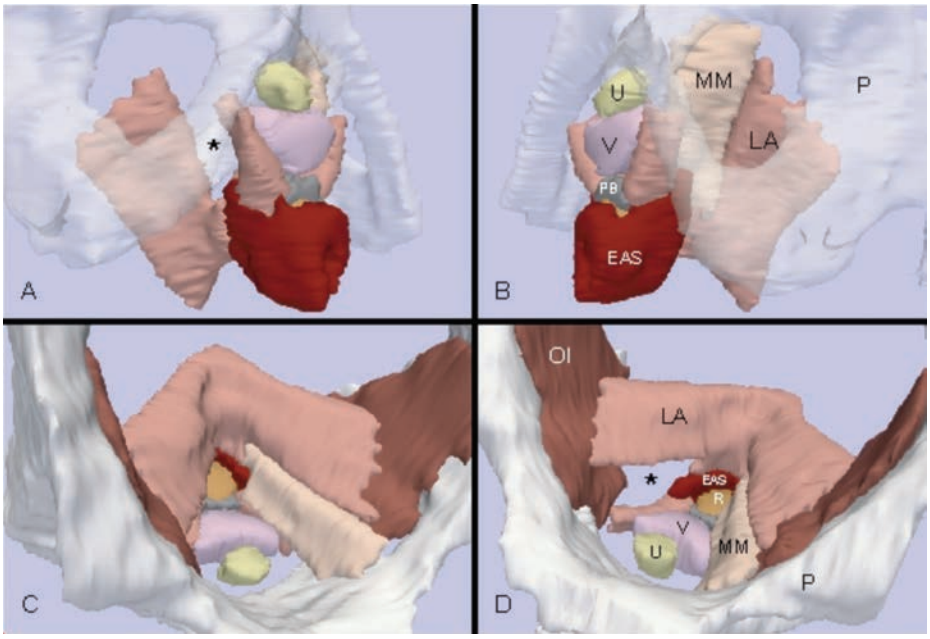

Figure B 38: Three-dimensional model generated from the axial MR scans shown in Figure A, and B, Oblique right and left inferolateral views, similar to the dorsal lithotomy position, are shown. In these panels the pubic bone is semitransparent and the obturator internus muscle is not shown. C, and D, Oblique right and left views peering over the pubic bone and down to the pelvic floor are shown. The urethra, vagina, and rectum have been truncated so as not to obscure the views of the levator muscles. EAS, external anal sphincter; LA, levator ani; MM, mirror image of the missing muscle; P, pubis; PB, perineal body; U, urethra; V, vagina. The missing muscle in A and D is denoted (asterisk). © DeLancey 2006 [52].

continence have recently been undertaken. Stein et al showed that bony pelvis dimensions are similar at the level of the muscular pelvic floor in white women with and without POP [57]. Further evaluation of the bony pelvis using MRI scans has also improved our understanding of the natural history of stress urinary incontinence as well as the associations of the bony pelvis dimensions with the prevalence of levator defects (Berger et al unpublished data). Other studies investigating the role that different pelvis shapes play for specific diseases will be described in subsequent sections of this review.

5. MRI OF PELVIC FLOOR AFTER VAGINAL DELIVERY

There are changes observed in the levator ani and pelvic floor musculature immediately after delivery, which change over time. Boreham [58] evaluated the normal visibility of the levator in post term nulliparas using 3-dimensional (3-D) MRI. LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of 84 nulliparas. Mean LA volume was 13.5 (3.7) cm3. Interestingly there was a positive association between LA volume and higher fetal station with increasing BMI. The muscle signal intensity appears increased at 1 day postpartum on T2 weighted images, but normal by 6 months. The urogenital and levator hiatus decreases significantly by 2 weeks postpartum [59]. More recently, Lienemann [60] found thinning of the puborectal muscle in primiparous women after vaginal delivery (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction during straining compared to healthy asymptomatic nulliparous volunteers.

The descent of the bladder and cervix on straining appears greater in women who delivered vaginally compared to those who had cesarean delivery and to nulliparous women. There is a positive correlation between the duration of labour and the area of the levator sling and also between birthweight and the descent of the cervix on straining [61].

The role of levator ani muscle damage and stress soon after birth has also been studied. An investigation of 80 nulliparous asymptomatic women and 160 vaginally primiparous women half of whom had new stress incontinence after their first birth was conducted 9 months after delivery. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. None of the nulliparous women showed these abnormalities [62]. In a further study of this cohort [63] evaluation of obstetric factors associated with levator ani injury after first vaginal birth showed increased odds ratios for levator defect: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum de-

livery (0.9) epidural use (0.9) or oxytocin use (0.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labour. Differences in gestational age, birth weight, and head circumference were not statistically significant.

Dannecker [64] compared women after spontaneous vaginal delivery to those delivered by vacuum extraction and a control group of healthy nulliparous volunteers. Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences were observed for the position of bladder base, bladder neck, posterior vaginal fornix, anorectal junction, hiatus perimeter and depth of rectocele. Looking into comparisons with the spontaneous vaginal delivery group, on clinical examination, there was more evidence of anterior vaginal wall descent after vaginal delivery, and TVL and GH. Differences between the groups with regard to points Ap and Bp reached only marginal significance. With MRI measurements primiparous women who underwent spontaneous vaginal delivery as compared to nulliparous women showed considerable and statistically significant descent of almost all assessed structures at rest and on straining. Bladder base, bladder neck and the anorectal junction descended even below the respective reference lines. The bladder neck showed considerably increased mobility, and the genital hiatus showed an increased change on straining. The depth of rectocele increased more than three times. One of 26 women (4%) had a rectocele >3 cm. POPQ measurements that differed significantly between primiparous women after vacuum extraction and nulliparous women of the control group indicated more evidence of anterior and posterior vaginal wall descent after vacuum extraction. In addition TVL and GH was increased and PB was decreased after vacuum extraction. MRI measurements after vacuum extraction, showed considerably increased descent and mobility of the bladder base and bladder neck on straining, and descent of the anorectal junction was prominent. The mean depth of rectocele was four times bigger than in the nulliparous group. Four of 49 women (9%) had a rectocele >3 cm.

Branham and colleagues [65] evaluated postpartum changes in the levator ani muscle in relation to obstetric events. In those subjects recovering to normal MR by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Younger white primiparous women had a better recovery at 6 months than older white women. Subjects experiencing more global injury, in particular to the iliococcygeous, tended not to recover muscle bulk.

Heilbrun and colleagues investigated the correlation between the presence of major LAM injuries on MRI with faecal incontinence (FI), POP, and urinary incontinence (UI) in primiparous women 6-12 months postpartum using a scoring system to characterise LAM injuries on MRI. Major LAM injuries were observed in 19.1% women who delivered vaginally with external anal sphincter (EAS) injuries, 3.5% who delivered vaginally without EAS injury, and 0% who delivered by cesarean section before labor (p=0.0005). Among women with EAS injuries, those with major LAM injuries trended toward more FI, 35.3% vs. 16.7% (p=0.10) and POP, 35.3% vs 15.5% (p=0.09), but not UI (p=1.0). These data confirm that both EAS and LAM are important for fecal continence and that multiple injuries contribute to pelvic floor dysfunction [66] .

Handa and colleagues used MRI to measure bony and soft tissue pelvic dimensions in 246 primiparas, 6-12-months postpartum. A deeper sacral hollow was significantly associated with fecal incontinence (p = 0.005). Urinary incontinence was marginally associated with a wider intertuberous diameter (p = 0.017) and pelvic arch (p = 0.017). There were no significant differences in pelvimetry measures between women with and without prolapse in this study[67].

6. MRI and biomechanical investigation of the pelvic floor

MRI has allowed anatomically based biomechanical models to be constructed. Simulations have demonstrated important interactions between muscle and connective tissue in providing anterior vaginal wall support [68]. MRI has enabled construction of finite element analysis [69] [70]. It has also allowed for capture of 3D shape variation of the levator ani during straining where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique [71].

Chen developed and validated recently a 3D finite element computer model of the anterior vaginal wall and its supports based on spatial data from MR scans of normal women. They determined the combinations of muscle and connective tissue impairments that result in cystocele formation, as observed on dynamic MRI geometry from a healthy nulliparous woman. It included simplified representations of the anterior vaginal wall, levator muscle, cardinal and uterosacral ligaments, arcus tendineus fascia pelvis and levator ani, paravaginal attachments, and the posterior compartment. The authors found that development of a cystocele requires a levator muscle impairment, an increase in abdominal pressure, and weakening of apical and paravaginal support [72]. These simulations provide a way to see what specific changes in structural components do to pelvic organ support in ways that would be impossible to study in living women.

7. Racial differences in pelvic dimensions

There are differences that exist in the occurrence of

prolapse in women from different racial backgrounds. Several groups have evaluated racial differences in the bony pelvis and the levator ani muscles [73] [74] [75]. In a study by Handa et al [73], a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were associated with pelvic floor dysfunction after controlling for age, race, and parity. Hoyte and colleagues found that levator ani volume was significantly greater in African-American (AA) asymptomatic nulliparous women without pelvic floor dysfunction compared to white American (WA) ones (mean = 26.8 vs. 19.8 cm3, P = .002). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, p = 0.003, 0.048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle [74]. In another study with 3D MRI levator thickness was significantly greater bilaterally in black nulliparas compared to white ones, yet obturator internus muscle thicknesses were similar [75].

Handa found that the pelvic inlet was wider among white women than African-American women (10.7+/-0.7 cm compared with 10.0.+0.7 cm, P<.001). The outlet was also wider (mean intertuberous diameter 12.3+/-1.0 cm compared with 11.8+/-0.9 cm, p<.001). There were no significant differences between racial groups in interspinous diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus. [76].

A broader group of races was studied by Rizk et al with MR in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group [77]. The white volunteers were taller (p< 0.0001) than the other women. Their levator hiatus was longer than the Emirati women (p= 0.03) and wider than the Filipino women (p= 0.04). The bladder neck descent on straining was also greater than the other groups (p< 0.00001). The white women also had the longest transverse diameter of the pelvic inlet (p= 0.002). Their sagittal outlet diameter was longer than the Emirati and Arab women (p= 0.02), and their interspinous diameter was longer than the Arab women (p= 0.002).

c) Pelvic Organ Prolapse

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of 3D ultrasound and MRI, the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

Evaluation of the degree of anterior compartment (bladder) and apical compartment (cervix) prolapse at maximal Valsalva using dynamic MRI showed a strong correlation between how far the bladder base and uterine cervix were below normal with r2 = 0.53 indicating that slightly over half of the observed variation in anterior compartment support may be explained by apical support [78]. Further analysis in the same patients showed that vaginal length was the strongest secondary factor determining 30% of the variation after apical descent was taken into account. This finding that a longer vaginal wall was associated with increasing cystocele size was unexpected, but seems consistent with clinical observations [79].

Hsu et al found that vaginal thickness is similar in women with and those without pelvic organ prolapse. However, in prolapse patients the vaginal perimeter and cross-sectional areas are 11% and 20% larger respectively [80].

Broekhuis et al studied the relationship between patient symptoms using questionnaires' domain scores and the perineal position on dynamic MR imaging of 69 women. They found that POP symptoms were associated with the degree of descent of the perineum but perineal descent was not related to anorectal and/or urinary incontinence symptoms [81].

In another study examining correlations of patients' symptoms with findings on clinical examination and dynamic MR imaging of the pelvic floor, only the domain score genital prolapse was significantly correlated in the positive direction with the degree of POP as assessed by POP-Q and dynamic MR imaging (rs = 0.64 and 0.27, respectively), whereas the domain score urinary incontinence was inversely correlated (rs = -0.32 and -0.35, respectively). The sensation or visualization of a bulge in the vagina was the only symptom which correlated positively with the degree of POP, with clinical examination and dynamic MR imaging showing similar correlation in this respect [82].

Broekhuis et al concluded that correlations for the POP staging with the use of POP-Q, dynamic MR imaging, and perineal ultrasonography are only observed in the anterior compartment [83].

1. Enterocele

In the past, enteroceles were usually only appreciated on radiographic examination after repeated straining after evacuation and usually required opacification of the vagina in order to demonstrate the insinuation of small bowel loops between the rectum and vagina [84]. MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In comparisons between physical examination, intraoperative findings and MR images in women with and without prolapse, MRI was significantly superior in detecting enterocele when compared to physical examinations with a sensitivity of 87%, specificity of

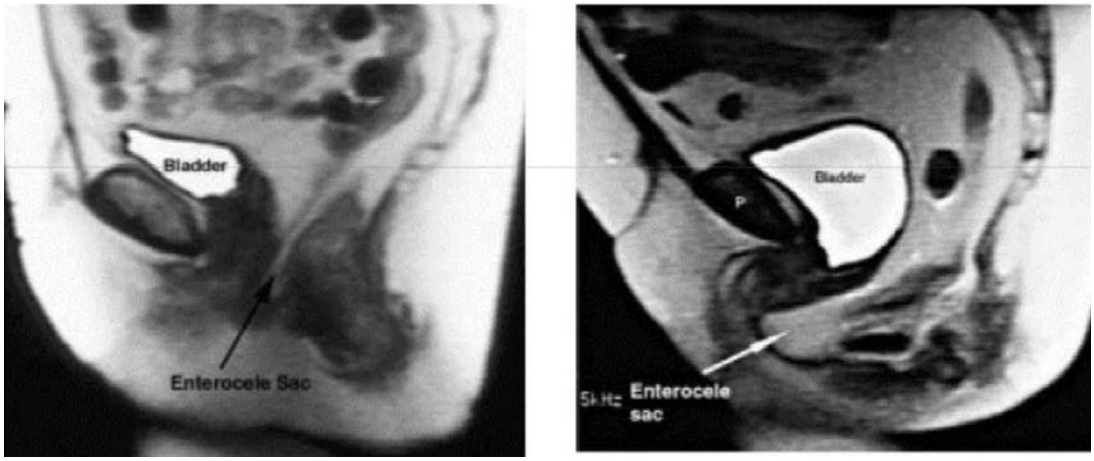

Figure B 39: Pelvic floor MRI: Enterocele at rest a) and during Valsalva b).

80%, and positive predictive value of 91% [16]. (**Figure B 39**). Similarly, MRI had a much higher sensitivity for detection of enteroceles when compared to physical exam and dynamic cystoproctography [85]. Whether or not this technique alters clinical outcome remains to be seen.

2. Cystocele

MRI has a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings. In addition, urethral hypermobility and post-void urine residual can be documented, as well as evaluation of ureteral obstruction, hydroureteronephrosis and other pelvic abnormalities. **Figures B 40 a, b**

MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy [86] [87] and differentiating such problems as Müllerian remnant cysts from cystocele [88].

Larson et al showed that in women with anterior wall prolapse, Valsalva causes downward translation of the vagina along its length. A transition point separates a proximal region supported by levator muscles and a distal, unsupported region no longer in contact with the perineal body. In this latter region, sagittal and frontal plane "cupping" occurs. The distal vagina rotates inferiorly along an arc centered on the inferior pubis. Downward translation, cupping, and distal rotation are therefore novel characteristics of cystocele demonstrated by 3-D MR imaging [89]. (**figure B 41-42**)

3. Rectocele

The reported sensitivity of pelvic examination for diagnosis of rectocele ranges from 31% to 80% [3] [4] [6] [90] [91]. This is usually secondary to organ competition for space in the vagina with other significant prolapse [7]. In addition, it is often difficult to reliably distinguish an enterocele from a high rectocele. **Figure B 43** shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles [16]. When rectal opacification is used, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings [19]. Rectal opacification by introducing sonographic transmission gel or gadolinium into

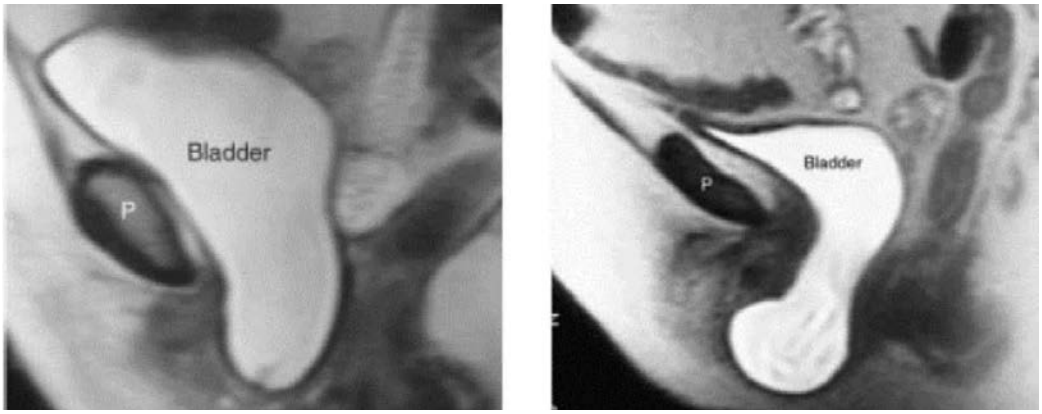

Figure B 40: Pelvic floor MRI: grade 2 (a) and grade 3 (b) cystocele

Uterovaginal junction shown with dark pink square. c Addition of midsagittal pelvic bones (white) and anterior vaginal wall model. d Powerpoint image of both resting and straining anterior vaginal wall models and their relationship to the normalized ATFP, shown here as green line extending from the pubic symphysis to the ischial spines (green square), or the P-IS line. © DeLancey 2009 [89].

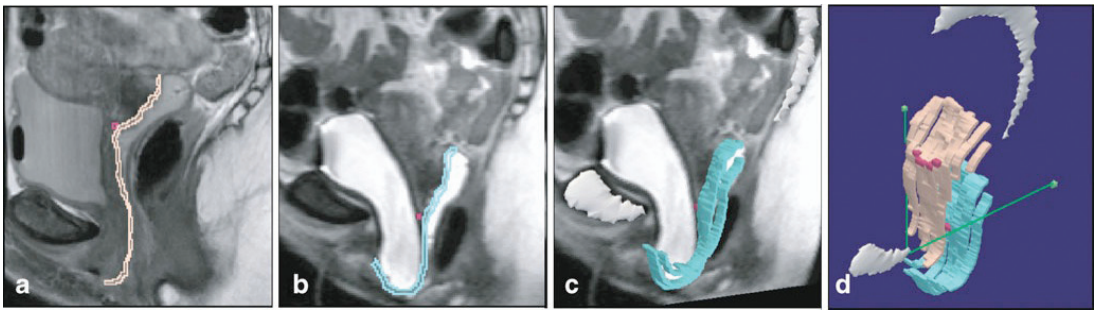

Figure B 42: Midsagittal view of pelvis with normal support (a) and with prolapse (b). Green represents area where levators (blue arrow) provide cranial reaction forces to counteract the action of intraabdominal pressure and caudal movement of the anterior wall. The red arrow delineates the transition to unsupported region lacking this opposing set of reaction forces (blue line), thereby creating a pressure differential acting caudally on that region. c Red arrow illustrates this point on midsagittal MRI with modeled anterior vaginal wall. U uterus, B bladder, Ur urethra. © DeLancey 2009 [89].

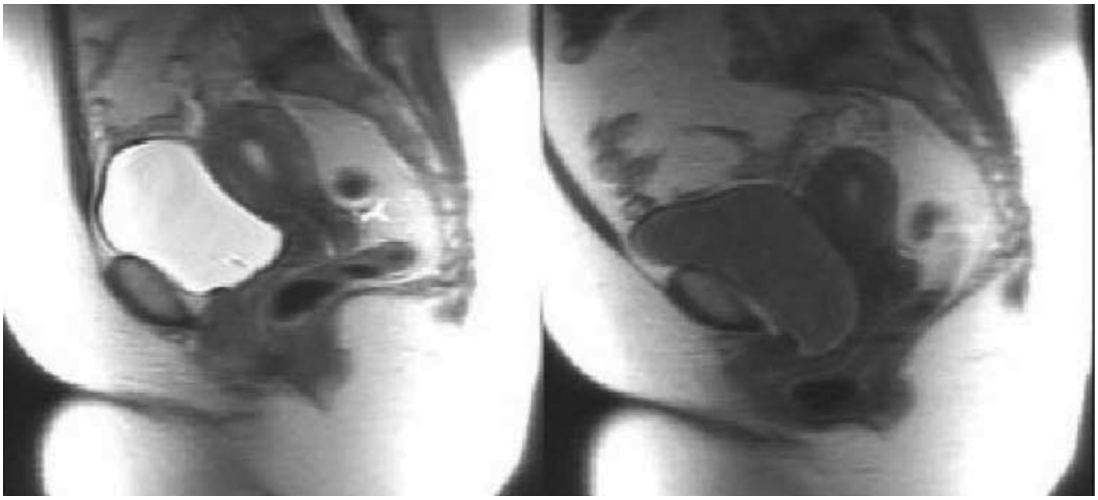

Figure B 43: Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.

the rectum is therefore necessary to increase MRI's ability to diagnose rectocele. In complex situations such as rectal intussusception [92] MR can provide important information by distinguishing mucosal from full-thickness descent. MR defecography also shows movements of the whole pelvic floor. In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

At maximal Valsalva on MRI, structures are more caudal and the hiatus longer in women with posterior prolapse. The posterior vaginal wall is longer; this length and point Bp strongly correlate with MRI prolapse size ($r=0.5$; $p=0.002$; $r=0.7$; $p<0.001$, respectively). [93]

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

4. Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to record the structural relationships with the bladder and rectum in patients with uterine prolapse (**Figure B 44**). In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits of evaluating uterine size, position, orientation (retroversion) and pathology (fibroids, tumors, Nabothian cysts. etc.), but also ovarian pathology (cyst or mass) which may sometimes prove useful if these problems have not been picked up on physical examination. This is helpful information in determining the route of hysterectomy. Furthermore, MR imaging provides information on the presence or absence of cystocele, rectocele, urethral hypermobility and urethral diverticula, and evaluates for ureteral obstruction [10] [11] [14] [15] [16] [94]. Gousse et al. report a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MR imaging to intraoperative findings. These numbers were similar when compared to physical examination alone [16]. More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated [16].

5. Grading of pelvic floor relaxation

A number of studies have described reference values for grading POP [15] [16] [18]. In order to evaluate pelvic organ descent, certain anatomic landmarks are used. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. [15], Gousse et

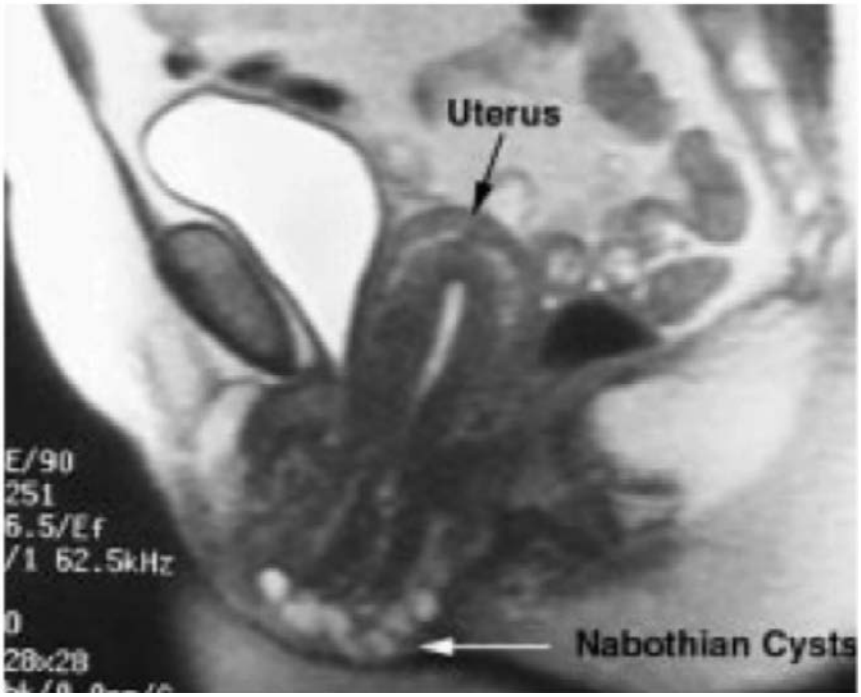

Figure B 44: Pelvic Floor MRI: Uterine Prolapse

al.[16],and Barbaric [23], the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the PCL. Using these three simple measurements, an MRI classification for degree of POP has been described [15] [23]. In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL. The upper urethra, urethrovesical junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. A combination of hiatal enlargement and pelvic floor descent constitutes relaxation. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line. By determining the degree of visceral prolapse beyond the H-line, the degree of rectocele, enterocele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0=none, 1=minimal, 2=moderate, and 3=severe (**Table 2**). Other similar systems have been described [18] highlighting the need for standardization of nomenclature and grading of organ prolapse using MRI. In a small study, Ginath et al showed that MRI measurements of pelvic landmark angles can differentiate between women with and without uterine prolapse and correlate best with POPQ point C [95].

Novellas and colleagues evaluated two classification systems (using the PCL and the midpubic line, MPL) in 30 patients with symptoms of POP. For prolapse detection, the correlation between clinical examination and MRI ranged between 74 and 89%. For prolapse staging, the correlation was poor to moderate. Inter-observer agreement was good to very good (kappa between 0.67 and 0.95). It was slightly better at the mid stage, with both systems (kappa between 0.83 and 0.97). Comparison of the inter-observer agreement between both MRI classification systems showed better results for the system using the pubococcygeal line ($p<0.005$). The classification system based on the pubococcygeal line appeared more reliable and simple for the evaluation of pelvic prolapse on MRI [96]. In another study, agreement between clinical and PCL staging was fair in the anterior (kappa = 0.29) and poor in the apical (kappa = 0.03) and posterior (kappa = 0.08) compartments. Agreement between clinical and MPL staging was fair in the anterior (kappa = 0.37), apical (kappa = 0.31), and posterior (kappa = 0.25) compartments. The MPL had higher agreement with clinical staging than the PCL in this study. However, neither reference line had good agreement with clinical staging [97]. The intra- and interobserver reliability of dynamic MR staging in POP patients has also been evaluated using various anatomical landmarks in relation to the PCL, H-line, and MPL. Clinical measurement points were assessed in relation to the mid-pubic line. Overall, the intra- and interobserver reliability of MR imaging measurements was excellent to good. The PCL showed superior reliability (intraclass correlation coefficients-ICC range 0.70-0.99). The reliability of clinical measurement points, however, was only moderate (ICC range 0.20-0.96). The intra- and interobserver reliability of quantitative prolapse staging on dynamic MR imaging were good to excellent. The PCL appeared the most reliable to use [98].

Singh et al [99] compared a new technique of grading POP by using dynamic MRI with the clinical staging proposed by the POP-Q system [100]. A new reference line, the mid-pubic line, was drawn on the MR image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). Torricelli [101] also used MRI to evaluate functional disorders of female pelvic floor. In symptomatic women MRI confirmed the pelvic examination findings in all cases; MRI also detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Deval [102] compared dynamic MR imaging with physical examination as an alternative to dynamic cystoproctography for the evaluation of POP. PCL and puborectalis muscle were the reference points. The grading system is based on degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used, the mid pubic line, which was drawn on the MR image to correspond to the hymenal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocystodefaecography and MRI were compared. The sensitivity, specificity and positive predictive value of MRI were 70%, 100%,

Table 2. Grading of hiatal enlargement, pelvic organ prolapse and pelvic floor descent using MRI

Grade	Hiatal enlargement	Pelvic Organ Prolapse	Pelvic floor descent
0	Less than 6 cm	Organ above H line	0-2 cm
1	6-8 cm	0-2 cm below H line	2-4 cm
2	8-10 cm	2-4 cm below H line	4-6 cm
3	10 cm or more	4 cm or more below H line 6	cm or more

100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele. More recently Etlik [103] found physical examination and MR findings to be very concordant in the diagnosis of pelvic prolapse. Statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment ($p < 0.01$), as well as for posterior compartment ($p < 0.05$).

d) Assessing Treatment Outcome

1. Pelvic Organ Prolapse Operations:

Several studies have evaluated the anatomic changes seen after surgical procedures using MRI to better understand how surgical therapies affect pelvic support and structures. Lienemann et al. [104] evaluated women after abdominal sacrocolpopexy and found that functional MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Sze [105] used MRI to study vaginal configuration on MR after abdominal sacrocolpopexy and sacrospinous ligament suspension. This study demonstrated the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane [106] used MRI to compare the vaginal configuration following transvaginal sacrospinous fixation (SSF), posterior intravaginal slingplasty (PIVS) (infracoccygeal sacropexy) and sacrocolpopexy (SCP) and demonstrated improvements in the restoration of vaginal configuration and differences between the procedures in final anatomy. Boukerrou [107] compared outcomes of 1) abdominal sacral cervicopexy, 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension with MRI. The correction provided by vaginal route was found to result in a return of the bladder and the vaginal apex to their normal positions. In addition, vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Relationship between assessment of surgical correction studied with MR imaging and symptoms have been studied. Gufler [108] compared preoperative evaluations with those two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al assessed symptomatic changes after anterior levatorplasty with morphologic changes visualized by MR defaecography [109]. Anterior levatorplasty improved quality of life in patients with symptomatic rectocele and correction of rectocele is accurately documented by MR defecography, however only moderate correlation between morphologic and clinical improvements was observed.

MRI has also been used for the evaluation of the effectiveness of POP surgical mesh procedures.

Dynamic MRI may evaluate the support of anterior and posterior pelvic floor structures by anterior and posterior polypropylene implant respectively. But dynamic MRI evaluations in a small series by Siegmann and colleagues suggest that if one compartment of the pelvic floor is repaired another compartment frequently (73.3%) develops dysfunction. These results did not correspond to clinical symptoms on short-term follow-up (3 months) indicating the need for long-term follow-up studies to prove if dynamic MRI can reliably identify significant POP after surgery and before the onset of symptoms [110]. In another small series of ten women by Kasturi et al [111] undergoing intervention for POP with Prolift, postoperative MRIs supported the inert nature of polypropylene mesh.

Recently Larson et al examined structural relationships between anterior mesh kit suspension points and the upper vagina in women with normal support. Using MRI generated 3D models, they found that the anterior vagina extended above superior attachment points in 100% of women at rest and in 73% during Valsalva. It extended posterior to them in 82% and 100% (rest and Valsalva, respectively). The mean percentage of anterior vaginal length above superior anchoring sites was 40 ± 14% at rest and 29 ± 12% during Valsalva. The upper vagina was therefore found to lie above and posterior to superior suspension points in the majority of women with normal support [112].

2. Pelvic Muscle Exercises

Studies on the effects of pelvic muscle training on the pelvic floor [113] demonstrate reduced levator ani surface area and volume encircled by the levator ani muscle during contraction. When elite athletes are compared to normal women significant differences appear in the cross-sectional area and width of the pelvic floor muscles, [114]. These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle [115].

3. Comparison Of Mri With Other Examinations And Assessment Of Reliability

Dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography (CCP) have previously been considered the best radiological studies for detecting POP. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase [4] [106] [109][113]. These studies fail to detect up to 20 percent of all enteroceles [94] [116] [117] [118]. Therefore, MRI has proven to be a much simpler and less invasive technique for the evaluation of

enteroceles. In addition, MRI is able to differentiate the enteroceles according to their contents (small bowel, large bowel, rectosigmoidocele or mesenteric fat). MRI is also an excellent study to differentiate high rectoceles from enteroceles, thus allowing adequate surgical planning and safer planes of dissection [15] [16] [19] [85]. Although multiphasic MRI with opacification of organs and multiphasic fluoroscopic CCP have similar detection rates for enterocele [116], excellent images can be obtained from dynamic MRI without contrast for opacification of the small bowel or rectal contrast. Thus the minimal added information obtained by contrast administration does not seem to warrant the invasiveness of organ opacification at this time [16] [84] [117]. However, recent data suggest that MRI without rectal contrast shows statistically fewer pelvic floor abnormalities than CCP. Except for enteroceles, MRI with rectal contrast shows statistically similar frequency of POP as CCP [119].

Evacuation proctography has been used to diagnose enterocele, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentography or fluoroscopic CCP have also been used [4] [90] [91] [116] [120] to diagnose rectoceles. The disadvantages of these techniques are the inability to visualise the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. With rectal opacification a correct diagnosis of rectocele can be made in 100% of patients in comparison to intraoperative findings [19]. Triphasic dynamic MRI and triphasic fluoroscopic CCP have similar detection rates for rectocele [116]. Upright dynamic MR defaecating proctography has been reported [121]. Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectocele.

Kaufman [122] evaluated dynamic pelvic MRI and dynamic CCP in the surgical management of females with complex pelvic floor disorders. Physical examination, dynamic MRI, and dynamic CCP were concordant for rectocele, enterocele, cystocele, and perineal descent in only 41% of patients. Dynamic imaging lead to changes in the initial operative plan for 41% of patients. Dynamic MR was the only modality that identified levator ani hernias. Dynamic CCP identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MR. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al [99] showed a reasonably good correlation between clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on MRI.

Torricelli [101] studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without POP. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. Deval [102] compared intraoperative findings as a gold standard for MRI based diagnosis. The sensitivity, specificity, and positive predictive value of MRI were 70%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enteroceles; 87%, 72%, 66% for rectocele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction in reasonable parameters.

e) Conclusions

Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman's pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

f) Consensus Statement

- MRI is not yet indicated in the routine evaluation of patients with [uncomplicated primary] pelvic organ prolapse; however data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases. [Level of evidence 3, Grade of Recommendation C]

g) Future Research Areas

- Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.
- Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluate the anatomic changes involved in pelvic floor prolapse.
- Standardization of measurement strategies and quality control in MRI, including issues related to consistency of measurement axes, maneuvers required to produce a maximal prolapse during MRI, bowel condition, bladder filling, pushing instructions, etc.)

III. SPECIAL ISSUES

1. POST-VOID RESIDUAL

Post-void residual urine (PVR) is defined as "the volume of urine left in the bladder at the end of micturition [1]. Evaluation of PVR prevalence in women with symptomatic pelvic floor dysfunction suggests that 81% have a post-void residual of 30 ml or less [2]. This is not significantly different from asymptomatic perimenopausal and postmenopausal women in whom 15% of subjects had a PVR greater than 50 ml [3]. If symptoms cannot predict elevated PVR, a urogenital prolapse beyond the hymen seems to be associated with incomplete bladder emptying [4]. Among patients older than 55 years with symptoms of overactive bladder, previous incontinence surgery, history of multiple sclerosis and vaginal prolapse stage 2 or greater, were found to be independent predictors of elevated PVR [5]. Similar data were obtained by Fitzgerald in patients with urgency incontinence, the presence of pelvic organ prolapse ≥stage 2, symptoms of voiding difficulty and absence of stress incontinence symptoms predicted 82% of patients with elevated PVR [6]. Higher prevalence of post-void residual was found in patients with stress urinary incontinence with 35.5% of women having a PVR >50 ml suggesting they have some degree of voiding dysfunction [7]. Although elevated PVR and bacteriuria are common among elderly residents in nursing homes, no association between the two was observed in a Swedish study [8]. Analysis of elderly patients with urinary incontinence failed to identify any significant association between PVR and any other clinical or urodynamic parameter [9]. Sanders and co-workers addressed the issue of the real need for measuring flow rates and post-void residual urine in women with urinary incontinence. Analysis of 408 women suggested a 4% incidence of PVR 200 ml or greater and a 6% rate of PVR 149 ml or greater. The authors calculated that only 1.5% of patients [6 of 408] had their management modified because of the results of free uroflowmetry and PVR measurement. In their opinion, these data do not justify the inclusion of these tests in the "minimal care" programme for assessing primary, uncomplicated, urinary incontinence in female patients [10].

PVR is often considered a safety parameter, which needs to be monitored in the follow-up of medical or surgical management of urinary incontinence. A number of studies have addressed the effect of antimuscarinic treatment in men with symptoms of overactive bladder to rule out the old dogma that banned the use of these drugs in elderly men. Actually, all published data suggest that antimuscarinic treatment is safe for men with benign prostatic enlargement and no significant change in PVR values was found in active treatment groups compared to placebo [11, 12]. In male patients with bladder outlet obstruction, antimuscarinic treatment may result in a significantly larger PVR (25 vs. 0 ml) that seems to be of no clinical relevance and with higher incidence of adverse events [13].

Measuring PVR is of importance in patients receiving intravesical injections of Botulinum toxin A for UUI. Significant increase of post void residual urine is observed following injection of onabolutinumtoxinA in patients with neurogenic urinary incontinence due to detrusor overcativity with 30 to 42% of patients needing to start clean intermittent catheterisation compared to 12 % in the placebo group [14]. In patients with idiopathic UUI, increase of PVR was observed in those receiving onabolutinumtoxinA compared to placebo although only 8 of 70 patients required CIC and only 3 patients had a PVR >200 ml at day 8 and only one at 6 months [15].

Although the prevalence of incomplete bladder emptying among male and female patients with urinary incontinence and pelvic floor dysfunction is low, there is a general consensus that PVR should be measured in incontinent patients [16] although the evidence suggests that only patients with UI and symptoms of voiding dysfunction are at risk [17].

a) Measuring PVR

The measurement of PVR can be performed by invasive and noninvasive means. Invasive methods include: in-and-out catheterisation and endoscopy. Noninvasive means are transabdominal ultrasonography with real-time ultrasound or fully automated systems, and radioisotope studies. In-and-out catheterisation has been considered for some time, the gold standard for the measurement of PVR. Nevertheless the method is subject to inaccuracies, if the person performing the catheterisation is not fully instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflux [18]. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urology nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate [19]. After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow. Both invasive means are usually performed with some kind of local anaesthesia and carry a small risk of urethral damage and urinary infection.

Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes [20, 21].

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this

technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated [22, 23]. Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or a ellipsoid body are utilised to estimate the bladder volume (**Table 3**). Twenty-one different formulae have been proposed over the years making assumptions about bladder shape which have often been questioned [24]. Comparison of values of bladder volumes obtained using different formulae did not result in any significant difference amongst the various calculations [25]. At present, no single formula can be regarded as the one best volume calculation formula. Several studies report sufficient accuracy with ultrasound estimation of PVR [23, 24, 26-29]. False negative results are rare with PVR less than 20 ml [30]. Recently portable scanners have been introduced, with automatic measurement of bladder volume. In a prospective comparison of one hundred measurements of PVR by portable ultrasound with measurements by catheterisation, the mean absolute error of the scanner was 52 ml [31]. For volumes below 200 ml and 100 ml, the error was 36 ml and 24 ml respectively. More recent studies suggest a good level of accuracy in both female and paediatric populations [32, 33]. Residual urine is usually referred to as an absolute value, but it can be measured as a percentage of bladder capacity.

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. [34, 35]. Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three different times of day on each of two visits separated by 2-4 weeks [36]. Within-patient variability was large (SD 128 ml) because of a large systematic variation with time of day, with greatest volumes in the early morning. The inherent random variability of the measurement was much smaller (SD 44 ml). Several factors can influence PVR variability: voiding in unfamiliar surroundings, voiding on command with a partially filled or overfilled bladder, the interval between voiding and the estimation of residual (it should be as short as possible), the presence of vesicoureteric reflux or bladder diverticula. Several studies reported the questionable value of PVR as an important outcome prognosticator in male patients with benign prostatic enlargement and benign prostatic obstruction [37-42]. The cause of PVR is probably mutifactorial, and no consensus exists on the relation of PVR, bladder outlet obstruction and detrusor contractility.

b) Conclusions

Knowledge regarding pathophysiology of PVR remains unclear. In patients with urinary incontinence there is no consensus as to its value as a safety parameter and particularly its relationship with upper tract dilatation, bacteriuria and urinary infection. The intra-individual variability of PVR has been investigated mainly in male patients with bladder outlet obstruction but little information is available as to its variability in patients with urinary incontinence.

Ultrasound is the recommended method for assessing PVR because it is the least invasive and it is sufficiently accurate for clinical purposes yet it is the most expensive. In-and-out catheterisation is invasive and can be inaccurate even if carefully performed.

The general opinion is that PVR measurement forms an integral part of the study of urinary incontinence, as a safety parameter to exclude voiding dysfunction associated with incontinence.

Table 3. Comparison of different formulae to assess PVR by transabdominal ultrasound in 30 men with BPH scanned three times (35).

c) Consensus Statements

1. Residual urine measurement is recommended in the initial assessment of urinary incontinence as a safety parameter and in the evaluation of treatment outcome (**Level of Evidence 3- Grade of Recommendation C**)

2. Measurements should be performed using real-time sonography or a portable scanner or in and-out catheterisation (**Level of Evidence 3- Grade of Recommendation C**).

3. Due to intra-individual variability, in cases where significant PVR is detected by the first measurement, several measurements should be performed (**Level of Evidence 3- Grade of Recommendation C**)

4. The method of measurement should be recorded **(Level of Evidence 3- Grade of Recommendation C)**

d) Future Research Areas

1. Pathophysiology of PVR in male and female populations with UI;

2. Circadian variation of residual urine in patients with UI;

3. Determination of the cut off value of significant residual urine in different patient populations with UI

4. Residual urine as a prognostic indicator of outcome in the treatment of incontinence (**Level of Evidence 3- Grade of Recommendation C**)

2. OPEN BLADDER NECK AND PROXIMAL URETHRA AT REST

The significance of open bladder neck and proximal urethra at rest observated during a voiding cystourethrogram or pelvic floor ultrasound scan remains doubtful [1] and the peer-reviewed literature is equally divided into papers associating such a condition with storage disorders and those suggesting this is a chance finding with no negative implications.

A 21% prevalence in nulliparous asymptomatic women has been reported [2]. In the non-neurogenic population there is no pathophysiological correlation between this and urinary incontinence, Digesu and co-workers reported a prevalence of 1:3 amongst females suffering LUTS. An open bladder neck at rest is not pathognomonic of sphincter incompetence although it is associated with USI [3]. In patients with stress incontinence, but also in asymptomatic women [4], funnelling of the internal urethral meatus may be observed on Valsalva and sometimes even at rest; funneling is often associated with leakage. However, funnelling may also be observed in urgency incontinence and cannot be used to prove SUI. Marked funnelling has been shown to be associated with poor urethral closure pressures [5, 6].

Reports in the peer reviewed literature suggest that an open bladder neck and proximal urethra at rest, during the storage phase, may be observed during cystography, videourodynamics or bladder ultrasound, both in patients with and without neurological disease and is interpreted as a sign of internal sphincter denervation as occurs in 53% of patients with Multiple System Atrophy [7]. Distal spinal cord injury has been associated with an open smooth sphincter area, but whether this is due to sympathetic or parasympathetic decentralisation or defunctionalisation remains uncertain [8]. Relative incompetence of the smooth sphincter area may also result from interruption of the peripheral reflex arc very similar to the dysfunction observed in the distal spinal cord injury. Twenty-one out of 54 patients with spinal stenosis were found to have an open bladder neck at rest [9]. In a review of 550 patients [10], 29 out of 33 patients with an open bladder neck had neurological disease. Although the association was more commonly seen in patients with thoracic, lumbar and sacral lesions, the difference when compared to cervical and supraspinal lesions was not significant. Damage to the sympathetic innervation to the bladder was also frequently observed in patients undergoing major pelvic surgery, such as, abdominal perineal resection of the rectum. Patients with myelodysplasia had an inordinately high incidence of open bladder neck (10 out of 18 patients versus 19 out of 290 having different neurological disorders).

Patients with sacral agenesis are included in the larger category of myelodysplastic patients and suffer from an open bladder neck with an underactive bladder. Shy-Drager syndrome is a Parkinson-like disorder with peripheral autonomic dysfunction. Neurogenic detrusor overactivity is usually found in association with an open bladder neck at rest and a denervated external sphincter [11]. Peripheral sympathetic injury results in an open bladder neck and proximal urethra from a compromised alpha-adrenergic innervation to the smooth muscle fibres of the bladder neck and proximal urethra [12). Although it can occur as an isolated injury it is usually associated with partial detrusor denervation and preservation of sphincter EMG activity. The loss of bladder neck closure suggests an autonomic neural deficit. The site and nature of the requisite deficit is unclear.

Most authors agree on the importance of the sympathetic system in maintaining the integrity of the bladder neck [13-16] although the possible role of parasympathetic innervation has been proposed by others [17, 18]. An open bladder neck at rest in children or in women without neurological disease can represent a different disorder, either related to a congenital anomaly or secondary to an anatomical pelvic floor defect. Stanton and Williams [19] described an abnormality in girls with both diurnal incontinence and bed-wetting, based primarily on

voiding cystourethrography, in which the bladder neck was wide open at rest. Murray et al [20] reported the "wide bladder neck anomaly" in 24.5% of the girls [35] and 9.3% of the boys [10] out of 251 children (143 girls and 108 boys) undergoing videourodynamics for the assessment of non-neurogenic bladder dysfunction (mainly diurnal incontinence). The authors considered the anomaly congenital and made the hypothesis that wide bladder neck anomaly in girls may provide a basis for the development of USI in later life.

The presence of an open bladder neck has been proposed to explain the pathophysiology of urinary incontinence but such hypothesis did not stand the test of time. An open bladder neck was a key point in defining type III stress incontinence according to the classification of Blaivas and Olsson [21]. This classification, no longer used in our daily practice, was based on history, imaging, and urodynamics, and distinguished five diagnostic categories of stress incontinence. Incontinence type III was diagnosed by the presence of an open bladder neck and proximal urethra at rest in the absence of any detrusor contraction suggesting an intrinsic sphincter deficiency.

In pelvic fracture with membranous urethral distraction defects, when cystography (and/or cystoscopy) reveals an open bladder neck before urethroplasty, the probability of postoperative urinary incontinence may be significant, although the necessity of a simultaneous (or sequential) bladder neck reconstruction is controversial [22-24]. Skala and co-workers suggest that an open bladder neck at rest is associated with an increased risk of postoperative complications and failure after open colposuspension [25].

a) Conclusions

In conclusion, the diagnosis of open bladder neck at rest does not seem to be helpful to diagnose the underlying cause of urinary incontinence.

b) Consensus Statements

When observing an open bladder neck and proximal urethra at rest in male patients, during the storage phase, whatever imaging technique is used, it may be worthwhile to evaluate the possibility of an underlying autonomic neural deficit. (**Level of Evidence 3, Grade of Recommendation C**)

c) Future Research Areas

1. The relation of open bladder neck and proximal urethra at rest to the different neurogenic disorder
2. Longitudinal study of wide bladder neck and proximal urethra at rest in asymptomatic women
3. Evaluate the prognostic value of the open bladder neck and proximal urethra at rest

3. FEMALE URETHRAL DIVERTICULA

The prevalence of urethral diverticula ranges between 1 and 6% with rates up to 10% in among symptomatic women from tertiary referral centres [1, 2]. The suspicion of a urethral diverticulum stems from LUTS or urethral masses on physical examination. Urethral masses include leiomyoma, vaginal cysts, malignancy, ectopic ureter, granuloma and urethral diverticula. The first case of female urethral diverticulum was reported in 1805 [3]. Since the report from Davis and Cian in 1956 [4] using positive-pressure urethrography (PPU), the diagnosis has become much more common even though, despite increased clinical awareness, this pathology continues to be frequently overlooked. Urinary incontinence is often associated with a urethral diverticulum. Incontinence may be a sequel to urine loss from the diverticulum itself with stress manoeuvres, SUI or urgency incontinence [5]. Aldrige et al. [6] reported urethral diverticula in 1.4% of patients with stress urinary incontinence.

The presenting symptoms of a urethral diverticulum have classically been described as the three Ds (Dysuria, postvoid Dribbling, and Dyspareunia). Since most patients present with nonspecific lower urinary tract symptoms, and the pathognomonic presentation (postvoid dribbling, urethral pain, tender periurethral mass and expression of pus from the urethra) is very uncommon, these patients undergo extensive evaluation and treatment before a correct diagnosis is established [7, 8]. The diagnosis of a urethral diverticulum may be achieved by physical examination, voiding cystourethrography, positive-pressure (double-balloon) urethrography, urethroscopy, endocavitary (transurethral or transvaginal) or transperineal ultrasound sonography, urethral pressure profile or MRI. Positive pressure urethrography is usually accomplished using a double balloon catheter according to the method described by Davis and Cian [4]. Two different models exist: the Davis-TeLinde and the Tratner catheter. Positive-pressure urethrography (and voiding urethrography) may result in a false negative study when the inflammation of the diverticulum neck prevents contrast medium from flowing into the diverticulum cavity.

The accuracy of a diagnostic test may depend upon the characteristics of the study population and conflicting data are often reported in the peer-review literature. Blaivas et al reported a diagnostic accuracy of VCUG of 97% in a series of 66 patients and similar results (95%) were obtained by Ganabathi et al. [7, 9]. Less favourable results have been reported by others. Comparison of VCUG versus PPU in the diagnosis of urethral diverticula showed a clear superiority of the latter with good consistency among different studies [10, 11]. In some patients, VCUG only delineated the lower part of the diverticulum [12]. Ultrasound scanning and MRI should theoretically be free of such false negative imaging. Chancellor et al. [13] described the use of intraoperative intraluminal echographic evaluation which may be of help in dissecting the diverticulum and achieving

complete excision without damaging the bladder neck and urethra. A number of studies have shown that MRI is better than both voiding cystourethrography and positive-pressure urethrography and can be considered, if available, the imaging of choice when the diagnosis of urethral diverticulum is suspected [14-19] (**Figure B 28 a,b**). MRI is superior to VCUG or double-balloon urethrography, particularly in diagnosing diverticula with narrow, noncommunicating necks [15, 16]. MRI proved to be superior to radiological studies because diverticula can go undiagnosed on voiding cystourethrogram, furthermore size and complexity of the diverticulum is better defined on MRI [17]. Endoluminal MRI is considered to be of particular importance in the diagnosis of a circumferential urethral diverticulum, a condition that is relatively rare but the diagnosis may increase with the increased use of this imaging technique. Proper evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery [1, 20]. MRI also proved to be useful in diagnosing inflammation or tumour in the diverticulum [21, 22]. Endoluminal MRI with either a vaginal or rectal coil, may provide even better image quality than simple MRI [18]. A comparison of MRI versus urethrography and urethroscopy, in a group of 20 women with urethral diverticulum, reported a 69 and 77 per cent accuracy of the two latter imaging studies versus MRI [14]. When surgical findings were compared to MRI, urethrography and urethroscopy, the diagnostic ability of the three methods was 70, 55 and 55 per cent, respectively. Diverticula ostia could not be identified by MRI not withstanding the use of contrast material. Neitlich et al. [15] reported in a series of 19 patients that MRI (using a fast spin echo T2-weighted pulse sequence and a dedicated pelvic multicoil) had a higher sensitivity for detecting urethral diverticula and a higher negative predictive rate in comparison to double balloon urethrography. Blander et al.[17], compared MRI and VGUG in 27 patients with urethral diverticula and found that endoluminal (endorectal or endovaginal) MRI was extremely accurate in determining the size and extent of urethral diverticula compared to VCUG; the related information can be critical when planning surgical approach, dissection and reconstruction. In conclusion, review of the peer reviewed literature suggests that positive pressure urethrography is still a valuable tool to diagnose female urethra diverticula notwithstanding both ultrasound sonography and particularly MRI represent better alternatives with a significantly higher diagnostic accuracy.

In males, both VCUG and ultrasonography can be successfully used to diagnose syringocele (cystic dilatation of the Cowper's gland), congenital and acquired diverticula [23].

a) Conclusions

Proper imaging of female diverticula is essential to diagnose the condition and, in planning and conducting proper surgical repair. Ultrasonography may suffice to identify size and location of the diverticulum although MRI imaging in preferable whenever available.

b) Consensus Statements

o In cases of female urinary incontinence if a urethral diverticulum is suspected, appropriate imaging (positive pressure urethrography, voiding cystourethrography, urethroscopy, ultrasound, MRI) is recommended. (The choice of the type of imaging depends on their availability. Data show a higher accuracy of MRI.) (**Level of Evidence 3 – Grade of Recommendation C**)

c) Future Research Areas

o Properly conducted prospective studies are needed to compare the accuracy of ultrasonography and MRI in the diagnosis and staging of female and male diverticula

d) References (see at the end of the chapter)

4. IMAGING OF THE NERVOUS SYSTEM

Lower urinary tract dysfunction often depends upon derangements of its neural control mechanism. Imaging of the spinal chord and central nervous system may help identifying occult neurological conditions or the site and extent of known neural damage. Functional imaging of the nervous system is a formidable research tool to better understand mechanisms of signal integration at the central level and its possible malfunctioning.

a) Lumbosacral Spine x-rays

In children with lower urinary tract dysfunction and urinary incontinence, the presence of a spinal dysraphism must be ruled out. Although in most of the cases abnormalities of the gluteosacral region and/or legs and foot are clearly visible, antero-posterior and lateral films of the lumbosacral spine have to be evaluated in order to identify vertebral anomalies. Sacral agenesis involves the congenital absence of part or all of two or more sacral vertebrae. In the absence of two or more sacral vertebrae a neurogenic bladder is usually found. Spina bifida occulta has a variable significance. Simple failure to fuse the laminae of the fourth and fifth lumbar vertebrae is unlikely to be important, but if the spinal canal is noticeably widened, there may be cord involvement (diastematomyelia, tethered cord syndrome).

b) CT, MRI, SPECT and PET

Numerous papers refer to rare neurological conditions presenting with different symptoms including urinary incontinence in which CT scan, MRI, SPECT, and PET imaging were carried out to identifying the underlying CNS disease. These references have little impact on daily practice although they can he helpful in occasional difficult cases.

With regards to the clinical diagnostic use of CT or MRI, a few papers evaluated the role of fetal MRI imaging. Fetal MRI has higher contrast resolution than prenatal sonography and allows better identification of normal and abnormal tissue. Moreover, MRI can

Figure B 28 ab: (a) MRI: urethral diverticulum (coronal view)
b: MRI: urethral diverticulum (sagittal view)

diagnose some abnormalities such as cerebral malformations and destructive lesions which can be occult on prenatal sonography, where the more anterior cerebral hemisphere cannot be properly evaluated due to reverberations by the overlying structures [2]. Common indications for fetal MRI include the evaluation of all the sonographically diagnosed abnormalities of ventriculi, corpus callosum, or posterior fossa, as well as all those fetuses at increased risk for brain abnormalities, such as in families with a history of a prior child or fetus with anomalies, genetic disorders, complications of monochorionic twinning, and maternal illness (such as maternal infection or major cardiac event). Moreover, with recent advances in fetal surgical techniques, fetal MRI is being increasingly used before surgical intervention [3]. The results of fetal MRI, whether verifying absence of abnormality, confirming sonographically detected abnormalities, or discovering additional abnormalities that were not apparent by sonography, have been shown to affect clinical decision-making during pregnancy, both by physicians and parents, resulting in changes in pregnancy management in nearly half of cases [2]. With regard to myelomeningocele, prenatal ultrasound can easily identify the absence of posterior elements of the vertebral bodies at affected levels and extension of the subarachnoid space posteriorly through the bony spina bifida, as well as the frequently associated presence of small posterior fossa alteration and herniation of cerebellar tissue into the cervical subarachnoid, which define the Chiari II malformation. However, fetal MRI can be a helpful adjunct when sonography analysis is limited, such as in cases of large maternal body habitus, oligohydramnios, low position of the fetal head, or when the fetal spine is positioned posteriorly with respect to the mother. Moreover, fetal MRI can be very useful to detect additional associated anomalies, such as callosal agenesis or hypogenesis, periventricular nodular heterotopia, cerebellar dysplasia, syringohydromyelia, and diastematomyelia [3]. If fetal surgery will be shown to improve long-term outcome, fetal MRI will surely become a routine examination for affected fetuses.

MRI is also recommended in children with anorectal abnormalities as abnormalities of the spine and of the spinal cord are diagnosed in 42 to 46% of cases and in about 50% of cases the spinal cord is involved [1]. Wraige et Borzyskowski suggested that spinal cord imaging should be considered in children in whom day-time wetting is associated with impaired bladder sensation or poor bladder emptying even in the absence of clinical or radiological suspicion of lumbosacral spine abnormalities. Four out of 10 children with these symptoms had a spinal cord defect diagnosed on MRI [4].

MRI of the lumbar spine is now the gold standard for evaluating children with spina bifida and adults in which an occult form of spina bifida is suspected. A potential technical update might be the use of intrathecal contrast medium to perform cisternography and ventriculography contrast-enhanced MRI. Munoz et al., evaluated a series of 10 patients with complex cerebrospinal fluid diseases, where other imaging techniques had been unclear or inconclusive, performing MRI with intrathecal administration of gadopentate dimeglumine. In 8 out of the 10 patients, imaging findings influenced or changed the clinical decision-making program and the surgical planning [5].

Sharma et al. recently evaluated with MRI the surgical outcome in patients with spinal dysraphism. Specifically, MRI spectroscopy was used to evaluated the composition of cerebrospinal fluid before and after surgery. Before surgery, high levels of lactate, alanine, acetate, glycerophosphorylcholine, and choline were observed in the cerebrospinal fluid of patients with spinal dysraphism, while these levels normalised postoperatively to those observed in control subjects. However, in those patients where cord tethering occurred, increased concentrations of lactate and alanine were found, suggesting that MRI spectroscopy might be a promising tool in the assessment of surgical outcomes in patients with spinal dysraphism [6].

Several papers refer to the use of CNS imaging in clinical research of voiding dysfunction and pathophysiology. Positron emission tomography (PET) and functional MRI studies provided information on specific brain structures involved in micturition in humans. During micturition an increase in regional blood flow was shown in the dorsomedial part of the pons close to the fourth ventricle, in the pontine micturition centre (PMC), in the mesencephalic periacqueductal grey (PAG) area, as well as in the hypothalamus including the preoptical area [1]. A good review on CNS imaging and lower urinary tract function was recently published by Drake and co-workers [7].

A couple of significant original studies have been published recently on the role of functional MRI in stress and urgency urinary incontinence. Specifically, previous brain imaging studies showed that during pelvic floor muscle contraction there was activity in the superior medial precentral gyrus, anterior cingulate cortex (ACC), cerebellum, supplementary motor cortex (SMA) and the thalamus [8, 9]. Similarly, during anal spincter contractions multifocal cerebral activity was shown in the primary and secondary sensory/motor cortices, the insula as well as the cingulate gyrus, prefrontal cortex, and the parietooccipital region [10]. Di Gangi Herms et al. evaluated the neuroplastic changes of cortical representation of pelvic floor motor function induced with pelvic floor muscle training (PFMT) by biofeedback in patients with SUI [11]. Specifically, the authors used functional MRI to evaluate 10 patients with SUI before and after a 12-week PFMT with EMG-biofeedback program. In the MRI performed before the beginning of PFMT, the authors identified significant brain activation in superior lateral and medial precentral gyrus and the superior lateral postcentral gyrus, in the SMA, the left premotor area, and in the left and middle cerebellum, as well as in the insula and in the ACC. In the MRI film after PFMT, less brain areas were activated, mainly the superior lateral and medial precentral gyrus, superior lateral postcentral gyrus and the insula. In other words, after PFMT there was more focused activation in the primary motor (superior lateral and superior medial precentral gyrus) and somatosensory areas, which is consistent with automation of the relearned skillful behavior [11]. PFMT with biofeedback may improve muscular strength therefore enhancing support of the urethra and also optimise central muscular control of the pelvic floor, modulate bladder sensation, and reflect the emotional neutralisation related to symptom reduction.

With regards to urgency urinary incontinence, Tadic et al. reported a small study, which used functional MRI to investigate 11 patients with urge urinary incontinence and 10 healthy controls. Specifically, the connections of the right insula (RI) and anterior cingulate gyrus (ACG) to other cortical area were evaluated, based on the assumption that the two areas were among the most important regions of the supraspinal neuronal network controlling the bladder. In normal subjects, there were significant positive effective connections with many of the regions involved in supraspinal bladder control, including left insula and frontotemporal and parietal regions, thalamus, putamen and claustrum, posterior cortex, cerebellum, pontine micturition centre and mesencephalic periacqueductal grey. Vice versa, in the patients with urgency incontinence, significant negative connections to left parieto-temporal lobes, hippocampus, parahippocampal gyrus and cerebellum were found, with few positive connections [12]. In subjects with normal bladder function, RI and/or ACG have been reconfirmed to have effective connections with many of the brain regions involved in bladder control such as the frontotemporal and sensorimotor regions, thalamus, putamen, cerebellum and midbrain, as well as to the posterior cortex, a region which may have a role in the control of bladder function. Vice versa, in the patients with urgency incontinence, the connections were shifted to an alternative complex of brain regions, such as left parieto-temporal lobes, parahippocampal gyrus and parts of cerebellum, which might represent expression of the recruitment of accessory pathways in order to control urgency and the voiding reflex as well as the emotional charge due to the abnormal sensation of urgency [12]. On the whole the data from these recently published studies have improved our knowledge of nervous functional anatomy related to vesicourethral function and dysfunction but, to date, have no clear clinical relevance.

In conclusion, central nervous system imaging is rarely indicated in urinary incontinence. Spinal cord imaging is recommended in cases of children with anorectal malformation and whenever spina bifida occulta is suspected. In the case of clinical neurological signs and/or symptoms suggestive of central nervous lesions, imaging may be indicated along with more specific neurophysiological tests (e.g., signal latency, testing, evoked potential, etc.). Further improvements in the knowledge of the correlation between morphological and functional evaluation of the CNS is foreseeable using present CNS functional imaging technology.

c) Consensus Statements

- In patients with suspected congenital neurogenic incontinence, with or without abnormalities of neurourological physical examination, lumbosacral spine anteroposterior and lateral radiological evaluation (or MRI) is indicated. (**Level Evidence 3, Grade of Recommendation C**)
- Neuroimaging should be considered when a nervous system disorder is suspected on the basis of clinical and/or neurophysiologic test findings (**Level of Evidence 3 - Grade of Recommendation C**)

d) Future Research Areas

- To investigate the effect of antimuscarinics and neuromodulation on brain activity;
- To standardise bladder filling parameters to investigate brain activity during different types and levels of bladder sensations;

- To investigate the effect of environmental and behavioural factors on brain activity in patients with urgency incontinence;
- To define the sequence of brain activation during bladder filling.

e) References (see at the end of the chapter)

5. ENDOSCOPY OF THE LOWER URINARY TRACT

Since the introduction of the cystoscope by Bozinni in 1805, endoscopy has played a critical role in the evaluation of lower urinary tract disorders [1]. Many investigators have proposed the routine use of urethrocystoscopy in the evaluation of urinary incontinence. These recommendations have rarely been based on evidence. There are five specific areas pertaining to urinary incontinence in which urethrocystoscopy has been advocated.

1. Observation of the female urethral sphincter to assess its ability to close and coapt. Urethrocystoscopy has been advocated in the static state to assess intrinsic sphincter deficiency (ISD) as well as in the dynamic state, when the patient is straining, to evaluate hypermobility and urethral closure while the patient is straining. It has been reported that sluggish closure of the bladder neck during periods of a rise in intra-abdominal pressure is associated with anatomical stress urinary incontinence. Intrinsic sphincter deficiency has classically been described as a fibrotic or pipe-stem urethra. It has been suggested that endoscopy can even help to differentiate between the hypermobile urethra and the intrinsically damaged urethra.

2. Assessment of the bladder, to rule out concomitant bladder conditions which may be the cause of detrusor overactivity and urinary incontinence or may simply require treatment.

3. Search of extraurethral causes of urinary incontinence, such as vesico-vaginal fistula and ectopic ureter.

4. Intraoperative cystourethroscopy during correction of USI to assess for bladder damage and ureteral patency.

5. Evaluation of the membranous and prostatic urethra in male patients with post-prostatectomy stress incontinence to evaluate possible iatrogenic damage of the external sphincter region. Assessment of bladder outlet in males with urgency incontinence considered to be secondary to bladder outlet obstruction to appraise prostate morphology.

a) Evaluation of the Female Bladder Outlet

Robertson described the procedure of dynamic urethroscopy to evaluate the bladder neck [2]. In this procedure a gas urethroscope is used to observe the urethra, bladder neck, and portions of the bladder. During visualisation manometric recording can be performed. Robertson described the appearance of SUI as a sluggish closure of the bladder neck and the appearance of the overactive bladder as a bladder neck that closes and then opens like the shutter of a camera. This procedure was reported to be extremely useful in patients with urinary incontinence as the bladder neck can then be observed at rest, with straining, and Valsalva manoeuvres. Unfortunately, in Robertson's original description of this procedure, it was never compared to other standard methods of measuring outlet resistance. Others who advocate the technique of Robertson reported that only 43% of patients with SUI actually had loss of bladder neck support on urethroscopy [3]. Scotti, et al performed a retrospective review of 204 patients who underwent dynamic urethroscopy for the evaluation of SUI [4]. Of the 204 patients, 99 had USI. Urethroscopy was found to be an imprecise predictor of USI with a 62% sensitivity, a 74.6% positive predictive value and a specificity of 79.1%. Moreover, there were many equivocal studies. The authors concluded that urodynamic evaluation rather than urethroscopy was a more accurate predictor of stress incontinence. Sand, and associates compared supine urethroscopic cystometry (dynamic urethroscopy) to the gold standard of multichannel urethrocystometry [5]. They found a sensitivity of only 24.6% and a positive predictive value of only 65.2% in predicting detrusor overactivity.

Horbach and Ostergard tried to predict urethral sphincter insufficiency in women with SUI using urethroscopy [6]. They retrospectively reviewed the records of 263 women who had a diagnosis of SUI. They defined ISD as a maximal urethra closure pressure of 20 cm H2O or less with the patient upright with a symptomatically full bladder. They then divided patients into two groups, those with ISD and those with maximal urethral closure pressures of more than 20 cm H2O. Based on this classification, 132 women, or 50.2%, had evidence of ISD. However, when urethral function was assessed by endoscopy, only six of 132 patients with ISD were found to have an open or partially open proximal urethra and urethrovesical junction at rest during urethrocystoscopy. Clinically, these patients had very low urethral pressures and reported difficulty with continuous leakage of urine. Endoscopy appeared to have little predictive value for ISD as defined by urethral pressure profilometry. Govier et al compared cystoscopic appearance of the female urethral sphincter mechanism to videourodynamic studies in 100 consecutive women with complex types of urinary incontinence [7]. Sphincter dysfunction was classified as minimal, moderate, and severe based on the radiographic appearance of the bladder neck with straining. Urethrocystoscopy underestimated the degree of sphincter deficiency 74% of the time in patients with moderate sphincter dysfunction and 44% of the time in patients with severe sphincter dysfunction. The authors concluded that cystoscopy is inadequate to judge the functional integrity of the bladder outlet. Furthermore, cystoscopy

alone will underestimate intrinsic sphincter deficiency in a large number of patients.

b) Evaluation of the Bladder

Is cystoscopy necessary to rule out concomitant bladder pathology in patients with urinary incontinence? Langmade and Oliver reported on 253 patients who were operated on for SUI [8]. They used a simple evaluation that consisted of history, stress tests, and urinalysis alone. They did, however, recommend cystoscopic evaluation if the patient also complained of symptoms of urgency. Although this dogmatic approach was recommended, it was never clearly stated if it made a difference to the treatment or outcome in these patients. Fischer-Rasmussen, et al performed extensive evaluation of women with urinary incontinence [9]. This included cystoscopy in 190 patients. They found cystoscopy to be abnormal in only 12 patients, 8 who had stress incontinence and 4 who had other types of incontinence. Abnormal findings were trabeculated bladder in five patients, benign bladder papillomas in four, and metaplasia of the trigone in two. None of these was considered to be a significant finding. The authors concluded that cystoscopic examination did not contribute to the classification of incontinence in any case. Cardozo and Stanton evaluated 200 patients with SUI and detrusor overcativity [10]. Cystoscopy revealed no abnormalities amongst the 100 patients with USI. Fourteen of the 100 patients with detrusor overactivity had cystoscopic abnormalities, eg trabeculation-11, injected mucosa- 1, sacculation -1, a bladder capacity of less than 100 cc-1. However, in none of these patients was the treatment affected by the results of cystoscopy. In support of these findings, Mundy has stated that there is no direct diagnostic value of endoscopy in a patient with an overactive bladder. It may sometimes be helpful to look for and exclude a cause of hypersensitivity when this is in the differential diagnosis [11]. Duldulao and colleagues found this necessary only in patients with haematuria [12]. They performed urinalysis, urine cytology, and cystoscopy on 128 women who presented with urgency incontinence and/or storage voiding symptoms. Of these, 68 patients had urgency incontinence, 35 of whom also had microscopic haematuria. One patient with urgency incontinence and haematuria was found to have a transitional cell carcinoma of the bladder. None of the patients with urgency incontinence (or storage symptoms only) and no haematuria were found to have significant cystoscopic findings. This would support the routine use of cystoscopy for patients with urgency incontinence only if haematuria is present.

c) Extra-Urethral Urinary Incontinence

Endoscopy can be an invaluable tool in the diagnosis and treatment of extraurethral incontinence due to vesico-vaginal fistula and ectopic ureter. With respect to vesico-vaginal fistula, cystoscopy can precisely localise the fistula site in the bladder and help plan surgical correction. Occasionally, a small fistula that is not seen on physical examination or radiographic studies, can only be diagnosed by cystoscopy. Incontinence due to ectopic ureter in the female is usually diagnosed by radiographic studies. However, the exact location of the ureteral orifice in urethra or vagina can be identified by cystourethroscopy and/or vaginoscopy. This can be extremely helpful in the planning corrective surgery.

d) Intraoperative Lower Urinary Tract Evaluation

Several authors have studied the value of routine cystoscopy during operative procedures for incontinence and prolapse. The approach may be transurethral [13] or transvesical [14]. The American College of OB/GYN has published a Bulletin on Operative Lower Urinary Tract Injuries [15] in which is stated “at the conclusion of the procedure, when hemostasis has been ensured, both ureters and the bladder should be inspected to confirm their integrity.” Harris and co-workers [13] reported 9 unsuspected ureteral or bladder injuries during urogynaecological surgery, which included 6 ureteral ligations, with four of these occurring after Burch cystourethropexy. Burch sutures were also found in the bladder as well as fascial lata from a sling procedure.

e) Evaluation of the Male Bladder Outlet

Urgency incontinence is one of the lower urinary tract symptoms associated with benign prostatic hyperplasia, bladder outlet obstruction, and aging in the male population. Based on the available evidence and world literature, The World Health Organization Fourth International Consultation on BPH made the following recommendation: “Diagnostic endoscopy of the lower urinary tract is an optional test in the standard patient with LUTS (lower urinary tract symptoms) because: 1) the outcomes of intervention are unknown, 2) the benefits do not outweigh the harms of the invasive study, 3) the patients’ preferences are expected to be divided. However, endoscopy is recommended as a guideline at the time of surgical treatment to rule out other pathology and to assess the shape and size of the prostate, which may have an impact on the treatment modality chosen [16]. Several contemporary series have described the value of urodynamics in the diagnosis of post-prostatectomy urinary incontinence [17-21]. However, only one describes the routine use of urethrocystoscopy. In that series 67% of patents had urethral fibrosis confirmed by endoscopy [18]. However, how this finding affected treatment was not discussed. In the study by Leach and Yun treatment of incontinence was based solely on urodynamic findings and was successful in 87% of patients [22]. Anastomotic strictures may be suspected based on uroflow and urodynamic (pressure-flow) studies and can be confirmed by voiding cystourethrogram or videourodynamics as well as by endoscopy. However, if intervention for the stricture is deemed necessary, endoscopy would be a more critical part of the evaluation. Furthermore if surgical treatment of incontinence, such as, an artificial urinary sphincter, is planned it would seem to make good clinical sense to evaluate the urethro-vesical anastomosis with endoscopy prior to surgery.

f) Evaluation of Urethral Sphincter In Post-Prostatectomy Incontinence.

Iatrogenic UI in males usually occurs after prostate surgery for benign and malignant conditions. The pathophysiology of UI following transurethral surgery for BPH includes sphincter damage from extending the resection too distal, particularly in the dorsal aspect of the sphincter where muscle fibres are more abundant. Endoscopy in post-TURP incontinence reveals insufficient closure at rest with tissue loss in the ventral aspect of the sphincter area, voluntary muscle recruitment is often good. The pathophysiology of UI in post-radical prostatectomy patients is unclear. Numerous studies have investigated the relationship between parameters of urethral pressure profile, morphology of the prostate apex and length of the external sphincter area to post-prostatectomy incontinence. Although the results of these studies suggest a relationship between sphincter competence and UI, no consensus has been reached regarding the gold standard test to be performed prior to surgery to assess the individual patient risk of incontinence. Recently, Gozzi and Rehder suggested that post-radical prostatectomy incontinence may be related to prolapse of the sphincter complex and that repositioning of it by a transobturator sling may be successful. Pre-operative selection of surgical candidates for such intervention include endoscopy of membranous urethra testing whether manual push-up of the centrus tendineus perinei results in recruitment of the sphincter fibres comparable to a voluntary contraction. Contraction of the sphincter muscle upon repositioning in a more cranial position is used as an indication for a transobturator sling with the Gozzi and Rehder technique [23-25]. Further research is required to confirm such an interesting pathophysiological explanation of post-radical prostatectomy incontinence and to support the role of endoscopy in the evaluation of these patients.

g) Consensus Statements

o Routine urethro-cystoscopy is NOT indicated in primary female urinary incontinence, when other pathologies are not suspected **(Level of Evidence 3, Grade of Recommendation C)**

o Endoscopy can be considered **(Level of Evidence 3, Grade of Recommendation C)**:

a) in urgency incontinence to rule out other pathologies, especially in case of microscopic haematuria (e.g., bladder tumour, interstitial cystitis, etc)

b) in the evaluation of recurrent or iatrogenic cases when surgery is indicated and planned

o Endoscopy is indicated in the evaluation of vesico vaginal fistula and extra-urethral urinary incontinence **(Level of Evidence 3, Grade of Recommendation C)**.

o Endoscopy is indicated intraoperatively in incontinence surgery to look for ureteral or vesical injury **(Level of Evidence 3, Grade of Recommendation C)**.

h) Future Research Areas

- The relationship between of bladder endoscopy and idiopathic detrusor overactivity
- The relationship between of bladder endoscopy and aging
- The relationship between bladder endoscopy and symptoms of voiding dysfunction in female patients with UI

i) References (see at the end of the chapter)

C. Imaging in Anal Incontinence

Anal incontinence may result from anatomical and/or neurological disruption of the anal sphincter complex. Prior to the development of anorectal imagining techniques, anal sphincter disruption was detected by digital palpation supported by EMG needle mapping and ano-rectal manometry. Use of endoanal ultrasonograpghy (EAUS) for anal sphincter imaging was first described by Wild in 1956 [1] but remained neglected for many decades because of the limitation of technology then available [2]. In 1989 Law and Bartum defined the technique of EAUS and endosonographic anatomy of the anal sphincter complex [3]. Since then EAUS has become the gold standard of imaging the anal sphincter complex.

Development of 3-D rendering technique over the last decade has enabled better quality imaging of the anal sphincter complex using the EAUS. Recently other imaging modalities such as transvaginal, transperineal and translabial ultrasonography, MRI, Defaecography and Sonoelastography have been described to assess the anal sphincter complex in patients with anal incontinence.

I. INDICATIONS

Anal sphincter imaging has become an integral part of the assessment of anal incontinence. Following detailed history and examination, the patient should be offered anal sphincter imaging (either 2D or 3D EAUS) depending on the availability of imaging modalities and the expertise. Even though ano-rectal physiological studies indicate dysfunction of the anal sphincter complex, they do not identify the anatomical site and the degree of anal sphincter disruption. EAUS has been the gold standard for detecting anal sphincter disruption or atrophy. EAUS is also used in the follow up of women after obstetric anal sphincter injuries to assess the success of the primary repair and to advise on subsequent delivery [4]. EAUS has been used intra-operatively to identify the damaged EAS prior to secondary repair and also to identify the IAS defects prior to injecting bulking agents.

II. IMAGING MODALITIES

1. ULTRASONOGRAPHY

The increased availability of ultrasound scanners to urologists and urogynaecologists and its high resolution

in the near field makes this the perfect tool to investigate patients with anal incontinence as a part of their physical examination.

a) ENDOANAL ULTRASOUND (EAUS)

EAUS is performed using a 360° rotating rectal probe with a 7-10 MHz transducer (focal range 2-4.5cm) with minimum beam width of 1.1mm. Several systems are currently available, and recently integrated 3D systems are also available (B&K Medical, Sandoften 9, 2820 Gentofte, Denmark). Women should be examined prone with an endoanal system to minimise anatomical distortion. **Figure C1** shows a schematic diagram of the anal sphincter complex in relation to the endoanal probe [4].

The standard EAUS image of the anal canal is of 4 layers (**Figure C 2**):

1. The subepithelial layer is moderately reflective.
2. The internal sphincter is the most obvious landmark and is a well-defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
3. The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanalis as well as the longitudinal muscle of the rectum (**Figure C 2**).
4. The external sphincter is better defined in men than women, where it tends to be less hypoechoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (**Figure C 2**). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse perineii muscles fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.

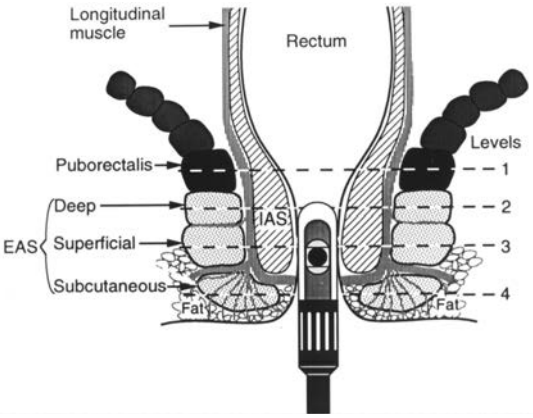

Figure C 1: A schematic diagram of the anal sphincter complex in relation to endoanal probe.

b) 3 Dimensional Endoanal Ultrasonography (3-D EAUS)

With 3D-EAUS, the anal canal is scanned in a conventional manner, and dedicated software provides a final 3D appearance (3D rendering). The data obtained from a series of closely spaced EAUS images (0.25 mm) are combined to create a 3D volume displayed as a cube. The image can then be freely rotated and it is possible to visualise defects at different angles and to obtain the most information from the data [5]. The advent of 3 D ultrasonographic multiplanar reconstruction of the anal canal has further improved the detection of anal sphincter injuries with nearly 95-100% sensitivity and specificity [6]. With 3D-EAUS, the aspect, localisation (circumference involved, height), size (in degrees or percentage of circumference) and number of sphincter defects can be described in detail, together with a calculation of the volume of such defects [7] (**Figures C3-C4-C5**). Defects of the puborectalis fibres of the levator ani are less common and these can be seen as heterogeneous remodelling or shortening of the two bands is visible after episiotomy or pelvic floor injury during vaginal delivery. Its role in the development of AI is probably underestimated and characterisation, particularly in terms of volume, would be of interest to assess the functional impact [6]. Two scoring systems has been introduced to objectively evaluate the anal sphincter defects detected in 3D EAUS [8, 9] and both these scoring system have shown acceptable intra observer and inter observer agreement [9].

Although EAUS has been accepted as the gold standard of imaging anal sphincter complex, the equipment and the expertise may not be readily available in some centres. Some patients may find EAUS

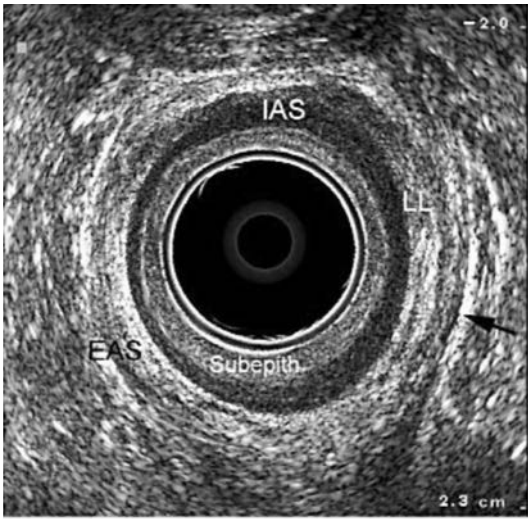

Figure C 2: Axial endosonography in the mid canal in a normal 38yr old female. Subepith: subepithial layer; IAS: internal anal sphincter; LL: longitudinal layer; EAS: external anal sphincter. The outer border of the external sphincter is defined by an interface reflection at the fat/muscle boundary (arrow).

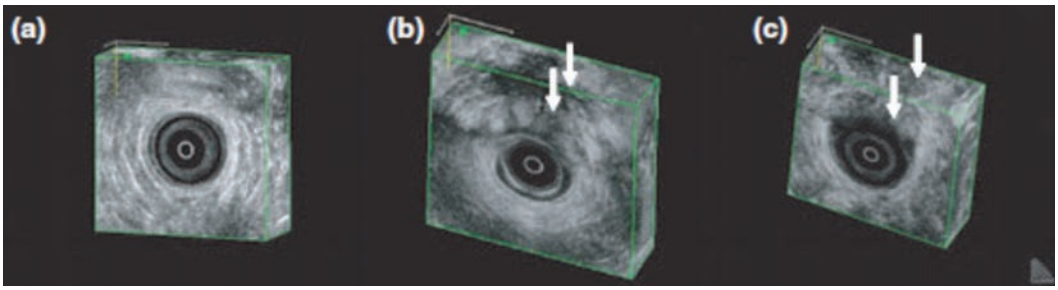

Figure C 3: Three-dimensional endoanal ultrasound showing no (a), partial (b) or complete EAS defect (c). Arrows indicate an EAS defect in the sagittal view (10).

technique embarrassing and unacceptable. Hard endoanal cone of EAUS may cause the disruption of normal anal canal anatomy. Because of these drawbacks, other imaging modalities such as Endovaginal, Transperineal and translabial ultrasonography have been evaluated to assess the anal sphincter complex.

c) Transvaginal Ultrasonography

Sultan et all first described the vaginal use of 360° rotating probe used for the EAUS and obtained clear images of anal sphincter complex [11]. Since then different types of probes including side-fire transrectal probe, a standard transvaginal probe and modified vaginal probe has been used to evaluate the anal sphincter complex with variable sensitivity and specificity for detecting anal sphincter injury [12].

d) Transperineal Ultrasonography

Transperineal ultrasonography (TPU) to image the anal sphincter complex was first described by Peschers et al. [13] and found to have a good inter observer reliability in detecting IAS and EAS defects compared with EAUS [14]. A recent study by Roos et al. [12] comparing endovaginal and transperineal ultrasonography to detect obstetric anal sphincter have concluded that neither of these modalities is sensitive enough to detect anal sphincter defects.

e) Translabial Ultrasonography

Translabial ultrasound (TLU) offers an alternative imaging modality of the anal sphincter complex and has proven to be well-tolerated by patients. It has been used to describe anal sphincter complex integrity [13, 15]. Hall et all evaluated 60 women with TLU and reported that mean sphincter measurements are given for symptomatic and asymptomatic intact women and are comparable to previously reported endoanal MRI and endoanal ultrasound measurements [16]. The advantages of TLU are that the equipment needed is readily available to all gynaecology and radiology imaging laboratories.

f) Integrated Multicompartmental Pelvic Floor Ultrasonography

Pelvic organ dysfunction includes multiple conditions such as pelvic organ prolapse, urinary incontinence, anal incontinence, defaecatory disorders and sexual dysfunction. Based on this concept integrated multicompartmental Pelvic Floor imaging including two-dimensional (2D), three-dimensional (3D) and 4D pelvic floor ultrasonography as well as transvaginal, endoanal and transperineal techniques, has been described from a global and multicompartmental perspective [17]. The value of this approach in routine assessment of pelvic floor dysfunction is yet to be evaluated.

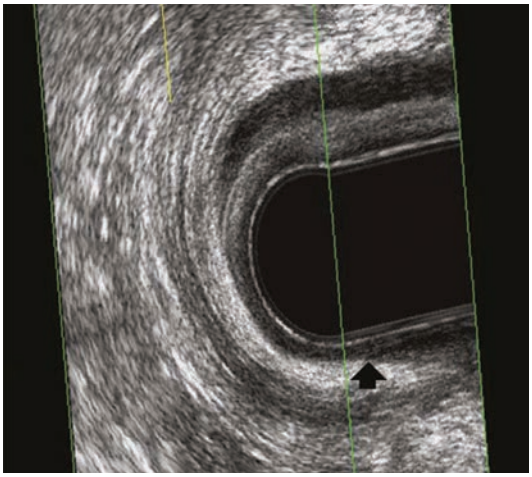

Figure C4: Complete defect of the internal anal sphincter

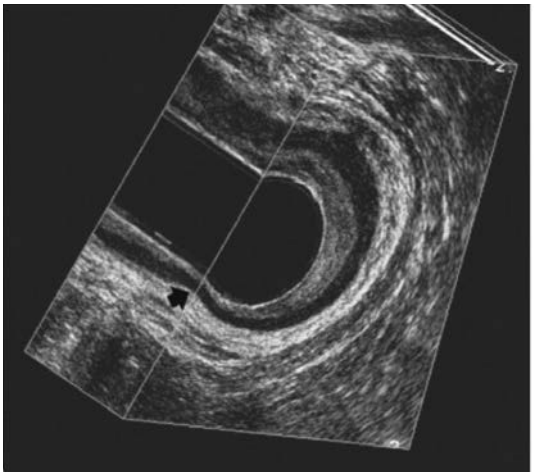

Figure C 5 : Partial defect of the internal anal sphincter (6).

g) Dynamic Anorectal Endosonography (DAE).

DAE uses a rigid biplane transrectal probe with a frequency of 7 MHz with the tip of the probe covered with a water-filled balloon to maintain the acoustic window for the ultrasound waves. By slowly and manually rotating the linear probe through 360°, various layers constituting the anal wall (mucosa, internal anal sphincter, and external anal sphincter), the layer forming the rectal wall, and the perirectal tissues (puborectalis muscle, bladder, and vagina, or prostate) has been demonstrated. After the initial examination, the patient simulates defaecation with the probe left in the same position [18]. In a study of 56 women using DAE and Dynamic MRI Defeaecography significantly more internal anal sphincter defects were found with DAE than with dynamic MRI defaecography. But there was no significant difference for the diagnosis of external anal sphincter defects [18].

h) Sonoelastography

Sonoelastography is a new imaging technique based on differences in radiofrequency signals following endogenous/exogenous compression due to different elastic properties of the targeted tissues or organs [19]. This technique has been evaluated in pathological conditions of breast, thyroid, pancreas and prostate. The elastographic pictures registered simultaneously with conventional grayscale B-mode images during sonography or endosonography are assumed to distinguish malignant from inflamed areas and thus facilitate diagnosis. Based on this concept it is assumed that Sonoelastograhy is able to diagnose different conditions causing anal incontinence. However there is only one published study comparing the conventional endoanal ultrasonography and elastography [20]. This prospective study included 50 patients with faecal incontinence following ano-rectal surgery and Crohn's disease. Elastogram colour distribution within the sphincter representing elastic properties was quantified using a visual analogue scale and an off-line computerised area calculation program. The IAS, a smooth muscle, and the EAS, a striated muscle, have different elastogram colour distributions, probably reflecting their different elastic properties. The absence of significant correlations with the major clinical and functional parameters suggests that in routine clinical practice ultrasound real-time elastography may not yield additional information in patients with faecal incontinence except in patients who have had radiation.

2. MRI

Anatomy of the anal sphincter complex has been redefined over the past 20 years by the use of body coil, endoanal coil and phased-array coil magnetic resonance imaging (MRI). However these different MRI techniques have led to conflicting anatomical descriptions of the anal sphincter complex [21]. Endoanal coil MRI studies by Rociu et al. [22, 23] have suggested that the levator ani muscle has only a transverse portion and that the EAS muscle is composed of only a subcutaneous and a superficial portion describing five image layers. **(Figure C6**)

However, body coil MRI studies by Guo and Li [24] suggested that the levator ani muscle also has a vertical portion (vertical levator), and separate body coil MRI studies by Hsu et al. [25] suggested that the EAS muscle has 3 separate components which has been identified in EAUS as well.

More recent study by Guo et al. [26] using multiplanar body-coil MRI studies demonstrated that the anal region actually has 7 image layers: the mucosa, submucosa, anal smooth muscle, inner space, vertical levator, outer space, and the EAS muscle (**Figure C7**). The authors reported that endoanal MRI does not reliably outline the superficial layers of the anal region because a blind zone is created in the anal canal near the coil. This blind zone led investigators to effectively ignore the mucosa, submucosa, anal smooth muscle, intersphincteric groove, and subcutaneous sphincter and this accounts for the early endoanal MRI description of the anal region as comprising only 5 image layers.

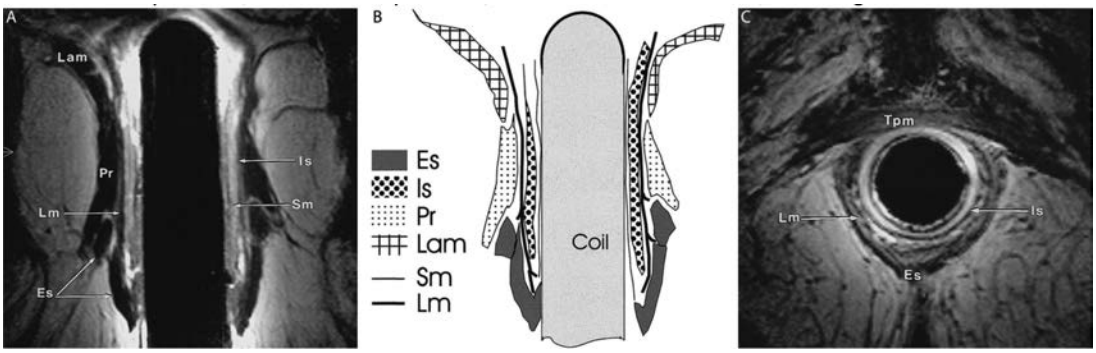

Figure C 6: Weighted turbo spin-echo endoanal coil MRI studies by Rociu et al.[22,23]
A: "5-layer" anal region and blind zone of the endoanal coil MRI.
B: Drawing of anal midcoronal section.
C: Inner intersphincteric space with high signal intensity is mislabeled as the internal sphincter.
Es - external sphincter; Is - internal sphincter; Lam - levator ani muscle; Lm -longitudinal rectal muscle; Pr -puborectalis; Sm -submucosa

Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal to noise ratio resulting in high spatial resolution images. Although the endoanal MRI allows comprehensive assessment of atrophy and focal defects of the external canal, the internal sphincter has been less well defined [27]. A meta analysis of nine studies, comparing endoanal MRI with endoanal ultrasound or surgical diagnosis in 157 patients by Tan et al. [28] has shown that Endoanal MRI was sensitive and specific for the detection of external sphincter injury and especially sphincter atrophy. It may be useful as an alternative to endoanal ultrasound in patients presenting with faecal incontinence. However, the limited availability of dedicated endoanal coils outside specialist units has resulted in less widespread familiarity with this technique and further clinical studies are needed to identify its best application in clinical practice.

In addition to the damage to the anal sphincter complex, levator ani muscle (LAM) injury has also been postulated as a cause for anal incontinence especially after childbirth. A recent MRI study by Helliburn et al. [29] reported major LAM injuries in 19% of women who delivered vaginally with external anal sphincter (EAS) injuries compared to 3% delivered vaginally without EAS injury, and 0% delivered by cesarean section before labour. Among women with EAS injuries, those with major LAM injuries tend to have more anal incontinence symptoms than those who did not have LAM injury. These data suggest that both EAS and LAM are important to maintain faecal continence.

3. EVACUATION DEFAECOGRAPHY (PROCTOGRAPHY)

Evacuation defaecography is indicated in patients with constipation, and in those with obstructive defaection associated with anal incontinence caused by overflow incontinence or post defaecation leakage. In these patients, defaecography is useful to visualise outlet obstruction due to an anatomical (e.g. enterocele, rectocele, intussusception) or a functional (e.g. anismus) cause. Evacuation defaecography is also useful to demonstrate bladder and uterovaginal prolapse as well as pelvic floor descent (**Figure C 8 a-b**) but gives limited information as to rectal function. Evacuation defaecography has shown good reproducibility in the diagnoses of enterocele, anterior rectocele and their grading in patients with faecal incontinence [30].

The rectum is opacified with 120 mls of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before defaecography starts. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (**Figure C 9 a-c**)

Compared to conventional evacuation defaecography, dynamic MR defaecography at a vertical open magnet unit has become popular recently as it produces multiplanar images with increased soft tissue contrast and avoids radiation exposure. However the comparative results between conventional

The dotted line indicates the position of the puborectal line. At rest (a) there is some descent as the anorectal junction (ARJ) is more than 1 cm below this. During pelvic stress (b) there is marked pelvic floor descent, with descent of the cervix (Cx) and bladder base (Bl).

defaecography and dynamic MR defaecography in patients with prolapse and anal incontinence are variable [31, 32]. Some of these variations have been attributed to the difference in technique. The main drawback of MR defaecography is the supine position required which causes sub optimal assessment of prolapse and evacation [31]. Since vertical open-magnet MR imaging units are not widely available, the role of MR defaecography in the diagnostic work-up of faecal incontinence is still limited.

III. SPHINCTERIC DISORDERS

1. THE INTERNAL ANAL SPHINCTER (IAS)

IAS is responsible for the maintenance of resting anal pressure and plays a vital role in maintaining anal continence. Isolated IAS defects are associated with surgery for ano-rectal malignancies, anal fissure and undetected obstetric anal sphincter injuries. These patients may present with passive faecal soiling and seepage rather than frank faecal incontinence.

Abnormalities of thickness are usually related to the patient's age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration **(Figure C 10**) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.

Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence [33]. Dilatation procedures are hazardous and may completely fragment (**Figure C 11**) the internal sphincter.

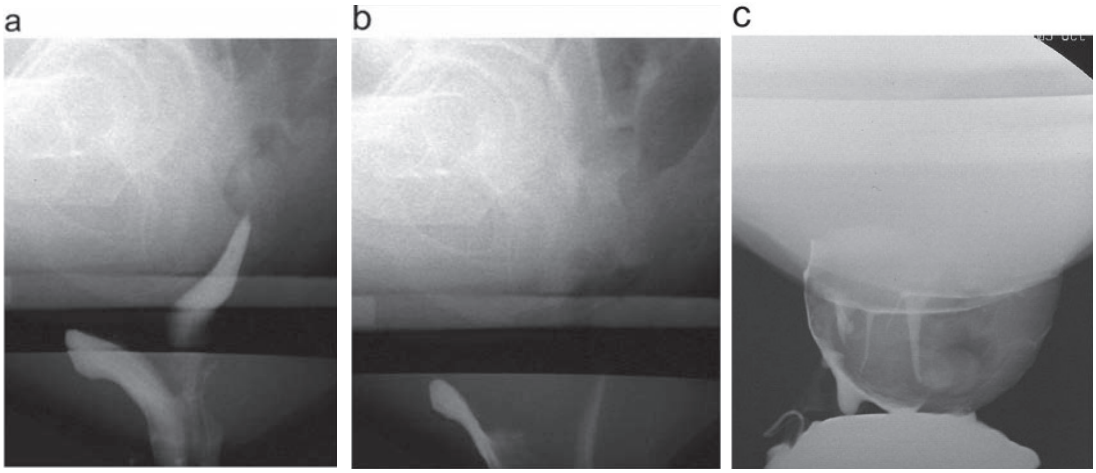

Figure C 9: Evacuation proctogram showing the development of rectal prolapse. Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse(c).

2. THE EXTERNAL ANAL SPHINCTER

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (**Figure C 12**). A key to the diagnosis is lack of symmetry with the anterior part of the external sphincter not fusing at 12 o'clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (**Figure C 13**). Other perineal structures, such as the puboanalis and transverse perineii are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perineii are not associated with a significant fall in squeeze pressure [34], and it is only damage to the external sphincter that results in a significant change. Childbirth damage to the puborectalis part of the levator ani muscle with intact EAS and IAS has been reported as a distinct cause of anal incontinence. 3-D EAUS is reported to be superior in detecting this type of injury [35].

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter [36]. The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy of EAS is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface

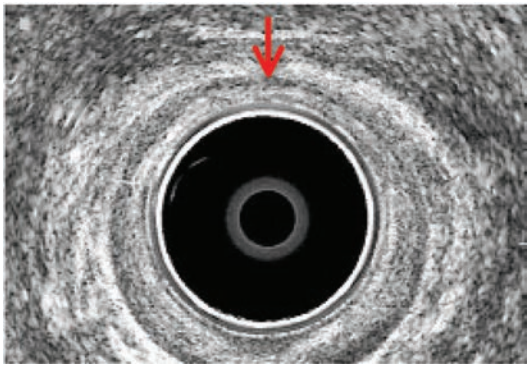

Figure C 10: Endosonography with an axial image in the mid canal of an elderly patient, aged 73yrs with passive faecal incontinence. The internal sphincter measures only 1.1mm (markers) indicative of internal sphincter degeneration

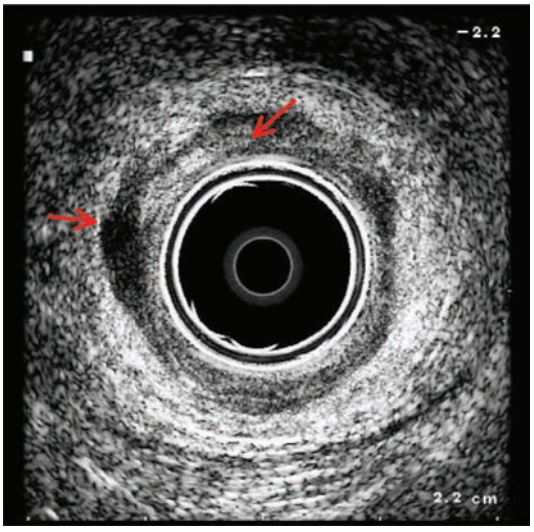

Figure C 11: Endosonography in the mid canalshowing gross internalsphincter irregularity, typicalof the "fragmented" appearance from trauma after an anal stretch procedure.

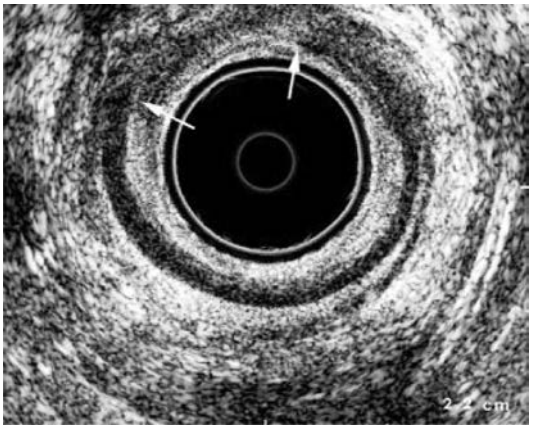

Figure C 12:Tears of internaland externalsphincters (arrows) between 10 and 1o'clock following a traumatic vaginal delivery

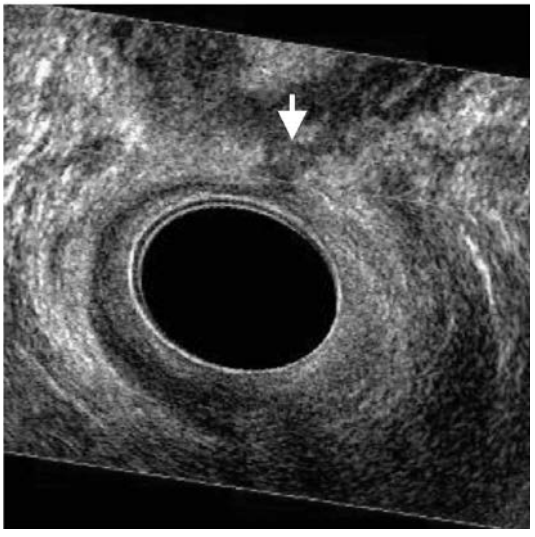

Figure C 13: 3D EAUS of a small tear to the external sphincter (arrow).

reflections between the longitudinal layer on the inside and subadventitial fat on the outer border. As atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured **(Figure C 14**). Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy [37]. Using 3D EAUS and a grading system based on definition and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy [38].

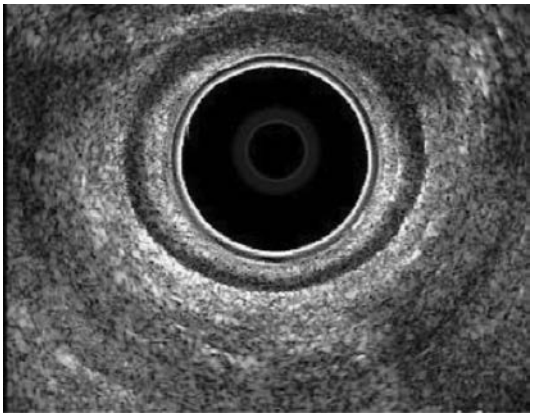

Figure C 14 : EAUS showing a normalinternal-sphincter, but the external sphincter is not visible as it is echogenic and the interface reflections due to advanced atrophy

IV. CONCLUSIONS

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the relative low cost and speed of EAUS makes this an ideal screening procedure to assess sphincter integrity. A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post partum [39], retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall 29.7% of women with tears were symptomatic, compared to only 3.4%without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% [40]. Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence [41], and its late onset [42,43]. Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery [44]. Tears that involve the internal sphincter increase the severity of incontinence [45]. A sphincter tear at EAUS is therefore an important finding, but how this is used to decide management is a little more controversial. Secondary anal sphincter repair has fallen out of fashion following the finding that results deteriorate over a few years46, although a more recent study [47] suggests a better response.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as obstructive defaectory symptoms and prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function.

EAUS therefore remains the first line imaging investigation for anal incontinence, giving accurate information regarding the external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important [48] with tears accounting for perhaps only 45% of incontinence [49].

V. CONSENSUS STATEMENTS

- EAUS is the first line imaging investigation for faecal incontinence providing accurate information regarding external and/or internal sphincter tears and the likelihood of atrophy. [**Level of Evidence 3, Grade of Recommendation C**].
- 3-D EAUS offer better quality images and diagnosis of the depth of anal sphincter injury. [**Level of Evidence 3, Grade of Recommendation C**]
- Routine use of 3-D EAUS is not recommended because of the cost. [**Level of Evidence 3, Grade of Recommendation C**]
- Routine use of transperineal, transvaginal and translabial ultrasonography to image the anal sphincter complex are not recommended. [**Level of Evidence 3, Grade of Recommendation C**].
- Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected [**Level of Evidence 3, Grade of Recommendation C**].
- MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and global view of the pelvis [**Level of Evidence 3, Grade of Recommendation C**]

VI. FUTURE RESEARCH AREAS

Better image quality with 3D EAUS and MRI have improved our understanding of pelvic floor anatomy, and this in turn has enabled sonographic anatomy to be re-evaluated, however, conflicting views of anal sphincter anatomy remain.

- Are clinical symptoms related to the size and the site of anal sphincter defect [50] or not [51]?
- Significance of imaging in detecting anal sphincter injury especially immediately after childbirth in preventing future anal incontinence [39, 52].
- The value of ano-rectal physiological studies combined with imaging in assessing the success of surgical repair of the anal sphincter complex [53].
- Identify (and modify) the risk factors leading to anal sphincter injury especially during childbirth and develop preventive strategies [54].

The most valuable aspect of 3-D ultrasonography and MRI imaging is that they give a global view of the pelvis, capable of investigating urological, gynaecological and coloproctological problems at the same time [17]. Many patients do not have faecal incontinence as an isolated symptom, but also have urinary, prolapse or defecatory problems. The overview provided by imaging sets the way for a combined approach to the pelvic floor and should be the prime area of future investigation [17].

D. PAD TESTING

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al. [1, 2]. Accuracy of this technique was, however, questioned by others and the technique was improved [3-8]. Walsh & Mills and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain [9, 10]. These tests were not standardised until Bates et al. described a "structured" one hour pad test which was endorsed by the International Continence Society in 1988 [11]. This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume [12, 13]. In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence [14].

I. DEFINITION

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardized conditions.

II. INDICATION AND METHODOLOGY

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided into four groups according to the length of the test: <1h, 1h, 24h and 48 h. (**Table 4**)

III. OFFICE-BASED PAD TESTING

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercises is usually implemented to elicit the occurrence of urine loss.

1. SHORT PAD TEST

a) Quantification:

These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobseny et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test [17]. The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms [18].

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between

Table 4: types of pad test

Author	Time	Bladder load	Exercise
Hahn & Fall (15)	20 min	50% of MCC*	stair climbing, 100 steps, coughing (10x), running (1 min), wash hands (1 min) jumping(1 min)
ICS (11)	1h	Drink 500 ml (15 min) before test	walking & stair climbing (30 min), standing up 10x, coughing (10x), running (1 min), bending (5x), wash hands (1 min)
Jorgensen et al. (16)	24h		Everyday activities
Jakobseny et al. (17)	48h		Everyday activities

*Maximum Cystometric Capacity

the perception of incontinence severity and pad test results [15].

These data suggest that short pad tests are more provocative than activities of daily living.

b) Reproducibility:

The correlation factor (Pitman's nonparametric permutation test) between two separate 20 minute tests was 0.94 ($p<0.001$) [15]. Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderatey reproducible ($r=0.74$) [18]. Using a 1 hour pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml [19].

2. ONE-HOUR PAD TEST

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

a) Quantification

Jakobseny et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) [17]. In the elderly, a one-hour ward test showed incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage [20]. A one hour pad test was found to reflect everyday incontinence in only 48% of patients in comparison to 81% with a 48 hour test and 77% with a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage [16]. Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) [21]. Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% [22]. Thind & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test [23].

b) Reproducibility

Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen [24]. The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one obstetrics & gynaecological departments (20 women) [13]. The test results in two urological departments did not differ with an average pad gain of 24g and 21 g ($p>0.1$). However, pad test results between the departments of urology and gynaecology differed significantly, with average pad weight gain 9 g and 24 g respectively ($p<0.05$).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) [12]. In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were corrected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor [25].

c) Validity

Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms [9, 26].

d) Bladder volume

Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 [16]. Fantl et al used a one hour test with the bladder filled to capacity and had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume [27]. Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g [28]. Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities [29]. The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by –44 to +66g in a test-retest situation [25]. The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) [30]. Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test [31]. This is to be expected as the questionnaires assess other urinary symptoms rather than just leakage.

e) Diagnosis

Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence [27, 32]. The reverse finding was reported by Matharu and co-workers [33].

There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

f) Sensitivity to change

The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy [34]. Ward et al. found the standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18g (IQR 6-37) and Burch colposuspension from 16g (IQR 6-38) both decreasing to 0g (IQR 0) [35]. The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy [36]. The changes were significant but there was moderate correlation (r = 0.53) with the changes in the St. George Urinary Incontinence Score.

3. TWO-HOUR PAD TEST

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume [37]. Han et al showed, however, that a 1-hour pad test is more practical [38]. In children a 2-hour ward pad test yielded 70% positive results for incontinence [39]. Richmond et al. compared two exercise regimens with a 2-hour pad test and showed no significant differences regarding which order the exercises were performed [40]. Walters et al. performed a 2-hour pad test with standard exercise in 40 women with SUI showing 78% positive tests (>1g pad gain) after 1 hour and 98% after the second hour [41]. Overall, the two-hour pad test was found to be superior to the one-hour one. There was no correlation between pad test results and the severity of a symptoms score.

IV. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

1. 12-HOUR PAD TEST

a) Quantification:

Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% [39].

2. 24-HOUR PAD TEST

a) Quantification

Lose et al. found a 90% correlation of a 24-hour pad test with a history of stress incontinence in 31 women [21]. This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mouritsen et al. showed that the 24-h home test was well tolerated and as good at detecting incontinence as a 48-h test [22]. Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population [20]. Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Lose et al. found that a 24h home test performed during daily activities was more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml [21]. High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% [42]. Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence [43].

b) Reproducibility

Lose et al showed poor correlation in a test-retest study with a variation of more than 100% [21] although Groutz et al. using Lin's concordance correlation coefficient (CCC), found the 24-h test to be very reliable instrument [44]. Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance. (**Table 5**)

The values for the pad test increase in asymptomatic men and women were reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women [45].

c) Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities [33]. Pad test loss is unaffected by the degree of hypermobility however there is increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH2O [46].

d) Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with urodynamic stress incontinence with incontinence episodes on a 3 day urinary diary (Kendall's corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) [47]. Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up [48].

3. 48-HOUR PAD TEST

a) Quantification

Jakobseny et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients [17]. No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) [49].

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exer-

cise sessions of 3.19 + 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients [53] (**Table 6**). Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test [14]. In his study (n=18) the Pyridium test was 100% positive in patients with SUI but had false positive results in normal women (52%).

Mean pad weight loss due to evaporation or leakage (was calculated to be 1.003 g, and ranged from -6.5 to +3.85 g (SD 1.85 g) [9]. Lose et al. showed no evidence of evaporation over 7 days if the pad was stored in a plastic bag [21]. Versi et al. showed pads wetted with saline showed no difference in weight after 1 week and less than 10% weight loss after 8 weeks [51]. Twelve pads were weighed by the patient and a healthcare worker with a coefficient of variance =1.55% with a mean deviation of 49%.

4. COMMENTS

Pad tests can either be used as a qualitative diagnostic tool to diagnose urinary incontinence and as a quantitative test to grade its severity. Pad test is unable to distinguish among different types of incontinence such as stress, urgency or mixed urinary incontinence. The ICS definition of urinary incontinence (the complaint of any involuntary leakage of urine) does not describe how the diagnosis is made but clearly refers to a patient's complaint that excludes urodynamics and rather points at the patient perception of the condition. Following this line of thought, research in this area has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relationship between the patient perception of UI and pad test. Franco and co-workers in London, UK tested the correlation between different questionnaires for UI

Table 5. test-retest correlation

and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall's tb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 VAS score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) [56]. In another study from Wijma and co-workers, the diagnostic accuracy of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting [57]. A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggested a good correlation between ICIQ-SF and the Patient Global Perception of Improvement (PGPI) with a 24-hour pad test [58].

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episode frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61 but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) [59]. In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but 24-hour pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus fascia sling [60]. An interesting result was obtained in a predominantely female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction in this difficult patient population [61]. In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence [62].

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented [63]. Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of patients [64]. This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusions about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed [65].

5. ROLE OF THE INVESTIGATION

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment results for different types of urinary incontinence in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials [66]. The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence [67]. No suggestion was made in the last two reports of which test to use.

V. CONCLUSIONS

- o The 1-hour pad test is not very accurate unless a fixed bladder volume is applied.
- o Set exercises during the test improve test-retest reliability.
- o The sequence of exercises has little effect on test results.
- o A pad weight gain >1 g suggests a positive 1h test.
- o A 24 hour test correlates well with symptoms of incontinence.
- o A 24-hour test has good reproducibility but poorer compliance.
- o A pad weight gain >1.3g = positive 24 h test.
- o A test lasting longer than 24 h has little advantage.
- o A pad test cannot distinguish between urodynamic stress incontinence and detrusor overactivity.

VI. CONSENSUS STATEMENTS

- o The pad test is an optional investigative tool in the routine evaluation of urinary incontinence (**Level of Evidence 3, Grade of Recommendation C**)
- o Pad test is a useful outcome measure in clinical trials and research studies. (**Level of Evidence 3, Grade of Recommendation C**)

The following standards are suggested:

- o 20 min - 1 h ward/office test with fixed bladder volume (pad weight gain ≥ 1g = positive test) (**Level of Evidence 3, Grade of Recommendation C**)
- o 24 h home pad test during daily activity (pad weight gain ≥ 1.3g/24h = positive test) (**Level of Evidence 3, Grade of Recommendation C**)

VII. FUTURE RESEARCH AREAS

- o Proper validation analysis using the coefficient of variability
- o Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)
- o Sensitivity to change in time of incontinence status for 24 hour pad tests
- o Validity of pad tests with other measures of incontinence such as urinary diaries and symptom questionnaires.

E. NEUROPHYSIOLOGY

I. INTRODUCTION

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated over 60 years ago, and have evolved with developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury, and are applicable in research. Compared to neurophysiological testing of the limbs and trunk, pelvic neurophysiological testing is relatively limited because of the restrictions imposed by pelvic neuroanatomy.

This text details the investigations, their applications and limitations, enabling investigator and clinicians to make a well informed decision regarding the use of these tests.

The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence [1], which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electromyography, reflex, evoked potentials.

1. CLASSIFICATION OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Although different types of tests may be included under the term “neurophysiological”, it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomical approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles and joints, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into: a) somatic motor system tests (EMG, terminal motor latency measurements/ motor nerve conduction studies, and motor evoked potentials (MEP)); b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP)); c) reflexes; and d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorised “technically” into those which “just” record some bioelectrical activity (for instance: electromyography), and those which record some biological response to stimulation (these may be subsumed under the term “conduction tests”).

2. BIOLOGICAL CORRELATES OF ELECTROPHYSIOLOGICAL TESTS

a) Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons). The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.

b) Electromyography (EMG)

Knowledge of the structure and function of the motor unit (**Figure E 1**) is fundamental to

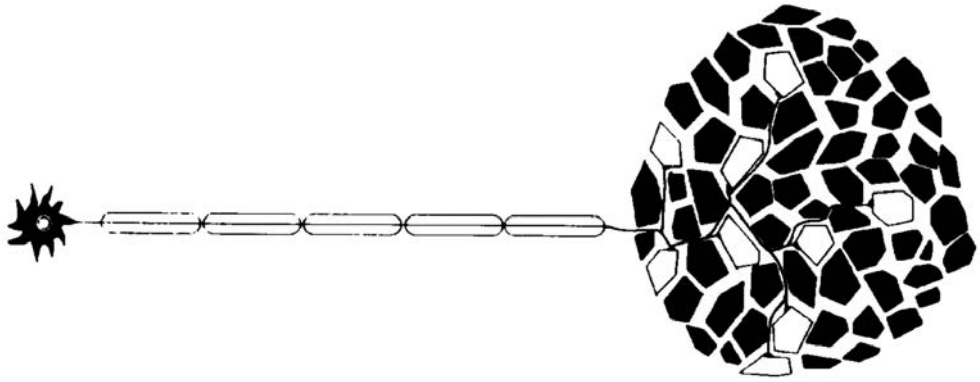

Figure E 1: Schematic representation of a motor unit. The alpha motor neuron with its cell body, its myelinated axon and the peripheral nerve endings is shown. The muscle fibres innervated by this alpha motor neuron are shown in white. (Note that the muscle fibres from one motor unit are intermingled with motor fibres from other motor units).

understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called "lower motor neurons". (Neurons that innervate the sphincters lie in Onuf's nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles). Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called "motor unit". The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.

It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the "innervation ratio") or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

3. GENERAL METHODOLOGICAL CONSIDERATIONS

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety; standardisation of concentric needle EMG and penilo/clitoro-cavernosal testing has been proposed.

a) Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Alhough this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genito-anal anatomy. As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

The common form of neurophysiological testing is electrophysiological. Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

Stimulation Parameters. The electrical stimulus should be specified and characterised both in technical (e.g., rectangular pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency, and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

b) Recording

1. Apparatus settings

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting

of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System.

2. Reproducibility and Reliability

Any potential elicited by stimulation should be reproducible; therefore, as a rule, at least two consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. CMAPs (i.e., M-waves), MEP, sacral reflexes and sympathetic skin responses (SSR) are recognisable after single stimuli. However, as a rule, several responses are recorded to demonstrate reproducibility. In contrast, other responses (e.g., SSR) show marked fatigability with stimulus repetition.

3. Waveform Analysis

For a particular stimulation procedure, the shape, latency, and amplitude of the recorded potentials are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and amplitude of the response. The onset of the response (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or "peak to peak".

II. CLINICAL NEUROPHYSIOLOGICAL TESTS

1. SOMATIC MOTOR SYSTEM TESTS

a) Electromyography (EMG)

The term "EMG" is often used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. The term applies particularly to recordings from striated muscles.

EMG is used a) "just" to record muscle activity (as for instance in combined sphincter EMG and pressure-flow study) and b) to differentiate between normal, denervated, reinnervated, and myopathic muscle. For a) see below – "Kinesiological EMG".

Although EMG abnormalities are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves ("myogenic" changes), and b) changes in their innervation ("neuropathic" changes). Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the external anal sphincter, extending from the motor neuron body, sacral nerve roots to the small branches within the external sphincter. In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated.

The EMG signal may be further used to indicate that muscle has been activated through its motor nerve, either by stimulation applied to motor pathways (M-wave, MEP) or to sensory pathways (reflex response).

1. General Technique for Needle EMG in Pelvic Floor Striated Muscles

All tests requiring needle electrodes are invasive and some pain is inevitable, even with the use of local anaesthetics. Local anaesthesia is infrequently used for needle EMG examination. Intramuscular electrodes need to be appropriately placed in the target muscle.

The pelvic floor and perineal muscles can be examined, including the levator ani, the bulbocavernosus muscle and the striated anal and urethral sphincter muscle. Proper placement of needle examination requires some practice. As a rule, several sites from one or more skin penetrations are sampled, which is difficult in small muscles.

The audio output from the loudspeaker of the EMG apparatus helps in assessment of the quality of recording as well as in recognition of electrophysiological phenomena.

2. Concentric needle EMG (CNEMG)

The examination is conducted with a single use, disposable electrode. The commonly used amplifier filter settings for CNEMG are 5 Hz – 10 kHz, and need to be defined if MUP parameters are to be measured, as are filter settings employed during data acquisition.

The concentric needle electrode consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres [2]. The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

CNEMG can provide information on a) insertion activity, b) abnormal spontaneous activity **(Figure E 2)**, c) MUPs, and d) interference pattern (IP).

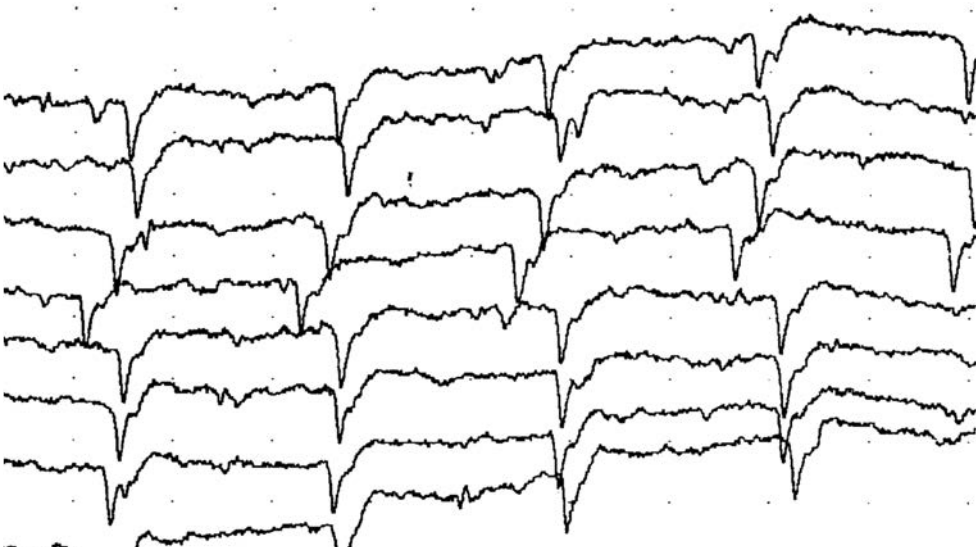

Figure E 2: Concentric needle EMG recording from right bulbocavernosus muscle of a 49-years old male with urinary incontinence diagnosed as possible Multiple system atrophy. Pathological spontaneous activity (a burst of positive sharp waves) is shown.

In normal muscle, needle movement elicits a short burst of "insertion activity," which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 μV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with an appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.

The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an "interference" pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation [3], MUP variability as well as MUP recruitment on reflex and voluntary activation can be observed [4].

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with "electrical silence" by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated "high-threshold MUPs" being larger than continuously active "low-threshold MUPs". As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested [5]. In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs). This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation [6], probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called "interference pattern" – IP. Exploring different sites of the activated muscle with a needle electrode provides "samples" of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems [6].

It is easy to grasp the "motor unit potential analysis", as it is simply a measurement (by different methods) of the "parameters" of single individual MUPs (ie. its amplitude, duration, number of phases…). The changes in MUP parameters furthermore are "direct" results of understandable physiological changes, and are thus "meaningful" to the interpreter.

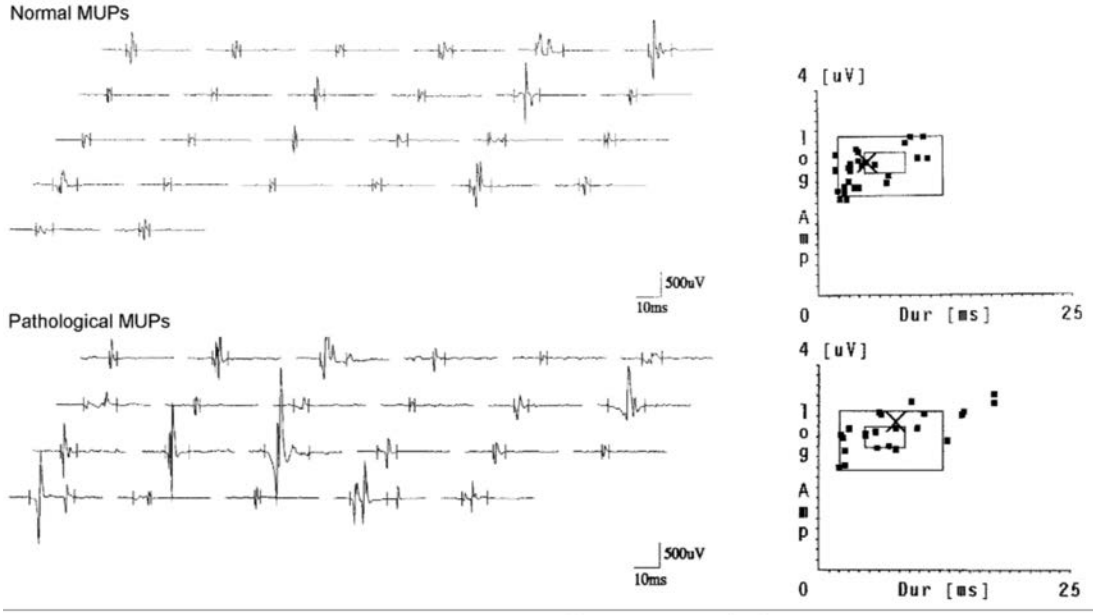
The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 μV); amplitude/

turn (change in volts between two turns); number of short segments (parts of signal that has "sharp" activity) percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95 % confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot ("cloud") that compares to the normative boundaries. (**Figure E 3**). It has been asserted that this approach does not require a standardised muscle contraction, but the shape of the "cloud" is dependent on the strength of muscle contraction. Therefore it has been suggested to standardise the method by measuring pressure exerted by the contracting sphincter [7].

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

• *CNEMG Findings Due to Denervation and Reinnervation*

After complete denervation, all motor unit activity ceases. In a denervated muscle, complete "electrical silence" is noted in the first days after such an event. The diagnosis of complete denervation



Anal sphincter muscle	#	Amp uV	Amp rel.SD	Amp <min	Amp >max	Dur ms	Dur rel.SD	Dur <min	Dur >max	Area uVms	Area rel.SD	Area <min	Area >max	Poly %
Normal	24	236	-1.6	1	0	5.0	-0.5	1	0	215	-1.0	2	0	8
Pathological	26	393	0.1	2	0	4.8	-1.8	2	0	317	-0.4	2	0	15

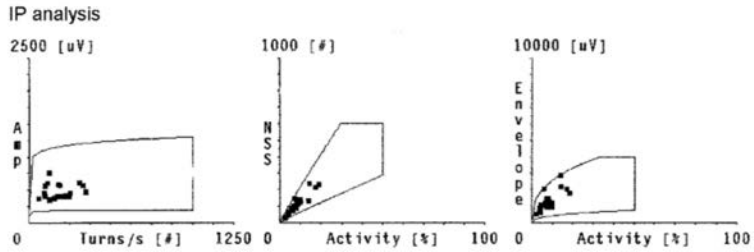


Figure E 3: Comparison of normal (above) and pathological (below) motor unit potentials (MUPs) sampled by multi-MUP analysis from the right halves of the subcutaneous parts of the external anal sphincter (EAS) muscles. To the right logarithm (amplitude) vs. duration plots of the MUPs are shown; the inner rectangle presents normative range for mean values, and the outer rectangle for "outliers". Below the MUP samples values are tabulated. Three plots on the bottom were obtained by turn/amplitude analysis in the cauda equina patient. Delineated areas ("clouds") present the normative range, and dots individual IP samples.

is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontaneous activity, but these may take up to three weeks to appear. The "insertion activity" becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (**Figure E 2**). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting "nascent" motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc).

Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor end-plates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the waveform of the MUP (**Figure E 3**) which may have small, late components ("satellite potentials"). MUPs show "instability" due to insecure transmission in newly formed axon sprouts and end-plates. This "instability of potentials" (meaning both "jitter" and "blocking" of individual components in a complex potential) is not routinely assessed during sphincter EMG. Nonetheless, it can be a helpful parameter, and may be evaluated not only by SFEMG, as originally described (8), but also by CNEMG, if a low frequency cut-off filter of 0.5 (up to 2) kHz is used along with a trigger – delay unit. In skeletal muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving synchrony of activation in the reinnervated motor unit. Thus MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation [9]. It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration) [10].

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e. most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results. It has been suggested that the combination of MUP thickness and number of turns might be even more accurate [11] than previously suggested combination of MUP area, duration, and number of turns [12].

• *CNEMG of the External Anal Sphincter*

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice, to a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis [13]. In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side ("quadrants") of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed [13, 14].

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values [15] that can be introduced into the EMG systems' software. It has been shown that normative data are not significantly affected by age, gender [15], number of uncomplicated vaginal deliveries [16], mild chronic constipation [17] and the part of EAS muscle (i.e. subcutaneous or deeper) examined [16].

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardised and is described in textbooks and primary literature.

3. Single fibre EMG (SFEMG)

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records [2]. Because of the arrangement of muscle fibres in a normal motor unit, a SFEMG needle will record only 1-3 single muscle fibres from the same motor unit.

The SFEMG parameter that reflects motor unit morphology is fibre density, which is defined as the mean number of muscle fibres belonging to an individual motor unit per detection site. To assemble these data, recordings from 20 different intramuscular detection sites are necessary [8].

SFEMG recording needles are very expensive, and disposable needles are not available.

4. Kinesiological EMG

Kinesiological EMG is used to assess patterns of individual muscle activity/inactivity during defined manoeuvres (**Figure E 4**), typically during urodynamics. As such, the specific interpretation of electrical activity within a muscle is based on its presence or absence, rather than the type of activity. Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

Although either standard EMG equipment or EMG facilities contained within urodynamic systems can be used, the better visual and audio control provided by standard EMG equipment facilitate optimal electrode placement and improve recordings [18]. When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). The quality of the EMG recorded from the external urethral sphincter (EUS) muscle is improved by a catheter-mounted surface electrode device that applies mild suction [19]. With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. pubococcigei) can be voluntarily activated typically for less than 1 minute [20]. Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough reflex [21]. A consistent contraction sequence of the superficial and deep pelvic floor muscles is found in continent but not in incontinent women [22].

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Needle electrodes are more useful than perineal patch electrodes to demonstrate MU quiescence during voiding [23]. A recent study using perineal surface patch electrodes confirmed that these electrodes are inappropriate [24].

Pathological incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia. In selected patients with neurogenic detrusor overactivity EMG of the EUS muscle can be also used to demonstrate the onset of detrusor contractions [20].

Apart from polygraph urodynamic recordings to assess detrusor-sphincter coordination, the diagnostic usefulness of kinesiologic EMG has not been established.

- *Surface Electromyography Using Noninvasive Electrode Arrays*

Recently, surface EMG recording using noninvasive electrode arrays and multichannel EMG amplifiers

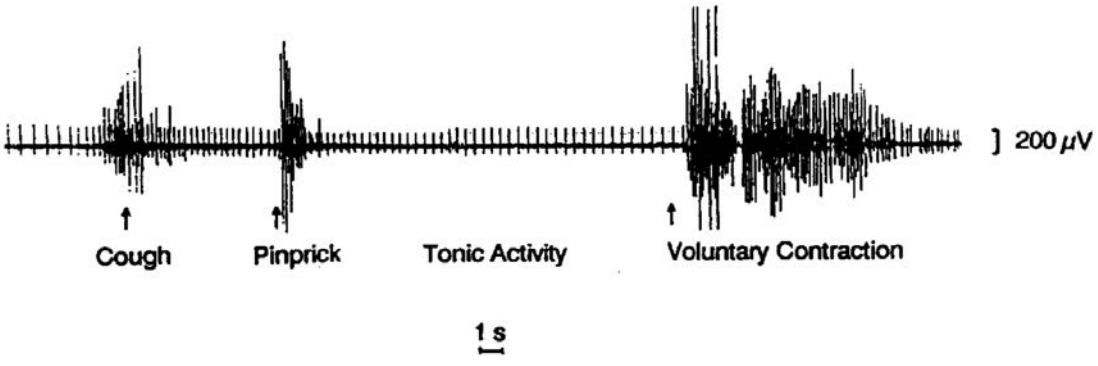

Figure E 4: Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53 years old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents "tonic activity". (Recorded with concentric needle electrode).

was introduced to the sphincter and pelvic floor muscles (eg, the EAS and puborectalis). Using this approach, investigators can localise muscle innervation zones and asymmetry in muscle innervation [25] and analyse discharge patterns of MUPs and propagation velocities along the muscle fibres [26]. Although observations in normal and pathological conditions have been published [27], the clinical value of these methods in diagnosing neurogenic sacral disorders has not yet been demonstrated.

5. Clinical application of EMG

• *Neurogenic Conditions*

Trauma, surgery, and neurological disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs. In a series of 194 consecutive patients referred for electrodiagnostic evaluation, quantitative needle EMG of the EAS muscles supported a diagnosis of a cauda equina or conus medullaris lesion in 36 patients, a lesion of the EAS muscle in 6, a pudendal nerve lesion in 2, and a sacral plexus lesion in 1 patient. Furthermore, neuropathic findings in the EAS were compatible with a diagnosis of multisystem atrophy in 11, and were most probably caused by severe polyneuropathy in 2 patients. In another 11 patients, the aetiology of the pathological findings could not be established at time of electrodiagnostic testing [28].

Lesions of the cauda equina or conus medullaris commonly cause pelvic floor dysfunction. These have mainly been a consequence of neural compression within the spinal canal caused by intervertebral disc herniation, spinal fractures, epidural haematomas, and, intraspinal tumours; or a result of spinal surgery, mainly on lumbar discs [29, 30]. Electrodiagnostic tests are also useful in the assessment of neurogenic lesions in children with spinal dysraphism [31]. After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiological testing assesses the severity of the lesion and may clarify the diagnosis. In the authors' series, 10 percent of patients with cauda equina lesions reported normal perianal sensation [32]. Electrodiagnostic tests that need to be considered are bilateral needle EMG of the EAS muscle and the bulbocavernosus muscle in subacute situations; and electrophysiologic evaluation of the bulbocavernosus reflex [33] (when this is absent or equivocal clinically) [34]. Detection of spontaneous denervation activity by needle EMG is common from approximately 3 weeks to several months after injury, and the bulbocavernosus muscle is particularly helpful in this respect. Later, MUP analysis becomes more important for demonstrating reinnervation. The bulbocavernosus reflex is useful for assessing the integrity of the sacral reflex arc in subjects with cauda equina or conus medullaris lesions [34]. Most of these lesions cause partial denervation; a traumatic lesion to the lumbosacral spine or pelvis is probably the only acquired condition in which complete denervation of the perineal muscles can be observed [35, 36, 37].

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns [6]. Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving [38]. After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. The bulbocavernosus muscle is particularly useful in suspected recent minor partial denervation as it lacks on-going activity of low-threshold MU during relaxation. (In women the muscle is thin).

Neuropathic changes can also be recorded in sphincter muscles of patients with multiple system atrophy (MSA) [39]. MSA is a progressive neurodegenerative disease, which can be mistaken for Parkinson's disease (PD). Urinary incontinence and erectile dysfunction occur, often some years before the onset of obvious neurological features [40]. Sphincter EMG has been used in distinguishing MSA from Parkinson's disease. EMG is probably not helpful to distinguish MSA from the later stages of Parkinson's disease and from progressive supranuclear palsy. Sphincter EMG may not be sensitive in the early phase of the disease [41, 42], and is not specific after 5 years of parkinsonism [43]. Among 30 patients with a pathological diagnosis of multisystem atrophy, 24 had abnormal, 5 had a borderline, and only 1 had a normal sphincter EMG [44]. Some studies have failed to demonstrate the effectiveness of MUP analysis in sphincter muscles [45, 46], probably because of the exclusion of late components from MUP duration [9]. Extensive discussion on the subject can be found elsewhere [47]. The changes of chronic reinnervation may also be found in progressive supranuclear palsy [48, 49] and in Machado–Joseph disease [50] in which neuronal loss in Onuf's nucleus has also been demonstrated histologically [51].

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal [52].

• *Changes in Primary Muscle Disease*

In skeletal muscle, the "typical" features of a myopathy are small, low amplitude polyphasic units recruited on mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal [53]. Myopathic EMG changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy [54] but not in another group of patients with myopathy [55].

• *Stress Incontinence*

Pelvic floor muscle denervation has been implicated in the pathophysiology of urodynamic stress incontinence (USI) [56]. EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with USI. Stress incontinence and genitourinary prolapse were associated with partial denervation of the pelvic floor [57]. The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies. In a recent study, nearly all EMG parameters showed significant differences between continent and SUI women consistent with better motor unit recruitment in continent women. Continent women had larger-amplitude, longer-duration MUPs with increased turns and better MUP recruitment during bladder filling ($P < 0.05$) [58].

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported [59], with some EMG support by another group [60]. Myopathic EMG changes (i.e. short, small MUPs) may, however, be a consequence of deficient reinnervation [35]. There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency [59].

Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurological origin, only a small amount of pathological muscle tissue remains in many incontinent parous women, which makes EMG of the muscle impractical [38]. CNEMG findings generally will not affect therapeutic considerations [61].

• *Idiopathic Faecal Incontinence*

"Idiopathic" faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but it has been often implied that it is a neurogenic condition. Vaginal delivery has been shown to cause structural sphincter defects; it may cause outright sphincter denervation in rare cases, but its more widespread implication in causing "idiopathic" incontinence is controversial.

CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds. Turns/amplitude, but not MUP analysis has been claimed to detect evidence of denervation and subsequent reinnervation in postpartum women with mild anal incontinence [62].

• *Idiopathic Urinary Retention in Women*

In the external urethral sphincter of young women with urinary retention (or obstructed voiding) complex repetitive discharges in profuse amounts (against a background of firing motor units) have been described, suggesting that these findings are of pathogenic and of diagnostic significance. The external urethral sphincter was reported to be hypertrophic. A percentage of these women were hirsute and had polycystic ovaries [63, 64]. The presence of such activity in the needle EMG of the EUS of young women with non-obstructive urinary retention (Fowler's syndrome) is the only predictor of the long-term success of therapeutic sacral neuromodulation [65]. The cause of this activity is unknown. In some women it may be the expression of an occult generalised dysautonomia [66].

Repetitive discharges are, however, prone to develop in chronically partially denervated sphincters, and are present even in a proportion of asymptomatic women [67]. The distinguishing feature of the spontaneous EMG activity defining the particular pathology in women with retention seems to be its abundance, but the issue remains disputed.

• *EMG in Urodynamic and Functional Anorectal Studies*

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of "kinesiological EMG". Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., 'detrusor-sphincter dyssynergia'). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described [68].

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson's disease. The pelvic floor muscle contractions of the so-called non-neurogenic voiding dyssynergia may be a learned abnormal behaviour [69], and are a feature of dysfunctional voiding [64].

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder filling, and reflex increases in activity during any activation manoeuvre performed by the subject such as talking, deep breathing, coughing. The pubococcygeus relaxes during voiding; the muscles on either side act in unison [20]. In stress-incontinent patients, the patterns of activation and the co-ordination between the two sides can be lost [70]. A delay in muscle activation on coughing has also been demonstrated, as compared to continent women [21].

Little is known about the complex activity patterns of different pelvic floor muscles (the urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani) during different

manoeuvres. It is generally assumed that they all act in a co-ordinated fashion functionally as one muscle. However there are demonstrable differences between the intra- and peri-urethral sphincter in healthy females [71] and in activation of the levator ani and the urethral sphincter [72]. Co-ordinated behaviour is frequently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra with the patient at rest and coughing may predict the outcome after certain types of incontinence surgery [73].

Current concepts suggest that defecation requires increased rectal pressure co-ordinated with relaxation of the anal sphincters and pelvic floor muscles. Pelvic floor relaxation allows opening of the anorectal angle and perineal descent, facilitating faecal expulsion. During defaecation puborectalis activity is as a rule inhibited, but was unchanged in 9 % and increased in 25 % of healthy subjects [74]. Thus, while "paradoxical" puborectalis contraction during defecation is used to diagnose pelvic floor dyssynergia in patients with typical symptoms, this finding may be a variation of the normal.

b) Pudendal Nerve Conduction Tests

Measurement of motor conduction velocity is routinely used to evaluate limb motor nerves, distinguishing between a demyelinating and axonal neuropathy. To make the measurement requires access to the nerve at two well-separated points and measurement of the distance between them, a requirement that cannot be met in the pelvis. Another way to evaluate peripheral motor nerve function is the measurement of the motor latency of a muscle response, requiring only a single stimulation site. The muscle response is the compound muscle action potential (CMAP) or M-wave. Because in limb nerves the site of stimulation to obtain only the motor latency (without measuring the actual conduction velocity) is as a rule placed distally on the nerve, it is also called the distal (or terminal) latency. For the pudendal nerve the site of stimulation may be more or less "distally", but the term distal or terminal has – in accordance to general clinical neurophysiology – become generally used. Distal motor latency can be measured by recording with a concentric needle electrode from the bulbocavernosus, the EAS and the urethral sphincter muscles in response to bipolar surface stimulation placed in the perianal/perineal region, or with selective needle stimulation of the pudendal nerve (branches) in the perineum.

The most widely employed technique to obtain pudendal nerve terminal motor latency (PNTML) relies on stimulation with a special surface electrode assembly fixed on a gloved index finger, known as the St Mark's stimulator [75]. It consists of a bipolar stimulating electrode on the tip of the gloved finger with the recording electrode pair placed proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is applied close to the ischial spine. It is assumed that, using this approach, the pudendal nerve is stimulated close to the ischial spine, and that the response recorded is of the EAS muscle. In women, intravaginal stimulation and recording from the bulbocavernosus muscles has also been undertaken, with similar distal latencies [76]. However, the latency of such a response is typically only around 2 msec, which seems unusually short compared with the perineal technique and with conduction in the much thicker motor fibers of peripheral nerves in the limbs. It seems unlikely that the PNTML using the St. Mark's electrode really evaluates conduction along the last 8 cm of the pudendal nerve. Stimulation of the terminal pudendal branches or pelvic floor muscles near their motor points seems more likely, and this is supported by the much longer PNTML (3.7 ± 0.9 msec) obtained with a monopolar intrarectal stimulation electrode [77].

If a catheter-mounted electrode is used for recording, EMG responses from the striated muscle of the urethral sphincter can be obtained. Experts differ in their estimation of validity of this test. A prospective evaluation of anorectal physiologic tests in 90 patients with faecal incontinence did not find that PNTML results changed treatment decisions [78]. Indeed, the American Gastroenterological Association statement indicated that "PNTML cannot be recommended for evaluation of patients with faecal incontinence" [79].

c) Anterior Sacral Root (Cauda Equina) Stimulation

Anterior root stimulation has been used to study conduction of the sacral nerve roots. Electrical stimulation with needle electrodes at vertebral laminae Th12-L1 elicit M-waves in the bulbocavernosus and EAS muscle [80].

Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments [81]. Lumbosacral stimulation often evokes a large stimulus artifact that can be decreased by positioning the ground electrode between the stimulating and recording electrodes [82]. Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g. with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency. Selective stimulation of

individual sacral roots is possible by appropriate positioning of surface stimulating electrodes [83].

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

d) Motor Evoked Potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (**Figure E5**). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectal muscle in adult women [84]. A central conduction time of 15 to 16 msec without and 13 to 14 msec with facilitation is obtained for pelvic floor and sphincter muscles [85, 86, 87]. The necessity to use concentric needle EMG for recording has been reconfirmed [88].

Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls [87, 88, 89]. However all patients in this study had clinically recognisable cord disease. Nevertheless, MEPs may be useful in patients with unclear localization of spinal lesions [87].

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition [90].

2. SENSORY SYSTEM TESTS

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

a) Sensory Measurements During Cystometry

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void.

Although not strictly a neurophysiologic test, measurement of electrical thresholds adds clinically non-obtainable information on sensory function of the lower urinary tract [91]. Bladder and urethral sensory thresholds have also been measured using electrical stimulation [91], and mechanical traction on the bladder trigone [92]. Electrical currents

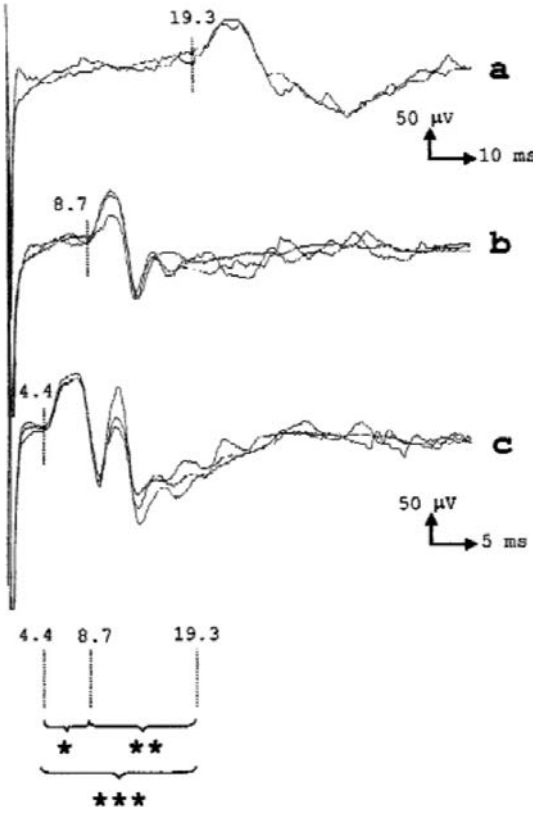

Figure E 5: MEPs recorded by concentric needle in the external urethral sphincter of a 51-year-old-woman. Cortical (a), thoracic (b), and sacral (c) stimulation. Central motor conduction time (CMCT) is calculated as cortical - lumbar latency (** = 10.6 ms). Cauda equina motor conduction time is calculated as lumbar - sacral latency (* = 4.3 ms). (From (Brostrom et al., 2003a), with permission).

are applied to the bladder, urethra or genital skin using catheter-mounted or surface electrodes. High-frequency stimulation (> 20 Hz), with a stimulus duration of 0.5 or 1 msec is used because it is more easily perceived in the lower urinary tract. Measurement of sensory thresholds with such stimulation is reproducible, and normative data have been published [91]. To date it has been used in only a few conditions (e.g., painful bladder syndrome) [93]. There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

In addition, palmar SSR and perineal surface EMG recordings can be used for more objectively demonstrating sensations during cystometry. The activity of both appears and increases in parallel with the first sensation of bladder filling, and with the first desire to void, respectively [94]. Further studies using these methods are needed to establish their clinical utility.

b) Assessment of Anorectal Sensation

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity [95]. The rate and pattern of distension affect rectal perception and internal sphincter relaxation [96].

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Temperature perception on the proximal anal canal has been found to be reduced in patients with passive anal incontinence compared to those with urgency incontinence [97].

c) Quantitative Sensory Testing

Quantitative sensory testing (QST) of the urogenitoanal system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration [98], temperature [99], and electrical current [100]. There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

d) Sensory Neurography

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with amplitude of about 10 µV. It can also be recorded by stimulating trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly [101]. This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoperative voiding dysfunction [102]. These tests are limited to their very specific intraoperative indications.

e) Somatosensory Evoked Potentials (SEP)

Somatosensory evoked potentials are electric waveforms of biological origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area – dermatome). The most commonly performed tests in the urogenitoanal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP). Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarisation of nerves, but a mesh of afferents.

1. Pudendal Somatosensory Evoked Potentials

• *Cerebral Pudendal SEP*

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (**Figure E 6**) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold [103]. The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test.

However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology [104].

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis [105]. However, even in patients with multiple sclerosis and bladder symptoms, the tibial

cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement [106]. The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with uro-genital symptoms [107]. Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control [108]. Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation [109].

• *Spinal Pudendal SEP*

Stimulating the dorsal penile nerve and recording with surface electrodes at the level of the Th12-L2 vertebrae (and the S1, Th6 or iliac spine as reference) reveals the postsynaptic segmental spinal cord activity (the spinal SEP). Unfortunately, this spinal SEP may be difficult to record even in normal (and particularly in obese) subjects.

3. SACRAL REFLEXES

Clinically, two reflexes are commonly elicited in the lower sacral segments: [1] the penilo- or clitoro-cavernosus (i.e. bulbocavernosus) reflex; and [2] the anal reflex [110]. To elicit sacral reflexes, electrical [111-118], mechanical [115, 116, 119] or magnetic [120] stimulation can be used. Whereas the latter two modalities have only been applied to the penis [117-119], clitoris, and the suprapubic area [115], electrical stimuli can be applied to various sites: to the dorsal penile or clitoral nerve; perianally; and, using a catheter-mounted ring electrode, to the bladder neck/proximal urethra [121].

a) Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms (29.9 ± 5.7 msec in one study in men) [117], traditionally called the bulbocavernosus reflex (**Figure E 6**). In addition to single-pulse electrical stimulation, two identical electrical pulses separated by a 3-msec interval can be used (i.e., double-pulse electrical stimulation) [117, 118]. Double-pulse electrical stimulation is more efficient in eliciting sacral reflexes [117]. Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g. following radical hysterectomy) the viscerosomatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus (penilo-/clitoro-cavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries [122].

The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool.

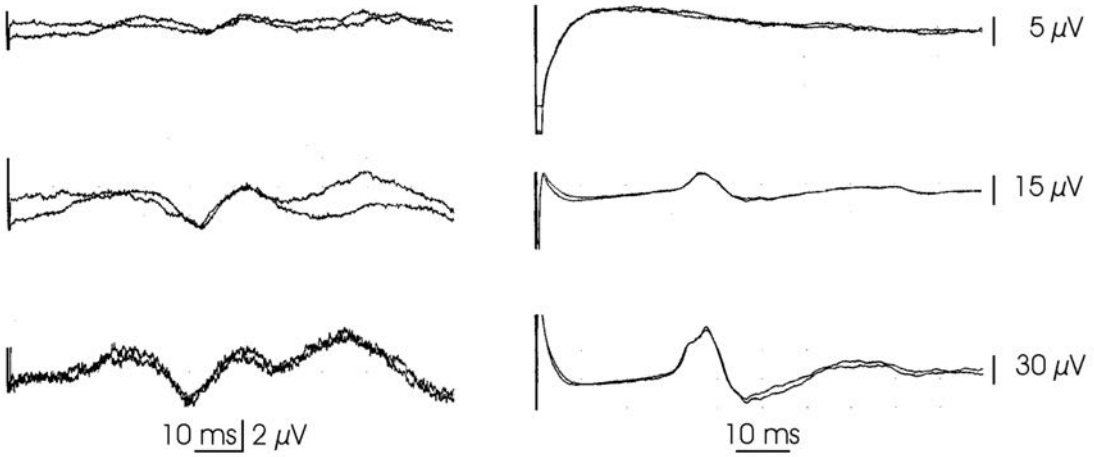

Figure E 6: SEPs (traces on the left) and sacral reflexes (traces on the right) in a healthy woman. Cerebral SEPs are recorded from Cz - 2 cm; sacral reflexes from the anal sphincter. The dorsal clitoral nerve is being stimulated with rectangular electrical pulses at 2 Hz. Stimulation and recording is performed with surface electrodes. The cerebral SEP and sacral reflex are recorded simultaneously. In the upper row the stimulation is just above sensory threshold, in the middle row the stimulation is 1.5, and in the lower row at 2-times sensory threshold (pulse duration 0.2 ms; two consecutive averages of 128 responses are superimposed).

On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with "returning" of the depolarisation orthodromically to the sphincter at a branching point of the motor axon.

EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females [123]. In men, value of 40, 36 and 36 msec have been suggested as the upper limit of normal for the shortest latency obtained on eliciting a series of reflex responses using single, double and mechanical stimulation, respectively [117].

In men with cauda equina lesions penilo-cavernosus reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and mechanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned [118].

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-/clitoro-cavernosus reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response [112]. The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation.

During voiding sacral reflexes are un-elicitable but in the presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernosus muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus by detection from the left and right bulbocavernosus (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that the sensitivity of the test can be increased by use of the interside latency difference (normative limits: < 3 ms), but finding could not be confirmed by others (normative limits: < 7.2 ms) [117]. In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiological measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% of faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions [118]. Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy. In a proportion of women with non-neurogenic sacral dysfunction clitoro-cavernosus reflex latencies were found to be much longer compared to those obtained in women with intact sacral function [124].

Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions [4].

In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation. These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), and reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen). They evaluate lower sacral sensory pathways, and excitation level of the sacral reflex pathway, respectively. Although for men normative data for these parameters are available [117], their utility in clinical situation remains unclear.

Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used [125].

b) Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Using a reflex hammer, the stimulus is applied to a wooden spatula placed on the glans penis or clitoris [117, 118]. Such stimulation is painless and can be used in children [119]. The latency of the BCR elicited mechanically is comparable to the electrically elicited

reflex in the same patients, but depends on the electromechanical device used [117, 119].

4. AUTONOMICAL FUNCTION TESTS

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

a) Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomic dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

b) Dartos reflex

In men, another approach to test lumbosacral sympathetic function is by neurophysiological measurement of the dartos reflex obtained by electrical cutaneous stimulation of the thigh. The dartos muscle is a sympathetically innervated dermal layer within the scrotum, distinct from the somatically innervated cremasteric muscle. A reliable and reproducible dartos reflex (i.e., scrotal skin contraction) with a latency of about 5 seconds has been demonstrated in healthy men [126].

c) Smooth Muscle Electromyography

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. There is no evidence to prove the clinical utility of these tests in the evaluation of urinary tract function.

d) Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles, and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis. Similarly, the SSR can be recorded from the genital region in women [127]. The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury [108]. Recording from the perineal region assesses sympathetic nerve function within the thoracolumbar cord [128].

III. EVIDENCE BASED USE OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection), which would provide a strong basis for its use. However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective, which is not applicable to interventions and lies outside the scope of evidence-based medicine. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on evidence that is, he or she can practice “evidence-based medicine”.

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in which the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to “evidence-based medicine”, whether or not there is narrowly-defined “evidence” that it improves outcomes.

Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a “gold standard” measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population

norms with the intent of determining whether they are “normal” or “abnormal”. Data can be classified as “abnormal” only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in discriminating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uroneurophysiological techniques, such data are scarce.

1. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN EVALUATION OF INDIVIDUAL PATIENTS

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice. In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology. Most patients, however, will not require a precise definition of the neurological lesion.

As is generally true for electrophysiological tests, uroneurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurological condition, neurophysiological testing is generally unnecessary. In patients with stress/urge, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory [61].

2. USEFULNESS OF CLINICAL NEUROPHYSIOLOGICAL TESTS IN RESEARCH

Uro-neurophysiological techniques have been most often applied in research, for instance to elucidate the innervation of pelvic floor muscles; to study the physiology of contraction of sphincter muscle, to describe activation patterns of pelvic floor muscles. Suggestions of increased efficacy of sacral neurostimulation with the use of neurophysiological tests have been made [129]. As understanding pathophysiology and neural control is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques, there seems to be a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy.

IV. CONSENSUS STATEMENT

1. CLINICAL NEUROPHYSIOLOGICAL TESTING

The information gained by clinical examination and urodynamic testing may be enhanced by uroneurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 – 5. Concentric needle EMG to diagnose denervation and reinervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests. **(Level of Evidence: 2b; Grade of Recommendation: B**)

Clinical neurophysiological testing should be performed in accredited laboratories, by trained and certified staff, with formal control of the quality of the results. Ideally, the uroneurophysiologist should be in liaison with general clinical neurophysiologists.

It seems optimal to create interdisciplinary programs between urology, urogynaecology, proctology, and neurology departments. Organisation of such teams in tertiary medical centres should be encouraged.

2. TECHNICAL STANDARDS

Even in the more widely used “general” clinical neurophysiology there is no universal standardisation of tests. This is mainly due to different historical backgrounds of testing developed in different countries. The need to standardise methods is, however, recognised.

Proposals for standardisation for external anal sphincter CNEMG [4] and the bulbocavernosus (penilo/clitoro-cavernosus) reflex [117] have been made, and seem to be widely adopted. (**Level of Evidence: 2b, Grade of Recommendation: B**)

3. FUTURE RESEARCH AREAS

Clinical neurophysiological methods should be further used to better define the neural control in lower urinary tract function, demonstrating both the nervous system’s “hardware” (integrity of anatomy) as well as “software” (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions. In particular, there is the opportunity to better define neurophysiological changes induced by therapeutic electrostimulation.

There is the challenge to develop tests to assess directly the sacral parasympathetic system.

F. OTHER INVESTIGATIONS

I. URINALYSIS

"Urinalysis is a fundamental test that should be performed in all urological patients" [1]. In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved [2]. A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urgency symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear [3].

A Norwegian survey of general practitioners' management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) [4]. Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination [5].The same apply, according to Stricker, for patient selection for collagen implant [6]. A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis [3, 7]. Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent [8], in peri- and postmenopausal women [9], in older women reporting urinary incontinence [10]. Belmin et al, suggested than significant urine samples can even be obtained from disposable pads in elderly incontinent women [11, 12]. It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI [12]. The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes [13], others consider that the condition does not require any treatment [11].

1. CONSENSUS STATEMENT

- It is considered standard practice to perform a urinalysis either by using a dipstick test or examining the spun sediment. (**Level of Evidence 3, Grade of Recommendation C**)
- If a dipstick test is used, it is recommended chosing of a "multiproperty" strip that includes testing for haematuria, proteinuria, glucose and ketones, leukocytes esterase (indicating the presence of leukocytes in the urine) and nitrite tests (suggesting bacteriuria). (**Level of Evidence 3, Grade of Recommendation C**)

2. FUTURE RESEARCH AREAS

- Needed to screen analysis of urinalysis in the diagnosis and treatment of UI, MUI and SUI

3. REFERENCES (SEE AT THE END OF THE CHAPTER)

II. BLOOD TESTS

The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or haematological tests in patients with urinary incontinence appears to be a prudent rule of good clinical practice in the following situations:

a) chronic retention with incontinence

b) neurogenic LUT dysfunction

c) when surgery is contemplated

d) when there is a clinical suspicion

e) sodium plasma concentration may be reduced in patients on desmopressin.

Special tests such as measurement of anti diuretic hormone (ADH) and atrial natriuretic polypeptide have proven useful in research of enuresis in childhood and nocturia in the elderly [1, 2]. Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

III. TISSUE ANALYSIS

Since the last report of the International Consultation on Incontinence in 2008, several papers have been published based on the analysis of sample of tissues coming from patients with stress urinary incontinence

(SUI) and/or pelvic organ prolapse aiming at evaluating the molecular bases of these conditions. The main targets of both preclinical and clinical research have been the pelvic floor-supporting tissues and the role of steroid hormones, with some intriguing linkages between the two lines of research.

Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the so called extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfill a large number of mechanical, chemical and biological functions [1]. While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organised and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs [2]. According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin [3].

The organised structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) [4].

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue [5-7], while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue [8]. Chen et al., evaluating cultures of fibroblasts taken from endopelvic fascia and skin biopsies in 14 patients with stress urinary incontinence and 12 controls, showed that the overall collagen synthesis and the ratio of type III and type I fibres were not significantly different between fibroblasts obtained from women with or without SUI [4], indicating that alteration in the collagen synthesis might not be involved in SUI.

On the other hand, a few studies reported change in the relative percentages of the different fibres, with a decrease in type I and increase in type III ones [9, 10]. In women with SUI, Skorupski et al. evaluated the transcription factor Sp1-binding site in the gene encoding a-1 chain of type I collagen, and suggested that the observed G-T polymorphism is a risk factor for incontinence [11]. Again at molecular level, some studies evaluated the cycle regulatory proteins in patients with pelvic organ prolapse, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapse [2].

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women [12]. After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable [12]. These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that overexpression of TGF-β might trigger the accumulation of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase [13-15]. Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapse, suggesting a further molecular basis for the alterations in collagens [16].

Some other studies investigated the role of proteinases that may degrade elements of the extracellular matrix. Chen et al., evaluating full-thickness peri-urethral vaginal wall tissues from patients with SUI or prolapsed and matched control women, found significant decrease in mRNA and protein expressions of alpha-1 antitrypsin (ATT), a neutrophil elastase inhibitor in tissues from affected women, while no difference was found in neutrophil elastase and cathepsin K expressions [17]. Similarly, Gabriel et al. studied the expression of different MMPs in 17 women with prolapsed and

18 control, identifying higher expression of MMP2 in patients with prolapse [18]. These studies allowed to hypothesize that altered catabolism of some components of the extracellular matrix might contribute to the connective tissue alterations observed in pelvic floor dysfunction.

Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women [1]. Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of women with SUI [1].

Oestrogens interact with specific receptors which, when activated by the ligand, have conformational change, dimerisation and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of oestrogen-responsive genes, called the oestrogen response elements, leading to the synthesis of proteins [19]. More recently, selective modulators of oestrogens receptors have been identified, that act modulating the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner [20]. Studies on these molecules supported a new role of oestrogens in SUI and pelvic organ prolapse. Specifically, in a randomized controlled trial testing one of these molecules (levormeloxifene) as osteoporosis treatment, a 3.4-fold increase in the reporting of pelvic organ prolapse and an almost 5-fold increase in the reporting of urinary incontinence have been observed [21]. To explain such effect, the expression of more than 500 proteins have been studied in the rat model, showing that oestradiol induced the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of oestrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypican, and biglycan [19]. Although the role of selective oestrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic organ prolapse observed with oestrogen therapy and SERMs such as levormeloxifene may be related to changes in expression of genes regulating collagen turnover that ultimately weaken the normal structural integrity and support for the genitourinary system [19].

1. CONSENSUS STATEMENT

- To date, all these tissue analyses are not part of the everyday clinical practice

2. FUTURE RESEARCH AREAS

- The relationship between tissue composition and risk of UI and POP
- The relationship between tissue composition and treatment outcome in patients with UI and POP

3. REFERENCES (SEE AT THE END OF THE CHAPTER)

G. CONCLUSIONS

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies and other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lacks adequate founding. We acknowledge that only a few of the imaging techniques and other investigations we reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

Safety tests - Intended to protect patients' health, they are indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-void residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit and cost-effectiveness of PVR

measurement in the primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

Tests with specific and selected indications. Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extraurethral incontinence. No other imaging technique is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrography remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Video urodynamics, is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamics is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteosacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remains the standard for evaluating rectal prolapse.

Investigational tests

Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enteroceles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking. Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and pelvic organ prolapse. Functional neuroimaging continues to provide new insight regarding functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee is made up of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research into this area but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and evidence based recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and pelvic organ prolapse.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.

Pharmacological Treatment of Urinary Incontinence

Karl-Erik Andersson

Christopher R Chapple, Linda Cardozo, Francisco Cruz, Christian Gratzke, Kyu-Sung Lee, Cara Tannenbaum, Alan J Wein

A. Introduction

The function of the lower urinary tract (LUT) is to store and periodically release urine, and is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. These structures form a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; Andersson and Wein, 2004; see, Andersson and Michel., 2011]. Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in overflow incontinence. A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2012].

Many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [Andersson 2007; 2011c; Colli et al., 2007; Athanasopoulos and Cruz, 2011].

In this report, we update the recommendations from the 2008 International Consensus meeting [Andersson et al., 2009]. The most relevant information obtained since the last meeting is briefly reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. Our clinical drug recommendations are based on evaluations made using a modification of the Oxford system (**Table 1**). The terminology used is that recommended by the International Continence Society (ICS) [Abrams et al., 2002].

I. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d'Urologie. There were no restrictions on the inclusion of publications by

Table 1. ICI assessments 2008: Oxford guidelines (modified)

Levels of evidence

Level 1: Systematic reviews, meta-analyses, good quality randomized controlled clinical trials (RCTs)
Level 2: RCTs, good quality prospective cohort studies
Level 3: Case-control studies, case series
Level 4: Expert opinion

Grades of recommendation

Grade A: Based on level 1 evidence (highly recommended)
Grade B: Consistent level 2 or 3 evidence (recommended)
Grade C: Level 4 studies or "majority evidence"(optional)
Grade D: Evidence inconsistent/inconclusive (no recommendation possible) or the evidence indicates that the drug should not be recommended

language; publications in languages other than English were translated into English.

II. CENTRAL NERVOUS CONTROL

In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (**Figures1-4**). In infants, the central pathways seem to be organized as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999; Beckel and Holstege, 2011]. Studies in humans and animals have identified areas in the brainstem and diencephalon (**Figure 5**) that are specifically implicated in micturition control, including Barrington's nucleus or the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons via inhibitory interneurons in the medial sacral cord. The periaqueductal grey (PAG) receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths et al., 2007; 2008; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008; Griffiths, 2011].

III. PERIPHERAL NERVOUS CONTROL

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in ***parasympathetic***, sympathetic, somatic, and sensory nerves. These nerves are parts of reflex pathways, which either keep the bladder in a non-contracted state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of parasympathetic neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 [de Groat et al., 1993; Beckel and Holstege, 2011]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Bridgewater and Brading, 1993; Hashimoto et al., 1993; Werkström et al., 1995].

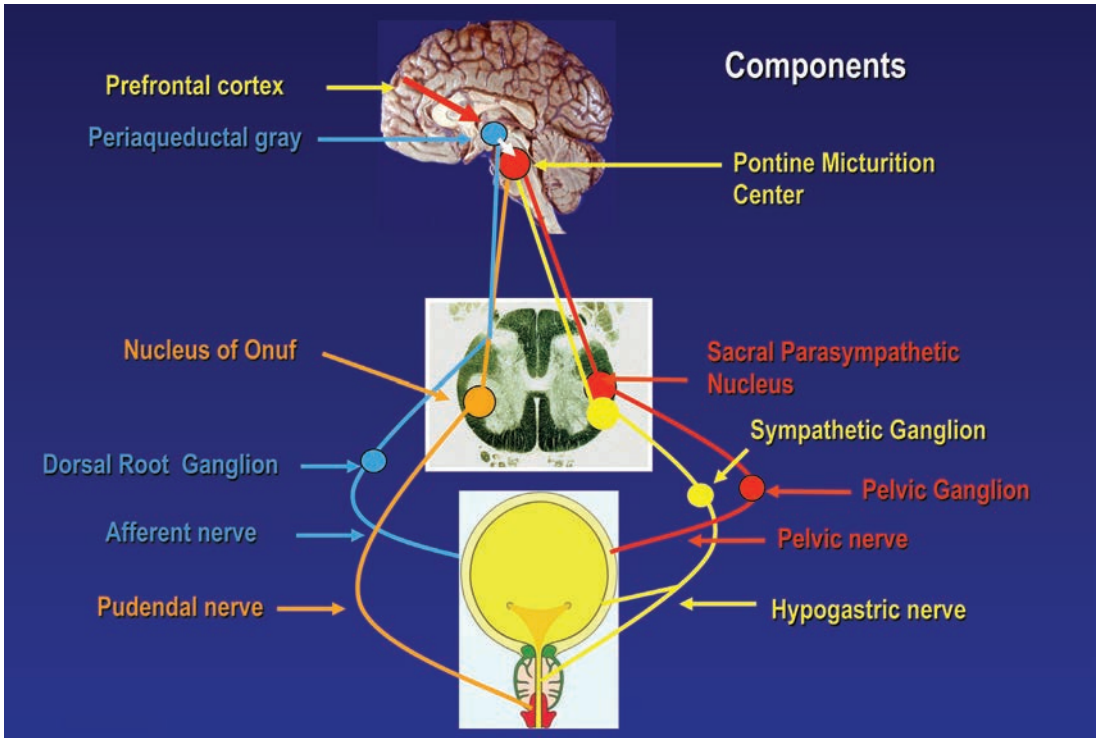

Figure 1 : Components of the micturition reflex.

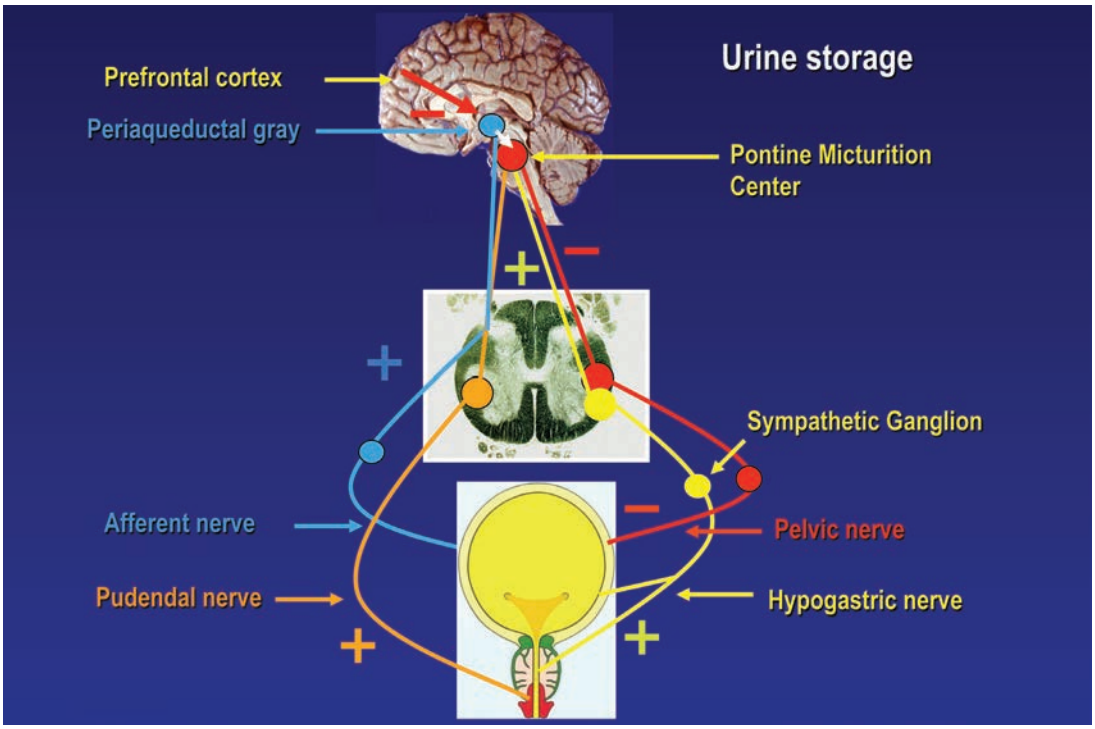

Figure 2 : Activity in the micturition reflex during storage. The pontine micturition center is inhibited by impulses from the prefrontal cortex, afferent impulses unable to initiate micturition. Activities in the hypogastric and pudendal nerves keep the bladder relaxed and the outflow region contracted.

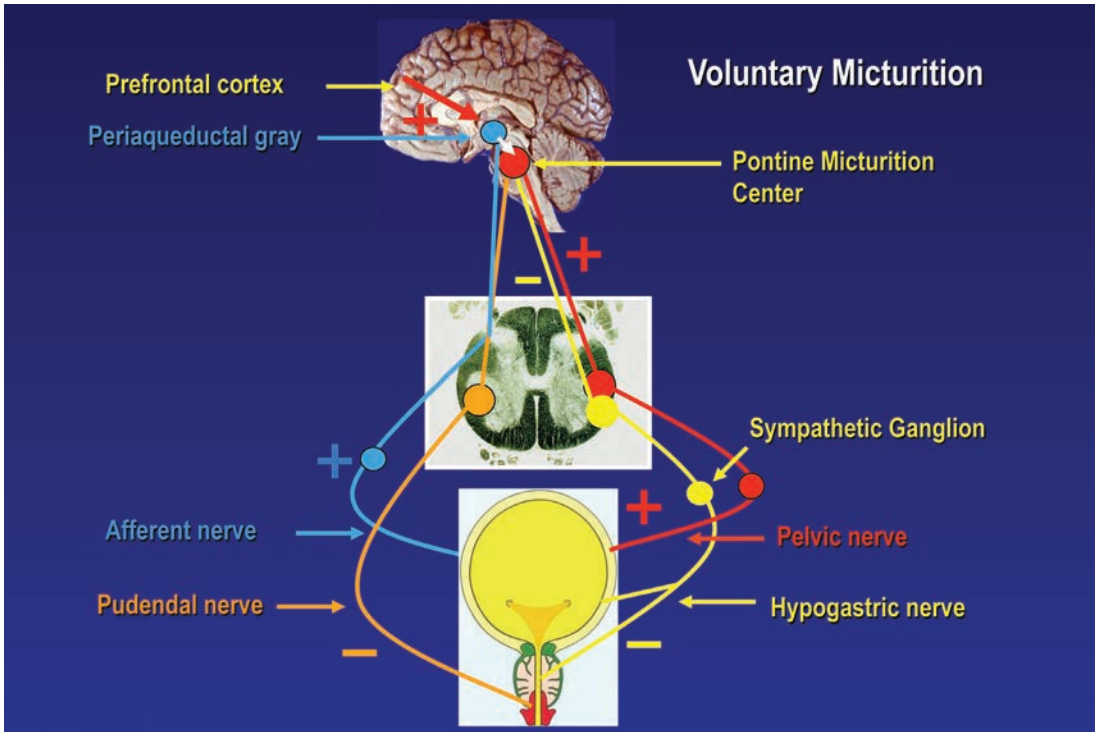

Figure 3 : Activity in the micturition reflex during voluntary voiding. The inhibitory impulses from the prefrontal cortex pontine micturition center are removed and afferent impulses are able to initiate micturition. Activities in the hypogastric and pudendal nerves are inhibited, the outflow region is relaxed, and the bladder is contracted by the activity in the pelvic nerve.

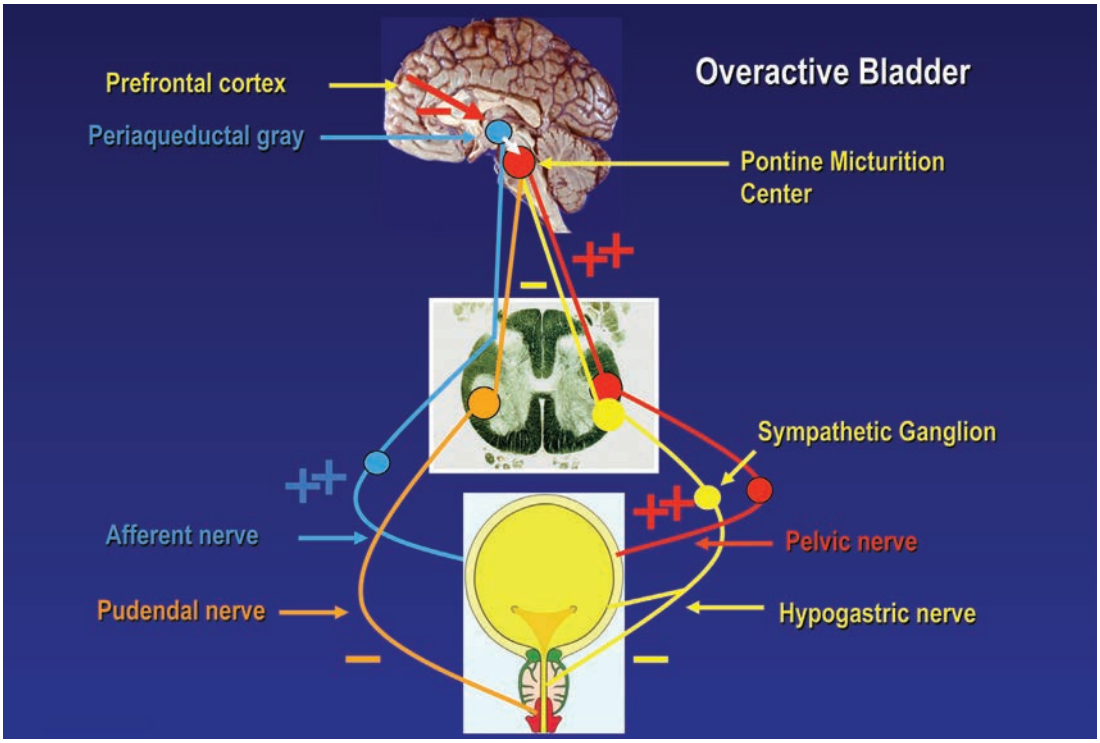

Figure 4 : Detrusor overactivity. Despite the inhibitory impulses from the prefrontal to the cortex pontine micturition center the enhanced (?) afferent impulses are able to initiate micturition.

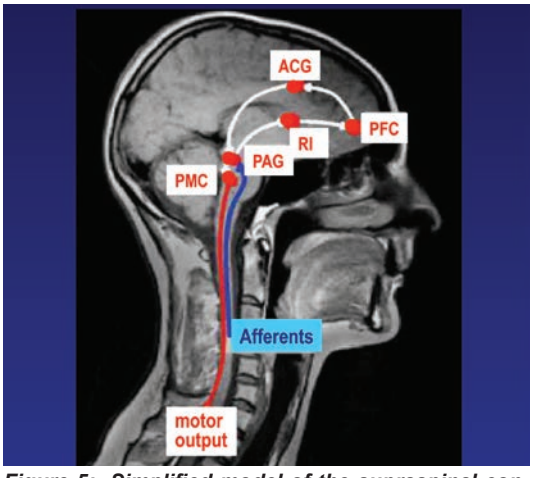

Figure 5: Simplified model of the supraspinal control system of micturition. Secondary bladder afferents synapse in the Periaqueductal Gray (PAG) and are relayed to the Insula (RI), forming the substrate for sensation. Insula representation may have slight right-sided predominance. The Anterior Cingulate Gyrus (ACG) is responsible for monitoring, arousal, and efferent output to the PAG and the Pontine Micturition Center (PMC). The prefrontal cortex (PFC) is involved in voluntary decision about voiding and generates efferent signals to control ACG and ultimately PMC. PMC provides motor output to cause voiding. Modified from Griffiths and Tadic, Neurourol Urodyn, 2008;27:466-474

Most of the ***sympathetic*** innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoraco-lumbar region (T10-L2) of the spinal cord [Beckel and Holstege, 2011]. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve, or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Lincoln and Burnstock, 1993].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra [shown in animals and man, see Andersson, 1993]. However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues in vitro, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

The ***somatic*** innervation of the urethral rhabdosphincter and of some perineal muscles (for exam-

ple compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve [Beckel and Holstege, 2011]. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in a region called Onuf´s (Onufrowicz's) nucleus).

Most of the ***sensory*** innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia [Kanai and Andersson, 2010]. In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Lincoln and Burnstock, 1993]. The most important afferents for the micturition process are myelinated Aδ-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Aδ-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990]. Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed "silent fibres".

IV. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2012]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome. The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. [2006], using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13 % in men and 14.7% in women [Herschorn et al., 2008]. In a Finnish study, taking into account bother, the prevalence of clinically meaningful OAB was was much lower than reported in these studies [Vaughan et al., 2011].

OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO; urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004; Aschkenazi et al., 2007]. DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, changes of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways, as can be seen in various neurological disorders, such as multiple sclerosis, cerebrovascular disease, Parkinson's disease, brain tumors, and spinal cord injury [Andersson and Pehrson, 2003; Ouslander, 2004; Banakhar et al., 2012; Wein and Dmochowski, 2012]. Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g. prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g. diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2011].

V. BLADDER CONTRACTION

Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle [Andersson and Wein, 2004] (**Figure 6**). Atropine resistance, i.e. contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Andersson, 1993; Bayliss et al., 1999]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been reported in normal human detrusor and may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Andersson and Wein, 2004; Kennedy et al., 2007]. ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G-protein-coupled receptor family (P2Y) [Ford and Cockayne, 2011]. Seven P2X subtypes and eight P2Y subtypes have been identified. In several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001; Ford and Cockayne, 2011]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X1 receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. P2X3 receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus

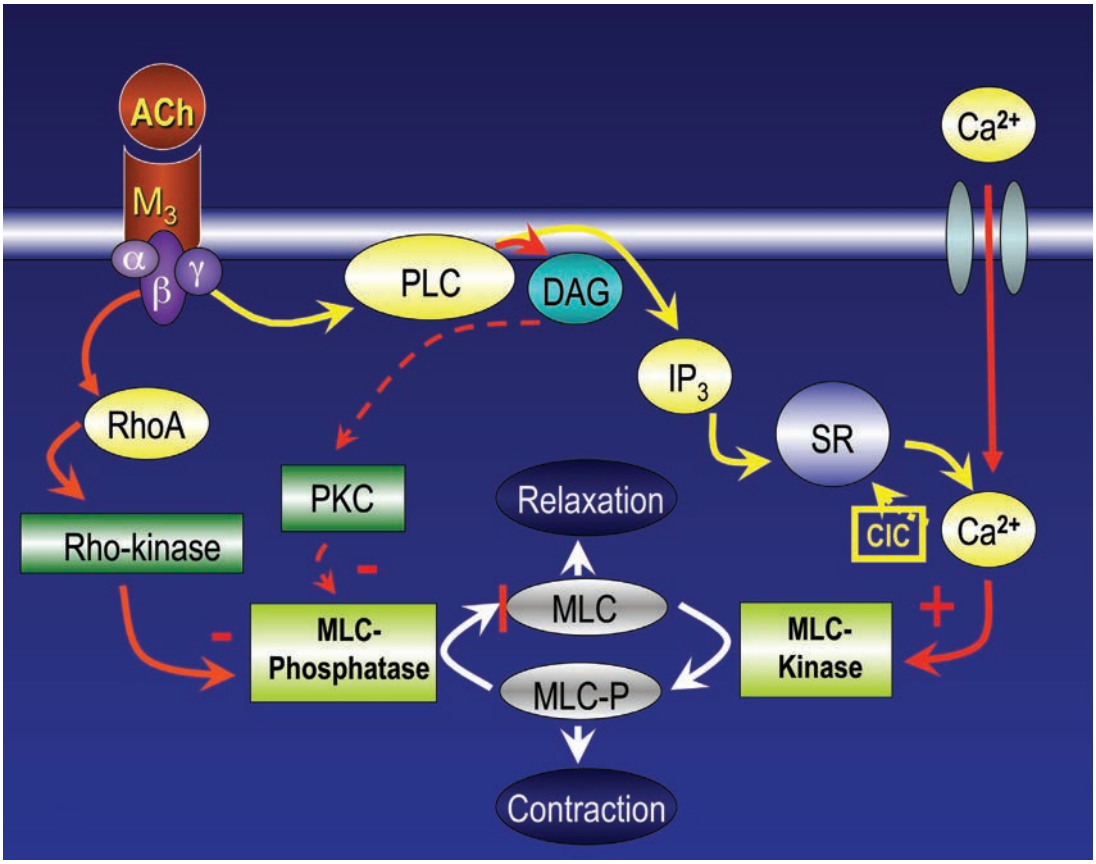

Figure 6: Muscarinic M3 receptor-mediated detrusor activation. Calcium influx and activation of the Rhokinase system are the main pathways mediating activation of the contractile system in the detrusor.

of afferent nerves. In P2X3 knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006; Ford and Cockeyne, 2011]. These data indicate that purinergic receptors are involved in mechanosensory signaling in the nonprimate mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders, and has been reported to occur in hypertrophic bladders [Sjögren et al., 1982], interstitial cystitis [Palea et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established [Andersson, 2006].

VI. MUSCARINIC RECEPTORS

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former play a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g. in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [Abrams and Andersson, 2007]. Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder, but can also be formed and released non-neuronally by the urothelium [Bschleiper et al., 2007; Mansfield et al., 2005; Zarghooni et al., 2007, Andersson, 2011]. Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M1-5 [Caulfield and Birdsall 1998]. Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M1, M3 and M5 on the one hand and the subtypes M2 and M4 on the other. The former prototypically couple via pertussis toxin-insensitive Gq proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive Gi proteins

to inhibition of adenylyl cyclase and modulation of several ion channels [Caulfield and Birdsall 1998]. While sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder [Abrams et al., 2006: Hegde, 2006], studies at the protein level, e.g. based upon radioligand binding, have typically detected only M2 and M3 receptors, with the former dominating quantitatively [Abrams et al., 2006: Hegde, 2006, Andersson, 2011]. Inhibitory pre-junctional muscarinic receptors have been classified as M2 in the rabbit and rat, and M4 in the guinea-pig, rat and human [d´Agostini et al., 2000; see Andersson, 2011] bladder. These receptors appear to be of the M1 subtype in the rat and rabbit urinary bladder, but have also been detected in human bladders. The muscarinic facilitatory mechanism seems to be upregulated (M3 receptors) in overactive bladders from chronic spinal cord transected rats.

Apparently, most muscarinic receptors in the bladder are found on the smooth muscle cells of the detrusor. While the detrusor expresses far more M2 than M3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M3 receptor [Hegde et al., 1997; Chess-Williams et al., 2001; Fetscher et al., 2002; Kories et al., 2003; Schneider et al., 2004a, b]. Studies in knock-out mice confirm this conclusion [Matsui et al., 2000; 2002; Stengel et al., 2002; Ehlert et al., 2007]. Under physiological conditions M2 receptor-selective stimulation causes little contraction [Schneider et al., 2005a], but rather appears to act mainly by inhibiting β-adrenoceptor-mediated detrusor relaxation [Hegde et al., 1997; Ehlert et al., 2007; Matsui et al., 2003]. It has been proposed that M2 receptors can also directly elicit bladder contraction under pathological conditions [Braverman et al., 1998; 2002; 2003; 2006; Pontari et al., 2003] , but such observations have not been confirmed by other investigators using distinct methodological approaches [Schneider et al., 2005a; b].

Based upon the prototypical signalling pathway of M3 receptors [Cauldfield and Birdsall, 1998] and the presence of phospholipase C stimulation by muscarinic agonists in the bladder [Kories et al., 2003; Schneider et al., 2005a] it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C [Ouslander, 2004]. While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs largely independent of phospholipase C [Schneider et al., 2004; Wegener et al., 2004; Frazier et al., 2007]. Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase (**Figure 6**) appear to contribute to muscarinic receptor-mediated bladder contraction in a major way [Frazier et al., 2008]. More recently, muscarinic receptors have also been identified in the urothelium [Chess-Williams, 2002; Kumar et al., 2005]. Similarly to the findings in bladder smooth muscle, the muscarinic receptors in the urothelium mainly belong to the M2 and M3 subtype, with the former dominating quantitatively [Mansfield et al., 2005; Bschleiper et al., 2007]. At present the functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e. by investigating the effects of urothelium removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction [Hawthorn et al., 2000; Wuest et al., 2005; Sadananda et al., 2008]. Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) [Andersson et al., 2008a]. Muscarinic receptor blockade in urothelial cells may also reduce ATP release induced by strech [Young et al., 2012]. Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established.

Assuming an involvement of muscarinic receptors in physiological voiding contractions of the bladder, numerous studies have explored whether an overactivity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors [Stevens et al. 2006]. However, according to Michel and Barendrecht [2008] the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive [Michel and Barendrecht, 2008]. This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during bladder filling (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions [Yoshida et al., 2001; 2008; Rapp et al., 2005]. These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies [Herbison et al., 2003; Chapple et al., 2005; 2008; Novara et al., 2008; Shamliyan et al., 2008].

B. Drugs used for treatment of overactive bladder symptoms/ detrusor overactivity

It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (**Table 2**). Helfand and coworkers showed that in a cohort of 7,244,501 patients over 45 years with an OAB diagnosis, 24.4% of these were treated mainly with antimuscarinic agents; 75.6% went untreated. Only 25.6% of those treated were men. [Helfand et al., 2009]. As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

I. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS

• Mechanism of action

Antimuscarinics block, more or less selectively, muscarinic receptors irrespective of location [Abrams and Andersson, 2007; Andersson 2011b] (**Figure 7**). The common view is that in OAB/DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the lower urinary tract [Andersson, 2004, 2007]. Furthermore, antimuscarinics are usually competitive antagonists. This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, but in the dose range used for beneficial effects in OAB/DO (**Figure 8**), there is little evidence for a significant reduction of the voiding contraction [Finney et al., 2006]. However, there is good experimental evidence that the drugs act during the storage phase by decreasing the activity in afferent nerves (both C- and Aδ -fibres) from the bladder [De Laet et al., 2006; Ijima et al., 2007] (**Figure 9**).

As mentioned previously, muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest [Andersson, 2002; Birder and de Groat, 2007], but whether the muscarinic receptors

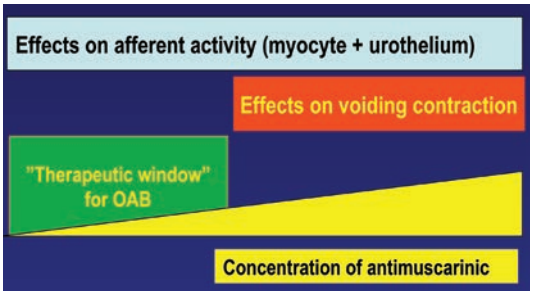

Figure 8: Rationale for use of antimuscarinics for treatment of OAB/DO. Blockade of muscarinic receptors at both detrusor and nondetrusor sites may prevent OAB symptoms and DO without depressing the contraction during voiding. The «Therapeutic window for OAB» can be obtained in most patients with recommended doses of antimuscarinics

on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues [2004; 2006; 2008] found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and, at least partly, generated by the urothelium. There is also indirect clinical evidence for release of ACh during bladder filling. Smith and co-workers [1974] found that in patients with recent spinal-cord injury, inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch and colleagues [2001] inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of overactive bladder, but in no patients without specific complaints suggesting DO. Thus, during the storage phase, ACh and ATP may be released from both neuronal and non-neuronal sources (eg, the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB/DO and represent possible targets for antimuscarinic drugs.

• Pharmacologic properties

Generally, antimuscarinics can be divided into tertiary and quaternary amines [Guay, 2003, Abrams and Andersson, 2007]. They differ with regards to lipophilicity, molecular charge, and even molecular size, tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the CNS, dependent on their individual physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood brain barrier, but in some cases, such as darifenacin, that is compensated by active transport out of the CNS by the product of the MDR1 gene. Quaternary ammonium compounds, like propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects [Guay 2003]. They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increases in heart rate, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites [Guay 2003]. The most commonly involved P450 enzymes are CYP2D6, and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration/effect of the antimuscarinic and /or interacting drug. Antimuscarinics secreted by the renal tubules (eg trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism. Some antimuscarinics and their active metabolites are excreted in urine in amounts that may affect the mucosal muscarinic receptors from the luminal side. This has not yet been demonstrated to imply superior clinical efficacy [Andersson et al., 2008b].

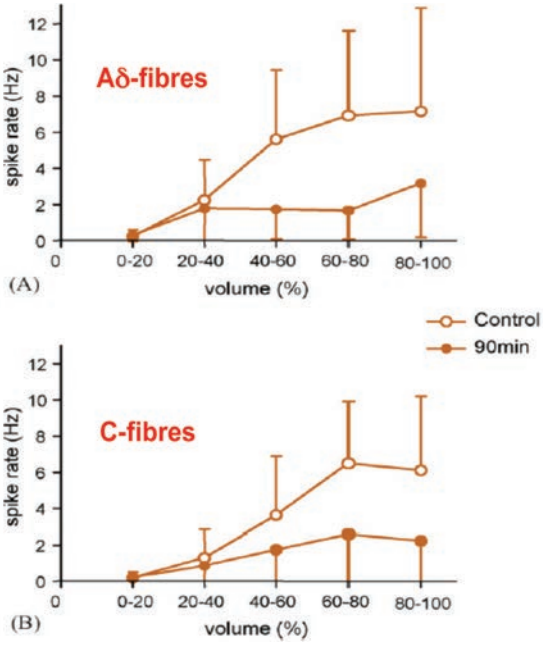

Figure 9: Influence of darifenacin on volume-related nerve activity in Aδ afferents (A) and C afferents (B) in the rat pelvic nerve. From Iijima et al. Eur Urol. 2007 Sep;52(3):842

Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence [Andersson, 2004, Andersson et al., 2009]. However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects, which limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained, if the subtype(s) mediating bladder contraction, and those producing the main side effects of antimuscarinic drugs, were different. Unfortunately, this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For some of them, documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepronium). Information on these drugs has not been included, but can be found elsewhere [Andersson, 1988; Andersson et al., 1999].

1. ANTIMUSCARINICS WITH "SPECIFIC" ACTION

Below data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term "specific"). The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

a) Atropine sulfate

Atropine (dl-hyoscyamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral tratment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al 2007]. It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO [Fader et al., 2007].

The pharmacologically active antimuscarinic component of atropine is l-hyoscyamine.

Assessment

Although still used, few clinical studies are available to evaluate the antimuscarinic activity of l-hyoscyamine sulfate [Muskat et al., 1996]. For assessment, see **Table 2**.

b) Darifenacin hydrobromide

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metabolised in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range [Skerjanec, 2006]. UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites of which only UK-148,993 is said to have significant anti-muscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects [Michel and Hegde, 2006]. The metabolism of darifenacin by CYP3A4 suggests that co-administration of a potent inhibitor of this enzyme (e.g. ketoconazole) may lead to an increase in the circulating concentration of darifenacin [Kerbusch et al., 2003].

Darifenacin is a relatively selective muscarinic M3 receptor antagonist. In vitro, it is selective for human cloned muscarinic M3 receptors relative to M1, M2, M4 or M5 receptors. Theoretically, drugs with selectivity for the M3 receptor can be expected to have clinical efficacy in OAB/DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes [Andersson, 2002]. However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day. The clinical effectiveness of the drug has been documented in several RCTs [Haab et al., 2004; Cardozo and Dixon 2005; Steers et al., 2005; Chapple et al., 2005; Foote et al., 2005; Hill et al., 2006; Haab et al., 2006; Zinner et al., 2006, Chapple et al., 2007; Abrams et al., 2008, Chancellor et al., 2008; Dwyer et al., 2008; for reviews, see Guay, 2005; Zinner, 2007; Novara et al., 2008; Chapple et al., 2008]. Haab et al. [2004] reported a multicentre, double-blind, placebo-controlled, parallel-group study which enrolled 561 patients (19−88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomised [1:4:2:3]to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n=53), 7.5 mg (n=229) or 15 mg (n=115) or matching placebo (n=164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6 and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg, respectively, was significantly superior

to placebo for (median) improvements in micturition frequency (7.5 mg: -1.6; 15 mg: -1.7; placebo -0.8, frequency of urgency per day [-2.0; -2.0; -0.9], and number of incontinence episodes leading to a change in clothing or pads [-4.0; -4.7; -2.0]. There was no significant reduction in nocturnal awakenings due to OAB.The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth and discontinuation related to constipation was rare (0.6% placebo versus 0.9% darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well-tolerated [Steers et al., 2005]. A 2-year open label extension study of these investigations [i.e., Haab et al., 2004; Steers et al., 2005], confirmed a favorable efficacy, tolerability and safety profile [Haab et al., 2006].

A review of the pooled darifenacin data from the three phase III, multicentre, double blind clinical trials in patients with OAB was reported by Chapple et al. [2005] After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, –8.8 [–68.4%; placebo -54%, P<004]; 15 mg, –10.6 [–76.8%; placebo 58%, p<0.001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (>65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile [Foote et al., 2005, Zinner et al., 2005; Hill et al. 2006].

The time-to effect with darifenacin was analyzed in a pooled analysis of efficacy and safety data fom 1,059 patients participating in three double-blind 12-week studies Khullar et al [2011]. Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin, on the 'warning time' associated with urinary urgency. Warning time was defined as the time from the first sensation of urgency to the time of voluntary micturition or incontinence. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks' washout, 2 weeks' medication-free run-in and a 2-week treatment phase [Cardozo and Dixon, 2005]. Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant (p<0.004) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a ≥30% increase in mean warning time. There were methodological problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centred environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study [Zinner et al., 2006] on 445 OAB patients, darifenacin treatment (15 mg) resulted in numerical increases in warning time, however, these were not significant compared to placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer et al., 2008]. It was shown that neither the positive effects on micturition variables, nor on HRQoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioural modification programme including timed voiding, dietary modifications and Kegel exercises [Chancellor et al., 2008].

Since darifenacin is a substrate for the P-glycoprotein drug efflux transporter [Miller et al., 2011;

Chancellor et al., 2012], which is present both in the blood-brain and blood-ocular barriers, several clinical studies have been devoted to investigate possible effect of darifenacin on cognition. Neither in healthy volunteers (19-44 years) and healthy subjects (>60 years), nor in volunteers 65 years or older, could any effect of darifenacin (3.75-15mg daily) be demonstrated, compared to placebo [Kay and Wesnes, 2005; Lipton et al., Kay et al., 2006; Kay and Ebinger 2008; Chancellor et al., 2012].

To study whether darifenacin had any effect on QT/QTc intervals [Serra et al., 2005] performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic Tmax versus placebo were –0.4 and –2.2 milliseconds in the darifenacin 15mg and 75 mg groups, respectively, compared with +11.6 milliseconds in the moxifloxacin group (P < .01). The conclusion was that darifenacin does not prolong the QT/QTc interval.

Darifenacin 15 mg per day given to healthy volunteers did not change heart rate significantly compared to placebo [Olshansky et al., 2008].

Assessment

Darifenacin has a well-documented beneficial effect in OAB/DO (**Table 2**), and tolerability and safety seems acceptable.

c) Fesoterodine fumarate

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by non-specific esterases [Michel, 2008, Malhotra et al., 2009a]. This compound, which is is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008]. The bioavailability of fesoterodine, averaging 52%, was independent of food intake and the drug may be taken with or without a meal [Malhotra et al., 2009b]. Peak plasma concentration of 5-HMT is reached at 5 h following oral administration and has a half-life of 7–9 h [Malhotra et al., 2008]. The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function due to the combination of renal excretion and hepatic metabolism of 5-HMT [Malhotra et al., 2009c; de Mey et al., 2011].

The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs [Chapple et al., 2007; Nitti et al., 2007; Dmochowski et al., 2010; Herschhorn et al., 2010; Kaplan et al., 2010; Nitti et al., 2010; see Dell'Utri et al., 2012]. In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1132 patients were enrolled and received treatment [Chapple et al., 2007]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8 mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only one subject from the fesoterodine 8 mg group and one subject from the tolterodine ER group withdrew from the study due to dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs [Khullar et al., 2008]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and urge UI as recorded by 3-day bladder diary, offering the possibility of dose titration.

A head to head placebo controlled trial has been completed comparing fesoterodine 8mg to tolterodine extended release 4mg and placebo [Herschorn et al., 2010]. The study randomized 1,590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, p = 0.015), mean voided volume per void (+32.9 ml vs. +23.5 ml, p = 0.005), and in patients' assessments of bladder related problems as measured by OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (40% vs. 33% with > 2 point improvement, p < 0.001), and Urgency Perception Scale (46% vs. 40% with improvement, p = 0.014) compared with tolterodine. The clinical significance of these statistically significant findings is questionable as there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4 %), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head to head trial comparing two drugs in class supports the use of fesoterodine 8mg for additional benefit over tolterodine ER 4 mg.

Wyndaele et al. [2009] reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centres worldwide and comprised 516 participants (men and women) >18 years who self-reported OAB symptoms for at least 3 months

before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence episodes, micturition-related urgency episodes and severe micturition-related urgency episodes per 24 h. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

The largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centres with a total of 2,417 patients enrolled, was performed by Kaplan et al. [2010]. All patients were healthy, >18 years of age and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables) than those receiving either tolterodine ER or placebo; UUI and urgency episodes, micturition frequency and MVV. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving of UUI and urgency episodes and 24-h micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, Dmchowski et al. reported statistically significant improvements at week 12 in the mean number of micturition per 24 h and in both UUI and urgency episodes. Between groups, difference in nocturnal micturition was not statistically significant.

Nitti et al. [2010] determined whether the presence of DO in patients with OAB and urgency urinary incontinence was a predictor of the response to treatment with fesoterodine in a phase 2 randomized, multicentre, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms, indicating that the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.

Kelleher et al. [2008] evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies Chapple et al., 2007; Nitti et al., 2007] were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine extended release (tolterodine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all KHQ domains, ICIQ-SF scores, and bladder related problems were observed at months 12 and 24 compared to open label baseline [Kelleher et al., 2011]. The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

Malhotra et al. [2010] performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 28 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on Days -1 (baseline), 1, and 3. The primary analysis was the time-averaged changes from baseline for Fridericia's-corrected QT interval (QTcF) on Day 3. Among 261 subjects randomized to fesoterodine 4 mg (n = 64), fesoterodine 28 mg (n = 68), placebo (n = 65), or moxifloxacin 400 mg (n = 64), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment

Fesoterodine has a well-documented beneficial effect in OAB (**Table 2**), and the adverse event profile seems acceptable.

d) Imidafenacin

Imidafenacin (KRP-197/ONO-8025, 4-(2-methyl-1H-imidazol-1-yl)-2,2-diphenylbutanamide) is an antagonist for the muscarinic ACh receptor with higher affinities for M3 and M1 receptors than for the M2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes [Kobayashi, Yageta et al. 2007]. The drug blocks pre- as well as postjunctional muscarinic receptors and was shown to block both detrusor contractions and acetylcholine release [Murakami, Yoshida et al. 2003]. The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary gland or colon [Yamada, Seki et al. 2011], and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect here than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed form the gastrointestinal tract and its absolute bioavailability in human is 57.8% [Ohmori, Miura et al. 2007; Ohno, Nakade et al. 2008]. It is rapidly absorbed with maximum plasma concentration occuring 1-3h after oral administration [Ohno, Nakade et al. 2008]. Metabolites in the plasma are produced mainly by

first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs [Kanayama, Kanari et al. 2007].

Kitagawa et al. [Kitagawa, Kuribayashi et al. 2011] reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that mean total OABSS decreased gradually during 2 weeks after administration.

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety/tolerability, and dose-response relationship of imidafenacin [Homma, Yamaguchi et al. 2008]. Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin/day (99 patients), 0.2 mg of imidafenacin/day [100], 0.5 mg of imidafenacin/day [101], or a placebo [101]. After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo was observed ($P < 0.0001$). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased dose-dependently. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment due to dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms were conducted by Homma et al.[Homma and Yamaguchi 2009]. They were randomized to imidafenacin (324), propiverine [310], or a placebo [147]. After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group ($P < 0.0001$). The non-inferiority of imidafenacin compared with propiverine was confirmed for the reduction in using incontinence episodes ($P = 0.0014$, non-inferiority margin: 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine ($P = 0.0101$). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group ($P < 0.0001$). However, there were no clinical arrhythmia and clinical arrhythmic events in any of the treatment groups.

The long-term safety, tolerability, and efficacy imidafenacin was studied in Japanese OAB patients [Homma and Yamaguchi 2008], of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin produced mean changes from baseline in the number of incontinence episodes (-83.51%), urgency incontinence episodes (-84.21%), voiding frequency (-2.35 micturitions/day), urgency episodes (-70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the King's Health Questionnaire. received the treatment and 376 patients completed the 52-week program. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or post-void residual volume.

A 52-week prospective, open randomized comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) was conducted in a total of 41 Japanese patients with untreated OAB [Zaitsu, Mikami et al. 2011]. They were randomly assigned to imidafenacin and solifenacin groups. There was no difference in OABSS and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group ($P = 0.0092$ and $P = 0.0013$, resp.). An important limitation of this study is the low number of patients. Only 25 patients (17 males 8 females) were available for long-term analysis.

Assessment.

Imidafenacin seems to be effective and to have an acceptable tolerability. However, the documentation is relatively scarce and the drug is not yet available in the Western countries.

e) Propantheline bromide

Propantheline is a quaternary ammonium compound, non-selective for muscarinic receptor subtypes, which has a low (5 to 10%) and individually varying biological availability. It is metabolized (metabolites inactive) and has a short halflife (less than 2 h) [Beermann et al., 1972]. It is usually given in

a dose of 15 to 30 mg 4 times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher dosages are required. Using this approach in 26 patients with detrusor overactivitycontractions [Blaivas et al., 1980] in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of dosages varied from 7.5 to 60 mg four times daily. In contrast, Thüroff et al. [1991] comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo, in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes et al. [1991] found no differences in efficacy between oxybutynin and propantheline. Controlled randomized trials (n=6) reviewed by Thüroff et al [1998], confirmed a positive, but varying, response to the drug.

Assessment

Although the effect of propantheline on OAB/DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective, and may, in individually titrated doses, be clinically useful (**Table 2**). No new studies on the use of this drug for treatment of OAB/DO seem to have been performed during the last decade.

f) Solifenacin succinate

Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-68 hours [Kuipers et al., 2002; Smulders et al., 2002; 2004]. It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) Cmax and AUC0-inf were increased by only approximately 40% and 56%, respectively [Swart et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Abrams and Andersson, 2007]. Supporting an effect on sensory function by solifenacin, 15 women with DO receiving 10 mg/day of the drug showed an increase in the area under the bladder-volume sensation curve [Lowenstein et al., 2011] Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies Tanaka et al., 2010; Hsiao et al., 2011].

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed [Chapple et al., 2004a, Smith et al., 2002]. The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple et al., 2004a]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least 8 micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (USA) [Smith et al., 2002]. This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials and these findings demonstrate efficacy as early as one week. The 5 mg, 10 mg, and 20 mg dosing groups experienced statistically significant increases in volume voided; the 10 mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo [Chapple et al., 2004b]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with placebo (-8%), mean micturitions/24 h were significantly reduced with solifenacin 10 mg (-20%), solifenacin 5 mg (-17%), and tolterodine (-15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo et al. [2004] randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo. The primary efficacy variable was change from baseline to study end

point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia and incontinence episodes per 24 hours, and mean volume voided per micturition. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), but not with placebo (-1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs 2.3% with placebo). A 40-week follow up of these studies [i.e., Chapple et al., 2004b and Cardozo et al., 2004] demonstrated that the favourable profile, both in terms of efficacy and tolerability was maintained over the study period [Haab et al., 2005].

The STAR trial [Chapple et al., 2005; 2007] was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week study was conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLT-ER 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummied throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was “non-inferior” to tolterodine concerning the primary effect variable, micturition freqency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30 and 6.4%, tolterodine 23 and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups.

Luo et al. [2012] performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and safety of the drug. Their results which largley confirmed what could be deduced from previouly published information, indicated that solifenacin could significantly decrease the number of urgency episodes per 24 h, micturitions per 24 h, incontinence episodes per 24 h, nighttime micturitions per 24 h, and UUI episodes per 24 h, and improve volume voided per micturitions compared with the placebo or tolterodine treatment.

A number of studies and reviews have further documented the effects of solifenacin [Cardozo et al., 2006; Chapple et al., 2006; 2007; Maniscalco et al., 2006, see also Chapple et al., 2008; Novara et al., 2008; Toglia et al., 2009; Vardy et al., 2009; Serels et al., 2010; Luo et al., 2012], including men with OAB without bladder outlet obstruction [Kaplan et al., 2010;] In a pooled analysis of four RCTs, Abrams and Swift (2005) demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald [2007] confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: -0.6, $p<0.025$; with 10 mg: -0.6, $p<0.001$vs placebo: -0,4) but without nocturnal polyuria. A positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin has also been reported in other studies [Takao et al., 2011; Yokoyama et al., 2011] Kelleher et al. [2006] and Staskin and Te [2006] presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (> 65 years) patients, and also showed a high level of persistence in a 40 week extension trial [Wagg et al., 2005]. Post-hoc analysis of two12-week, open lable, flexible-dosing studies on 2645 patients over 65 years of age with OAB, revealed that solifenacin was associated with improvements in measures assessing patients’ perception of their bladder problems, symptom bother, and aspects of health-related quality of life [Capo et al., 2011]. Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients [Herschorn et al., 2001]. An exploratory pilot study with single doses of solifenacin 10 mg to 12 elderly volunteers suggested no clear propensity to impair cognitive functions [Wesnes et al., 2009].

Improvement of QoL by solifenacin treatment has been documented in several studies [Kelleher et al., 2005; Garely et al., 2006]. In 30 patients with mutiple sclerosis, van Rey and Heesakkers [2011] improved OAB symptoms as well as neurogenic disease-specific QoL measures.

Information on solifenacin treatment in children is scarce. In a prospective open label study in 72 children (27 with neurogenic bladders) Bolduc et al.[2010] improved urodynamic capacity and im-

proved continence.Chart review of 138 children with therapy resistant OAB treated with solifenacin increased mean voided volume and improved continence [Hoebeke et al., 2009]

In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multi-dose, randomized, double-blind, placebo and positive-controlled (moxifloxacin 400 mg) trial. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4, 13: 90%CI) compared to the 10 mg (2 msec, -3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel et al. [2008] studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that "in real-life conditions, i.e. with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comedications, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure".

Assessment

Solifenacin has a well-documented beneficial effect in OAB/DO (**Table 2**), and the adverse event profile seems acceptable.

g) Tolterodine tartrate

Tolterodine is is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound [Nilvebrant et al., 1997], and significantly contributes to the therapeutic effect of tolterodine [Brynne et al., 1997; Brynne et al., 1998]. Both tolterodine and 5-HMT have plasma half-lifes of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4 % of the dose; 5 – 14% of 5-HMT is eliminated in the urine [Brynne et al., 1997]. Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. [2005] and Chuang et al., [2008], do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Hills et al., 1998, Clemett et al., 2001; Salvatore et al., 2008]. However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP 2D6 [Diefenbach et al., 2008].

Tolterodine has no selectivity for muscarinic receptor subtypes, but is claimed to have functional selectivity for the bladder over the salivary glands [Stahl et al., 1995; Nilvebrant et al. 1997b]. In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug [Stahl et al., 1995]. However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder [Andersson, 2011b]. Cirfirming data in humans were found by Vijaya et al. [2012]. In a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO in comparison to placebo, by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz upon both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz (P-value <0.05).

Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability [Van Kerrebroeck et al. 2001].

Several randomised, double blind, placebo-controlled studies on patients with OAB/DO (both idiopathic and neurogenic DO), have documented a significant reduction in micturition frequency and number of incontinence episodes [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment), and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily [Appell et al., 2001] in a 12-week randomized, double blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main

outcome measures adjusted for baseline (see also below: oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of central nervous system and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study [Diokno et al., 2003], OXY-ER at 10 mg/d or TOLT-ER at 4 mg/d were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence (primary end point), total (urgency and non urgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8 and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable; including adverse events involving the central nervous system.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) [Sussman and Garely, 2002] study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the the open label design of the study.

Zinner et al. [2002] evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability endpoints were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (< 2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. [2003] presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

In the IMprovement in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study [Elinoff et al., 2005], the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open label, primary care setting. Patients with OAB symptoms for >3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes, nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms

can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs [Dmochowski et al., 2007a; 2007; Barucha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Rogers et al., 2008; Rovner et al., 2008a; see further: Novara et al, 2008, Chapple et al., 2008]. Importantly, the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo was performed. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 ms absolute QTc or 60ms change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval [Malhotra et al., 2007].

Olshansky et al. [2008] compared the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean heart rate per 24 hours. The proportion of subjects with an increase >5 beats/min was significantly greater in those receiving TOLT-ER (25% than with darifenacin (8.9%).

Hsiao et al. [2011] compared the urodynamic effects, therapeutic efficacy and safety of solifenacin [5 mg] versus tolterodine ER [4 mg] treatment inwomen with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy and adverse events, however, tolterodine had a greater effect in increasing heart rate than solifenacin.

In a prospective, open study, Song et al. [2006] compared the effects of bladder training and/or tolterodine as first line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training (BT), tolterodine (2 mg twice daily) or both for 12 weeks. All treatments were efficacious, however, combination therapy was the most effective. Mattiasson et al. [2003] compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training (BT) with tolterodine alone in patients with OAB in a multicenter single blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine + BT than with tolterodine alone (33% vs. 25%; $p<0.001$), while the median percentage increase in volume voided per void was 31% with tolterodine + BT and 20% with tolterodine alone ($p<0.001$). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine + BT (-87%). It was concluded that the effectiveness of tolterodine 2mg twice daily can be augmented by a simplified BT regimen. However, Millard et al. [2004] investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence, however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open label study tolterodine extended release plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics [Klutke et al., 2009].

Abrams et al. [2006] studied the safety and tolerability of tolterodine for the treatment of OAB symptoms in men with BOO. They found that tolterodine did not adversely affect urinary function in these men. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. It was suggested that antimuscarinics can be safely administered in men with BOO. Lee et al. [2008] reviewed the safety and efficacy of antimuscarinic agents in treating men with BOO and OAB and emphasized their safety and efficacy. They also concluded that combination therapy of antimuscarinic and α1-AR antagonists improves the symptoms effectively without increasing the incidence of acute urinary retention.

The beneficial effect of TOLT-ER in men with benign prostatic enlargement (BPE) and LUTS, including OAB, has been well documented. Both as monotherapy, but in particularly in combination with α1-adenoceptor (AR) antagonist, TOLT-ER was found effective [Kaplan et al., 2006; Höfner et al., 2007; Kaplan et al., 2008a; 2008b; Rovner et al., 2008; Roehrborn et al., 2008]. This effect was obtained irrespective of prostate size, and was not associated with increased incidence of acute urinary retention (AUR) [Roehrborn et al., 2008]. A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women aged ≥ 18 years that were diagnosed with OAB and reported ≥ 8 micturitions/24 hr and ≥ 4 urgency episodes/week on 5-day bladder diary at baseline [Marencak et al.2011]. Subjects were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg twice daily [BID]/4 mg once daily [QD], n=102), pregabalin alone (150 mg BID, n=105), tolterodine ER alone (4 mg QD, n=104), low-dose pregabalin/tolterodine ER (75 mg BID/2 mg QD, n=105), and placebo (n=103). Subjects completed 5-day diaries at the end of treatment and washout periods. The primary endpoint was change from baseline to week 4 in mean voided volume (MVV) per micturition. Baseline-adjusted changes in MVV were significantly greater after

treatment with standard-dose pregabalin/tolterodine ER (39.5 ml) versus tolterodine ER alone (15.5 ml; P<0.0001), and with pregabalin alone (27.4 ml) versus tolterodine ER alone (P=0.005) and placebo (11.9 ml; P=0.0006). Treatments were generally well tolerated; discontinuation rates due to adverse events were 4%, 2%, 5%, 0%, and 1% with standard- and low-dose pregabalin/tolterodine ER, pregabalin,tolterodine ER, and placebo, respectively. See further section on Combinations].

Assessment

Both the IR and ER forms of tolterodine have a well-documented effect in OAB/DO (**Table 2**), and are well tolerated.

h) Trospium chloride

Trospium is a quaternary ammonium compound with a biological availability less than 10% [Fusgen and Hauri, 2000; Doroshyenko et al., 2005]. The drug has a plasma half-life of approximately 20 h, and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim et al., 2006]. Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system [Beckmann-Knopp et al., 1999; Doroshyenko et al., 2005]. It is expected to cross the blood-brain to a limited extent since it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain [Gever et al., 2009]. This was demonstrated by Staskin et al. [2010], showing that trospium chloride levels in CSF samples were undetectable on Day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects [Fusgen and Hauri, 2000; Todorova et al., 2001; Widemann et al., 2002; Staskin et al., 2010; Chancellor et al., 2012].

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Uckert et al., 2000].

Several RCTs have documented positive effects of trospium both in neurogenic [Stöhrer, et al., 1991; Madersbacher et al., 1995; Menarini et al., 2006] and non-neurogenic DO [Allousi et al., 1998; Cardozo et al., 2000; Junemann et al., 2000; Halaska et al., 2003; Zinner et al., 2004a; Rudy et al., 2006; Staskin et al., 2007; Dmochowski et al., 2008]. In a placebo-controlled, double blind study on patients with with neurogenic DO [Stöhrer et al, 1991], the drug was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equieffective; however, trospium seemed to have fewer side effects [Madersbacher et al., 1995].

The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi et al. [1998] compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. [2000] investigated 208 patients with DO, who were treated with trospium 20 mg twice daily for two weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 ml; placebo 254 to 255 ml) and in maximum bladder capacity (from 329 to 356 ml; placebo 345 to 335 ml) in the trospium treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann et al. [2000] compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary endpoint, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7 and 9%, respectively).

Halaska et al. [2003] studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomisation in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning, and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 ml after 26 weeks and 115 ml after 52 weeks (P=0.001). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the

mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability.

Zinner et al. [2004] treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinent episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action and change in Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinent episodes 59% compared to placebo (-1.29; 44%). It significantly increased average volume per void (32 ml; placebo: 7.7) ml, and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) - and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%). In a large US multicenter trial with the same design, and including 658 patients with OAB, Rudy et al. [2006] confirmed the data by Zinner et al [2004], both with respect to efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomised, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence received trospium chloride 15 mg TID (n = 828) or 2.5 mg oxybutynin hydrochloride TID (n = 830). After four weeks, daily doses were doubled and not readjusted in 29.2% (242/828) of patients in the trospium group, and in 23.3% (193/830) in the oxybuytnin group, until the end of treatment. At study end, there were no relevant differences between the “dose adjustment” subgroups and the respective “no dose adjustment” subgroups (trospium: P = 0.249; oxybutynin: P = 0.349). After dose escalation, worsening of dry mouth was higher in both dose adjusted subgroups compared to the respective “no dose adjustment” subgroups (P < 0.001). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups [Bödeker et al., 2010].

An extended release formulation of trospium allowing once daily dosing, has been introduced [Silver et al., 2010], and and its effects tested in controlled trials [Staskin et al., 2008; Dmochowski et al., 2008; Chancellor et al., 2010; MacDiarmid et al., 2011; Sand et al., 2011a; b; c; Zinner et al., 2011]. These studies demonstrated similar efficacy as found with previous formulations, but include experiences in e.g., elderly patients (>75 years), obese patients, and in patients who use multiple concomitant medications. The most frequent side effects were dry mouth (12.9% ; placebo 4.6) and constipation (7.5%; placebo 1.8) [Dmochowski et al., 2008].

Intravesical application of trospium may be an interesting alternative. Frölich et al. [1998] performed a randomised, single-blind, placebo-controlled, mono-centre clinical trial in 84 patients with urgency or urgency incontinence. Compared to placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed [Walter et al., 1999], thus offering an opportunity for treatment with minimal systemic antimuscuscarinic effects.

Assessment

Trospium has a well-documented effect in OAB/DO, and tolerability and safety seems acceptable (**Table 2**).

2. ANTIMUSCARINICS WITH “MIXED” ACTION

Some drugs used for treatment of the OABsyndrome/DO have been shown to have more than one mechanism of action. They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined “direct” action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca2+ channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsade de pointes) in some patients [Connolly et al., 1991; Stewart et al., 1992].

a) Oxybutynin chloride

Oxybutynin is a tertiary amine that is well absorbed, and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck et al., 1997], but occurs in much higher concentrations after oral administration [Hughes et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active

metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander et al. [1988]. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation [Hughes et al., 1992; Douchamps et al, 1988].

Oxybutynin has several pharmacological effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Waldeck et al., 1997; Nilvebrant et al., 1988]. The drug was shown to have slightly higher affinity for muscarinic M1 and M3 receptors than for M2 receptors [Nilvebrant et al., 1986; Norhona-Blob et al., 1991], but the clinical significance of this is unclear.

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other anti-muscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosing schedules and side-effect profile [Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002]. An extended release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability. Some of the available formulations of oybutynin were overviewed by McCrery and Appell [2006].

Immediate-release oxybutynin (OXY-IR). Several controlled studies have have shown that OXY-IR is effective in controlling DO, including neurogenic DO [Yarker et al., 1995; Andersson and Chapple, 2001]. The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. [1998] summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 h was 33% (data on placebo not presented). The overall "subjective improvement" rate was reported as 74 % (range 61% - 100%). The mean percent of patients reporting an adverse effect was 70 (range 17% - 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved quality of life of patients suffering from overactive bladder in a large open multicenter trial. In this study, patients´ compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients [Amarenco et al., 1998]. In nursing home residents (n=75), Ouslander et al. [1995] found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double blind, cross-over trial. On the other hand, in another controlled trial in elderly subjects (n=57), oxybutynin with bladder training was found to be superior to bladder training alone [Szonyi et al., 1995].

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit [Szollar et al., 1996; Kim et al., 1996].

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose-limiting [Baigrie et al., 1988; Jonville et al., 1992]. The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence [Hussain et al., 1998]; no changes were found. It cannot be excluded that the commonly recommended dose 5 mg x 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg x 2 with following dose-titration would reduce the number of adverse effects [Amarenco et al., 1998].

Extended release oxybutynin (OXY-ER). This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy [see Arisco et al., 2009]. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared to OXY-IR. DEO is still formed through the hepatic cytochrome P-450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR [Appell et al., 2003]. Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day [Chancellor et al., 2001].

The effects of OXY-ER have been well documented [Siddiqui et al., 2004]. In the OBJECT study [Appell et al., 2001], the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose

of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6 to 6.1%; TOLT-IR 24.1 to 7.8), total incontinence (OXY-ER from 28.6 to 7.1%; TOLT-IR 27.0 to 9.3), and frequency (OXY-ER from 91.8 to 67.1%; TOLT-IR 91.6 to 71.5) and both medications were equally well tolerated. The basic study was repeated as the OPERA study [Diokno et al., 2003] with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In the 1999 study [Anderson et al., 1999], 105 patients with urgency or mixed incontinence were randomized to receive 5-30 mg OXY-ER once daily or 5 mg of OXY-IR 1-4 times/day. Dose titrations began at 5 mg and the dose was increased every 4-7 days until one of three endpoints was achieved. These were 1) the patient reported no urgency incontinence during the final two days of the dosing period; 2) the maximum tolerable dose was reached; the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR but dry mouth was reported statistically more often with OXY-IR. In the 2000 study [Versi et al., 2000], 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study, OXY-ER again achieved a >80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naïve patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naïve population [Gleason et al., 1999].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al. [2006] found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

In a multicentre, prospective, observational, flexible-dosing Korean study, Yoo et al. [2012] investigate the prescription pattern and dose distribution of OXY-ER in patients the OAB syndrome in actual clinical practice. The dosage of for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12 week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered, the patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5–10 mg/day oxybutynin ER as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment and 89.3% were satisfied.

Transdermal oxybutynin (OXY-TDS). Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study [Davila et al., 2001] comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinent episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study [Dmochowski et al., 2002] the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%). In a third study [Dmochowski et al., 2003] OXY-TDS was compared not only to placebo but to TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, 2-way crossover study [Appell et al., 2003]. Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared to OXY-ER which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. [2005] analyzing the combined results of two RCTs concluded that transdermal

oxybutynin was shown to be efficacious and well tolerated. The most common sytemic side effect was dry mouth (7.0 % vs placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1 %. Also Cartwright and Cardozo [2006], reviewing published and presented data concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower that with oral antimuscarinics – however, this benefit was offset by the rate of local skin reaction. The reviews of Sahai et al. [2008] and Staskin and Salvatore [2010] largely confirmed these conclusions, which also have been supported by further studies [Cartwright et al., 2011].

Oxybutynin topical gel. Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. oxybutynin topical gel (OTG) was approved by the US FDA in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area [Staskin et al., 2009]. The 1 gram application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations and a "favorable" N-desethyloxybutynin metabolite: oxybutynin ratio believed to minimizing antimuscarinic side effects [Staskin and Robinson, 2009]. In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks [Staskin et al., 2009]. The mean number of urgeny episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm (P <0.0001). Urinary frequency decreased by 2.7 episodes per day and voided volume increased by 21 mL (versus 2.0 episodes [P = 0.0017] and 3.8 mL [P = 0.0018], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly upon application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site [Dmochowski et al., 2011]. The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand et al. [2012] showing that in 704 women with OAB OTG significantly reduced the number (mean ± standard deviation) of daily incontinence episodes (OTG, -3.0 ± 2.8 episodes; placebo, -2.5 ± 3.0 episodes), reduced urinary frequency, increased voided volume, and improved select health-related quality-of-life domains vs placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

Other administration forms. Rectal administration [Collas and Malone-Lee, 1997] was reported to have fewer adverse effects than the conventional tablets.

Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults [Lose and Norgaard, 2001; Fader et al., 2007; George et al., 2007; Guerra et al., 2008], although adverse effects may occur [Kasabian et al., 1994; Palmer et al., 1997].

Effects on cognition. Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children [see, e.g., Kay et al., 2006; Klausner al Steers, 2007; Kay and Ebinger, 2008]. This factor should be taken into consideration when prescribing the drug.

Assessment.

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (**Table 2**). Despite the adverse effect profile, it is still an established therapeutic option.

b) Propiverine hydrochloride

Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine have been reviewed by Madersbacher and Murz [2001]. The drug is rapidly absorbed (tmax 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound [Haustein et al., 1988; Muller et al., 1993; Wuest et al., 2006; Zhu et al., 2008; Sugiyama et al., 2008]. Most probable these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended release preparation was shown to be effective [Junemann et al., 2006; May et al., 2008]. Oral absorption of propiverine is sitedependent and influenced by dosage form and circadiantime– dependent elimination processes [May et al., 2008].

Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992; Tokuno et al., 1993]. The importance of the calcium antagonistic component for the drug´s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes. The effects of propiverine on cardiac ion channels and action potentials were investigated by Christ et al., [2008]. Propiverine blocked in a concentration-dependent manner HERG channels expressed in HEK293 cells, as well as native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea-pig and human ventricular

tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug .

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al [1998] collected 9 randomized studies on a total of 230 patients, and found a 17% reduction in micturitions per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement. Side effects were found in 14 % (range 8-42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine´s superiority over placebo [Stöhrer et al., 1999]. Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate and placebo [Wehnert et al., 1989], and propiverine, oxybutynin and placebo [Wehnert et al., 1992; Madersbacher et al., 1999], have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared [Stöhrer et al., 2007]. The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin.

Also in children and adolescents with neurogenic DO, propiverine was found to be effective [Schulte-Baukloh et al., 2006; Grigoleit et al., 2006], with a low incidence rate of adverse events: <1.5% [Grigoleit et al., 2006]. A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed by Marschall-Kehrel et al. [2009]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary endpoints included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo.

In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Junemann et al., 2005]. The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary endpoint. Secondary endpoints were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, post void residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly ($p < 0.01$) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups.

Madersbacher et al. [1999] compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner et al. [2000] investigated in a double-blind, multicentre, placebo-controlled, randomized study, the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years), suffering from urgency, urgency incontinence or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine – 2 out of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes. The cardiac safety of propiverine was further studied by Donath et al. [2011] in two comprehensively designed mono-centric ECG studies (including 24 healthy females, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathological Pardee-Q-wave in the ECG). Both studies were placebo-controlled and compared the effects of single (30 mg s.i.d.) and multiple dosing (15 mg t.i.d.) of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively., They were performed to investigate the influence of propiverine hydrochloride and its main metabolite propiverine-N-oxide on cardiac function with regard to QTc prolongation, QTc dispersion and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams et al. [2006] compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring (AUM) parameters, safety, and tolerability in OAB patients. Patients (n=77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had

a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi et al. [2008] performed a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at endpoint in number of voids/24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume voided/void, restoration of continence and quality of life (QoL) were examined. It was found that at endpoint, there were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada et al. [2011] performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks then solifenacin(5 mg) for 8 weeks or solifenacin for 8 weeks then propiverine for 8 weeks. At baseline, 8th week and 16th week, symptoms were assessed using overactive bladder symptom score (OABSS). Of the 121 patients enrolled 83 were analysed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicentre, prospective, parallel, doubleblind, placebo-controlled trial, Lee et al. [2009] studied the effects of 30 mg propiverine/day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with >75 compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing 'much benefit', compared with 15 % in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable.

Masumori et al. [2011] examined prospectively the efficacy and safety of propiverine in patients with overactive bladder (OAB) symptoms who poorly responded to previous treatment with solifenacin, tolterodine or imidafenacin. Of 73 patients enrolled (29 males and 44 females, median age 71 years), 52 completed the protocol treatment. The OABSS was significantly improved by propiverine treatment. The scores of OAB symptoms (nighttime frequency, urgency and urge incontinence) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event was dry mouth (13.7%), followed by constipation (6.8%).

In a non-controlled study in patients with wet OAB the efficacy of propiverine on symptoms and quality of life was confirmed [Komatsu et al. 2009].

Assessment

Propiverine has a documented beneficial effect in the treatment of OAB/DO (**Table 2**), and seems to have an acceptable side effect profile.

c) Flavoxate hydrochloride

Flavoxate is often discussed as a drug with mixed actions, however, its main mechanism of action may not be antimuscarinic.Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% [Guay, 2003]. The drug is extensively metabolized and plasma half-life was found to be 3.5 h [Sheu et al., 2001]. Its main metabolite (3-methylflavone-8-carboxylic acid, MFCA) has been shown to have low pharmacological activity [Cazzulani et al., 1988; Caine et al., 1991]. The main mechanism of flavoxate's effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase, and to have local anesthetic properties; no antimuscarinic effect was found [Guarneri et al., 1994]. Uckert et al. [2000], on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable, It has been suggested that pertussis toxin-sensitive G-proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhytmic bladder contractions in anesthetized rats [Oka et al., 1996].

The clinical effects of flavoxate in patients with DO and frequency, urgency and incontinence have been studied in both open and controlled investigations, but with varying rates of success [Ruffman, 1988]. Stanton [1973] compared emepronium bromide and flavoxate in a double-blind, cross-over study of patients with detrusor overactivity and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered as 200 mg 3 times daily. In another double-blind, cross-over study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, and utilising both clinical and urodynamic criteria, Milani et al. [1993] found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects of flavoxate with those of placebo, have not been able

to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily [Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995]. In general, few side effects have been reported during treatment with flavoxate. On the other hand its efficacy, compared to other therapeutic alternatives, is not well documented (**Table 2**).

• Assessment

No RCTs seem to have been performed with flavoxate during the last decade. The scarcity of documented clinical efficacy should be considered before using the drug.

3. CLINICAL USE OF ANTIMUSCARINICS

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herbison et al. [2003] stated in a widely discussed article: "Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo. The benefits are, however, of limited clinical significance" Large meta-analyses of studies performed with the currently most widely used drugs [Chapple et al., 2005; 2008; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al. [2008] reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references, Chapple et al. [2008], based their conclusions ("antimuscarinics are efficacious, safe, and well tolerated treatments") on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known and the relapse rate of symptoms after discontinuation of treatment has not been systematically studied. In 173 women with OAB symptoms for >6 months, Lee et al.[2011] studied in a prospective, randomized, open-label, trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6-months. The relapse rate was 62%, and the request for treatment was 65 %, indiretly suggesting an efficacy of treatment. None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenacin, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as a first-line treatment for all OAB/DO patients. Optimal treatment should be individualized, implying that the patient´s co-morbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. [2012] analyzed 86 trials, 70 with parallel and 16 with cross-over designs (31,249 adults). They concluded that when the prescribing choice is between oral immediate release oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. ER preparations of oxybutynin or tolterodine might be preferred to immediate release preparations because there is less risk of dry mouth. Comparing solifenacin and immediate release tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy, but has higher risk of withdrawal due to adverse events and higher risk of dry mouth.

Several studies have documented that the persistence with prescribed antimuscarinic therapy for overactive bladder is low [Kelleher et al., 2005; Basra et al.,2008; Sears et al; Wagg et al., 2012]. The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. [2012] analysed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period. At 12 months, they found that the proportions of patients still on their original treatment were: solifenacin 35%, tolterodine ER 28%, propiverine 27%, oxybutynin ER 26%, trospium 26%, tolterodine IR 24%, oxybutynin IR 22%, darifenacin 17%, and flavoxate 14%. The longest mean persistence was reported for solifenacin (187 days versus 77 − 157 days for the other treatments). Gomes et al. [2012] compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians aged 66 years and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, $p < 0.0001$). The median time to discontinuation of oxybutynin and tolterodine was 68 and 128 days, respectively. Kessler et al. [2011] analyzed 69 trials enrolling 26,229 patients with OAB with the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first choice drugs to start the treatment of OAB, except for oral oxybutynin dosages of ≥ 10 mg/day, which may have more unfavorable adverse event profiles.

Even if the use of antimuscarinics are associated with many adverse effects, they are generally

considered to be 'safe' drugs. However, among the more serious concerns related to their use is the risk of cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsade de pointes), and increases in heart rate (HR) [Andersson and Olshansky, 2007; Andersson et al., 2011]. QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart. However, the experiences with terodiline, an antimuscarinic drug that caused torsade de pointes in patients [Connolly et al., 1991; Stewart et al., 1992], have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart (**Figure 10**) opposes the excitatory actions of the sympathetic nervous system, and slows the heart rate (**Figure 11**). An elevated resting HR has been linked to overall increased morbidity and mortality, particularly in patients with cardiovascular diseases. The prevalence of CV comorbidities was found to be significantly higher in patients with than without OAB [Andersson et al., 2010]. Since mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk of cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences between drugs cannot be excluded, but risk assessments based on available evidence are not possible.

II. DRUGS ACTING ON MEMBRANE CHANNELS

1. CALCIUM ANTAGONISTS

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone [Berridge, 2008] Two major groups of calcium channels include the voltage-gated [Caterall et al., 2003] and the store-operated channels [Leung et al., 2008]. While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004 a; b]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type [Frew and Lundy, 1995] and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in

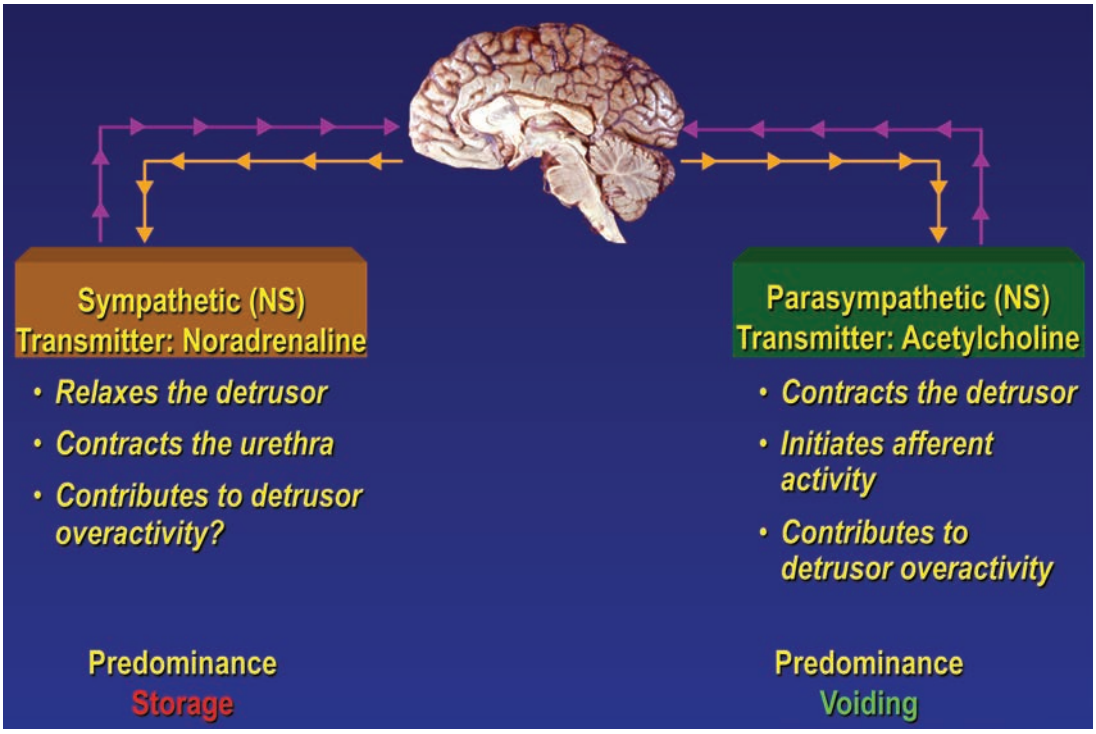

Figure 10 : Cardiac control via the autonomic nervous system. Acetylcholine, released from parasympathetic nerve terminals activate muscarinic receptors that mediate decrease in heart rate, decrease in force of contraction, and decrease in conduction velocity.

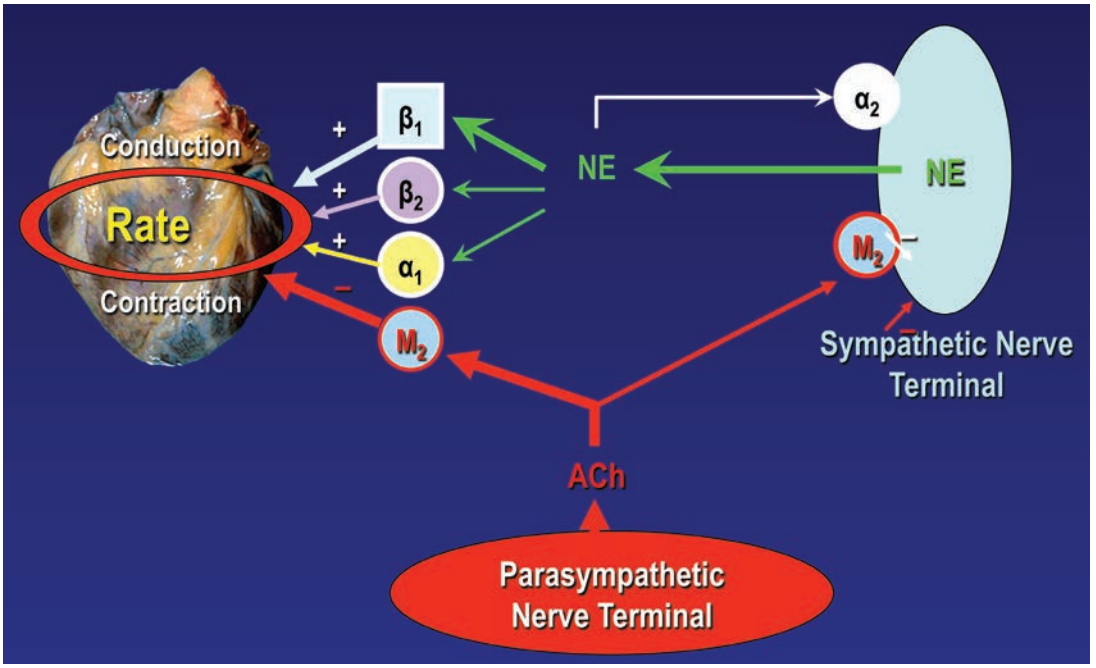

Figure 11: Autonomic receptors controlling heart rate. Acetylcholine, released form parasympathetic nerve terminals, activate muscarinic M2 receptors that mediate a decrease in heart rate. Inhibition of these receptors by antimuscarinics may increase heart rate.

vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2008]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]. In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical installation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Fröhlich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Naglie et al., 2002]. Larger studies with clinical endpoints related to effects of calcium channel inhibitors have not been reported in incontinent patients (based upon a Medline search using the MeSH terms “calcium channel blockers” and “urinary incontinence”). Moreover, it should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (**Table 2**). No new information has been added since the assessment in 2008 [Andersson et al., 2009].

2. POTASSIUM CHANNEL OPENERS

In a similar fashion to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist [Gutman et al., 2003; Petkov et al., 2012]. With regard to bladder function, ATP-dependent (KATP) and big calcium-activated (BKCa) channels have been studied most intensively. The BKCa channels also appear to be important physiologically as their activation can cause hyperpolarization of bladder smooth muscle cells and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, e.g., β-adrenoceptor agonists [Frazier et al., 2008]. Openers of both KATP [Howe et al., 1995; Hu et al., 1997; Martin et al., 1997] and

BKCa channels [Hu et al., 1997; Sheldon et al., 1997] have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly between species. Some potassium channel openers have also been shown to suppress non-voiding detrusor contractions in vivo in animal models of DO [Howe et al., 1995; Martin et al., 1997; Tanaka et al., 2003] and this also includes activators of the KCNQ type of potassium channels [Streng et al., 2004]. Although potassium channel openers are believed to mainly act directly on smooth muscle cells [Gopalakrishnan and Shieh, 2004; Petkov et al., 2012], they may also at least in part affect bladder function by modulating the activity of afferent neurones [Tanaka et al., 2003].

While the above data demonstrate the potential of potassium channel openers to inhibit non-voiding detrusor contractions, these channels are expressed not only in bladder, but also e.g. in vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure [Howe et al., 1995; Shieh et al., 2007]. While some compounds of this class have a certain degree of selectivity for the bladder as compared to the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the KATP opener ZD0947 has been reported [Chapple et al., 2006]. While ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one due to a lack of selectivity for bladder over cardiovascular tissues (**Table 2**).

Another way to use potassium channels to normalize bladder function was suggested by Christ et al. [2001] in a rat model of detrusor hyperactivity. They injected “naked” hSlo/pcDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. As to whether this principle can be therapeutically useful in man is currently under investigation.

III. α-ADRENOCEPTOR (AR) ANTAGONISTS

It is well documented that α1-AR antagonists can ameliorate lower urinary tract symptoms in men [Andersson, 2002; McVary et al., 2011; Oelke et al., 201l; Lepor et al., 2012]. Currently used α1-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of BPH [Lepor et al., 2012]. However, in a study where tamsulosin was given alone, or together with tolterodine, to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective [Kaplan et al., 2006]. In an RCT from Korea, doxazosin monotherapy resulted in only minimal effects in IPSS storage subscore, urgency episodes and no improvement in the patient perception of bladder condition (PPBC) [Lee et al., 2011]. Thus, there is no convincing evidence that α-AR antagonists, given as monotherapy, are effective in patients with storage symptoms only.

A pivotal question is if better efficacy and/or tolerability can be obtained by highly subtype selective drugs than with the commonly used alternatives. α1-ARs include three receptor subtypes, α1A, α1B, and α1D, that are structurally and pharmacologically distinct and have different tissue distributions [Andersson and Gratzke, 2007]. α1A-ARs are the predominant subtype in the human prostate, where they mediate smooth muscle contraction. A fourth subtype, α1L, also present in human prostate, is derived from the same gene as α1A, but α1L- and α1A-receptors have different pharmacologic properties and bind some α-AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated.

Selectivity for α1B-AR has been considered disadvantageous from a cardiovascular point of view [Schwinn et al,, 2004; Schwinn and Roehrborn, 2008]. Kojima et al. [2008)] studied the expression of α1-AR in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin presumed to block α1A-ARs and naftopidil presumed to block α1D-ARs. However, the selectivity of naftopidil for α1D- vs α1A-ARs is modest [Take et al., 1998] and its use as a tool to separate between α1-AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as α1A-AR dominant (22 and 12 patients) and α1D-AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the α1-AR subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the α1A-AR subtype, whereas naftopidil was more effective in those with dominant expression of the α1D-AR subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of α1-AR subtype mRNA and severity of LUTS or bladder outlet obstruction [Kojima et al., 2010]. They found no direct correlation between the expression of α1-AR subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima et al. [2010] concluded that the expression level of α1-AR subtype mRNA in the prostate could be a predictor of the efficacy of subtype selective α1-AR antagonists in patients with BPH, and

suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for α1A-ARs [Tatemichi et al., 2006a; b; Lepor and Hill, 2010; Yoshida et al., 2011], had clinically good effects on both voiding and storage symptoms in men with BPH [Kawabe et al., 2005; Yoshida et al., 2007; Marks et al., 2009a,b; Chapple et al., 2010; Morganroth et al., 2010; Yoshida et al., 2011]. Chapple et al. [2010] conducted a multicenter double-blind, placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men ≥50 yr of age with an International Prostate Symptom Score (IPSS) ≥13 and a urine maximum flow rate (Qmax) >4 and ≤15ml/s were selected at 72 sites in 11 European countries. The patients were entered into a 2-wk wash-out and a 4-wk placebo run-in period. A total of 955 patients were randomized (2:2:1) to silodosin 8 mg (n=381), tamsulosin 0.4 mg (n=384), or placebo (n=190) once daily for 12 wk. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference between the two α1-AR antagonists and the placebo in terms of Qmax. There was also no difference between the two α-AR antagonists for the QoL parameter, whereas both were better than the placebo. Active treatments were well tolerated, and discontinuation rates due to adverse events were low in all groups (2.1%,1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively).The most frequent adverse event with silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α1A-AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment due to this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, bladder outlet obstruction index and Schafer´s obstruction class significantly [Yamanishi et al., 2009]. In a different open, nonblinded prospective study silodosin 8 mg lead to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase mean detrusor pressure at maximum flow significantly decreased, mean bladder outlet obstruction index decreased significantly and obstruction grade as assessed by the Schaefer nomogram improved significantly [Matsukawa et al., 2009].

It thus seems that selective blockade of α1A-ARs is a clinically effective approach, and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focussed on the α1-ARs (α1D), specifically in the bladder [Schwinn et al., 2004; Schwinn and Roehrborn, 2008], assuming that these receptors were responsible for storage symptoms. However, the inter-relationship between the α1D-ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear. Naftopidil was shown to significantly improve the OAB symptom score [Sakai et al., 2011] and urgency episodes [Yokoyama et al., 2009]. Ikemoto et al. [2003] gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the I-PSS for storage symptoms, tamsulosin monotherapy decreased the I-PSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α1-AR subtypes between the drugs) could not be reproduced in a randomized head to head comparison between the drugs [Gotoh et al, 2005]. Based on available evidence, it therefore cannot be concluded that the α1D-ARs on the detrusor smooth muscle are the main therapeutic target. However, α1D-ARs may have effects on different locations in the bladder beside the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia [Andersson and Gratzke, 2007]. The importance and functional role of this observation remain to be established.

In females, treatment with OAB, α1-AR antagonists seem to be ineffective. In an RCT, comprising 364 women with OAB, no effect of tamsulosin vs placebo could be demonstrated [Robinson et al., 2007]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were treated (with modest success) with an α1-AR antagonist [Kessler et al., 2006, Low et al., 2008]. It should be remembered that in women, these drugs may produce stress incontinence [Dwyer and Teele, 1992].

In patients with neurogenic DO, treatment with a1-AR antagonists was moderately successful [Abrams et al., 2003].

IV. β-ADRENOCEPTOR AGONISTS

In isolated human bladder, non-subtype selective β-AR agonists like isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in man [Andersson, 1993]. However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β1-, nor β2- ARs, since they could be blocked by propranolol, but not by practolol or metoprolol (β1) or butoxamine (β2) [Nergard et al., 1977; Larsen, 1979]. On the other hand, early receptor binding studies using subtype selective ligands, suggested that the β-ARs of the human detrusor are primarily of β2 subtype [Andersson

1993], and favourable effects on DO were reported in open studies with selective β2-AR agonists such as terbutaline [Lindholm and Lose, 1986]. In a double-blind investigation clenbuterol 0.01 mg 3 times daily was shown to have a good therapeutic effect in 15 of 20 women with DO [Gruneberger, 1984]. Other investigators, however, have not been able to show that non-subtype selective β-ARs agonists represent an effective therapeutic principle in elderly patients with DO [Castleden and Morgan, 1980], or in young patients with myelodysplasia and DO [Naglo et al, 1981].

However, three subtypes (β1, β2, and β3) have been identified in the detrusor of most species, including humans [Andersson and Arner, 2004; Michel and Vrydag, 2006]. Also the human urothelium contains all three receptor subtypes [Otsuka et al., 2008]. Studies, using real-time RT-PCR, have revealed a predominant expression of β3-AR mRNA in human detrusor muscle [Nomiya and Yamaguchi, 2003; Michel and Vrydag, 2006, , Igawa et al., 2010] and the functional evidence for an important role in both normal and neurogenic bladders is convincing [Fujumura et al., 1999; Igawa et al., 1999; Takeda et al., 1999; Morita et al., 2000; Igawa et al., 2001; 2010; Biers et al., 2006; Michel and Vrydag, 2006; Badawi et al., 2007; Leon et al., 2008]. The human detrusor also contains β2-ARs, and most probably both receptors are involved in the physiological effects (relaxation) of noradrenaline in this structure [Andersson and Arner 2004; Michel and Vrydag, 2006; Igawa et al., 2010].

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species, is activation of adenylyl cyclase with the subsequent formation of cAMP (**Figures 12 and 13**). However, there is evidence suggesting that in the bladder K+ channels, particularly BKCa channels, may be more important in β-AR mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008]. Aizawa et al. [2010] showed that the β3-AR agonist, CL316,243, could inhibit filling-induced activity in mechanosensitive Aδ-fibers, but not in C-fiber primary bladder afferents of the rat bladder. However, the drug was able to inhibit prostaglandin (PG) E2-induced C-fiber mediated hyperactivity.

Since β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated [Murakami et al., 2007; Otsuka et al., 2008]. Murakami et al. [2007] found that the relaxation responses of the detrusor were not influenced

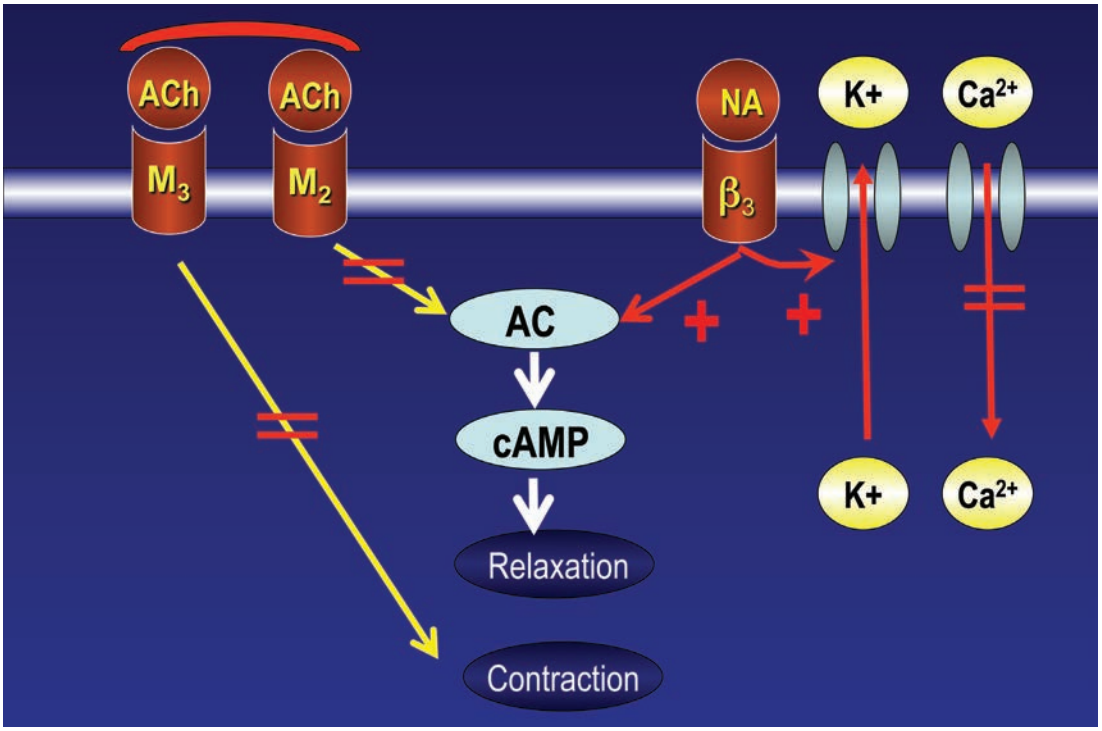

Figure 12 : During bladder filling, there is normally no parasympathetic nervous outflow to the bladder and no release of acetylcholine (ACh). The sympathetic nervous system is active and releases noradrenaline (NA) that via β3 adrenoceptors stimulates adenylyl cyclase (AC) and generation of cyclic AMP (cAMP) which mediates relaxation of the bladder. In addition, β3-adrenoceptor stimulation activate K+ channels, stimulating outflow of K+, which causes hyperpolarisation and inhibition of Ca2+ inflow.

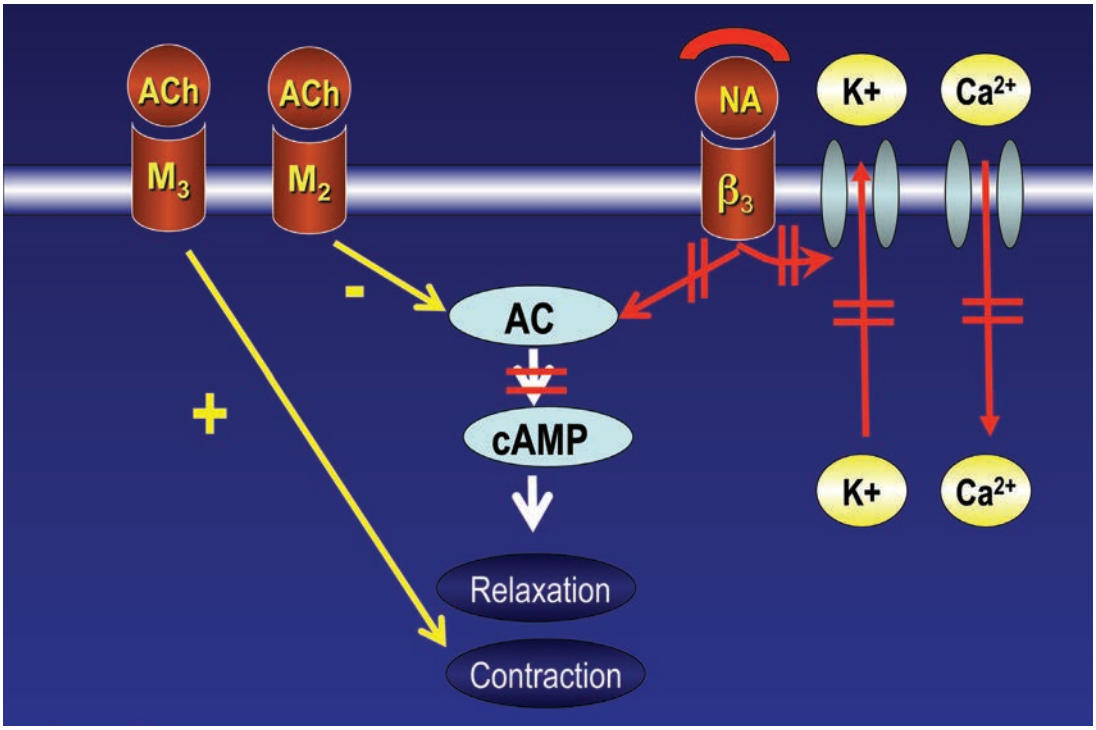

Figure 13: During voiding, the parasympathetic system is activated, releasing acetylcholine (ACh) which causes bladder contraction, directly via muscarinic M3 receptor stimulation, and indirectly by inhibition of adenylyl cyclase (AC) via stimulation of muscarinic M2 receptors. The sympathetic nerve activity is turned off. In vivo exogenous stimulation of the β3-adrenoceptors by β3-adrenoceptor agonists is not sufficient to inhibit the muscarinic receptor mediated activation, which implies that the voiding contraction is not compromised.

by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka et al. [2008]. However, to what extent a urothelial signaling pathway contributes in vitro and in vivo to the relaxant effects of β-AR agonists in general, and β3-AR agonists specifically, remains to be elucidated.

The in vivo effects of β3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), β3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume [Fujimura et al., 1999; Woods et al., 2001; Takeda et al., 2002; Kaidoh et al., 2002; Igawa et al., 2010]. For example, Hicks et al. [2007] studied the effects of the selective β3-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid evoked bladder hyperactivity, without affecting voiding.

A number of β3-AR selective agonists are currently being evaluated as potential treatment for OAB in humans including GW427353 (solabegron) and YM178 (mirabegron) [Colli et al., 2007; Igawa et al., 2010; Saito et al., 2011; Tyagi and Tyagi, 2011] (**Figure 14**).

Mirabegron. Takusagawa et al. [2012] found that mirabegron was rapidly absorbed after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites. Of the administered dose, 55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces, almost entirely as the unchanged form. Mirabegron is highly lipophilic and is metabolized in the liver via multiple pathways, mainly by cytochrome P450 3A4 and 2D6 (CYP2D6) [van Gelederen et al., 2009]. In a Phase I pharmacokinetic study, sixteen healthy volunteers, phenotyped as either poor or extensive metabolizers of CYP2D6 were enrolled The volunteers received a 160 mg single oral dose after overnight fasting. Poor metabolizers excreted a slightly higher urinary fraction of mirabegron (15.4±4.2%) than extensive metabolizers (11.7±3.0%). Tmax in both extensive and poor metabolizers was about

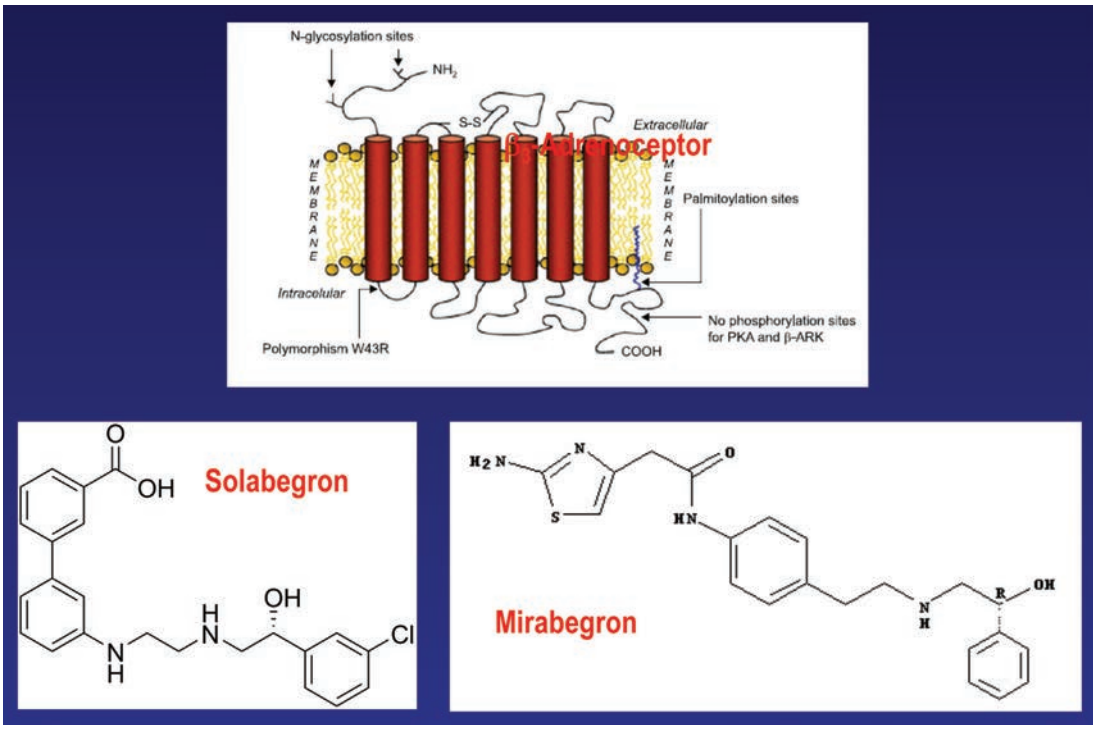

Figure 14: The β3-adrenoceptor is the predominating β-adrenoceptor subtype in the bladder. Stimulation by highly selective β3-adrenoceptor agonists like mirabegron and solabegron may inhibit symptoms of overactive bladder without affecting the ability to empty the bladder.

2 hours and the terminal elimination half-life (t1/2) approximately 23-25 hours.

Chapple et al. [2008] reported the results of a phase IIA trial of mirabegron in patients with OAB. The Blossom trial, conducted in several European countries, was a proof of concept study. It enrolled 314 patients with OAB symptoms - 262 patients were randomly assigned to 4 groups: placebo, mirabegron 100 mg bid, mirabegron 150 mg bid, and tolterodine 4 mg qd for a 4-week treatment period. The primary endpoint was efficacy, and the primary efficacy variable was the change in the mean number of micturitions per 24 hours as recorded on a frequency/volume chart. In both mirabegron groups significant improvements in the mean number of micturitions per 24 hours were found compared with the placebo group (−2.19 and −2.21 vs. −1.18, respectively). Mean volume voided was dose-dependently increased in the mirabegron groups, and the change reached significance in the mirabegron 150 mg group. Urgency episodes per 24 hours decreased significantly in both mirabegron groups compared with the placebo group. No severe adverse events were reported and treatment was generally well tolerated. A small, mean increase in pulse rate with mirabegron 150 mg (5 beats per minute) was demonstrated, but this was not associated with a clinically significant increase in adverse events such as tachycardia and palpitations. This successful phase IIA trial was followed by a phase IIB trial in OAB patients carried out in Europe [Chapple et al., 2010]. This trial was a dose-ranging study of once-daily mirabegron (an extended release formula of mirabegron) with multiple arms (placebo, mirabegron 25 mg, 100 mg, 150 mg, and 200 mg qd, for a 12-week treatment period), and the primary endpoint was to evaluate the dose-response relationship on efficacy. The mean number of micturitions per 24 hours decreased dose-dependently, and the decreases were statistically significant with mirabegron 50 mg, 150, and 200 mg compared with placebo. The mean volume voided per micturition increased dose-dependently, and the increases were significant with mirabegron 50 mg and more. Adverse events were experienced by 45.2% of the patients - the incidence of adverse events was similar among all treatment groups (placebo 43.2% vs. mirabegron 43.8-47.9%). The overall discontinuation rate owing to adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4-5.3%). The most commonly reported adverse events considered treatment-related was gastrointestinal disorders, including constipation, dry mouth, dyspepsia, and nausea. There was no patient-reported acute retention. No significant difference in ECG parameters between

the groups was demonstrated. However, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 200 mg (1.6 and 4.1 beats per minute, respectively), although this was not in associated with an increase in cardiovascular adverse events.

Nitti et al. [2011] reported on a phase III multicentre, randomized, double-blind, parallel-group,placebo-controlled trial of mirabegron in North America. They enrolled 1328 patients ≥18 years with OAB symptoms for ≥3 months. Patients who completed a 2-week, single-blind, placebo run-in and had ≥8 micturitions/24 h and ≥3 urgency episodes/72 h (with or without incontinence) during a 3-day micturition diary period, were randomized to receive placebo, or mirabegron 50 or 100 mg once daily for 12 weeks. Co-primary endpoints were change from baseline to final visit (study end) in the mean number of incontinence episodes/24 h and micturitions/24 h. Efficacy was assessed according to patient micturition diaries and safety assessments included adverse event (AE) reporting. Patients were randomized and received study drug (placebo: n=453; mirabegron 50 mg: n=442; mirabegron 100 mg: n=433). Mean age was 60.1 years, 74.3% were female, 29.7% had urgency incontinence, 38.1% had mixed stress/urgency incontinence with urgency predominant and 32.2%had frequency without incontinence. At the final visit, mirabegron 50 and 100 mg showed statistically significant improvements in the co-primary efficacy endpoints and mean volume voided/micturition compared with placebo. Statistically significant benefits were achieved at the first-measured time point of Week 4. The incidence of AEs was similar across the placebo and mirabegron 50 and 100 mg groups (50.1, 51.6 and 46.9%, respectively). The most common (≥3%) AEs in any treatment group were hypertension (6.6, 6.1 and 4.9%, respectively), urinary tract infection (1.8, 2.7 and 3.7%), headache (2.0, 3.2 and 3.0%) and nasopharyngitis (2.9, 3.4 and 2.5%).

Khullar et al. [2011] performed a similarly designed study i Europe and Australia, enrolling 1978 patients, which included a fourth arm in which tolterodine SR 4 mg was used as a comparator. Like the American study, Khullar et al. [2011] found that mirabegron caused a statistically significant improvements from baseline compared with placebo in the number of urgency incontinence episodes and number of micturions per 24 hours. Mirabegrom 50 and 100 mg was numerically superior to tolterodine in these two key OAB symptoms, but the study was not powered for further analysis. Mirabegrom 50 and 100 mg was well tolerated, no differences being found between the placebo arm and the two mirabegron arms. In particular, the incidence of hypertension or UTI were identical. In contrast with tolterodine, no increased dry mouth incidence was observed with mirabegron.

Mirabegron has been shown to be effective in the treatment of the OAB syndrome and has been approved for clinical use on this indication in Japan. The Japanese label contains a warning: “Avoid administration to patients of reproductive age”. Mirabegron is currently under consideration for approval in Europe (EMA). In the US, the drug was approved in June 2012.

A positive effects of solabegron in patients with the OAB syndrome has also been documented in an RCT [Ohlstein et al., 2012].

V. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson, 1999; Andersson and Wein, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach [Andersson et al., 1997; 2007; 2011]. There are presently 11 families of PDEs, some of which preferentially hydrolyse either cAMP or cGMP [Uckert et al., 2006] (**Figure 15**).

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [2006] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside, and to agents acting via the cGMP system [Truss et al., 2000]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [Truss et al., 2001]. Significant dose-dependent relaxations were also induced by human cAMP analogs [Truss et al., 2001]. With these studies as a background, Truss et al. presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy [Truss et al., 2000]. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [Truss et al., 2001]. Studies with other PDE 1 inhibitors than vinpocetin (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

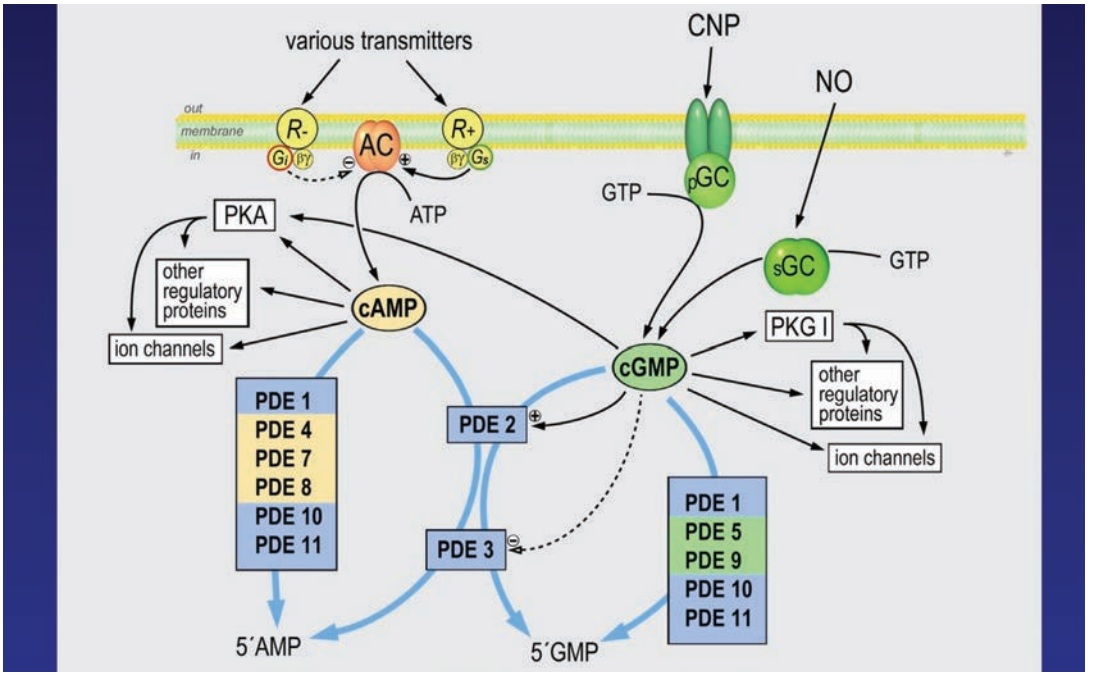

Figure 15: Families of phosphodiesterases (PDE). Inhibitors of both cyclic AMP and cyclic GMP may have inhibitory effects on bladder contraction. However, so far only inhibitors of PDE5 (inhibiting degradation of cyclic GMP) have been clinically useful for treatment of lower urinary symptoms in males.

PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder [Gillespie and Drak., 2004; Nishiguchi et al., 2007]. Previous experiences with selective PDE 4 inhibitors showed emesis to be a dose -limiting effect [Giembycz, 2005]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

Oger and co-workers showed that PDE5-inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K(+) channel-dependent signalling pathways, with a minor contribution from NO [Oger et al., 2010]. In combination with the α1-AR antagonist doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle and their combination provided a significant benefit when targeting relaxation of both tissues [Oger et al., 2008].

In-vivo, several studies have indicated a role for PDE5-inhibitors in the regulation of micturition function. Systemic vardenafil reduced both non-voiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord injury rats, indicating potential mechanisms by which PDE5-Is improve storage symptoms in SCI patients [Behr-Roussel et al., 2010]. The effect of vardenafil on OAB-symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (SHR) [Morelli et al., 2009a; Morelli et al., 2009b]. Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment [Morelli et al., 2009b]. Thus, besides relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalfil was shown to increase prostate tissue oxygenation in SHR and human vesicular-deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results suggest another possible mechanism through which PDE5i exert beneficial effects on LUT symptoms [Morelli et al., 2011].

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Arner, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. examined the effects of isoproterenol, prostaglandin E1 and E2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra [Morita et al., 1994]. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al.[2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra,

and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NO-NO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations. Fibbi et al. [2009] confirmed that the highest expression and biological activity of PDE5 was found in bladder. However, a consistent PDE5 expression and activity was also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fibre afferent activation, it was shown that the NO/cGMP signalling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather on the motor component of the micturition reflex [Caremel et al., 2010].

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS [Sairam et al., 2002], this observation has been confirmed in several well designed and conducted RCTs.

To date, 12 RCTs are available comparing the effect of PDE5 inhibitors alone to placebo and the combination of alpha-blockers and PDE5 inhibitors vs alpha-blockers alone [Bechara et al., 2008; Gacci et al., 2011; Kaplan et al., 2007; Liguori et al., 2009; McVary et al., 2007a; b; Porst et al., 2009; 2011; Roehrborn et al., 2008; Stief et al., 2008; Tamimi et al., 2010; Tuncel et al., 2010]. In these studies, different PDE5 inhibitors and different doses were administered.

PDE5-inhibitors significantly improve IPSS and IIEF scores, but not Qmax when compared to placebo. According to a recent meta-analysis by Gacci and co-workers, differences in IPSS score were significantly lower in older and obese patients [Gacci et al., 2011]. The combination of PDE5-inhibitors and alpha-blockers lead to significant improvements of the IPSS and IIEF score as well as Qmax when compared to the use of alpha-blockers alone. Recently, Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pressure at maximum urinary flow rate or such as maximum detrusor pressure and bladder outlet obstruction index while improving IPSS [Dmochowski et al., 2010]. PDE5-inhibitors were generally shown to be safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. In none of the trials referred to such an effect was found. (However, see Oelke et al.[2012]). On the other hand, there are several other structures in the LUT that may be involved, including those in the urothelial signaling pathway (urothelium, interstital cells, and suburothelial afferent nerves). In general, it is believed that major mechanisms contributing to LUTS include reduced nitric oxide/cyclic guanosine monophosphate signaling pathway, increased RhoA kinase pathway activity, autonomic overactivity, increased bladder afferent activity and pelvic ischemia [Andersson et al., 2011].

In practical considerations it has to be mentioned that only tadalafil has been recently approved for the the treatment of LUTS due to benign prostatic obstruction; long-term experience with PDE5 inhibitors in patients with LUTS is still lacking [Oelke et al., 2011]. In addition, insufficient information is available on the combination of PDE5 inhibitors with other LUTS medications such as 5-alpha-reductase-inhibitors.

VI. ANTIDEPRESSANTS

Several antidepressants have been reported to have beneficial effects in patients with DO [Lose et al., 1989; Martin and Schiff, 1984]. The use of antidepressants was shown to be an independent risk factor for lower urinary tract symptoms suggestive of benign prostatic hyperplasia in a community based population of healthy aging men (Krimpen Study) [Kok et al., 2009].

1. IMIPRAMINE

Imipramine is the only drug that has been widely used clinically to treat this disorder. Imipramine has complex pharmacological effects, including marked systemic antimuscarinic actions [Baldessarini, 1985] and blockade of the reuptake of serotonin and noradrenaline [Maggi et al., 1989], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Even if it is generally considered that imipramine is a useful drug in the treatment of DO, no good quality RCTs that can document this have been retrieved. It has been known for a long time that imipramine can have favourable effects in the treatment of nocturnal enuresis in children with a success rate of 10-70 % in controlled trials [Glazener et al., 2003; Hun-

sballe and Djurhuus, 2001]. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giardina et al., 1979]. Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants [Baldessarini, 1985]. The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have have been performed during the last decade [Hunsballe and Djurhuus, 2001; Natalin et al., 2009]. No good quality RCTs have documented that the drug is effective in the treatment DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study the impact of the "three-drug therapy" (antimuscarinic, alpha-blocker and tricyclic antidepressants) on the treatment of refractory detrusor overactivity (DO) showed a significant increase on bladder capacity and decreases on urgency, urge-incontinence and frequency. Objective urodynamic data as well as symptom score improved significantly with triple therapy [Natalin et al., 2009].

Selective serotonin-reuptake-inhibitors (SSRIs) have been tested with regard to their effects on OAB symptoms. Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor (SNRI), or paroxetine hydrochloride, a selective serotonin reuptake inhibitor, were analyzed in a prospective open trial in neurogenic OAB-patients. Milnacipran reduced daytime urinary frequency, improved the quality of life index and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the lower urinary tract symptoms questionnaire or urodynamic studies, or in the paroxetine group [Sakakibara et al., 2008].

2. DULOXETINE

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Katofiasc et al., 2002; Thor and Katofiasc, 1995]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser and Chancellor, 2003]. In a placebo-controlled study, the drug showed efficacy in patients with OAB [Steers et al., 2007]. The number of micturition episodes, the primary outcome, was reduced by 2 in the duloxetine arm and by 0.5 in the placebo arm. Episodes of urgency incontinence were also significantly reduced by duloxetine. These data have not been reproduced so far in another trial. However, the high withdrawal rate observed across all studies in which the drug was evaluated fou SUI, affecting 20-40% of the patients at short-term and up to 90% in long-term studies, do not predict clinical utility of duloxetine in OAB.

VII. CYCLOOXYGENASE (COX) INHIBITORS

Prostanoids (prostaglandins and thromboxanes) are synthesized by cyclooxygenase (COX) from a common precursor, arachidonic acid. Prostanoids may be involved in the control of bladder function under normal and pathological conditions, including DO and OAB. Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human bladder muscle, it is still unclear whether prostaglandins contribute to the pathogenesis of unstable detrusor contractions. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Cardozo et al. performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg 3 times daily [Cardozo et al., 1980a]. The drug was shown to have favourable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms. Palmer studied the effects of flurbiprofen 50 mg x 4 versus placebo in a double-blind, cross-over trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial) [Palmer, 1983]. Active treatment significantly increased maximum contractile pressure, decreased the number of voids and decreased the number of urgent voids compared to baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, cross-over study [Cardozo and Stanton, 1980b]. The incidence of side effects was high, occurring in 19 of 32 patients.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication mainly due to side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.

VIII. TOXINS

Intravesical pharmacological therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacological agents can be given to the bladder tissue producing enhanced local effects. Second, drugs inappropriate for systemic administration due to off target effects can be safely used. Attractive as it may be, intravesical pharmacological therapy should still be considered as a second line treatment in patients refractory to oral therapy or patients who do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if patients subgroups will benefit of intravesical therapy as first line is clearly necessary. An ongoing trial to define tolerability and cost effectiveness of daily antimuscarinic therapy versus a single intra-detrusor injection of 100U of BoNT/A for treatment of urgency urinary incontinence is at this moment under way [Visco et al., 2012].

1. BOTULINUM TOXIN

a) Mechanism of action of BONT

Botulinum toxin (BonT) is a neurotoxin produced by *Clostridium botulinum*, Of the seven subtypes of BONT, sub-type A (BONT-A) has the longest duration of action, making it is the most relevant clinically. BoNT/A is available in three different commercial forms, with the proprietary names of Botox®, Dysport®, Xeomin®, and Prosigne. Although the toxin is the same, it is wrapped by different proteins which modify the relative potency of each brand. This was the basis for the introduction of the non-proprietary names onabotulinum toxin A (onabotA), abobotulinum toxin A (abobotA) and incobotulinum toxin A (incobotA) for Botox®, Dysport® and Xeomin®, respectively. Prosigne is the proprietary name of a BoNT/A produced in China, which currently does not have a known non-proprietary name. Although potency of each one is usually expressed in units (U) the doses are not inter-changeable. Clinical dose conversion studies for the lower urinary tract do not exist. Available information indicates that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless these equivalences should be approached with caution. Comprehensive reviews have been produced during the last few years. [Chapple and Patel., 2006; Nitti, 2006; Patel et al., 2006; Dinis et al., 2007; Karsenty et al., 2008; Apostolidis et al., 2009; Silva and Cruz, 2009; Dowson et al., 2010; Duthie et al., 2011; Mangera et al., 2011].

Most of the information available about intravesical application of BoNT/A derives from the use of onabotA (Botox®). However, in addition to sub-type A, some studies have investigated the effect of detrusor injection sub-type B, rimabotulinumtoxinB (proprietary names being Miobloc™ or Neurobloc™ according to countries). For further details see section 9.1.13 below.

BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 [Dong et al., 2006] by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles (**Figure 16**). The two chains are then

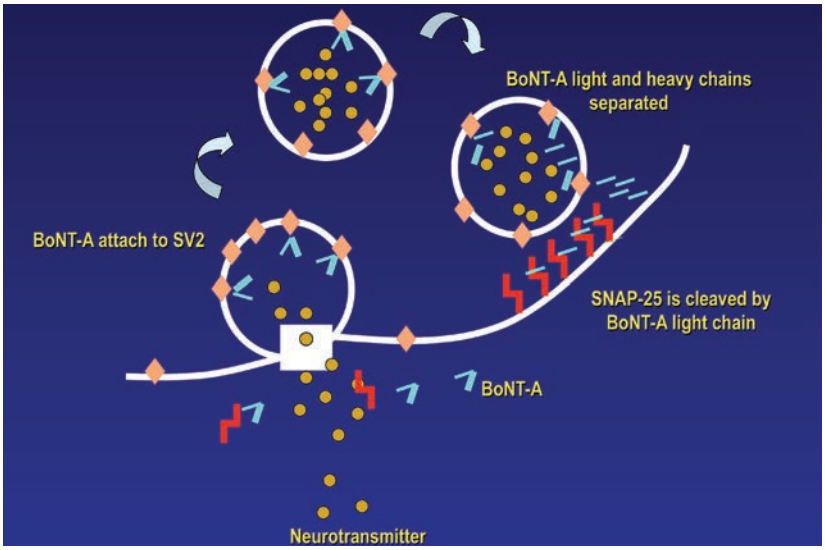

Figure 16 : Mechanism of action of botulinum toxin (BoNT). BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles. The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin.

cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin. BonT/A cleaves SNAP 25 rendering the SNARE complex inactive [Humeau et al., 2000; Chancellor et al., 2008]. Subtype B, acts preferentially through the inactivation of VAMP [Humeau et al., 2000].

BonT/A application was extensively evaluated in striated muscle. In this tissue paralysis occurs by prevention of acetycholine (ACh) release from cholinergic motor nerve endings [Humeau et al., 2000]. Accumulation of neurotransmitter containing synaptic vesicles is followed by terminal axonal degeneration. Striated muscle paralysis recovers within 2 to 4 months time. During this time axons develope lateral sprouts and eventually regenerate completely [de Paiva et al., 1999].

In the human bladder SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic and sensory fibers [Coelho et al., 2011]. Almost all parasympathetic nerves express the two proteins [Coelho et al., 2011]. As these nerves play a fundamental role for detrusor contraction during voiding, the blockade of ACh release is believed to play an essential role in detrusor hypo- or acontractility that follows BoNT/A injection in the bladder. In accordance with this view, it was shown that in normal or SCI animals BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions [Ikeda et al., 2012]. However cholinergic axon sprouting concomitant with clinical remission could not been documented in the detrusor [Haferkamp et al., 2004].

Bladder sensory impairment is also expected to play an important role in the final effect of BoNT/A bladder injection. About half of the peptidergic sensory fibers express SV2 and SNAP25 [Coelho et al, 2011]. BoNT/A inhibits the spinal cord release of glutamate, substance P (SP) and CGRP from sensory nerves [Purkiss et al., 2000; Aoki et al., 2005; Meng et al., 2007] as well as the release of neuropeptides at the peripheral extremities [Rapp et al., 2006; Lucioni et al, BJU Int, 2008]. BoNT/A has also been shown to reduce the suburothelial immunoreactivity for TRPV1 or P2X3 [Apostolidis et al., 2005]. Morenilla Palao et al. [2004] have shown that BonT/A impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, a process that is also dependent on SNARE proteins. All these mechanisms may contribute to the recent observation that BoNT/A reduces afferent firing from bladder afferents and antidromic release of neuropeptides [Ikeda et al., 2012]. Although SV2 and SNAP-25 immunoreactivity has not been detected in urothelial cells [Coelho et al., 2011], urothelial function seems also compromised after BoNT/A administration. BonT/A has been shown to inhibit ATP release from urothelium in animal models of spinal cord injury [Khera et al.,2004; Smith et al., 2008]. Therefore, it is not surprising that administration of BoNT/A to inflamed rat bladders reduces spinal c-fos counts at the L6 and S1 spinal cord segments [Vemulakonda et al., 2005].

Cleaved, inactive SNAP-25 appears rapidly after BoNT/A injection. In the guinea-pig a robust expression of cleaved SNAP 25 could be detected already at 12 hours and maximum intensity could be detected at 24 hours with little changes afterwards. In guinea-pigs cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic and postganglionic were affected while less than half of the sensory fibers express the cleaved protein [Coelho et al., 2012a; b]. In the human urinary bladder cleaved SNAP 25 could be detected in NDO patients up to 11 months after BoNT/A injection. [Schulte-Baukloh et al., 2007]. The longer duration of cleaved SNAP 25 in the detrusor smooth muscle than in striated muscles, has no firm explanation at the moment. However the longer persistence of the inactive form of SNAP-25 plus the involvement of pre and postganglionicparasympathetic neurons may contribute to persistence of the BoNT/A effect in the bladder.

Interstitial cells (ICs) in the suburothelium form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that ICs act as modulators of bladder behaviour [Wiseman et al., Apostolidis et al., 2006]. However, the expression of connexin 43 is not altered by BoNT/A [Roosen et al, 2009]. Hence, at the moment a firm evidence for the action of BoNT/A on ICs is scant.

BonT/A may decrease the levels of neurotrophic agents in the bladder tissue. Levels of Nerve Growth Factor (NGF) [Giannantoni et al.,; Liu et al., 2009] and Brain-derived Neurotrophic Factor (BDNF) [Pinto et al., 2010] have been shown to decrease in the bladder and/or urine following BoNT/A injections. As both neurotrophins have paramount roles for growth, maintenance and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BonT/A acts upon the bladder.

b) BoNT/A effects on bladder histology

There is no evidence that repeated injections of onabotA into the detrusor muscle cause inflammatory infiltrates, fibrotic activity or apoptosis within the bladder wall [Comperat et al., 2006, Apostolidis et al., 2008, Kessler et al.]. Rather the reverse, one study demonstrated that NDO patients treated with BonT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. The presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

c) BoNT/A injection protocol

When the treatment was first described in 1999 for NDO patients, onabotA was diluted in normal saline in order to obtain a concentration of 10 units/ml [Schurch et al., 2000]. Under visual control through a rigid cystoscope and a flexible 6 Fr injection needle, 30 injections of 1 ml (10 units of onabotA) were done in 30 different bladder wall locations above the trigone to prevent vesico-urethral reflux. Additional refinements have been added to this technique along the following years, including the use of a local anaesthetic agent (4% lidocaine) and a flexible cystoscope [Harper et al., 2003]. The recent demonstration that onabotA 200 U applied in 30 injections sites (1ml saline each) above the trigone is preferable to 300 U in NDO patients (200 U in 30 injections sites is the approved protocol by medical authorities) reduces the amount of onabotA per injection site to 6.66 U/ml. For abobotA larger studies used a similar technique albeit the number of injections was only 20 [del Popolo et al., 2008; Grise et al., 2010]. The number of units per injection site is obviously different taking in consideration that 500-1000 U are used [del Popolo et al., 2008]. The volume of saline at each injection site is commonly 1 ml but volumes so low as 0.25 ml per site were also used [Grise et al., 2010].

The effect of BONT/A after increasing the dose per injection site and decreasing the number of injected sites was investigated in one study. Patients were randomized to receive 300 U either in 10 or 30 sites [Karsenty et al., NAU, 2005]. The authors reported that 10 site injection was quicker and less painful and that no differences in efficacy between the two procedures could be detected up to 24 weeks. In accordance, it was found that patients receiving 300 U of onabotA distributed over 30 injection sites (30 ml of fluid in total) or the same dose of toxin distributed over 10 injection sites (10 ml of fluid in total) had a similar distribution of the fluid, as determined by MRI. About 1/3 to 1/4 of the total detrusor volume was covered by the two protocols, respectively [Mehnert et al, 2009].

When considering IDO or BPS/IC patients the most relevant aspects in the injection protocol is the smaller amount of toxin at each site, as most studies used onabotA 100 or 200 U or abobotA 500 U [see Mangera et al., 2011, Giannantoni et al., 2012 for reviews]. Another variable at stake is the trigone injection. The suggested risks of injecting bladder trigone were never demonstrated, whether onabotA or abobotA was used [Karsenty et al., 2007; Citeri et al., 2008; Mascarenhas et al., 2008; Pinto et al, 2010). A few studies have, therefore, compared trigonal vesus trigonal sparing protocols in IDO patients. A recent trial randomised 22 IDO patients to receive abobotA 500 U administration in 20 injections (1ml each) sparing the trigone against 15 off the trigone plus 5 injections in the trigone [Manecksha et al., 2011]. Mean postvoid residual volumes and clean intermittent self-catheterisation rates between the two groups were similar. However the change from baseline of the OABSS score was greater in the trigone injected group.

Another study compared 10 trigonal injections versus 40 detrusor or suburothelial injections of 100 U of onabotA in IDO patients [Kuo, 2007]. The most effective protocol was the 40 detrusor injections because it brought more robust symptomatic improvement which lasted longer. The trigone injection only protocol was the less effective and durable of the three, although the risk of urinary retention was null [Kuo, 2007].The suburothelial protocol brought intermediate results, worse than the detrusor but better than the trigone only technique [Kuo, 2007]. Pinto et al. [2010] injected 100 U distributed by 10 sites only in the trigone in 26 women with BPS/IC: No cases of voiding dysfunction were observed. PVR remained normal and bladder contractility index was not changed by onabotA.

Another variable of the injection technique is the volume of the saline used to reconstitute the toxin. Most studies used 1.0 mL per injection, although a few used 0.5 mL [Grosse et al., 2005; Schulte-Baukloh et al., 2005], 0.2 mL [Kuo et al., 2004], 0.25 ml [Grise et al., 2010] or even 0.1 mL per injection site [Rapp et al, Urology, 2004]. In a recent experimental study the amount of cleaved SNAP-25 induced by a fixed amount of onabotA was directly related with the volume of the injection [Coelho et al., 2012]. Thus more controlled studies designed to compare different number and locals of injection and the volume od each injection are necessary.

BoNT/A does not cross the urothelium if instilled in the bladder [Coelho et al., 2012]. Onabot/A instillation in the bladder encapsulated in liposomes may eventually overcome the urothelial barrier and induced distinctive bladder effects [Chuang et al., 2009]. However this technology has not yet been tested in humans. In contrast, electromotive administration seems to overtake this problem, at least in children. In 15 children with NDO due to myelomeningocele, a 10F indwelling catheter containing a silver spiral electrode was placed in the bladder, after providing a local transurethral anaesthesia with 2% lidocaine. The bladder was filled with saline and 10 U/kg of abobotA was added. A maximal current of 10 mA (100 mA increment/s) for 15 minutes was applied using abdominal pads [Kajbafzadeh et al., 2010]. The urodynamic and symptomatic results were excellent (see below). Skin erythema and burning sensation were de only side effects reported with this method. If this technique can be applied to adults it is not known. However, it would certainly simplify BoNT/A administration.

d) Effect of Bont/A on NDO adult patients

OnabotA 200 U is by now approved by FDA and by several European countries to treat NDO in SCI and MS patients. This was in part the consequence of the

findings of two large pivotal phase 3 studies where efficacy and safety of onabot A in about 700 patients with NDO was compared against placebo in patients with NDO and incontinence caused by multiple sclerosis (EDSS ≤ 6.5) or spinal cord injury below T1 [Cruz et al., 2011; Ginsberg et al., 2012]. About 60% of the patients were taking antimuscarinics and maintained the same dose throughout the study. Two doses, 200 and 300 U of onabotA were compared against placebo. Primary outcome measure was the change from baseline in week episodes of urinary incontinence at week 6 after treatment. Secondary outcome measures included the change from baseline in maximum cystometric capacity, maximum detrusor pressure during first involuntary detrusor contraction and quality of life using the I-QOL total score. Both studies yielded similar findings. In the first study [Cruz et al., 2011] onabotA significantly reduced UI and improved QOL in both MS and SCI patients, with no clinically relevant differences between the two doses. At week 6 mean change from baseline in weekly incontinence episodes was -21.8 in onabotA 200U, -19.4 with 300U and -13.2 with placebo ($p < 0.01$). At the same time point 7.6%, 38.0%, and 39.6% of patients in the placebo, 200U, and 300U onabotutA groups, respectively, were fully continent. The proportion of patients with no IDC was around 60% after onabotA 200 and 300 groups but only 17.4% after placebo. In the second study [Ginsberg et al., 2012], onabotA resulted in a 23,0%, 26,7% and 27,4% change from baseline in the incontinence episodes in the placebo, and 200 and 300 groups, respectively. Furthermore, 36% and 41% of patients in the 200 and 300 U groups, respectively, achieved dry status, contrasting with 10% in the placebo arm. In both studies, detrusor pressure and cystometric capacity increased significantly in the two onabotA groups, without clinically relevant differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. Patients could request a retreatment 12 weeks after initial treatment. Median time for saline treated patients was about 90 days days and 250 to 300 days for those treated with 200 or 300 onabotA, without differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. No diferences were found between patients with SCI or MS in terms of clinical response to onabotA [Cruz et al., 2011; Ginsberg et al., 2012].

The most common adverse event was UTI [Cruz et al., 2011; Ginsberg et al., 2012]. In the SCI population, the majority of which was performing CIC at baseline, the incidence was similar across all treatment groups (around 50%). In the MS population, it was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%) in the study by Cruz et al. [2011] whereas the incidence of UTI was similar, around 50%, after 200 and 300 onabotA doses in the study by Ginsberg et al., [2012]. This was related with dose dependent incidence of de novo CIC in MS patients (12.2% after saline, 29.5 after 200U, 42.2 after 300U [Cruz et al., 2011]. Ginsberg et al. [2012] observed that the incidence of CIC in patients not catheterizing at baseline was dose dependent, 10% on placebo, 35% on 200 U and 42% on 300 U, and mainly affected MS patients. The higher incidence of adverse events and the lack of clinically advantages of 300 U led to the approval of 200 U dose in NDO.

These pivotal phase 3 trials confirms observations coming from smaller trials. Schurch et al., [2005] randomized 59 NDO patients due to spinal cord injury to received onabotA 200 U, 300 U or placebo. OnabotA treated patients had a significant reduction in incontinence episodes and amelioration of urodynamic parameters versus placebo, that were still sustained 6 month post-treatment. In an additional subanalysis, onabotA also improved quality of life over placebo [Schurch et al., 2007]. No differences between onabotA 200 and 300 U were detected [Schurch et al., 2005]. A Canadian multicenter double-blind study [Herschorn et al., 2011] randomised 57 patients with NDO secondary to spinal cord injury or multiple sclerosis and urinary incontinence despite current antimuscarinic treatment to onabotA 300 U (28) or placebo (29). The mean daily number of incontinence episodes was significantly lower for onabotA than for placebo at week 6 (1.31 vs 4.76, $p<0.0001$). This effect was sustained at weeks 24 and 36. onabotA induced improvements were also seen in urodynamic and quality of life parameters and were maintained up to week 36.

Although not officially approved for NDO, abobotA has been the object of investigation in a few comparative clinical trials. A small study randomized a total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of abobotA 500 U or placebo [Ehren et al., 2007]. Patients in the abobotA arm had a significantly higher cystometric capacity at 6 and 12 weeks, lower maximum detrusor pressure and episodes of urinary incontinence and less consumption of antimuscarinic drugs. Efficacy and safety of abotoA were, additionally, investigated in NDO patients that had abandoned antimuscarinic therapy. Two doses, 500 U (n = 39) or 750 U (n = 38) were compared. Complete continence at day 30 was observed in 22 patients (56.4%) and 28 patients (73.7%) receiving 500Uor 750U. The median delay in the reappearance of leakages was 168 days. Although there was a trend towards a greater improvement with 750 U, no statistically significant differences in terms of clinical and urodynamic variables and QoL were found between the treatment groups. Tolerability was excellent and equivalent for both doses.

The symptomatic improvement brought by BoNT/A injection in the bladder does not coincide with the moment of injection. The onset of BoNT/A effect was evaluated in a small open-label prospective study that specifically investigated the chronology of the symptomatic changes. Some improvement in urgency, nocturia and frequency could already be demonstrated as soon as 2 days after neurotoxin

injection in NDO patients [Kalsi et al., 2008]. In SCI and MS patients treated with onabotA, 200 or 300U, significant decrease in the number of incontinence episodes over placebo was first detected at week 2 after injection [Cruz et al., 2011].

A recent subanalysis of a phase 3 study showed that similar reductions in urinary incontinence episodes and proportion of patients fully dry were achieved, regardless of antimuscarinic use. Moreover, increment of maximal cystometric, decrease in detrusor pressure, improvement in quality of and median time to patient request for re-treatment were similar in anticholinergic users and non-users [Sievert et al., 2012] These observations go along with those made Reitz et al. [2004] and Grosse et al. [2005] who concluded that a substantial proportion of SCI patients could reduce or interrupt anti-muscarinic medication after BoNT/A injection.

Multiple Sclerosis patients represent a particular subgroup of patients in whom a careful analysis of the efficacy and safety of BoNT/A additional attention if voluntary voiding is present before treatment. Cohort studies clearly suggest that using onabotA 300 U reduces markedly episodes of urinary incontinence. Highly significant improvements in urgency, incontinence episodes, frequency, nocturia and urodynamic parameters (bladder capacity, volume to detrusor overactivity and maximal detrusor pressure) were observed. However, most of the patients required CIC to empty the bladder after receiving onabotA 300 U [Kalsi et al., 2007; Khan et al., 2011] In spite of this drawback, improvement in quality of life was quite remarkable indicating that patients may prefer CIC to incontinence [Kalsi et al., 2007; Khan et al., 2011]. A subanalysis of the large pivotal phase 3 study for 154 MS patients was recently reported [Cruz et al., 2011]. Fifty received saline injections, 51 onabotA 200U and 53 onabtA 300U. Weekly episodes of urinary incontinence decreased 18.1, 24.4 and 25.9 at week 6 after saline, 200 U and 300 U, respectively. About 40% of onabotA treated patients were dry at that visit, without relevant differences between the two doses. Quality of life and urodynamic parameters improved in both onabtA groups, also without relevant differences between 200 and 300 U. However, there was a dose dependent increase in post-void residual that led to CIC 2.6%, 24.3% and 37.5% of the patients after saline, 200U or 300U, respectively [Cruz et al., 2011]. Urinary infections were also higher after 200 U (58.5%) than after 300 U (70%). Therefore this subanalysis indicates that 200 U should be preferred to 300 U in for MS patients.

Whether lower that 200 U onabotA can still be effective in controlling urinary incontinence in MS patients without impairing pretreatment voluntary voiding, it is yet unclear. A pilot study with 12 MS patients with a mean EDSS of 5.0 (3.0-7.5) treated with onabotA 100 U seems to indicate that this is a valid alternative [Mehnert et al., 2010]. Daytime and night-time frequency, urgency and pad use significantly decreased while maximum bladder capacity increased. Post-void residual volume increased moderately during the initial 12 weeks but no patients required CIC. Median time to re-injection was 8 months. So, additional studies specifically designed to evaluated onabotA 100 U seems warranted in MS patients with voluntary voiding.

e) BONT/A and UTI in adult NDO patients

UTI are one of the most frequent adverse event of BoNT/A injection. In a phase 3 trial in SCI patients performing CIC, the incidence after saline or onabotA 200 and 300 U was similar, around 50%, reflecting the fact that most patients were on CIC across the three groups before treatment. In the MS population, the incidence of UTI was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%). This was eventually related with a dose dependent increase in post void residual and incidence of de novo CIC in MS patients receiving onabotA (12.2% after saline, 29.5 after 200U, 42.2 after 300U) [Cruz et al., 2011]. In a similar phase 3 trial, Ginsberg et al. [2012] found a similar incidence of UTI, of about 50%, in SCI and MS patients whether 200U or 300U were used. Although most of these infections were non-complicated, a careful exclusion of active UTI at the moment of injection and a cautious UTI screening after each BoNT/A bladder treatment seems justifiable.

A consequence of BONT/A treatment only recently noticed is a decrease in the incidence of severe urinary tract infections in NDO patients. In 30 SCI patients Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the 6 month before onabotA 300U, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first 6 month after treatment. In 17 SCI patients that received onabotA injections for a period of 6 years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a multicentre, cross-sectional retrospective cohort study, data from 214 NDO patients treated in 7 German centers were collected. The rate of urinary tract infections in 12 months proceeding and in the 12 months following onabotA was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesico-ureteral reflux [Wefer et al., 2009].

f) BONT/A in IDO patients

The enthusiasm of investigators rapidly produced a reasonable number of pilot studies investigating BoNT/A in patients with IDO refractory to antimuscarics. Although proper dose-escalating studies capable of defining ideal doses were lacking, investigators opted for the administration of BoNT/A in doses smaller than those initially used in NDO. That is the reason why most pilot studies used either onabot 200 U or abobot 500 U ([see list at the end, see also Mangera et al,, 2011] and 4 RCT trials compared

onabotA 200 U against placebo [Sahai et al., 2007; Brubaker et al., 2008; Flynn et al., 2009; Tincello et al., 2012]. Due to high incidence of voiding dysfunction associated with the use of onabotA 200U in IDO patients one large cohort, 100 patients, investigated the effect of onabot 100 U. Two dose escalating placebo controlled studies [Dmochowski et al., 2010; Rovner et al.,2011; Denys et al.,, 2012] investigated the ideal dose of onabotA. That dose seems to be 100 U. However, data from pivotal phase 3 studies with this dose are not yet available.

The largest placebo controlled RCT carried out until the moment was conducted in 8 centers in UK (the RELAX study) and randomised a total of 240 women with refractory DO to receive onabotA 200 U or placebo distributed by 20 bladder wall sites above the trigone (10 U/1ml) [Tincello et al., 2012]. Primary outcome was voiding frequency per 24 h at 6 months. Secondary outcomes included urgency and incontinence episodes and quality-of-life data. A total of 122 women received onabotA and 118 received placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in onabotA vs 6.0 in the placebo group. Continence was more common after onabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group. Urinary tract infections (31% vs 11%) and voiding difficulty requiring CIC (16% vs 4%) were more common after onabotA [Tincello et al., 2012].

Only one placebo controlled RCT on IDO [Sahai et al., 2007] included male patients (onabotA 200 U: 9 females and 7 males; Placebo 11 females and 8 males). Maximum cystometric capacity was the primary outcome measure and changes in overactive bladder symptoms, post-void residual, maximum detrusor pressure during filling cystometry, reflex detrusor volume and Quality of Life questionnaires were secondary outcome measures. Follow-up occurred at 4 and 12 weeks after injection, at which point the study was unblinded. Significant improvement in maximum cystometric capacity, urinary frequency and incontinence episodes were observed at 4 and 12 weeks in patients treated with BONT/A. Urgency was also significantly reduced over placebo only at 4 weeks. Post-void residual increased at 4 weeks but differences to placebo became insignificant by 12 weeks. Despite significant improvements in quality of life observed among patients treated with BONT/A, 37.5% of them required intermittent self-catheterization to empty the bladder. Two additional small RCT compared onabotA 200 U against placebo in women with IDO. Brubaker et al. [2008] randomized 28 women for onabotA 200 U and 15 for placebo. Approximately 60% of the women who received toxin had a clinical response based on the Patient Global Impression of Improvement. The median duration of their responses was 373 days, significantly longer than the 62 days for placebo. Post-void residual urine increased in 43% of the women in the BONT/A group (12 out of 26 women) and urinary tract infection developed in 75% of these women (9 of 12). These numbers exceeded by far the expected ranges and forced the suspension of the trial. Median duration of urinary retention after the first injection was approximately 2 month but increased to 5 months at a second injection [Brubaker et al., 2008].

Flynn et al. [2009] reported the preliminary results of a study comparing onabotA 200 or 300 U against placebo in patients with urinary incontinence. The primary outcome measure was the number of incontinence episodes per 24 hours whereas 24 hours pad weights, number of pads, voiding frequency, nocturia and urodynamic parameters at cystometry were secondary outcomes. Until the moment only 15 patients received onabot 200 or 300 U and 7 placebo, distributed by 10-12 sites above the trigone. Incontinence episodes were halved and pads per day were reduced by 2/3 in the onabotA group whereas no changes occurred in the placebo group. No changes were observed in nocturia, daily voiding frequency, peak flow or detrusor pressure in either group. Post-voiding residual over 200 ml was observed in the onabotA group. Four subjects experienced UTI, 2 in onabotA and 2 in the placebo group.

The obvious necessity of reducing micturition dysfunction in IDO patients treated with onabotA 200 U led to the investigation of the efficacy and safety of lower doses. Schmid et al. [2006] injected onabotA 100 U in 100 IDO patients refractory to antimuscarinic therapy. Treatment remained highly effective, incontinence and urgency sensation disappearing in 86% and 82% of patients, respectively, during an average period of 6 months. Temporary urinary retention only occurred in 4% of the cases, with additional 15% reporting moderate voiding difficulties.

The utterly necessary dose escalating studies were only recently accessible. Dmochowski et al. [2010] conducted a phase 2, multicenter, randomized, double-blind study were 288 females and 25 males with IDO experiencing ≥ 8 urgency incontinence episodes per week and ≥ 8 or more micturitions per day. They were randomized to receive 50, 100, 150, 200 or 300 U onabotA or placebo in 20 sites above the trigone (0.5 ml of fluid injected per site). A dose response was observed at week 12 for full continence (15.9%, 29.8%, 37.0%, 40.8%, 50.9% and 57.1% in the placebo, and 50, 100, 150, 200 and 300 U groups, respectively. However, during the full time course of the study, clear differentiation among doses of 100 to 300 U was not always apparent. MCC had small increases in placebo (49.5 ml), 50 U (50 ml) and 100 U (71 ml). At higher doses the increment become marked larger, 101 ml, 91 ml and 130 ml in 150 U, 200 U and 300 U groups [Dmochowski et al., 2010]. For other parameters like frequency and urgency, the magnitude of change was consistently less and a dose dependent response was not evident. A sustained response was absent in the placebo and 50 U

group compared to groups receiving 100 U or more. The proportion of patients with posttreatment PVR of 200 ml or greater was dose dependent and patients requiring CIC were 0%, 3,6%, 9,1% 12,7% 18,2% and 16,4 for placebo, and 50, 100, 150, 200 and 300 U groups, respectively. Another common adverse event were UTI, 16,3%, 33,9%, 44%, 48.1% and 34.5% for placebo, and 50, 100, 150, 200 and 300 U groups, respectively [Dmochowski et al., 2010]. The conclusions was that 100 U may be the dose that appropriately balances the symptom benefits with most common adverse events, in particular the risk of CIC due to increase post-void residual urine. Another dose-escalating study randomized 107 patients (87.9% women) for placebo or onabotA (50 U, 100 U or 150 U) applied through 15 injections of 1ml each above the trigone [Denys et al., 2011]. A >50% improvement in urgency and urgency incontinence versus baseline, the primary end point, was observed in 65% and 56% of patients who received 100 U and 150 U, the difference being only numerically superior to placebo. Complete continence was observed in 55% and 50% patients after 100 U and 150 U, respectively, Urodynamic improvements were consistent with 100 U and 150 U but not with 50U. The proportion of patients with a high PVR was low in all groups [Denys et al., 2011].

Two additional non-placebo controlled RCT also support onabotA 100 U as the ideal dose for IDO. Cohen et al [2009] randomized 44 OAB-dry and wet patients to receive 100 U or 150 U. No significant differences in clinical or urodynamic outcome measures were noted between the two doses. QOL was significantly improved in both groups with no difference between 100 U or 150 U. Altaweel et al. [2011]randomized 11 patients for onabotA 100U and 11 patients to onabotA 200U. No clinical or urodynamic differences were detected between the 2 groups at 3 months follow-up. Urinary retention occurred in 2 patients in the 200 U and in 1 patient in the 100 U arm.

Successful OAB treatment with onabotA does not appear to be related to the existence of DO. In a subanalysis of the dose finding study for onabotA, no differences in outcomes were found between those with and those without baseline DO [Rovner et al., 2011]. Likewise, in a cohort of 5 male and 27 female patients with OAB and without DO, improvement in frequency and urinary incontinence was observed after treatment with onabotA [Kanagarajah et al., 2011]. Two doses were tested, 100 and 150U, without no clinically relevant differences between them [Kanagarajah et al., 2011].

A small open-label prospective study specifically investigated the chronology of the onabot 200 U in IDO patients. Urgency, nocturia and frequency improved as soon as 4 days in IDO patients, therefore slightly later than in NDO cases [Kalsi et al., 2008].

These positive data must, nevertheless, be weighed against a recent negative trial for onabotA 100 U [Dowson et al., 2011]. The RCT enrolled 23 patients with a diagnosis of OAB without DO refractory to antimuscarinics to receive intradetrusor injections of either botn-A (100 U Botox) or saline (placebo). An interim analysis was performed and the trial halted as a result of poorly perceived patient benefit. Storage symptoms remained statistically unchanged following onabotA while 3 patients in the treatment arm initiated CIC [Dowson et al., 2011].

In IDO, BoNT/A is recommended for patients refractory to antimuscarinics, that is, patients that do not respond or do not tolerate the first line medication. In a retrospective analysis of the efficacy of 100-150 U of onabotA BTX-A injections in 85 patients, treatment was more successful in patients who did not tolerate anticholinergics than in those who abandoned the medication due to poor efficacy (86% vs. 60%, respectively) [Makovey et al., 2011].

g) BONT/A in children and elderly patients

In children, the dose of BONT/A should be calculated according to body weight. Doses of between 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] and 4 U/Kg [Corcos et al., 2002] have been used for onabotA. The maximum suggested for abobotA is 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006; Akbar et al BJU Int 2007). BoNT/A has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006]. Like in adults, the toxin increased bladder capacity and decreased maximal detrusor pressure. In 26 children with a mean age of 6,9 years, 19 of them (73%) became completely dry between clean intermittent catheterizations while 88% reported a global improvement in urine incontinence. Interestingly, in 11 (73%) out of the 15 children who had vesicoureteral reflux before injection, reflux either disappeared or decreased in grade. BONT/A also improved bowel function in 66% of the children with intestinal problems [Kajbafzadeh et al., 2006]. The success rate in terms of continence and cessation of antimuscarinic medication may, however, be substantially inferior to that seen in adults, potentially due to irreversible bladder wall changes associated with longstanding detrusor overactivity [Altaweel et al., 2006]. In a group of 20 children with myelomenigocele continence was achieved in only 13 children. At a second injection, this number also did not change appreciably [Altaweel et al., 2006].

Electromotive administration of BoNT/A may represent a substantial breakthrough among children. In 15 children with NDO due to myelomeningocele, electromotive administration of abobotA instilled in the bladder in a dose of 10 U/kg, proved very effective and safe. . The mean reflex volume (99 ± 35 ml to 216 ± 35 ml) and maximal bladder capacity (121 ±39 ml to 262 ± 41 ml) increased substantially while maximal detrusor pressure decreased

from 75 ± 16 cm H2O to 39 ± 10 cm H2O. Urinary incontinence improved in 12 patients (80%), [Kajbafzadeh et al., 2011].

To date, two case series have looked at the use of BoNT/A in children with non-neurogenic OAB refractory the anti-cholinergics. Both studies have shown an excellent response to treatment [Hoebeke et al., 2006; Marte et al., 2010]. Data have been updated recently [McDowell et al., 2011]. A total of 57 children of both gender received abobotA 12 U/kg up to a maximum dose of 480 U in multiple bladder sites. A total disappearance of OAB symptoms occurred in 66% and a partial improvement in 19% of the patients. About half of the cases had repeated injections after a mean time slightly exceeding 6 months No cases of voiding dysfunction or UTI were reported [McDowell et al., 2011].

Elderly patients represent, as well, a very special population where urgency and incontinence are not only very distressful but also particularly prevalent. Nevertheless, only 1 study specifically addressed efficacy and safety of BoNT/A in elderly patients. Twenty one patients with refractory IDO (18 females and 3 males) with a mean age of 81.2 years (range 75 to 92) received onabotA 200 U in 20 bladder sites [White et al , 2008]. A significant decrease in the number of daily voids, from 11.4 ± 1.67 to 5.19 ± 0.83 and incontinence pads per day, from 4.0 ± 0.89 to 1.3 ± 0.60, occurred. One month after treatment 16 of the 21 patients (76%) reported greater than 50% improvement in symptoms after 1 injection while only 3 did not show improvement after 2 injections [White et al., 2008]. Mean time to deterioration was 7.12 months. There were no treatment related complications.

h) Effect of BoNT/A on quality of life

Firm evidence that BoNT/A bladder injection in IDO patients increase quality of life can be extracted from several RCT in which QoL changes were in most cases secondary outcome parameters.

A multicenter, randomized, double blind placebo controlled trial by Schurch et al. [2007] which randomized 59 NDO patients with urinary incontinence for onabotA 200U or 300U or placebo. I-QOL scores improved significantly over placebo, at all time points whether 300U or 200U were used. A single center, double blind, placebo controlled study was performed by Ehren et al. [2007]. Thirty-one NDO patients with incontinence were randomized to abobotA 500 U or placebo. Patients in the abobotA group showed improved quality-of-life parameters compared to the placebo group. The Canadian multicenter double-blind study [Herschorn et al., 2011a] that randomised to onabotA 300 U or placebo 57 incontinent patients with NDO secondary to spinal cord injury or multiple sclerosis also found significant advantage of onabotA in terms of I-QoL score. One pivotal phase 3 study used the I-QoL questionnaire to evaluate quality of live changes in SCI and MS patients randomized to 200 and 300 U of onabotA or placebo. Change from baseline was 24 points for both onabotA doses ar 6 and 12 weeks but only 11 points at week 6 and 8 points at week 12 in the placebo group. The I-QoL questionnaires requires that a minimum change of 11 point occur in order to QoL to be detectable by patients, a barrier that was overcome by both onabotA doses [Cruz et al., 2011]. Improvements were present both in SCI and MS patients. In another large phase 3 trial these data were totally confirmed [Ginsberg et al., 2012]. Interestingly, a comparison in QoL in patients performing and non-performing CIC in the placebo, 200U and 300U arms did not show differences in patient perception, indicating that improvement in the continence condition was a more relevant outcome [Ginsberg et al., 2012].

Improvement in QoL was also found in a study that compared abobot 500 U versus /750 in a NDO population predominantly suffering from SCI. A disease- and organ-specific Qualiveen questionnaire with four domains (limitations, constraints, fears, and feelings) was used to assess the Specific Impact of Urinary Problems on QoL The initial evaluation was repeated at days 30, 90, 180, and 360. Identical improvements were detected for the two doses [Grise et al., 2010] The importance of continence for patients quality of life is also confirmed by the study of 43 MS patients treated with onabotA 300 U [Kalsi et al., 2007]. Although 98% of patients had to perform CIC after treatment, there were sustained improvements in all quality-of-life scores with a mean duration of effect was 9.7 months. Results were maintained with repeat treatments for 11.7 months. These results were confirmed in a larger MS cohort by Khan et al. [2011]. Urogenital Distress Inventory and Incontinence Impact Questionnaire 7 scores showed considerable improvement 4 weeks after onabotA 300 U treatment even when repeated 6 times. Again, the fact that 76% of the patients were dry seemed more relevant for QoL score than the necessity of CIC that was required by almost all patients [Khan et al., 2011].

Two RCT compared quality of life after BoNT/A administration to IDO patients. Sahai et al. [2009] used the King's Health Questionnaire (KHQ) at baseline and at 4 and 12 weeks, after injection of onabotA 200 U or saline in 16 and 18 patients of both genders. Overall QoL was significantly improved in the onabotA treated patients compared with placebo in the KHQ subdomains, 'Incontinence Impact', 'Emotions', 'Physical imitations', 'Social Limitations' and 'Severity Measures' at all time points. Other subdomains were improved only at some follow-up visits. The RELAX study that randomised a total of 240 women with refractory IDO to receive onabotA 200 U or placebo [Tincello et al., 2012] showed significant improvement in ICIQ-SF and I-QoL scores. However, none of the questionnaires were restored to the normal score (0 for ICIQ; 100 for IQOL)[Tincello et al. 2012]. The dose finding study by Dmochowski et al. [2010] in which placebo and onabtA 50, 100, 150, 200 and 300 U were compared showed a sustained improve-

ment in the King's Health Questionnaire score only in patients that received doses of 100 U or higher. In contrast, patients randomized to onabotA 50 U had changes similar to those observed after placebo [Dmochowski et al., 2010]. The dose finding study by Denys et al. [2011] showed an I-QoL improvement in patients receiving onabotA 100 U and 150 U, though at some time points scores were only numerically higher than in placebo or 50U groups. The general health status, as measured by the EQ-5D visual analogue scale also improved in patients that received 100 or 150 U [Denys et al., 2011].

i) Side effects of bladder wall injection of BoNT/A

The most frequent side effects reported after intradetrusor BonT/A injection are bladder pain and urinary infections [Karsenty et al., 2008; Del Popolo et al., 2008]. Hematuria may also occur, most of the times mild in nature. The most dangerous one, paralysis of the striated musculature due to circulatory leakage of the toxin has never been reported. Transient muscle weakness was, nevertheless, reported with abobotA application in several studies [Wyndaele and Van Dromme, 2002; Akbar et al., 2007; Del Popolo et al., 2008]. Among 199 NDO patients followed during 8 years, 5 developed hypostenia when injected with after abotbotA 1000 U [Del Popolo et al., 2008]. In another study with 44 patients, 3 adults also treated with 1000 units developed muscular weakness which subsided after 5 to 7 weeks [Akbar et al., 2007]. No such cases were reported with onabotA [Karsenty et al., 2008]. The reason for the lack of transient muscle weakness among Botox-treated patients is unclear but might be related with the larger size of its molecule which limits diffusion into the blood stream. Anyway, the risk of hyposthenia associated with abobotA might be avoided by using lower doses of the toxin, no more that 750 units for adults and 20 units/kg for children [Akbar et al., 2007, Del Popolo et al., 2008]. In addition, caution should be used in selecting high risk patients for botulism including children, patients with low pulmonary reserve or patients with myasthenia gravis. Aminoglycosides should be avoided during BoNT-A treatment since they might blockade motor plates and therefore enhance BoNT/A effect.

The risk of vesicoureteral reflux, which for long precluded trigonal injections [Schurch et al., 2000b, Reitz et al., 2004] seems unfounded [Karsenty et al, J Urol, 2007; Mascarenhas et al., 2008; Citeri et al., 2008; Eichel et al, 2008].

The most feared complication of BoNT/A application in patients with voluntary voiding is urinary retention and a transient necessity to perform CIC. It is, therefore, strongly recommended that in patients with spontaneous voiding BoNT/A administration is preceded by a complete information of this risk. Caregivers should ideally teach CIC to each patient before toxin injection.

In one cohort of 137 MS patients, 65% of whom relied on CISC to empty their bladder, repeated onabotA 300 U injections systematically increase that percentage to 95% [Khan et al., 2011]. In a subanalysis of MS patients with an EDSS around 5 included in the pivotal phase 3 RCT in which NDO patients were randomized for placebo, onabot 200 or 300 U the incidence of de novo CIC was dose dependent, 2.6%, 24.3% and 37.5%, respectively [Cruz et al., 2011]. A reduction of onabotA to 100 units might not be enough to solve the inconvenience. In a small cohort of 12 MS patients with a mean EDSS of 5, 25% of the patients required CIC or a suprapubic cathether to empty the bladder [Mehnert et al., 2010]. Future studies are needed in this area.

In IDO patients injected in the detrusor the rate of urinary retention or high post-voiding residuals requiring CIC is dose dependent [Dmochowski et al., 2010]. After injection of onabot 200 U 16-40% of the treated patients needed CIC [Kuo et al., 2004; 2005; Popat et al., 2005; Sahai et al., 2007; Brubaker et al., 2009; Dmochowski et al., 2010; Tincello et al., 2012). With onabotA 100 U the risk was substantially lower, from 4% to 13% [Schmid et al., 2006; Kuo, 2007; Dmochowski et al., 2010; Cohen et al., 2009]. Onabot 50 U was associated with the lower risk of increasing postvoid residuals and de novo CIC, 3,6%. [Dmochowski et al., 2010]. In contrast, detrusor injection of onabotA 100 U restricted to the trigone [Kuo et al., 2007; Kuo et al., 2010] were devoid of any risk of dysfunctional voiding. The same lack of dysfunctional voiding after trigonal injections of onabotA 100U was confirmed by Pinto et al. [2010] in BPS/IC women.

At this moment it is not possible to identify beforehand patients that will develop voiding difficulty after BoNT/A injection. The positive or negative status of the ice water test does not correlate with the risk of urinary retention after onabotA injection in NDO patients [Huwyler et al., WJU 2007]. A retrospective analysis of 217 patients receiving their first intravesical BoNTA injection for refractory IDO in a tertiary center concluded that risk factors for dysfunctional voiding and urinary retention included male gender ($p = 0.013$), baseline postvoid residual (PVR) > 100 ml ($p = 0.003$) and onabotA > 100 U ($p = 0.029$) [Kuo et al., 2010]. Also in a retrospective analysis of a cohort of 67 patients with IDO treated with onabotA 200 U CIC was necessary in 19 (28%). When compared to those not requiring CIC, those that started CIC had lower pretreatment maximum flow rate (15 vs 22 mL/s, P=0.003), lower projected isovolumetric pressure (43 vs 58, P=0.02) and lower bladder contractility índex (113 vs 180, P=0.001) [Sahai et al, BJU Int 2009].

Another common adverse event related with intradetrusor injection of BoNTA/ is UTI. In NDO patients due to SCI, almost all doing CIC at baseline, the risk of UTI in patients receiving onabotA, whether 200 U or 300 U was similar to those treated with placebo, slightly above 50% [Cruz et al., 2011]. The Canadian study randomised 57 NDO patients to placebo or

onabotA 300U. NDO was mostly due to SCI and the incidence of UTI was similar, 55% and 57%, respectively in the placebo and onabotA groups [Herschornet al., 2011]. However, in MS patients the risk was dose-dependent, 32%, 58.5% and 70%, respectively, eventually related with the increase in post-voiding urine residual volume and necessity of performing CIC in the MS population [Cruz et al., 2011]. In the cohort of 137 MS patients subjected to repeated injections of onabot 300 U and almost all emptying the bladder by CIC, after the 3-day prophylactic course further antibiotics for UTI were required in 9% of the total of 327 treatment sessions. Low dose long-term antibiotic prophylaxis was needed in additional 17% of the patients [Khan et al., 2011]. An word of caution shoukd however be left here. Most of these UTI were mild in nature. Severe infections like pyelonephritis, orquites or prostatitis seem to be substantially reduced after BoNT/A treatment of NDO [Game et al, 2008].

In IDO patients the risk of UTI is higher in males than in females [Kuo et al., 2010] and may well affect more than 1/3 of the patients. In RCT comparing placebo against onabot 200U the incidence of UTI was 0% vs 7% [Sahai et al., 2007], 22% vs 44% [Brubaker et al., 2009] or 11% vs 31% [Tincello et al., 2012], respectively. This adverse event seems to be dose related, eventually associated with the post-voiding urine volume increase. Domochowski et al. [2010] detected UTI in 16,3%, 33,9%, 44%, 48.1% and 34.5% of patients randomized for placebo, and 50, 100, 150, 200 and 300 U groups, respectively.

Although it is a concerned frequently rose by caregivers, at this moment there is no evidence that repeated BoNT/A injections cause detrusor atrophy or bladder wall fibrosis. Whether onabotA or abobotA were used, repeated injections in NDO patients in the short to medium term did not decrease bladder compliance which would presumably be the case if fibrosis were to develop [Reitz et al., 2007; Del Popolo et al., 2008]. Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008]. Rather the reverse, one study demonstrated that NDO patients treated with BonT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. Curiously, the presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

j) Effectiveness of repeated injections in NDO and IDO patients

Median time for NOD patients due to SCI or MS to request a retreatment was around 300 days after onabotA 200 or 300 U but only 92 days after placebo [Cruz et al., 2011]. Therefore for patients that respond to BoNT/A a programme of reinjections is inevitable. The mean duration of the BoNT/A effect after repeated injections seems to remain stable, without any evidence of tachyphylaxis.

Three studies were identified that assessed the effect of repeated injections of onabotA and abobotA in NDO patients. A cohort of 199 patients with spinal cord lesions treated with abobotA 500 U to 1000 U was analyzed retrospectively, after 8 years of repeated injections. The intervals of between injections remained constant. Urodynamic improvements, patients satisfaction with treatment and number of pads or other protective devices was also constant after treatments [Del Popolo et al., 2008]. Intervals exceeded 12 months in 19.5% of the patients, ranged between 10-12 months in 40.2%, was < 10 months in 30.5% and < 6 months in only 10% of the patients [Del Popolo et al., 2088].

In another study, 20 consecutive NDO (SCI 18, MS 2) patients received at least five intradetrusor injections of onabotA 300 U in 30 sites above the trigone. Intervals between injections remained constant, between 193 and 199 days. Clinical continence improved significantly after the first injection and then remained constant after repeat injections. The median reflex volume increased from a 200 ml at baseline to values between 440 and 500 ml at follow-up studies. The presence of NDO decreased by 60–75%. Maximum cystometric capacity increased more than 2 folds and maximum detrusor pressure from a median of 70 cm H2O to values of about 20 cmH2O [Reitz et al., 2007].

In a MS cohort with137 patients who underwent detrusor onabot 300 U, 99 (72%) returned for a second treatment, and 47, 25, 14 and 5 returned for retreatments 3 to 6, respectively. The median interval for 1st, 2nd , 3rd, 4th, and 5th re-injections ranged between 12 and 13 months. The outcome in terms of continence did not differ among treatments [Khan et al., 2011].

Four studies were identified that analyzed repeated injections in IDO patients. In general, longer duration of BoNT/A effect and a relatively higher rate of treatment drop out is seen among IDO patients.

From a cohort of 34 IDO patients treated with onabotA 200 U, 58% received a 2nd injection and 26% received a 3rd and 4th injection. Significant improvements in OAB symptoms, QoL and urodynamic parameters were observed after each injection as compared with baseline, without differences in efficacy parameters between the 1st and last treatment. When analyzing the reasons why 20 out of the 34 patients abandoned the programme, the fear of CIC (25%) and poor response (20%) were the leading causes [Sahai et al., 2010].

This study was recently updated for 100 patients [Dowson et al., 2012]. A statistically significant reduction in frequency, urgency, and urge urinary

incontinence were seen following onabotA 200 U injection compared to baseline. Such improvement was again maintained after repeated injections. The mean inter-injection interval was 322 days. Interestingly, 37% of the patients stopped treatment after the first two injections, dropouts being rare thereafter. The most common reason for discontinuing treatment was poor efficacy (13%). CIC related issues was pointed out by 11% of patients in spite of the incidence of CIC after the first injection being 35% [Dowson et al., 2012].

In a prospective, observational study after 1 single onabotA 100 U injection, 26 patients were followed up for 2 years. One was a primary failure, 3 were lost to follow-up, and 11 patients had a repeated injection at 5–26 months. At 2 years 7 of the remaining 11 patients were recommended repeated injection or another treatment, and four required no other treatment.

Schmid et al. [2008] reported on 25 women and 5 men that received repeated [2] injections of onabotA for treatment of IDO. The interval between two subsequent treatments ranged between 4 and 26 months (mean 12 months). Improvement of OAB symptoms, quality of life and urodynamic parameters were observed after reinjection.

k) Cost-effectiveness of BoNT/A

Economic aspects of BonT/A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, In UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BonT/A treatment was shown to be cost-effective in both NDO and IDO cases [Kalsi et al, 2006]. Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BoNT/A (Botox) compared with standard care [Kalsi et al., 2006]. In Germany a multicenter cost analysis showed that BonT/A (onabotA) treatment halved costs for incontinence aids and for urinary tract infection treatment in 214 NDO patients. In patients using incontinence aids, mean costs per patient decreased from €2 to €1 per day, whereas the mean cost of drugs to treat UTIs per patient decreased from €163 to €8 per year [Wefer et al., 2009].

Also in NDO patients, break-even point for BoNT/A and augmentation cystoplasty costs may be reached at five years. However BoNT/A may be substantially more cost-effective if the duration of effect of each injection is superior to 5 months or if the complications associated with augmentation cystoplasty overtake 40% of the patients [Padmanabhan et al., 2011].

For OAB/IDO, an assessment of costs, from a US payer perspective, extending up to 3 years, was made for 3 interventions, sacral neuromodulation, BoNTA, and augmentation cystoplasty in patients refractory to antimuscarinics. The initial treatment cost was $22,226, $1,313, and $10,252 for sacral neuromodulation, BoNTA, and augmentation cystoplasty respectively. Three years after initiating treatment, the cumulative cost was $26,269, $7651, and $14,337 respectively. Sensitivity analyses revealed that sacral neuromodulation persisted as the most costly intervention [Watanabe et al., 2010].

l) Comparisons between different BoNT/A brands

Systematic head-to-head comparisons between the different brands of BoNT/A are still lacking. Within each brand very few studies compared different doses for neurogenic or idiopathic DO. However, metanalysis and systematic reviews are already available which give some light on this important topic.

A recent metanalysis identified 19 randomised or quasi-randomised controlled trials for OAB/DO treatment in adults in which at least one management arm involved intravesical injection of botulinum toxin. Comparison interventions could include no intervention, placebo, lifestyle modification, bladder retraining, pharmacological treatments, surgery, bladder instillation techniques, neuromodulation, and different types, doses, and injection techniques of BoNT/A. Most patients in the studies had neurogenic DO, but some included patients with idiopathic DO. All studies demonstrated superiority of botulinum toxin to placebo. Lower doses of onabotA (100 to 150 U) appeared to have beneficial effects, but larger doses (300 U) may have been more effective and longer lasting, but with more side effects [Duthie et al., 2011].

Mangera et al. [2011] in a systematic review identified good-quality studies that evaluated onabotulinumtoxinA for all the indications in adults. However that was not the case with abobotA. Although this does not imply that onabotA is more effective than abobotA, it should be a consideration when counselling patients on the use of botulinum toxin in urologic applications. The two preparations should not be used interchangeably, either in terms of predicting outcomes or in determining doses to be used.

The only study available that compares two different brands used onabotA 200 or 300 U against the Chinese BoNT/A Presigne in the same dosage. Improvement in MCC was significantly greater with onabotA Botox versus Prosigne (+103.3% vs. +42.2%; P = 0.019). Continence was achieved by week 12 in 16 onabotA recipients (76.2%) and in 10 Presigne recipients (47.6%; P = 0.057) [Gomes et al., 2010]. Future studies seems, therefore, justified to assess the relative potencies of the different brands of BoNT/A.

m) BONT/B

Some humans repeatedly injected with BONT-A may develop resistance to the toxin, possibly due to antibody formation. Although this event seems very rare in the case of bladder injections, a minimum interval of 3 months between two BoNT/A injections is gener-

ally recommended to decrease its occurrence. If resistance appears, recent reports [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004] investigated the replacement of BONT-A serotype by BONT-B. At this moment empiric doses of BoNT/B are being used as there is no clear potency equivalents for the two serotypes and between BoNT/B brands.

In 3 patients with spinal NDO, bladder injection of 5000 UI [Pistolesi et al., 2004] or 7500 UI [Reitz and Schurch, 2004) of BONT-B (Neurobloc ®) restored bladder function for 6 months [Reitz and Schurch, 2004]. Interestingly, 1 patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BONT-A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BONT-B (rimabotB in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only 1 patient failed to respond and a clear dose-dependent effect, was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which rimabotB 5000 U were used, Hirst and coworkers [2007] observed a limited duration of action, with most of the symptomatic beneficial effects wearing off by 10 weeks in most of the patients. The short duration of action for BONT-B at safe doses may, therefore, limit the clinic usefulness of this serotype.

n) BONT/A in IC/PBS

BONT/A significantly inhibits the noxious sensory input from the bladder [Vemulakonda et al., 2005; Rapp et al., 2006; Lucione et al., 2008]. Therefore several pilot studies were carried out in the last few years. None is placebo controlled, a fact that limits the scientific value of the observations. On the other hand different techniques of administration have been assessed. These two facts may explain some heterogeneity of results.

The first pilot study with 13 females observed that, 9 (69%) had subjective improvement after onabotA 100 or 200 U injected in the trigone and above the trigone. Mean scores in the Interstitial Cystitis Symptom Index and the Interstitial Cystitis Problem Index improved by 71% and 69%, respectively. Daytime frequency, nocturia, and pain measured by a Visual Analogue Scale (VAS) decreased by 44%, 45%, and 79%, respectively. Symptom improvement lasted a mean of 3.7 months (range 1 to 8) [Smith and Chancellor, 2004]. In another pilot study with 15 patients, Giannantoni et al. [2006; 2008] reported similar obervations after bladder injection of onabotA 200 U (150U above the trigone, 50 U in the trigone). Subjective improvement at 1 and 3 month follow-up occurred in 86% of the patients but at 5-month only persisted in 26.6% . Importantly, 9 patients experienced moderate to severe voiding difficulties [Giannantoni et al., 2006; 2008] A third study could not demonstrate any effect of onabotA in 13 IC/PBS patients treated with onabotA 100–300 U in the bladder [Davies et al., 2006].

Three other studies, which added substantial modifications to the above protocol, reported, on the contrary, considerable improvement in clinical and urodynamic outcomes after BoNT/A adminitration.

A prospective, randomized study enrolled 67 patients with refractory IC/PBS Of these, 44 patients received suburothelial injection of onabotA 200 U [15] or 100 U [29] followed by cystoscopic hydrodistention 2 weeks later. The control group (23 patients) only received hydrodistention. The IC/PBS symptom score significantly decreased in all three groups, but VAS pain reduction and urodynamic improvement were only observed at 3 months in the arms that received onabotA, without any relevant differences between the two doses. A successful result at 12 and 24 months was reported in 55% and 30% of onabotA treated patients, respectively, compared with only 26% and 17% in the control group. The validity of these positive long-term results should however be interpreted with caution since all patients remained on baseline pentosan polysulphate throughout the study [Kuo and Chancellor, 2009].

Taking in consideration that most of the bladder nociceptors course in the trigone, Pinto et al. [2010] restricted 100 U onabotA injections to the trigone, in 10 sites (10 U/ 1 ml each. Twenty six women with positive findings at cystoscopy and biopsy were enrolled. All patients reported subjective improvement at 1- and 3-month follow-up in pain, daytime and nighttime voiding frequency, O'Leary-Sant score and QoL. Bladder volume to first pain and maximal cystometric capacity more than doubled. Treatment remained effective in >50% of the patients for 9 months. Retreatment was equally effective in all cases, with similar duration of the effect [Pinto et al., 2010]. No cases of dysfunctional voiding were reported after trigonal injections of onabotA 100U. Also PVR at urodynamics and bladder contractility index were not impaired [Pinto et al., 2010].

The third was a small placebo controlled trial comparing periurethral injections of onabotA 50U (n=9) versus saline (n=11). The rationale was to investigate the participation of periurethral somatic afferents to pain. The solution, 2 ml, was injected in the region of the bladder neck, at the 3 o'clock and 9 o'clock positions. Unfortunately, there was no differences between the onabotA and the at 3-month follow-up in terms of symptoms.

At this moment, without a well conducted placebo controlled RCT it is difficult to state how effective is BoNT/A in BPS/IC. However, taking in consideration the effects the toxin induces in nociceptors and in the urothelium and the favourable results of the two largest clinical trials, it is tempting to suggest that further assessments are warranted.

2. CAPSAICIN AND RESINIFERATOXIN (RTX)

a) Rationale for intravesical vanilloids

The rationale for intravesical vanilloid application in patients with detrusor overactivity (DO) was offered by the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent upon a sacral micturition reflex [de Groat, 1997]. The C-fiber micturition reflex is usually inactive but it was shown that it is enhanced in patients with chronic spinal-cord lesions above sacral segments [de Groat, 1997] in those with chronic bladder outlet obstruction [Chai et al., 1998) and in those with IDO [Silva et al., 2002]. In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of sub-urothelial C-fibers expressing TRPV1 [Brady et al., 2004]. Curiously, NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas non-responders experience a non-significant variation [Brady et al., 2004]. A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX [Apostolidis et al., 2005; 2006].

Changes in sub-urothelial C-fibers expressing neuropeptides [Smet et al. 1997] or TRPV1 [Liu and Kuo, 2007] were also reported in patients with and sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the over-expression of the receptor in the bladder mucosa [Liu and Kuo, 2007]. In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry further indicating that TRPV1 play a role in premature bladder sensation [Liu et al., 2007].

b) Intravesical capsaicin

Intravesical capsacin for NDO was studied in 6 non-controlled [Fowler et al., 1992; Fowler et al., 1994; Geirsson et al., 1995; Das et al.,1996; Cruz et al., 1997, De Ridder et al., 1997] and 1 controlled clinical trial [de Seze et al., 1998]. Capsaicin was dissolved in 30% alcohol and 100-125 ml (or half of the bladder capacity if lower than that volume) of 1-2 mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found among patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70-90% the patients [Fowler et al., 1994, Cruz et al., 1997; De Ridder et al., 1997]. In patients with complete spinal cord lesions the success rate was much lower [Geirsson et al., 1995].

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin and found a significant regression of the incontinence and urge sensation. In contrast, only 1 among the 10 patients that received ethanol had clinical improvement [de Seze et al., 1998].

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. In particular, the possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions has progressively restrained its use. The relevance of capsaicin might however be back with a recent observation by de Séze et al.[2006] with a new capsaicin formulation. They conducted a double blind placebo controlled study with a glucidc solution of capsaicin in 33 NDO patients. The glucidic-capsaicin treated group showed improvement both in symptoms and urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent [de Sèze et al.,. 2006].

c) RTX in NDO

Resiniferatoxin (RTX) has the advantage over capsaicin in being much less pungent [Cruz et al., 1997]. Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al., 1997; Lazzeri et al., 1997; 1998; Silva et al., 2000; Kuo 2003). Different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 μM were tested. RTX brought a rapid improvement or disappearance of urinary incontinence in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to first detrusor contraction and maximal cystometric capacity. In general, in patients receiving 50-100 nM RTX the effect was long-lasting, with a duration of more than 6 month being reported. In patients treated with 10 μM doses, transient urinary retention may occur [Lazzeri et al., 1998].

In a recent placebo-controlled study, the urodynamic effects of RTX in NDO patients was specifically evaluated. Only in the RTX arm a significant increase in first detrusor contraction and maximal cystometric capacity was found [Silva et al., 2005]. RTX also caused a significant improvement in urinary frequency and incontinence [Silva et al., 2005].

RTX, 600 nM was compared against BONT/A (Botox, 300U) in a study involving 25 patients with NDO due to chronic spinal cord injury. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BONT/A turned out to be more effective.

d) RTX in IDO

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 mL to 440 ± 153 mL at 30 days, and to 391 ± 165 mL at 90 days. An increase in mean MCC from 291 ± 160 mL to 472 ± 139 mL at 30 days and to 413 ± 153 mL at 90 days was also observed.

These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo, 2003; Dinis et al, 2004; Kuo et al., 2005].

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials [Kuo et al., 2006; Rios et al., 2007]. Kuo et al. [2006] randomised 54 patients to receive 4 weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle solution, 10% ethanol in saline [Kuo et al., 2006] Three months after completing the 4 intravesical treatments, the RTX treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group, 14.2% and 7.1% respectively. At 6 months treatment remained effective in 50% patients in the RTX group but only in 11% in the placebo group [Kuo et al., 2006]. Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo. Patients were followed-up only for 4 weeks. During this period a single 50 nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence [Rios et al., 2007].

e) RTX and urgency

The involvement of bladder C-fibers in IDO has led some investigators to explore the role of these sensory afferents to the genesis of urgency. In a non-controlled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved following intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely due to improvements in scores related to urgency, in addition to improvement in nocturia and frequency [Dinis et al., 2005]. In another open-label study 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain/discomfort, and without urodynamic evidence of DO received one single 50 nM RTX solution. A trend towards an improvement of urgency was noticed [Apostolidis et al., 2006].

In a quasi-randomised study, 23 OAB patients with refractory urgency entered a 30 day run-in period in which medications influencing the bladder function were interrupted. At the end of this period patients filled a 7-day bladder diary. Then, patients were instilled with 100 ml of 10% ethanol in saline (vehicle solution) and 30 days later a second 7-day diary was collected. Finally, patients were instilled with 100 ml of 50 nM RTX in 10% ethanol in saline and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 1 and 3 months after RTX instillation the number of episodes of urgency decreased to 39 ± 9 ($p = 0.002$) and 37 ± 6 ($p = 0.02$), respectively [Silva et al., 2007].

f) Intravesical RTX and IC/PBS

TRPV1 involvement in pain has stimulated the investigation of RTX as a treatment for bladder pain in IC/PBS. After desensitization of bladder C-fibers, RTX reduces the spinal expression of c-fos, a pain evoked gene, in animal models of cystitis [Dinis et al., 2004]. TRPV1 knock-out mice, which do not express the receptor in the bladder, do not experience an increase in the frequency of bladder reflex contractions or in the expression of c-fos in the spinal cord during cystitis [Charrua et al., 2007]. Patients with IC/PBS have more TRPV1 expressing sensory fibers in their bladder mucosa than normal individuals [Mukerji et al., 2006].

In a placebo-controlled study of 18 patients with IC/PBS, Lazzeri et al. [2000] reported an improvement in pain and urinary frequency after administration of intravesical RTX in 10 nmol/L concentration. This effect was short-lasting, eventually due to the use of a low dose of RTX. Chen and co-workers conducted a dose-escalating study and concluded that the most commonly reported adverse event with RTX was pain during instillation. However, at 10 or 5 nM RTX was safe and could improve bladder pain [Chen et al., 2005]. Additionally, 3 non-controlled studies have also reported bladder pain improvement after intravesical RTX [Lazzeri et al., 2004; Apostolidis et al., 2006; Peng and Kuo, 2007]. A randomized, double-blind study in 163 patients with IC/PBS, in which several doses of intravesical RTX (10 nmol/L, 50 nmol/L, and 100 nmol/L) were compared with placebo, failed, however, to show any advantage for the neurotoxin over placebo in terms of overall symptoms, pain, urgency, frequency, nocturia, or average voided volume during 12 weeks of follow up [Payne et al., 2005].

IX. OTHER DRUGS

1. BACLOFEN

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex at several points along its central pathway [de Groat, 1997; Pehrson et al., 2002]. Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin induced detrusor overactivity, suggesting that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al, 2002]. In spinal intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)-like changes whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions [Miyazato et al., 2009]. After spinal cord injury (SCI), Miyazato et al.

[2009] found signs of hypofunction of the GABAergic system (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased), and showed that activation of GABA(A) and GABA(B) receptors in the spinal cord inhibited DO as evidenced by a reduction in non-voiding contractions. GABA(B) receptor activation preferentially reduced DO prior to inhibiting voiding contractions while GABA(A) receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA(B) receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. Baclofen is one of the most effective drugs for the treatment of spasticity following spinal cord injury, traumatic or hypoxic brain injury, and cerebral palsy [Ochs, 1993], and intrathecal baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al. [2000] found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days the volume to first detrusor contraction had increased from 143 ml to 486 ml. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

X. COMBINATIONS

1. α_1-AR ANTAGONISTS WITH ANTIMUSCARINICS

Traditionally, male lower urinary tract symptoms (LUTS) were thought to result from benign prostatic obstruction (BPO) secondary to benign prostatic enlargement (BPE). However, male LUTS may arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosis and appropriate treatment of men with OAB symptoms are complex and difficult. α1-AR antagonists remain the most widely used pharmacologic agents for relief of bladder outflow resistance, as they relax prostatic and urethral smooth muscle tone, the dynamic component of BPO [Andersson and Gratzke, 2010; Lepor et al., 2012]. In contrast, antimuscarinics, which function by competitively blocking the muscarinic receptors, are the first-line pharmacologic treatment for OAB [Andersson et al., 2009]. Given the prevalence of combined voiding and OAB symptoms as well as the finding that the QoL of these patients is affected primarily by the symptoms of OAB, it might be logical for this category of patients to be given antimuscarinic drugs [Ruggieri et al., 2005].

A variety of such combinations have been evaluated. Several randomized, controlled trials demonstrated that the combination treatment of antimuscarinic drugs and α1-AR antagonist was more effective at reducing male LUTS than α1-AR antagonists alone in men with OAB and coexisting BPO [Saito et al., 1999; Athanasopoulos et al., 2003; Lee et al., 2004; 2005; Kaplan et al., 2006; 2008]. Therapeutic benefit of combining an antimuscarinic agent (propiverine) with α1-AR antagonists (tamsulosin), as compared to α1-AR antagonists alone, was reported by Saito and colleagues [Saito et al., 1999]. The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the α1-AR antagonist-alone group. The postvoid residual (PVR) was unchanged in both groups, and there was only one case (1.5%) of acute urinary retention (AUR) with the combined treatment.

Subsequently, Lee et al. [2005] compared the efficacy and safety of combination therapy with propiverine and doxazosin in 211 men with urodynamically confirmed bladder outlet obstruction (BOO) and OAB symptoms for 8 weeks. Compared with the doxazosin arm, the patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of international prostate symptom score (IPSS). Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial (the TIMES study) demonstrated the efficacy and safety of tolterodine extended release (ER) alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO [Kaplan et al., 2006]. In the primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 ($p<0.001$ vs. placebo; $p=0.001$ vs. tolterodine ER; $p=0.03$ vs. tamsulosin). In the secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any diary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (−8.02 vs. placebo, −6.19, $p=0.003$) and QoL (−1.61 vs. −1.17, $p=0.003$). Although there were significant improvements in the total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients that received tolterodine ER versus placebo were not significant. The combination of antimuscarinics and α1-AR antagonists may be the most effective therapy in men with OAB symptoms in the presence of BPO.

A subanalysis [Rovner et al., 2008] of data from the TIMES study focused on the urgency perception scale and concluded that the group of 217 men who received tolterodine plus tamsulosin showed

significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as willingness to continue the treatment. Another subanalysis [Kaplan et al. 2008] of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms. However, these results should be considered with caution, as they were derived from post-hoc analysis of the TIMES data.

Maruyama et al. [2006] reported different results in their prospective, randomized, controlled study in which naftopidil (25-75 mg/day), an α1d-AR antagonist, alone or in combination with propiverine hydrochloride (10-20 mg/day) or oxybutynin hydrochloride (2-6 mg/day), was administered for 12 weeks to 101 BPH patients. In the study, the IPSS and QoL index improved significantly in both groups, with no marked differences between groups. Maximum flow rate (Qmax) and PVR tended to improve in both groups, again with no differences between groups. However, median post-therapeutic PVR was significantly larger in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, $p = 0.021$). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy (22.9%) group versus the monotherapy group (5.0%, $p = 0.038$). The authors of this study concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than the monotherapy group.

The results of another study using low-dose antimuscarinic therapy was published by Kang et al. [2009]. They evaluated the efficacy and safety of combined treatment with tamsulosin 0.2 mg and propiverine hydrochloride 10 mg compared with tamsulosin monotherapy. After 3 months, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index was significantly different between groups in favor of the combination group. No cases of AUR were recorded in this low-dose study.

Medical therapy to reduce detrusor overactivity in a neurogenic bladder has focused on antimuscarinic therapy, which increases bladder capacity, decreases bladder filling pressure, and improves compliance [Goessl et al., 1998; Stohrer et al., 2007]. Although antimuscarinics combined with clean intermittent catheterization is the most commonly recommended medical therapy for neurogenic bladder, the results are sometimes unsatisfactory, and many patients continue to have poor bladder compliance and remain incontinent [Razdan et al., 2003]. MacGuire reported that α-AR antagonists decreased bladder pressure with filling and increased capacity, and that the addition of an antimuscarinic enhanced these effects, indicating that α-AR antagonists and the antimuscarinic had a synergistic effect on detrusor tone in the decentralized bladder [McGuire and Savastano, 1985]. This finding led to the widespread use of α1-AR antagonists in the treatment of neurogenic bladder [Chancellor et al., 1994; Swierzewski, Gormley et al. 1994; Abrams et al., 2003). Swierzewski treated 12 patients with spinal cord injury who had poor bladder compliance, despite therapy with clean intermittent catheterization and an antimuscarinic, with 5 mg terazosin for bladder management (Swierzewski et al., 1994). After 4 weeks, compliance increased by 73%, bladder pressure decreased by 36 cmH2O, and capacity increased by 157 mL. These results support the theory that α-AR antagonists and antimuscarinics have a synergistic effect on the bladder in the neurogenic population.

In a retrospective chart review, combination therapy with an antimuscarinic agent, an α1-AR antagonist, and imipramine produced superior results to those obtained using a single agent in patients with neurogenic bladder dysfunction [Cameron et al. 2009]. These patients showed significant improvement in clinical parameters and compliance, and decreased bladder pressures at capacity. It has been shown that in the decentralized human detrusor, there may be an increase in α-1-AR sites sites and a switch to α-1-AR mediated contractile function from the typical ß-AR mediated relaxation function during bladder filling [Sundin et al. 1977]. The tricyclic antidepressant imipramine is a muscarinic receptor agonist and a direct smooth muscle inhibitor that decreases bladder overactivity by blocking the reuptake of serotonin. Other effects include the peripheral blockade of noradrenaline, stimulating the ß ARs at the dome of the bladder, and decreasing bladder contractility [Hoebeke and Vande Walle, 2000]. These results suggest that targeting multiple receptors may maximize the effectiveness of pharmacological treatment of neurogenic bladder and should be considered in patients in whom treatment with antimuscarinics alone fails.

2. COMBINED ANTIMUSCARINICS

Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effect of detrusor stability and continence, especially for patients with spinal cord injury or neurologic diseases such as multiple sclerosis or meningomyelocele. In these patients, the goal of urological therapy is to maintain continence and to reduce intravesical pressure. When antimuscarinic treatment fails,

however, invasive procedures such as the injection of botulinum toxin, intravesical application of drugs, or surgery are necessary.

A combined antimuscarinic regimen was evaluated as a non-invasive alternative by Amend and colleagues [Amend et al., 2008] for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dosed antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dosed antimuscarinic monotherapy. The study drugs were tolterodine, oxybutynin, and trospium. After a 4-week combined regimen, incontinence episodes decreased and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side-effects were comparable to those seen with normal-dosed antimuscarinics. Those positive findings were speculated to be due to: 1) synergistic activation of different muscarinic receptors or interactions of receptors on different parts of the bladder wall, 2) undiscovered faster metabolism of antimuscarinics requiring an increased dosage of different antimuscarinic drugs, and/or 3) down-regulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug. The combined regimen needs further investigation to verify its efficacy as a non-invasive alternative for patients in whom antimuscarinic monotherapy fails.

3. ANTIMUSCARINICS AND 5α-REDUCTASE INHIBITORS

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α1-AR antagonist, a 5α-reductase inhibitor, or combination therapy with both. Both α1-AR antagonist and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance. Alpha1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, while 5α-reductase inhibitors reduce prostate volume. As mentioned, several trials have demonstrated the efficacy and safety of the combination therapy of antimuscarinics and α1-AR antagonist for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study [Kaplan et al., 2006] suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates [Roehrborn et al., 2008; Roehrborn, Kaplan et al., 2009]. Chung and coworkers conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with a large prostate (≥30 g) and persistent OAB symptoms after α1-AR antagonist therapy who had been unsuccessfully treated with dutasteride alone [Chung et al. 2010]. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months and α1-AR antagonist therapy had failed. All patients were given 4 mg tolterodine ER daily for 12 weeks and had discontinued α1-AR antagonist before the start of the study. At 12 weeks, the frequency (-3.2/24hrs, $p < 0.02$), urgency (19.2%, $p < 0.03$), number of severe OAB episodes (71.4%, $p < 0.05$), and incidence of nighttime voiding (-0.9, $p < 0.003$) were found to have decreased significantly from baseline. The IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 ($p < 0.001$). Storage symptoms decreased from 9.8 to 4.5 ($p < 0.001$). Dry mouth occurred in four (7.5%) subjects, constipation in one (2%), and decreased sexual function in two (3.9%). Post-void residual increased by 4.2 mL, Qmax decreased by 0.2 mL/s, and no patients went into retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well-tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO.

The results of this study indicate that antimuscarinics are safe and effective in selected patients with OAB and BPO when used in combination with 5α-reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in these patients.

4. α_1-AR ANTAGONISTS WITH 5A-REDUCTASE INHIBITORS

It has been well established that the combinations of α1-AR antagonists with 5-α reductase inhibitors (doxazosin finasteride: MTOPS; dutasteride+ tamsulosin: CombAT) can improve clinical outcomes and reduce the incidence of BPH and LUTS progression measured as symptom worsening, retention or progression to surgery [McConnell et al., 2003, Roehrborn et al., 2010].

XI. FUTURE POSSIBILITIES

1.PERIPHERALLY ACTING DRUGS

a) Vitamin D_3 receptor analogues

It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status.Weakened pelvic floor musculature is thought to be associated with the development of urinary incontinence and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction and vitamin D insufficiency. However, to date, only small case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al., 2012). Rat and human bladders were shown to express receptors for vitamin D [Crescioli et al., 2005],

which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D3 have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells [Crescioli et al., 2002; 2003; 2004]. Experiments in rats with bladder outflow obstruction [Schröder et al., 2006] showed that one of the analogues, BXL-628, at non-hypercalcemic doses, did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle which occurred with increasing bladder weight [Schröder et al., 2006]. The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007]. Upregulation of his pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO [Peters et al., 2006; Christ and Andersson, 2007]. In rats with outflow obstruction, previous elocalcitol-treatment improved the effects of tolterodine on bladder compliance [Streng at al., 2012]. It was suggested that in rats elocalcitol exerted additional beneficial actions on outflow obstruction-induced functional changes during the filling phase of micturition. This supports combined therapy in BPH-related LUTS. If the results are valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that BXL628 was able to arrest prostate growth within 12 weeks in men aged>or=50 years with prostatic volume > or = 40 ml [Colli et al., 2006]. In an RCT enrolling 120 female patients with OAB, where the primary endpoint was an increase in the mean volume voided, a significant increase vs placebo (22% vs 11%) was demonstrated [Colli et al., 2007]. Whether or not vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further RCTs. However, currently, the development of the drug seems to be stopped [Tiwari, 2009].

b) TRP channel antagonists

The transient receptor potential (TRP) channel superfamily has been shown to be involved in nociception and mechanosensory transduction in various organ systems, and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder, and may act as sensors of stretch and/or chemical irritation [Araki et al., 2008; Everaerts et al., 2008; Andersson et al., 2010; Araki, 2011]. TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder [Tominaga et al., 1998; Birder et al., 2001; Gevaert et al., 2007]. TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans [Ji et al., 2002; Charrua et al., 2009a]. TRPV4 was initially described in the urothelium of rodents and humans [Janssen et al., 2011]. Co-expression of the two receptors was observed in 20% of rat urothelial cells [Kullmann et al., 2009]. Recent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder co-express TRPV1 and TRPV4 [Cao et al., 2009; Charrua et al., 2012a]. The physiological meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild type (WT) controls [Birder et al., 2001]. In cystometries performed under anaesthesia, the TRPV1 KO mice phenotype seems also very benign. Some studies reported that this animals have totally normal cystometric traces [Charrua et al., 2007]. However, other studies showed that TRPV1 KO mice develop a few non-voiding contractions preceding the voiding contraction [Birder et al., 2001; Frias et al., 2012]. Accordingly, TRPV1 antagonists (GRC 6211) did not show any relevant effect on bladder activity of intact rodents [Charrua et al, 2009b]. In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most probably due to incomplete bladder emptying [Gevaert et al., 2007] Cystometric studies carried out under physiological conditions revealed that TRPV4 KO mice have an marked increase in the inter-contraction interval when compared to wild-type (WT) littermates. [Gevaert et al., 2007; Birder et al. 2002]. Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the inter-contraction interval [Everaerts et al, 2010]. These observations indicated that TRPV4 has a role in the control of normal micturition reflex.

Indisputably, TRPV1 or TRPV4 have a role in the increase of micturition frequency associated with cystitis [Charrua et al., 2007; Everaerts et al., 2010]. While inflamed WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal c-fos expression [Charrua et al., 2007]). The The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide [Everaerts et al, 2010].

The blockade of TRPV1 and TRPV4 with specific antagonist confirm the observations carried out in knock-out animals. As a matter of fact, the TRPV1 antagonist GRC 6211 or the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis [Everaerts et al. 2010; Charrua et al., 2009b]. Recently,

it was shown that the systemic co-administration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist [Charrua et al., 2012b]. In particular, the effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related with the application of some of these antagonists [Planells-Cases et al., 2011]. Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk of cardiac ischemia [Avelino et al., 2012] while TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence [Gevaert et al., 2007].

It is known for long that TRPV1 is involved in the emergence of neurogenic detrusor overactivity following spinal cord transaction [Avelino & Cruz, 2006]. Quite recently a TRPV1 antagonist GRC 6211 has been shown to decrease reflex detrusor overactivity in rats after chronic spinal cord transaction. With increasing doses it was possible to obtain a total suppression of bladder activity [Santos-Silva et al., 2012]. The clinical relevance of this finding will certainly be further investigated in the future.

There seem to be several links between activation of different members of the TRP superfamily and LUTS/DO/OAB, and further exploration of the involvement these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof of concept studies in humans are still lacking.

c) Prostanoid receptor agonists/antagonists

Recent developments in the field of prostanoid receptors may open new possibilities to use selective prostanoid receptor antagonists for DO/OAB treatment [Aoki et al., 2009; Jones et al., 2009]. There is evidence suggesting that PGE2 contributes to the pathophysiology of DO/OAB: PGE2 infused into the bladder induces DO in humans and animals, increases PGE2 production in DO models and there are high concentrations of PGE2 in the urine of patients with OAB [McCafferty et al., 2008]. PGE2 is an agonist at EP receptors 1 to 4, all G-protein coupled, which mediate its physiological effects. Based on studies using knockout (KO) mice and EP1 receptor antagonists, it was suggested that the effects of PGE2 on bladder function were mediated through EP1 receptors [Schroder et al., 2004]. EP receptors can be found on urothelium/urothelium, in detrusor smooth muscle and in intramural ganglia [Wang et al., 2008; Rahnama'i et al., 2010; Rahnama'i et al., 2011]. Functionally, it has been proposed that modulation of bladder activity exerted via EP1 receptors occurs via an afferent mechanism. Schröder et al. [2004] found no difference in urodynamic parameters between unobstructed EP1 receptor KO and WT mice. However, EP1 receptor KO mice did not respond to intravesical PGE2 instillation, while WT mice developed DO. The lack of EP1 receptor did not prevent bladder hypertrophy due to partial bladder outflow obstruction but after obstruction WT mice had pronounced DO, while this was negligible in EP1 receptor KO mice.

Lee et al. [2008] found that in normal rats a selective EP receptor antagonist significantly increased bladder capacity, micturition volume and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE2, and decreased the frequency and amplitude of non-voiding contractions in animals with BOO. More recently it has been shown that also EP3 receptor KO mice have a diminished response to bladder infusion of PGE2, and demonstrate an enhanced bladder capacity under basal conditions [Jones et al., 2009]. This findings suggest an important contribution for EP3 receptors in the modulation of bladder function under physiological conditions as well as under conditions of enhanced PGE2 production evoking DO. Thus, EP1 and EP3 receptors may have a role in PGE2 mediated DO.

Interestingly, activation of EP3 receptors evoked diuresis and EP3 receptor antagonism was found to induce an antidiuretic effect [Jugus et al., 2009]. Thus, to modulate bladder activity, it appears that the EP3 receptor has a role in regulating urine production. Both effects may be useful for treatment of DO/OAB. It cannot be denied that EP1/EP3 receptors constitute interesting and promising targets for drugs aimed at DO/OAB treatment. However, a randomised, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP-1 receptor antagonist, ONO-8539, in patients with the overactive bladder syndrome suggests that the role of EP1 receptor antagonism in the management of OAB syndrome is minimal [Chapple et al., 2011].

d) Intraprostatic Injections of drugs

Intraprostatic injection therapy is probably the oldest minimally invasive surgical therapy for BPH and has been investigated for over 100 years with renewed interest recently. There are different injectables and various routes of administration, transperineal, transrectal and transurethral.

1. Ethanol

Ethanol injection is one of the most investigated intra-prostatic therapies and have been investigated for more than a decade [Goya et al., 1999]. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated and long-term results are scarce. It seems that ethanol causes inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, sloughing of prostatic tissue resulting in cavity

formation [Plante et al., 2003]. The majority of trials demonstrated a significant reduction in symptoms and post-void residual volume as well as a significant improvement in Qmax and QoL and prostate volume also decreased significantly in the majority of studies [Goya et al., 2004; Grise et al., 2004; Plante et al., 2007; Sakr et al., 2009]. The durability of clinical effects beyond 1 year seems poor. One trial with a mean follow-up of 3 years showed a retreatment rate of 41% [Goya et al., 2004].

2. BoNT-A

BoNT-A investigation for the treatment of benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH) started in 2003 [Maria et al., 2003] after the experimental study by Doggweiler et al. [1998] demonstrating prostatic atrophy in the rat after intraprostatic injection of the neurotoxin. In an exploratory study, which involved injection of 200 U of onabotA in moderate to large prostate glands, a rapid prostate volume decrease was induced and still present at 12 months [Maria et al., 2003]. Following this study, Kuo [2005] reported similar findings when injecting prostate glands of 50 ml or larger. BoNT-A injection in smaller prostate glands caused a much lesser reduction in prostate volume, but a 15% reduction was still observed [Chuang et al., 2005; Chuang et al., 2006c). Independent of the extent of prostate volume reduction, improvement of LUTS and flow were consistently reported [Maria et al., 2003; Kuo, 2005; Chuang et al., 2005; Chuang et al., 2006c], while a decrease in total serum PSA were observed only in some studies [Maria et al., 2003; Guercini et al., 2005]. In a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of BPH, Crawford and coworkers concluded that intraprostatic injection of 100 or 300 units of onabotA passed predetermined criteria for treatment efficacy and safety (30% improvement from baseline to 3 months in American Urological Association symptom index and/or maximum urinary flow rate and safety). The ideal dose was not found, but it seemed that 100 unit dose may be preferable due to similar efficacy with reduced costs and adverse effects [Crawford et al., 2011]. Some serious adverse events were reported, including 3 cases of urosepsis related to the onabotA injection. Other minor adverse events reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford ED et al., 2011].

Silva et al. [2008], selected a particular group of patients with high co-morbidity in which more invasive treatments were contraindicated. Intraprostatic BoNT-A injection was carried out transrectally, under ultrasound guidance. Twenty-one men with large BPE, 70±10 ml, on chronic indwelling catheter for at least 3 mo who were not candidates for surgery because of poor general condition received 200 U BoNT-A in the transition zone. Baseline prostate volume of decreased to 57±10 ml at 1mo and to 47±7ml at 3 months. At 1 month, 16 patients (76%) could resume voiding with a mean Qmax of 9.0±1.2 ml/s. At 3 months, 17 patients (81%) voided with a mean Qmax of 10.3±1.4 ml/s. Residual urine was not significant and mean serum total PSA showed a slight decrease [Silva et al. 2008]. The analysis of 11 patients of the initial cohort showed that the duration of prostate atrophy after the single injection of 200U of BoNT-A was found to be about 18 months [Silva et al., 2009b].

Intraprostatic injection of BoNT/A seems devoid of sexual adverse events. Sixteen sexually active men aged > 60 years with BPH/benign prostatic enlargement (BPE) refractory to standard medical therapy received 200U of BoNT/A by transrectal route. Erectile function was evaluated using the International Index of Erectile Function – Short Form (IIEF-5) questionnaire. Orgasmic/ejaculatory function and libido were evaluated using questions 9, 10, 11 and 12 of the IIEF – Long Form. Intraprostatic injection of BoNT-A did not cause deterioration of any domain of sexual function [Silva et al., 2011].

Although necrosis of the gland at the places of BoNT-A injection could explain the rapid volume reduction, transrectal ultrasound examination of the glands, performed in these or in previous studies [Maria et al., 2003; Kuo , 2005; Chuang et al., 2005; Silva et al., 2008, was unable to detect signs of cavitation that indirectly could suggest the presence of necrosis. Therefore, the reason for the decreased prostate volume should be more appropriately related to the widespread apoptosis detected in the gland after BoNT-A administration. Apoptosis was reported in rats, dogs, and humans, and affected both the epithelial and stromal components [Doggweiler et al., 1998; Chuang et al., 2005; Chuang et al., 2006b; Chuang et al., 2006d, Silva et al., 2009a].

Although until now, no important side-effects have been reported after intraprostatic injection of the neurotoxin in doses ranging between 100 and 300 U, a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of benign prostatic hyperplasia, was recently published [Crawford et al., 2011]. onabotA prostatic injection met the two safety criteria proposed, (a dose failed if: 1- a life threatening, disabling or fatal event was determined to be related to the onabotA injection, or 2- 40% or more of the participants reported a moderate or severe side effect related to the botulinum toxin injection). Nonetheless, some serious AEs were reported, including 3 cases of urosepsis related to the onabotA injection and the remaining events were judged not related to the injection. Other minor AEs reported were urinary tract infection,

pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford et al., 2011].

3. NX-1207

NX-1207 is a new drug under investigation for the treatment of LUTS associated with BPH. It is a new therapeutic protein of proprietary composition with selective pro-apoptotic properties [Shore , 2011]. The drug is injected directly into the directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to non-regressive prostate shrinkage and both short- and long-term symptomatic improvement. Information about the drugs is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two US Phase II trials have been performed [Shore , 2011]. One of them was a multicenter, randomized, non-inferiority study involving 32 clinical sites with 85 subjects and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Subjects and investigators on NX-1207 were double-blind as to dosage. The primary endpoint was change in AUASI at 90 and 180 days for a single injection of NX-1207 as compared to finasteride on a non-inferiority basis. Inclusion criteria included an AUA Symptom Score ‡ 15, diminished peak urine flow (< 15 ml/s) and a prostate size of > 30 and < 70 mg. The mean AUA Symptom Score improvement after 90 days in the intent to- treat group was 9.71 points for 2.5 mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24) (p = 0.001) and 4.29 for 0.125 mg NX-1207 (n = 7) (p = 0.034). The 180-day results also were positive (NX-1207 2.5 mg non-inferior to open-label finasteride).

No significant changes in serum testosterone or serum PSA levels in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two US multicenter, double-blind, placebo-controlled Phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

4. PRX302

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by prostate-specific antigen (PSA) [Sing et al., 2007]. The safety and efficacy of PRX302 was evaluated in men with moderate to severe BPH [Denmeade et al.,2010]. The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS >12, a quality of life (QoL) score >3, and prostate volumes between 30 and 80 g. Fifteen patients were enrolled in phase 1 studies, and 18 patients entered phase 2 studies. Subjects received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase 1 subjects received increasing concentrations of PRX302 at a fixed volume; phase 2 subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax), IIEF, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase 1 study and 64% of men in the phase 2 study treated with PRX302 had >30% improvement compared to baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving >1 ml of PRX302 per deposit had the best response overall. There were no deleterious effect on erectile function. Adverse eventswere mild to-moderate and transient in nature. The major study limitation was the small sample size.The promising safety profile and evidence of efficacy in the majority of treated subjects in these phase 1 and 2 studies supports further development of PRX302 as a minimally invasive, targeted treatment for BPH. However, no further studies, verifying the initial data, seem to have been published.

e) Cannabinoids

There is increasing evidence that cannabinoids can influence micturition in animals as well as in humans, both normally and in bladder dysfunction [Ruggieri, 2011]. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. However, additional receptor subtypes cannot be excluded [Pertwee et al., 2010; Ruggieri 2011]. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant [Pertwee et al., 2010; Ruggieri, 2012] (**figure 17**). CBI as well as CB2 receptors have been identified in all layers of the human bladder [Merriam et al., 2008; Gratzke et al., 2009; Tyagi et al., 2009; Walczak et al., 2009]; their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB1 was higher than that of CB2 [Tyagi et al., 2009]. Gratzke et al. [2009] found higher expression of CB2 receptors, but not CB1 receptors, in the mucosa than in the detrusor. Compared to the detrusor, larger amounts of CB2receptor containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB2 receptors and VAChT (cholinergic neurons) were located in the detrusor. In general, activation of CB1 peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB2 appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions [Pertwee et al., 2010; Ruggieri, 2011]. Several animal studies have suggested a modulatory role of CB2 receptors in both afferent signalling and cholinergic nerve activity [Gratzke et al., 2009; 2010; 2011]. Thus, in vivo the selective CB2 receptor agonist, cannabinor, increased micturition intervals and volumes, and

increased threshold and flow pressures, suggesting that peripheral CB2 receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabinor, bladder weight was lower, the ability to empty the bladder was preserved and nonvoiding contraction frequency was low compared to those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids, is fatty acid amide hydrolase (FAAH, **Figure 18**). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB2 receptors. In rats, a FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechanoafferent functions [Strittmatter et al., 2011].

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminay report Blywert et al. [2003] demonstrated an effect of combined CB1/CB2 receptor activation on detrusor overactivity in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

The clinical experiences the cannabinoid treatment of micturition disturbances inclung LUTS are limited [Ruggieri, 2011], but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic overactive bladder (OAB) symptoms refractory to first-line treatment [Brady et al., 2004; Freeman et al., 2006; Kavia et al., 2010]. Brady et al. [2004] evaluated the efficacy of 2 whole plant extracts (δ9-tetrahydrocannabinol and cannabidiol) of Cannabis sativa in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency and nocturia decreased significantly following treatment. Freeman et al. [2006] tested in a subanalysis of a multicenter trial (the CAMS study) whether cannabinoids could decrease urge incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral administration of the cannabis extract δ9-tetrahydrocannabinol or matched placebo. Based on incontinence diaries a significant decrease in incontinence episodes was demonstrated.

Kavia et al. [2010] assessed the efficacy, tolerability and safety of Sativex(®) (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and overactive bladder (OAB). The primary endpoint, reduction in daily number of urinary incontinence episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four out of seven secondary endpoints were significantly in favour of Sativex, including number of episodes of nocturia, number of voids/day, and number of daytime voids. The improvement in I-QOL was in favour of Sativex, but did not reach statistical significance.

Systemic cannabinoids have effects on the lower urinary tract that may have a therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT

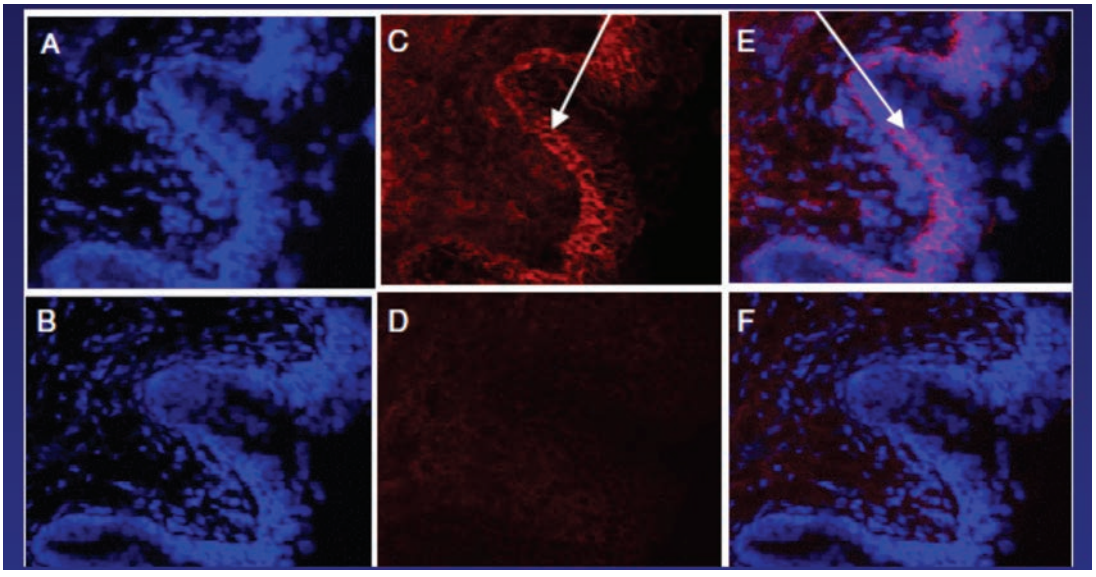

Figure 17 : CB2 receptors in the urothelium/lamina propria. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant.

is incompletely known, and further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders.

2. CENTRALLY ACTING DRUGS

Many parts of the brain seem to be activated during storage and voiding [see, Griffiths 2007; Fowler et al., 2008; Griffiths and Tadic, 2008], and there is increasing interest in drugs modulating the micturition reflex by a central action [Andersson and Pehrson, 2003]. Several drugs used for pain treatment also affect micturition; morphine and some antiepileptic drugs being a few examples (**Figure 19**). However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, since selective actions may be difficult to obtain. Holstege [2005], reviewing some of the central mechnisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC), suggested that "the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level."

a) Gonadotropin-releasing hormone antagonists

The beneficial effects of the 5α-reductase inhibitors, finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as luteinizing hormone-releasing hormone: LHRH) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density following long-term androgen ablation [Schroeder et al., 1986; Peters et al., 1987; Bosch et al., 1989; Eri and Tveter, 1993]. With GnRH antagonists submaximal, non-castrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus avoiding medical castration. Several GnRH antagonists – such as cetrorelix, ozarelix and teverelix - have been tested in Phase IIA/IIB clinical trials for their ability to improve LUTS in patients with BPH [Colli and Tanko, 2011].

Debruyne et al. [2008] demonstrated in a phase 2 RCT that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS > 13, peak urinary flow rates 5-13 ml/s), rapidly caused a significant improvement in the mean IPSS: the peak decrease was -5.4 to -5,9 vs -2,8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment of male LUTS.

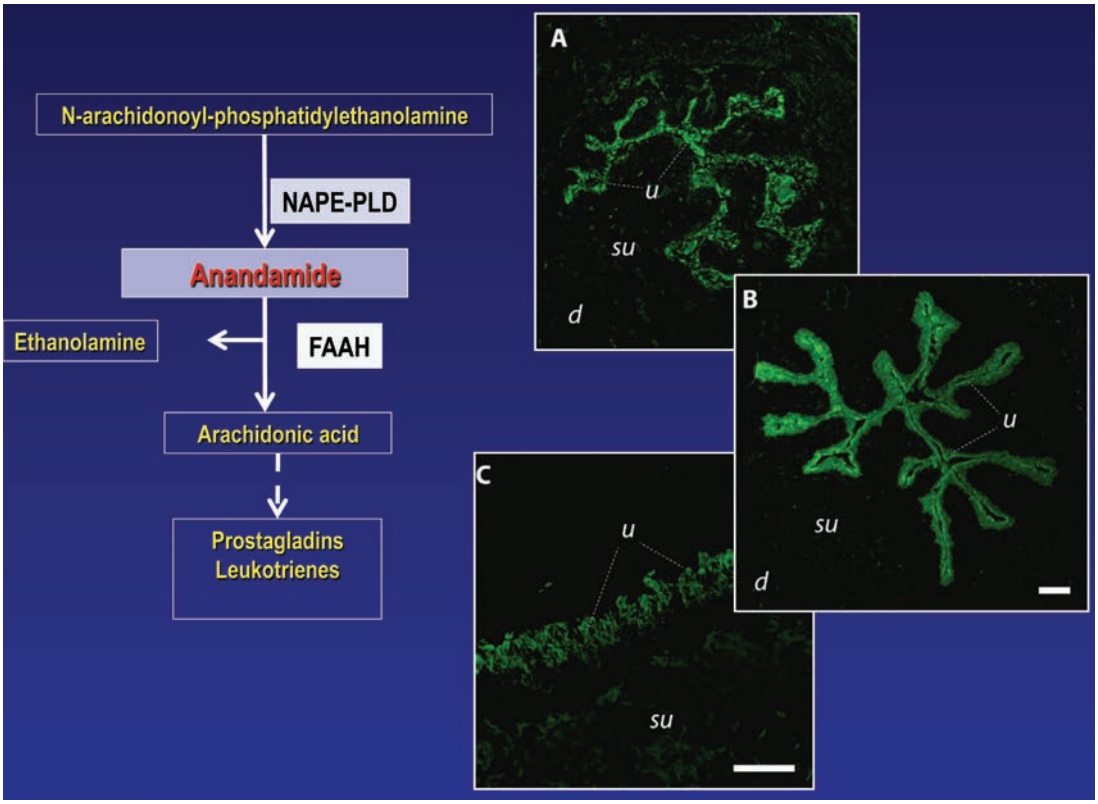

Figure 18: Metabolism of and distribution of fatty acid amide hydrolase (FAAH; cannabinoid degrading enzyme) immunoreactivity in the rat urothelium

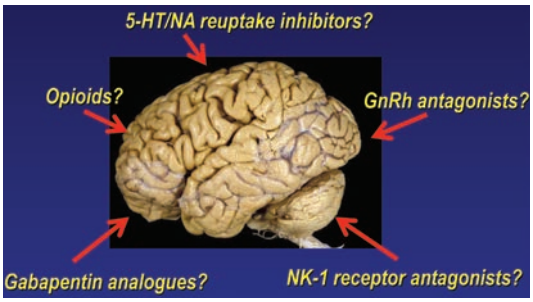

Figure 19 : OAB drugs with a central mode of action. Several principles seem to work, but currently used drugs have low efficacy and/or unacceptable side effects. However, there is great potential for further developments

Due to these results, two phase III studies were conducted in the United States and Europe [AEterna Zentaris] ; in the US study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

b) Gabapentin

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders [Striano and Striano 2008]. It was originally designed as an anticonvulsant GABA (y-aminobutyric acid) mimetic capable of crossing the blood-brain barrier [Maneuf et al., 2003]. The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial [Maneuf et al., 2003]. It has been suggested that it acts by binding to a subunit of the α2δ unit of voltage dependent calcium channels [Gee et al., 1996; Striano and Striano, 2008]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone et al. [2006] reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters, and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-neurogenic DO. Kim et al. [2004] studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 out of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other α2δ ligands (e.g., pregabalin and analogs) will offer new therapeutic alternatives, but convincing RTC are still lacking.

c) Tramadol

Tramadol is a well-known analgesic drug [Grond and Sablotzski, 2004]. By itself, it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [Grond and Sablotzski, 2004]. This profile is of particular interest, since both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placobo controlled study with duloxetine [Steers et al., 2008].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [Pehrson et al., 2003]. Tramadol also inhibited DO induced by apomorphine in rats [Pehrson and Andersson, 2003] – a crude model of bladder dysfunction in Parkinson´s disease. Singh et al. [2008] gave tramadol epidurally and found the drug to increase bladder capacity and compliance, and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini [2006] evaluated in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 h for 12 weeks. Clinical evaluation was performed at baseline and every two weeks during treatment. Tramadol significantly ($p<001$) reduced the number of incontinence periods per 24 hours from 3.2+/- 3.3 to 1.6+/-2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. Even if tramadol may not be the best suitable drug for treatment of LUTS/OAB, the study suggests efficacy for modulation of micturition via the μ-receptor.

d) NK1-receptor antagonists

The main endogenous tachykinins, substance P (SP), neurokinin A (NKA) and neurokinin B (NKB), and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control [Lecci and Maggi, 2001; Saffroy et al., 2003; Covenas et al., 2003]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated [Ishizuka et al., 1994] in normal, and more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced detrusor overactivity was reduced by blocking NK1

receptor-expressing neurons in the spinal cord, using intrathecally administered substance P-saponin conjugate [Seki et al., 2002]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 1995a].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses, and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction [Gu et al., 2000]. Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 2000]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [Massaro and Lenz, 2005], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), as shown in a well designed pilot RCT [Green et al., 2006]. The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes, and urgency episodes. Aprepitant significantly ($p<0.003$) decreased the average daily number of micturitions (-1.3+/-1.9) compared with placebo (-0.4+/-1.7) at 8 weeks. The average daily number of urgency episodes was also significantly ($p<0.047$) reduced (-23.2+/- 32%) compared to placebo (-9.3+/-40%), and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. Since this initial proof of concept study suggested that NK-1 receptor antagonism hold promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with overactive bladder (8 or more average daily micturitions and 1 or more daily urge incontinence episodes) [Frenkl et al., 2010]. After a 1-week placebo run-in the patients were randomized to treatment with 8 weeks of daily 0.25, 1 or 4 mg serlopitant, 4 mg tolterodine extended release or placebo. Patients kept 7-day voiding diaries. The primary end point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urge incontinence episodes and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change from baseline in daily micturitions was significantly greater for 0.25 (-1.1) and 4 mg (-1.1) serlopitant, and for tolterodine (-1.5) than for placebo (-0.5), but not for 1 mg serlopitant (-0.8). No serlopitant dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopitant (3.3%) was comparable to placebo (4.6%) and lower than tolterodine (8.8%). Serlopitant was generally well tolerated.

NK-1 receptor antagonists may have a role in the treatment of overactive bladder but at least the componds tested so far does not offer advantages in efficacy compared to tolterodine.

A different approach, modulation of neuropeptide release rather than NK receptor blockade, was tested in a pilot study with cizolirtine, which is a substance-P and CGRP release modulator at the spinal cord level. The modulation of substance-P and CGRP is probably related to the increase of extracellular levels of noradrenaline and serotonin. Cizolirtine 200 and 400 mg were compared to placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 68% and 81% of the patients on cizorlitine 200 and 400mg. More commonly reported side effects were gastro-intestinal in nature, including dry mouth and vomiting [Martınez-Garcıa et al., 2008]. No further developments of this compound have been reported.

C. Drugs used for treatment of stress incontinence in women

Many factors seem to be involved in the pathogenesis of stress urinary incontinence (SUI) in women: urethral support and function, bladder neck support and function of the nerves and musculature of the bladder, urethra, and pelvic floor [Delancey, 1997; Mostwin et al, 2005, Koelbl, Nitti et al, 2009; Chapple and Milsom, 2012]. Pure structural factors cannot be treated pharmacologically. However, SUI in women is generally thought to be characterized by decreases in urethral transmission pressure and, in most cases, resting urethral closure pressure [Henriksson et al, 1979; Hilton et al, 1983, Koelbl and Nitti, 2009]. It, therefore, seems logical that increasing urethral pressure should improve the condition.

Factors which may contribute to urethral closure include the tone of the urethral smooth and striated muscle (the rhabdosphincter) and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacological evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released noradrenaline [Andersson, 1993; Andersson and Wein, 2004; Andersson and Wein, 2012]. A contributing factor to SUI, mainly in elderly

women with lack of estrogen, may be lack of mucosal function. The pharmacological treatment of SUI (**Table 3**) aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated musculature, either directly or through increased motorneuron activity. Several drugs may contribute to such an increase [Andersson and Wein, 2012], but relative lack of efficacy or/and side effects have limited their clinical use.

I. α-ADRENOCEPTOR AGONISTS

Several drugs with agonistic effects on peripheral α-ARs have been used in the treatment of SUI. Relatively recently, a central role of noradrenaline (NA) in increasing the excitability of urethral rhabdosphincter motorneurons in the rat analogue of Onuf's nucleus, an effect due at least in part to α1-AR receptor dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI [Yashiro et al, 2010]. Ephedrine and norephedrine (phenylpropanolamine; PPA) seem to have been the most widely used [Andersson and Wein, 2012]. The original United States Agency for Healthcare Policy and Research Guidelines [Agency for Healthcare Policy and Research, 1992] reported 8 randomized controlled trials with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in continence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3% respectively. The most recent Cochrane review on the subject [Alhasso et al, 2005, reprinted virtually unchanged in 2008] assessed randomized or quasi-randomized controlled trials in adults with stress urinary incontinence which included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, eskornade in 1 and RO 115-1240 in 1). The authors concluded, "there was weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of pad changes and incontinence episodes, as well as, improving subjective symptoms". There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to adrenergic stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson and Wein, 2012]. Kernan et al. [2000] reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some [Bent et al., 2003) had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the Food and Drug Administration of the US decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate α1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects [Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998].

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman et al. [2004] reported on a phase 2 randomized crossover study with RO 115-1240, a peripheral active selective α1A/1L-AR partial agonist [Blue et al., 2004] in 37 women with mild to moderate SUI. A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-3774076, a CNS penetrating partial α1A-AR agonist, increased peak urethral pressure in dogs and was selective with respect to α1B and α1D receptors,

Table 3. Drugs used in the treatment of stress incontinence. Assessments according to the Oxford system (modified)

Drug	*Level of evidence*	*Grade of recommendation*
Clenbuterol	***3***	***C***
Duloxetine	***1***	***B***

Methoxamine	***2***	***D***
Midodrine	***2***	***C***
Norephedrine (phenylpropanolamine)	***3***	***D***

but heart rate and blood pressure changes caused significant concern (Conlon et al., 2009). Furuta et al. [2009] reported that the α2-AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that α2-AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing.

II. β-ADRENOCEPTOR AGONISTS

Clenbuterol. β-AR stimulation is generally conceded to decrease urethral pressure [Andersson, 1993], but β2-AR agonists have been reported to increase the contractility of some fast contracting striated muscle fibers and suppress that of slow contracting fibers of others [Fellenius et al.,1980]. Some β-AR agonists also stimulate skeletal muscle hypertrophy – in fast twitch more so than slow twitch fibers [Kim et al., 1992]. Clenbuterol has been reported to potentiate the field stimulation induced contraction in rabbit isolated peri-urethral muscle preparations, an action which is suppressed by propanolol and greater than that produced by isoprotererol [Kishimoto et al, 1991]. These authors were the first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yaminishi et al. [1994] reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β-AR blockade.

Yasuda et al. [1993] described the results of a double blind placebo controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from 11.7± 17.9g to 6.0± 12.3g for drug and from 18.3± 29.0g to 12.6± 24.7g for placebo, raising questions about the comparability of the 2 groups. The “significant” increase in MUCP was from 46.0± 18.2 cm H2O to 49.3± 19.1 cm H2O, versus a change of -1.5 cm H2O in the placebo group. 56/77 patients in the clenbuterol group reported some degree of improvement versus 48/88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko et al. [2000] investigated the effects of Clenbuterol on 61 female patients with stress incontinence in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of stress incontinence and the patient’s own impression were used as the basis for the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al [1997] reported positive results with clenbuterol (20 mg b.i.d. for 1 month) in 9 of 14 patients with mild to moderate stress incontinence after radical prostatectomy. No subsequent published reports have appeared. Further well-designed RTCs investigating effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

There have been no recent reports of clinical trials with α1- or β-AR agonists or antagonists for SUI.

III. β –ADRENOCEPTOR ANTAGONISTS

The theoretical basis for the use of β-AR antagonists in the treatment of stress incontinence is that blockade of urethral β-ARs may enhance the effects of noradenaline on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence [Gleason et al., 1974; Kaisary, 1984] but there are no RCTs supporting such an action. In the Gleason et al. [1974] study, the beneficial effects become manifest only after 4 to 10 weeks of treatment, a difficult to explain phenomenon. Donker and Van der Sluis [1976] reported that β-AR blockade did not change UPP in normal women. Although suggested as an alternative to α-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

IV. SEROTONIN-NORADRENALINE UPTAKE INHIBITORS

1. IMIPRAMINE

Imipramine, among several other pharmacological effects has classically been reported to inhibit the reuptake of noradrenaline and serotonin in adrenergic nerve endings. In the urethra this could be expected to enhance the contractile effects of noradrenaline on urethral smooth muscle. Gilja et al. [1984] reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean maximal urethral closure pressure (MUCP) from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin et al. [1999] assessed the efficacy of imipramine (25 mg imipramine three times a day for three months) as a treatment of genuine stress incontinence in 40 women with genuine stress incontinence. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of “successful treatment” was 60% (95% CI 11.8-75.2). There are no RCTs on the effects of imipramine on SUI. No subsequent published reports have appeared.

Interestingly, Gillman [2007] reported that clomipramine had far greater 5HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with less effects than imipramine on 5HT uptake (desipramine superior).

2. DULOXETINE

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been

shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser et al., 2003]. The sphincteric effects were reversed by α1 adrenergic (praxosin) and 5HT2 serotonergic (LY 53857) antagonism, while the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the synaptic cleft [Fraser et al., 2003]. Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 h [Sharma et al., 2000].

Thor et al. [2007] described the mechanisms of action and the physiologic effects of duloxetine. 5HT (serotonin) and NA terminals are dense in spinal areas associated with lower urinary tract functioning especially around the pudendal nerve neurons in Onuf's nucleus. These are projections from separate areas in the brain stem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in Onuf's nucleus causing contraction of the urethral rhabdosphincter (**Figure 20**). The rhabdosphincter innervation is proposed as distinct from that of the levator ani [Thor and de Groat, 2010]. The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5HT (through 5HT2 receptors) and NA (through α1 -ARs). 5HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and the rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for 5HT1A (indirect through a supraspinal stimulation), TRH, Vasopressin, NMDA and AMPA; inhibitory effects are similarly mediated by κ2 opioid, α1 ARs, GABA-A, GABA-B and glycine receptors [Thor and de Groat, 2010]. Some CNS penetrant selective 5HT2C agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the treatment of SUI [Brennan et al., 2009, Andrews et al., 2011].

Sevral RTCs have documented the effect of duloxetine i SUI [Norton et al., 2002; Dmochowski et al, 2003; Millard et al., 2004]. A Cochrane review of the effects of duloxetine for stress urinary incontinence in women is available, the last substantive amendment listed as 25 May 2005 [Mariappan et al., 2005]. Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to 1 or 2 of the primary references. An additional analysis "performed under the auspices of the Cochrane Incontinence Group" was performed on just the 9 primary trials comparing duloxetine and placebo, and published separately [Mariappan et al., 2007]. The results can be summarized as follows. Subjective "cure" in the duloxetine 80 mg daily (40 mg b.i.d.) was higher than in the placebo group (10.8%

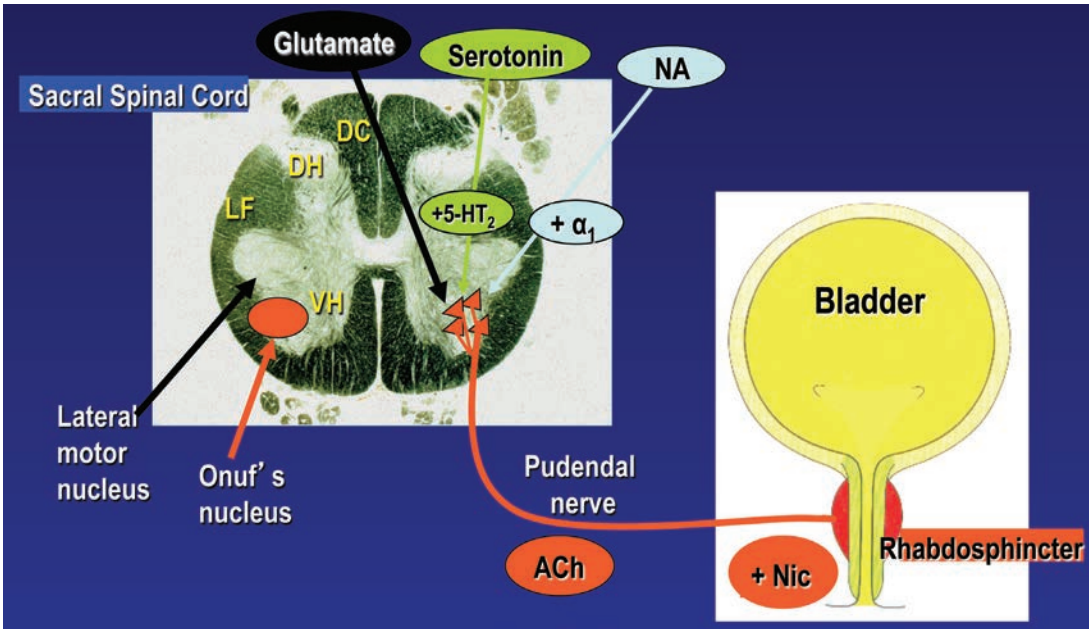

Figure 20: The striated urethral sphincter is innervated by the pudendal nerve, which contains the axons of motor neurons whose cell bodies are located in Onuf's nucleus. Glutamate exerts a tonic excitatory effects on these motor neurons, and this effect is enhanced by noradrenaline (NA) and serotonin (5-HT), acting on α1- adrenoceptors and 5-HT2-receptors, respectively. By inhibition of the reuptake of noradrenaline and serotonin, duloxetine increases the contractile activity in the striated sphincter (nicotinic receptors: + Nic). DC = dorsal commissure; DH = dorsal horn; VH = ventral horn; LF = lateral funiculus; ACh = acetylcholine

vs 7.7%, overall RR = 1.42; 95% CI, 1.02-1.98; p = 0.04). The estimated absolute size of effect was about 3 more patients cured of every 100 treated. Objective cure data, available from only 1 trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in I-QOL (WMD for 80 mg: 4.5; 95% CI 2.83-6.18, p<0.00001). Adverse effects in 6 trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event and the incidence ranged from 23-25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness and insomnia, overall RR 1.30 (95% CI, 1.23-1.37). Across these 6 trials 17% in the drug group withdrew, 4% in the placebo arm. In the 2007 article, the authors conclude by saying that further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared to other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that "longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications".

Hurley et al. [2006] characterized the safety of duloxetine for treatment of SUI in women, using an integrated database generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (N=958) or placebo (N=955), examining adverse events (AEs), serious adverse events (SAEs), vital signs, electrocardiograms, and laboratory analytes. AEs occurring initially or worsening during the double-blind treatment period were considered treatment-emergent (TEAE). Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common TEAEs included: nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most TEAEs that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall AE discontinuation rates were 20.5% for duloxetine and 3.9% for placebo (P<.001). Most discontinuations (83%) occurred within the first month of treatment. SAEs were uncommon and did not differ between treatments. Statistically significant, but clinically unimportant mean increases in heart rate (2.4 bpm) and systolic and diastolic blood pressure (<or=2 mmHg) occurred. No arrhythmogenic potential was observed and any rare, transient, asymptomatic increases in hepatocellular enzymes normalized. The authors concluded that duloxetine was safe and tolerable, although transient AEs were not uncommon. Hashim and Abrams [2006] suggested, to reduce the risk of nausea, to begin with a dose of 20 mg twice daily for 2 weeks, then to increase to the recommended 40 mg b.i.d. dosage.

Ghoniem et al. [2005] randomized women with SUI to 1 of 4 treatment combinations: duloxetine alone (40 mg b.i.d.), pelvic floor muscle training, combination and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, while pad results and QOL data favored combination therapy to single treatment. Cardozo et al. [2004] reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett et al. [2006], offered a 4-week course to women awaiting a TVT operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8/33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of AEs, 9 (27%) found the drug ineffective.

Bent et al. [2008], reported on the effects of 12 weeks of duloxetine (40 mg b.i.d.) vs placebo in a large group of women with MUI. For SUI episodes, the mean IEF (incontinence episode frequency) per week decreased 58.9% with drug [7.69 to 3.93] vs 43.3% for placebo [8.93 to 6.05]. Interestingly, corresponding decreased for UUI episodes were 57.7% vs 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute change for SUI amounted to -3.76 episodes per week for drug, -2.87 for placebo. Nausea was reported by 18% of patients on drug, 4.5% on placebo. Corresponding percents for other AEs include, dry mouth (12 vs 2.8), dizziness (9.7 vs 2.4), constipation (8.3 vs 4.2), fatigue (6.7 vs 2.8). Nausea and dizziness were less common in a subgroup taking concurrent antidepressants. Women 65 years and older with SUI or stress predominant MUI (S-MUI) were given duloxetine (40 mg b.i.d. after a 2-week start on 20 mg b.i.d.) or placebo for 12 weeks by van Leeuwen et al [2008]. They conclude, "this study supports the use of duloxetine in elderly women with SUI or S-MUI". The data show an absolute change in SUI + S-MUI episodes of -11.7 and -6.9 IEF/week (drug and placebo) and median percent changes of -52.5% vs -36.7% from 24h diaries, both significant at p<0.001. However, the changes for SUI alone were -53% vs -42% (NS) while for S-MUI alone they were -51.6% vs -32.7% (p<0.001). Nausea was less than in other trials (7.5% vs 3.1%), perhaps due to the lower starting dose. Other AEs included fatigue (14.2% vs 5.4), constipation (10.4 vs 0.8), dizziness (9.0 vs 4.6), excess sweating (5.2 vs 0).

Schagen van Leeuwen et al. [2008] investigated efficacy and safety of duloxetine in elderly women with stress urinary incontinence or stress-predominant mixed urinary incontinence. Duloxetine-treated patients had a significantly greater decrease from baseline to endpoint in mean incontinence episode frequency/week than placebo-treated patients (-52.47% vs. -36.70%). The

responder rate (> or =50% reduction in incontinence episode frequency/week) was 57.1% in the duloxetine group and 35.2% in the placebo group (P<0.001). Significant benefits of duloxetine were also demonstrated for weekly continence pad usage, mean time between voids, incontinence quality of life questionnaire scores (P<0.001), and global impression of improvement ratings (P<0.001). Patients with depressive symptoms and cognitive impairments were few and changes were insignificant.

Persistence on duloxetine was studied by Vella et al. [2008] who found that only 31% of an original cohort of 228 were still taking drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, 33% to lack of efficacy, Bump et al. [2008], however, reported that the positive effects of duloxetine were maintained in patients who continued treatment up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months Shaban et al. [2010] concluded that duloxetine is “optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE guidelines in the UK”. Similar sentiments are expressed by Robinson and Cardozo [2010].

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union [European Medicines Agency, Scientific Discussion, 2005] in women with moderate to severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI, but is approved for the treatment of major depressive disorder (20-30 mg b.i.d. initially, 60 mg once daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily, fibromyalgia (c0 mg once daily initially, 60b mg once daily maintenance) and chronic musculoskeletal pain (30 mg once daily initially,60 mg once daily as maintenance. The product information contains a “black box” warning of “increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders”, noting also that “depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide” [Prescribing Information, revised September 2011, Eli Lilly and Company, Indianapolis, Indiana 46285]. Other warnings and precautions in the U.S. in the United States Product Information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding SSRIs and SNRIs), abrupt discontinuation (may result in dizziness, paresthesias, irritability and headache), inhibitors of CYP1A2 (such as ciprofloxacin), thioridaxine (do not administer concomitantly) potent inhibitors of CYP2D6 (may increase concentration), and others. Adverse events for 6801 drug and 4487 placebo treated patients reported in the US Product Information (treatment for the indications mentioned) are nausea (24% vs 8%), dry mouth (13 vs 5), fatigue (10 vs 5), somnolence (10 vs 3), insomnia (10 vs 6), constipation (10 vs 4), dizziness (10 vs 5).

D. Stress urinary incontinence in men

Although a problem of significant magnitude, especially after radical prostatectomy (RP) for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention.

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by radical prostatectomy. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle and extrinsic paraurethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra [Koelbl, Nitti et al, 2009]. Tsakiris et al [2008] searched for articles on drug treatment of male SUI published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using alpha adrenergic agonists, beta-2 antagonists or SNRSs. Only one of these included a comparison arm [Filocamo et al, 2007], 40 mg b.i.d. duloxetine plus pelvic floor exercise (PFE) vs PFE with placebo. The results suggested a positive effect of drug, but were a bit confusing. Of those patients completing the 4 month trial [92/112] 78% of the drug treated patients vs 52% of those in the placebo group were “dry”. However, one month after the end of the study, the corresponding figures were 46% vs 73%, a shift still observed 2 months later. The authors of the review article suggested further larger and well designed studies on duloxetine for this potential usage.

Cornu et al. [2011] reported a series of post RP men with SUI or MUI (stress predominant) randomized to duloxetine [l5] and placebo [16] after a 2-week placebo run in. Dosage was 20 mg b.i.d. for 7d, 40 mg b.i.d. for 67d, 20 mg for 14d. Subjects were at least 1 year post surgery. Outcome measures included percent decrease in IEF, 1h pad test and various QOL measures. Statistical significance for IEF percent decrease occurred only at week 8 & 12 [(-) 52.2 ± 38.6% vs (+)19 ± 43.5%] but there was clearly a trend at 4 weeks. There was no statistical difference in 1h pad test weights but there was in various QOL scores. A 50-100% decrease in IEF was seen at 12

weeks in over half of the patients. Adverse events for drug and placebo included fatigue (50 vs 13%), insomnia (25 vs 7), libido loss (19 vs 7), constipation (13 vs 7), nausea (13 vs 7), diarrhea (13 vs 7), dry mouth (6 vs 0), anorexia (6 vs 0), and sweating (25 vs 20). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QOL. There were 4 men with MUI in the drug group, 5 in the placebo group. Results for SUI and UUI were not separated. One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy or neuromuscular function. In an uncontrolled usage study on men with post RP SUI, Serra et al [2011] reported that the benefit remained in 85% after the drug was stopped. In that series, 25% of patients withdrew because of AEs and 33% because of lack of effect.

Usage of duloxetine for SUI in the male is universally off label. A drug for this indication would be welcome. Larger controlled and better designed studies are necessary to provide conclusive positive or negative data on this subject.

E. Drugs to treat overflow incontinence/acute urinary retention

Urinary incontinence most often results from involuntary bladder contractions and/or too little resistance generated by the bladder outflow tract during the storage phase of the micturition cycle (urgency incontinence and stress incontinence, respectively). More rarely, incontinence can also occur because of too little pressure generation and/or too much outflow resistance, which can lead to a markedly distended bladder and urinary retention and, secondarily, overflow incontinence [Abrams et al., 2002].

Based upon theoretical reasoning, animal studies [Kamo et al., 2005; Gu et al., 2004], and reports of drugs that can cause overflow incontinence [Anders et al., 1985], a variety of medical approaches to the treatment of overflow incontinence have been proposed [Chutka and Takahashi, 1998; Diokno AC, 2004; Hampel et al., 2005]. Treatment may aim to increase bladder contractility, decrease bladder outlet resistance, or both. Theoretically, all drugs that improve decreased sensation (and increase afferent activity) or drugs that increase detrusor contractile force could be useful. Alternatively, agents that decrease outflow resistance, thereby restoring an appropriate balance between detrusor strength and urethral resistance, could be used.

These drugs include direct or indirect muscarinic receptor agonists, α1-AR antagonists, choline esterase inhibitors, prostaglandins (PG), and skeletal muscle relaxants [Diokno AC, 2004]. The use of muscarinic receptor agonists, such as bethanechol, to stimulate detrusor muscarinic receptors, or choline esterase inhibitors, such as distigmine, to reduce the degradation of acetylcholine, is based upon the idea that stimulation of muscarinic receptors may overcome a hypocontractile detrusor [Barendrecht et al., 2007]. However, a recent systematic review of controlled clinical studies that used direct and indirect parasympathetic agonists in patients with an underactive detrusor reported that these drugs do not provide consistent benefits and may even be harmful. The available information indicates that muscarinic receptor agonists and choline esterase inhibitors have little, if any, beneficial effects on preventing and treating detrusor underactivity. While there is a theoretical basis for the use of β-agonists to relax the sphincter, no definite improvements in symptoms have yet been demonstrated [Riedl et al., 2000; Dasgupta et al., 2003; Barendrecht et al., 2007; Ahmad et al. 2009]. As bethanechol exerts its effect on intact smooth muscle cells only, it is of limited use for the treatment of bladder atony. Idiopathic detrusor atony is poorly responsive to medical treatment [Noel et al. 2010].

The use of α1-AR antagonists has repeatedly been shown to be beneficial in patients with acute urinary retention due to benign prostatic enlargement[McNeill et al., 2004; 2005; Fitzpatrick et al., 2012]. These drugs are believed to facilitate bladder emptying by relaxing tone at the bladder neck. Administration of alfuzosin 10 mg daily almost doubles the likelihood of a successful trial without a catheter, even in patients who are elderly with a PVR > 100 mL. Continued use of alfuzosin significantly reduced the risk of BPH surgery in the first 3 months; however, this effect was not significant after 6 months [Fitzpatrick and Kirby, 2006; Emberton et al., 2008; Kalejaiye et al., 2009]. Thus, α1-AR antagonists provide rapid symptom relief from outlet obstruction caused by benign prostatic enlargement and delay the time to acute urinary retention; however, they do not decrease the overall risk of acute urinary retention or surgery [Emberton et al., 2008; Edwards, 2008; Fitzpatrick et al., 2012].

Acute urinary retention may ocur after surgery. Buckley and Lapitan [2010] reviewed drugs used for treatment of post-operative urinary retention either alone or in combination, assessing cholinergic agents, α1-AR blockers, sedatives and prostaglandins. A statistically significant association between intravesically administered prostaglandins and successful voiding was detected, but no such association was found for the other drugs investigated. When cholinergic agents were combined with sedative there was an improved likelyhood of spontaneous voiding compared with placebo.

There are some potential new agents for the treatment of an underactive bladder. Misoprostol, a cholinesterase inhibitor, and cholinergic agents are potential candidates for the treatment of the under-

active bladder, but their safety and lack of benefit is of concern. Novel muscarinic receptor manipulation using the presynaptic M2 receptor antagonist or postsynaptic allosteric receptor enhancement is promising. The prokinetics used in gastroenterology and the smooth muscle ionotropics used in cardiology warrant consideration. The use of trophic factors such as insulin-like growth factor and nerve growth factor may improve muscle and nerve function in the lower urinary tract. Furthermore, the use of stem cells, regenerative medicine, and gene therapy might facilitate improved contractility in a weak detrusor [Chancellor et al., 2008].

However, these agents have never been tested systematically in patients with overflow incontinence; there have been no randomized controlled trials to demonstrate the effectiveness and safety of these agents. Therefore, there is no empirical basis to select medical treatments for overflow incontinence and all previously recommended treatments must be rated as “expert opinion” at best. Better systemic studies are required to determine the best medical treatment for overflow incontinence. Any medical treatment for overflow incontinence should be compared to catherization or surgery.

F. Hormonal treatment of urinary incontinence

I. OESTROGENS

1. OESTROGENS AND THE CONTINENCE MECHANISM

The oestrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intra-vesical pressure at all times except during micturition. The urethra has four oestrogen sensitive functional layers all of which have a role in the maintenance of a positive urethral pressure 1) epithelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of oestrogen receptor, (α and β) have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al., 1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause oestrogen receptor α has been shown to vary depending upon exogenous oestrogen therapy [Fu et al., 2003]. In addition exogenous oestrogens affect the remodeling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that oestrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986].

2. OESTROGENS FOR STRESS URINARY INCONTINENCE

The role of oestrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results but this may have been because they were small observational and not randomised, blinded or controlled. The situation is further complicated by the fact that a number of different types of oestrogen have been used with varying doses, routes of administration and duration of treatment.

Fantl et al.[1996] treated 83 hypo-oestrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine oestrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables had not changed significantly in either group. Jackson et al. [1996] treated 57 post menopausal women with urodynamic stress or mixed incontinence with Oestradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit.

Two meta analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of oestrogens to treat all causes of incontinence in post menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, Maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect.

In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of oestrogen treatment. They also found that oestrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Oestrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence.

Several studies have shown that oestrogen may have a role in combination with other therapies e.g. α-adrenoceptor agonists. However, phenylpropa-

malamine (the most widely used α-adrenoceptor agonist in clinical practice) has now been restricted or banned by the US Food and Drug Administration (FDA).

In a randomised trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and oestriol (1 mg per day) in 66 patients with post menopausal stress urinary incontinence. Efficacy was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with oestriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. Unfortunately this has not been reproduced in other clinical trials.

Thus even prior to the more recently reported secondary analyses of the heart and oestrogens/progestogen replacement study (HERS) [Grady et al., 2001] and women's health initiative (WHI) [Hendrix et al., 2005] it was already recognised that oestrogen therapy had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo 2003].

3. OESTROGENS FOR URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYMPTOMS

Oestrogen has been used to treat post menopausal urgency and urge incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000]. A double blind multi centre study of 64 post menopausal women with "urge syndrome" failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either sensory urgency or detrusor overactivity. They were randomised to treatment with oral oestriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Oestriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another randomised controlled trial from the same group using 25 mg oestradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a high complication rate in the oestradiol treated patients (vaginal bleeding).

Symptoms of an overactive bladder increase in prevalence with increasing age and lower urinary tract symptoms and recurrent urinary tract infections are commonly associated with urogenital atrophy. Whilst the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings and higher serum oestradiol levels [Cardozo et al 1998]. Overall vaginal oestradiol has been found to be the most effective in reducing patient symptoms although conjugated oestrogens produced the most cytological change and the greatest increase in serum oestradiol and oestrone. The most recent meta anlysis of intravaginal oestrogen treatment in the management of urogenital atrophy was reported by the Cochrane group in 2003 [Suckling et al 2003]. Overall 16 trials including 2129 women were included and intravaginal oestrogen was found to be superior to placebo in terms of efficacy although there were no differences between types of formulation. 14 trials compared safety between the different vaginal preparations and found a higher risk of endometrial stimulation with conjugated equine oestrogens as compared to oestradiol.

Thus theoretically there could be a role for combination treatment with an anti muscarinic agent and vaginal oestrogen in post menopausal women. However, the two clinical trials which have been reported to date differ in their outcome. Tseng et al.[2009] showed superior efficacy in terms of symptom improvement for the overactive bladder when Tolterodine was used with vaginal oestrogen cream as opposed to Tolterodine alone. However, Serati et al. [2009] found no difference between Tolterodine with or without topical oestrogen in women with symptomatic detrusor overactivity.

4. EVIDENCE REGARDING OESTROGENS AND INCONTINENCE FROM LARGE CLINICAL TRIALS

The HERS study included 763 post menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of oestrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated oestrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo group worsened compared with 39% of the hormone group (P=0.001). This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinence episodes per week increased an

average of 0.7 in the hormone group and decreased by 0.1 in the placebo group ($p< 0.001$). The authors concluded that daily oral oestrogen plus progestogen therapy was associated with worsening urinary incontinence in older post menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women's Health Initiative (WHI) was a multi centre double blind placebo controlled randomised clinical trial of menopausal hormone therapy in 27347 postmenopausal women age 50-79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year [Hendrix et al., 2005]. The women were randomised based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine oestrogen (CEE) plus 2.5 mg per day of medroxyprogesterone Acetate (CEE+MPA), whereas those who had undergone hysterectomy received oestrogen alone (CEE). At one year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% continence interval) CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urge urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.49; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus based on this secondary analysis of data from a huge study conjugated equine oestrogen alone or in combination with Medroxyprogesterone Acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996 39436 post menopausal women aged 50-75 years was reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased amongst post menopausal women taking hormones compared to women who had never taken hormones (oral oestrogen: RR1.54 95% CI 1.44, 1.65; transdermal oestrogen: RR1.68, 95% CI 1.41, 2.00; oral oestrogen with progestin: RR1.34, 95% CI 1.24, 1.44; transdermal oestrogen with progestin: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta analysis of the effect of oestrogen therapy on the lower urinary tract has been performed by the Cochrane Group [Cody et al., 2009] and is notable as the conclusions are starkly different from those drawn from the previous review [Moehrer et al., 2003]. Overall 33 trials were identified including 19313 incontinent women (1262 involved in trials of local administration) of which 9417 received oestrogen therapy.

Systemic administration (of unopposed oral oestrogens – synthetic and conjugated equine oestrogens) resulted in worse incontinence than placebo (RR1.32; 95% CI: 1.17-1.48). Although this is heavily influenced by the size of the WHI study [Hendrix et al 2005]. When considering combination therapy there was a similar worsening effect on incontinence when compared to placebo (RR1.11; 95% CO: 1.04-1.08). There was some evidence suggesting that the use of local oestrogen therapy may improve incontinence (RR0.74; 95% CI: 0.64-0.86) and overall there were 1-2 fewer voids in 24 hours and less frequency and urgency.

The authors conclude that local oestorgen therapy for incontinence may be beneficial although there was little evidence of long term effect. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition they report that there are too few data to comment reliably on the dose type of oestrogen and route of administration.

II. OTHER HORMONES

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence have been reported to increase in the progestogenic phase of the menstrual cycle [Hextall et al., 2001]. In similar studies progesterone has been shown to increase beta adrenergic activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progestin was given in addition to oestrogen [Hendrix et al., 2005].

Selective oestrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both oestrogenic and anti oestrogenic effects. In the clinical trials of levormeloxifene there was a fourfold increase in the incidence of incontinence leading to cessation of the clinical trial [Hendrix et al., 2001]. However raloxifene has not been shown to have any effect at all on urinary incontinence [Waetjen et al., 2004].There are no reported clinical trials evaluating the effect of androgens, and in particular Testosterone, on urinary incontinence in women.

Assessments, hormone treatment

Oestrogen has an important physiological effect on the female lower urinary tract and its deficiency is an aetiological factor in the pathogenesis of a number of conditions. However the use of oestrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of oestrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have only been based on self reported symptoms of urinary leakage without any objective data. Despite this all of these large randomised controlled trials show a worsening of pre-existing urinary incontinence both stress and urgency and an increased new incidence of urinary incontinence with both oestrogen and oestrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine oestrogen and this may not be representative of all oestrogens taken by all routes of administration.

In a systematic review of the effects of oestrogens for symptoms suggestive of an overactive bladder the conclusion was that oestrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration [Cardozo et al., 2004]. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urge incontinence may be a manifestation of urogenital atrophy in older post menopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal oestrogen therapy there is currently no evidence that oestrogens with or without progestogens should be used in the treatment of urinary incontinence.

III. DESMOPRESSIN

The endogenous hormone vasopressin (also known as anti-diuretic hormone) has two main functions: it causes contraction of vascular smooth muscle and stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors of which there are two major subtypes, namely the V1 and V2 receptors. The V2 subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V2 receptor can cause nephrogenic diabetes insipidus [Insel et al., 2007]. Accordingly, decreased vasopressin levels are believed to be important in the pathophysiology of polyuria, specifically nocturnal polyuria, which can lead to symptoms such as nocturia [Matthiesen et al., 1996; Weiss et al., 2011a]. Nocturia is currently defined by the International Continence Society (ICS) as the complaint that an individual has to wake at night one or more times to void. It is, however, “an underreported, understudied, and infrequently recognized problem in adults” [Weiss et al., 2011b]. Nocturia leads to decreased quality of life [Kupelian et al., 2011], and has been associated with both increased morbidity and mortality [Nakagawa et al., 2010; Kupelian et al., 2012]. While it remains largely unknown in which fraction of patients nocturia can indeed be explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist. While it remains largely unknown in what fraction of patients nocturia is explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioral factors that can explain it (e.g. excessive fluid intake) is usually considered to indicate decreased vasopressin levels [Bosch and Weiss., 2011, Weiss et al., 2011b]. Based upon these considerations, vasopressin receptor agonists have been used to treat nocturia, both in children and in adults. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for anti-diuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration [Rittig et al., 1998]. Because of symptomatic hyponatremia with water intoxication which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin [Thumfart et al. 2005; Robson et al. 2007; Van de Walle et al. 2010], the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate (MELT) formulation requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, cross-over study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children]. A recent study confirmed the superior pharmacodynamic charac-

teristics of desmopressin MELT to desmopressin tablets [De Guchtenaere et al., 2011].

The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener et al. 2002]. These authors evaluated 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to their analysis, desmopressin was effective relative to placebo in reducing bed-wetting (e.g. a dose of 20 µg resulted in a reduction of 1.34 wets/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that desmopressin suppresses symptom enuresis but does not cure the underlying cause. Additionally, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates [Alloussi et al. 2011]. The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone [Austin et al., 2008; Alloussi et al., 2009). For non-responders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic receptor antagonists may be ineffective in such children (De Guchtenaere et al., 2007; Neveus and Tullus, 2008).

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms “desmopressin” and “nocturia” was performed and limited to clinical studies of de novo nocturia, i.e. those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis [Eckford et al., 1994;1995]. One study with single dose administration reported a reduction in nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with a small patient number (16-33 patients total per study) reported a significant reduction in nocturia [Hilton et al., 1983; Eckford et al., 1994; Valiquette et al., 1996]. Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 h after desmopressin administration rather than nocturia as their primary endpoint. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious [Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998]. While desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment due to asymptomatic or minimally symptomatic hyponatremia [Valiquette et al., 1996]. Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study, desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou, Karagiannis et al. 2007].

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. The recruited patient populations were based upon different criteria, including having at least two nocturia episodes per night or having nocturnal polyuria. Earlier studies mostly used a desmopressin dose of 20 µg given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (≤25 patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1-0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults [Mattiasson et al., 2002; Lose et al., 2004; van Kerrebroeck et al., 2007]. A total of 632 patients entered the dose-titration phase and 422 patients entering the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed-out following the dose-titration phase and in order to be randomized, it was a requirement that the patients returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2 or 0.4 mg) is effective in both men and women aged ≥ 18 years with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared to 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as ≥ 50% reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response (Lose et al. 2004). An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects [Johnson et al. 2006].

Around 75% of community-dwelling men and women with nocturia (≥2 voids/night) have nocturnal

polyuria (NP) [Rembratt et al., 2003; Swithinbank et al. 2004]. The key urological factors most relevant to nocturia are NP and OAB in women [Irwin, Abrams et al., 2008], and NP and benign prostatic hyperplasia (BPH) in men. About 74% of women with OAB have nocturia and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP; 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or bladder outlet obstruction [Chang et al., 2006]. Therefore, desmopressin combination therapy with α1-AR antagonists and/or antimuscarinics should be considered for patients with treatment–resistant nocturia. Seventy-three percent of α1-AR antagonist-resistant BPH patients experienced a ≥50% reduction in nocturnal voids with oral desmopressin [Rembratt et al., 2003; Yoong et al., 2005]. A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low dose (0.1 mg) oral desmopressin in elderly (≥ 65 years) patients reported that low dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH [Wang, Lin et al. 2011].

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, non-randomized pilot study of men believed to have BPH, desmopressin was reported to improve not only nocturia, but also to reduce the overall international prostate symptom score (IPSS) [Chancellor et al., 1999]. An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence reported that intranasal administration of 40 μg desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in voids along with an improvement in quality of life (QoL) [Hashim et al., 2009]. While these data indicate that desmopressin may be effective in treating voiding dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side-effects of demopressin usage is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al. 2003]. Based on a meta-analysis, the incidence is around 7.6% [Weatherall; 2004]. Increased age and female gender are well-known risk factors for the development of desmopressin-induced hyponatremia. Bae et al. [2007] assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (greater than 3 voids nightly), who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration serum sodium should be assessed regularly, at least every 6 months.

Little focus has been on exploring gender differences in the antidiuretic response to desmopressin. Juul et al. [2011] found an increasing incidence of hyponatremia with increasing dose, and at the highest dose level of 100 μg decreases in serum sodium were approximately twofold greater in women over 50 yr of age than in men. A new dose recommendation stratified by gender was suggested in the treatment of nocturia: for men, 50- to 100 μg melt was suggested to be an efficacious and safe dose, while for women a dose of 25 μg melt was recommended as efficacious with no observed incidences of hyponatremia. Initiation of desmopressin is currently not indicated for patients aged ≥65 years. The mechanisms behind desmopressin-induced hyponatraemia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to recommended dosing, should be followed to minimize the risk of hyponatremia [Vande Walle et al., 2007].

Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. The drug has been proven to be well-tolerated and effective by several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see **Table 2**.

G. Considerations in the Elderly

I. ANTIMUSCARINIC AGENTS

1. EFFICACY AND TOLERABILITY

The efficacy of antimuscarinic agents for treating symptoms of overactive bladder and urge urinary incontinence in older people is similar to that observed in younger and middle-aged adults. Age-related pooled results or sub-analyses from randomized controlled trials of tolterodine [Malone-Lee et al., 2001, Zinner et al., 2002], solifenacin (Wagg et al., 2006), darifenacin [Foote et al., 2007], fesoterodine [Kraus et al., 2010, Sand et al., 2012], and trospium chloride [Sand et al., 2011] indicate that reductions of 25-75% in urgency urinary incontinence episodes can be expected with use of these agents in older (65+) adults. Higher doses may be needed in those over age 75 [Kraus et al., 2010]. In a post-marketing surveillance study of darifenacin, Michel et al. [2010] found that increasing age was negatively associated with improvements in urgency episodes and incontinence, with a statistically significant, but non-clinically relevant effect (0.01 more urgency episodes per year of age). Older adults may derive greater benefit from use of a combined drug and behavioural therapy regime as compared to treatment with drug therapy alone [Burgio et al., 2000]. Dry mouth is the most frequently reported treatment-related adverse event, however overall tolerance has been reported as good to excellent with fewer treatment-motivated withdrawals in recent trials of older patients persisting on antimuscarinic therapy [Sand et al., 2012, Sand et al., 2011]. Constipation is also common and may be particularly bothersome for older adults already suffering from chronic bowel dismotility [Meek et al., 2011, Gallegos-Orozco et al., 2012].

However, the therapeutic effectiveness and tolerability of antimuscarinic agents in the elderly in the real world practice setting may differ from the results obtained in randomized controlled trials for several reasons. First, research trials generally exclude individuals with concomitant consumption of other antimuscarinic agents. In practice, older adults are a heterogeneous group, often consuming many medications that may augment, desensitize or alter the response to antimuscarinic therapy. As well, there is a higher prevalence of comorbidity among the elderly, which can further reduce treatment efficacy and heighten the potential for side effects to occur (see the Section on Incontinence in the Frail Elderly). Failure to acknowledge the multifactorial nature of urinary incontinence in the elderly often leads to suboptimal treatment. Urgency symptoms may be exacerbated by consumption of caffeinated beverages, pelvic floor muscle weakness, diuretics or other functional and systemic dysfunctions. Treatment should therefore address all possible etiologies, and not be limited to a solitary intervention.

2. COGNITIVE SAFETY

A growing body of literature has emerged to address the concern that antimuscarinic agents used to treat symptoms of overactive bladder may cross the blood-brain barrier and provoke subtle or not so subtle cognitive impairment [Callegari et al, 2011; Jakobsen SM et al., 2011; Wagg et al., 2010; Pagoria et al., 2011]. Large randomized controlled trials were not designed to adequately measure central nervous system adverse events [Paquette et al, 2011]. As a result, evidence on the relative risk of different antimuscarinic agents for crossing the blood brain barrier and inducing changes in cognitive comes primarily from in-vitro studies and experimental studies using detailed neuropsychological testing.

Early studies suggested that administration of antimuscarinic agents such as scopolamine could impair memory and attention in older adults, and possibly induce hallucinations and confusion [Flicker et al., 1992; Sperling et al., 2002]. Oxybutynin in particular, due to its small molecular size and increased propensity to cross the blood-brain barrier, has consistently shown potential to elicit cognitive impairment in new users after a single high dose of this agent or at steady state, and should be avoided in the elderly [Donellan et al., 1997; Katz et al., 1998; Kay et al., 2008, Wesnes et al., 2009]. Katz et al. [1998] used a double-blind, placebo-controlled cross-over design to test a convenience sample of 12 healthy continent older adults, and revealed cognitive decrements on seven of fifteen cognitive measures resulting from oxybutynin use. Impairments were observed in verbal learning, memory, reaction time, attention, concentration and psychomotor speed. In a sleep study, oxybutynin was found to significantly alter EEG patterns compared to placebo [Todorova et al., 2001]. Oxybutynin was compared to darifenacin and placebo in a 3-week randomized multicentre double-blind parallel-group study in 150 healthy volunteers aged 60-83 [Kay et al., 2006]. Darifenacin produced no impairments compared to placebo at 3-weeks, but oxybutynin caused significant memory deterioration in delayed recall compared to the other two groups. Darifenacin was associated with significantly slower reaction times than placebo in the Divided Attention Test, but not in other tests of information processing speed. Oxybutynin also reduced accuracy scores for immediate recall in one of three tests. Wesnes et al. [2009] showed in a single-dose crossover study with 12 healthy older volunteers that oxybutynin IR 10 mg induced significant deficits in attention and memory compared to placebo, whereas solifenacin 10 mg did not.

Studies with the antimuscarinic agents solifenacin, trospium chloride ER and darifenacin suggest that these agents confer significantly lower cognitive risk than oxybutynin. Administration of trospium chloride ER to 12 cognitively intact adults with overactive bladder aged 65-75 was found to have no effect on memory testing with the Hopkins Verbal Learning

Test on day 10 post-administration compared to baseline, and was also found to be undetectable in the cerebral spinal fluid of participants [Staskin et al., 2010]. In a study of darifenacin among 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Lipton et al., 2005]. No data on fesoterodine and memory were found.

New onset delirium also does not appear to be a significant concern in patients taking antimuscarinic agents. Although several published case reports have documented the acute onset of delirium following initiation of tolterodine, in incontinent adults with and without dementia [Womack and Heilman, 2003; Salvatore et al., 2007; Edwards et al., 2002; Williams et al., 2004; Tsao et al., 2003], these deficits resolved upon discontinuation or dose reduction of tolterodine. In a randomized controlled study of extended-release oxybutynin in nursing-home residents with mild to severe dementia, there was no incidence of delirium over the duration of the study [Lackner et al., 2008]. Furthermore, more recent evidence puts into question the traditionally held belief that new use of anticholinergic agents provokes incident delirium in hospitalized older patients [Campbell et al., 2011; Luukkanen et al., 2011].

Taken together, increasing evidence suggests that with the exception of oxybutynin, use of the other antimuscarinic agents poses little or no cognitive risk to otherwise healthy older adults with symptoms of overactive bladder. However, two caveats apply. First, the integrity of the blood brain barrier may be compromised in many older adults with cerebrovascular disease, diabetes, or certain forms of dementia, with the results of studies in healthy older adults not generalizable to frailer individuals [Kay et al., 2005]. Second, long-term use of antimuscarinic agents over months or years may yield more detrimental cognitive effects than single dose or short-term use. A number of large observational studies have linked chronic consumption of antimuscarinic drugs with an increased risk of cognitive impairment, although most studies simultaneously examined the cumulative effect of drugs with any antimuscarinic properties rather than each drug class alone. [Ancelin et al., 2006; Campbell et al., 2009; Fox et al., 2011]. The Eugenia study of aging randomly recruited 372 adults 60 years and older from Montpellier, France, and showed that antimuscarinic drug users displayed significantly poorer reaction time, attention, immediate and delayed visuospatial memory, narrative recall, and verbal fluency than did non drug users [Ancelin et al., 2006]. A 2-year longitudinal study of 13,000 participants enrolled in the Medical Research Council Cognitive Function and Ageing Study also showed that use of medication with antimuscarinic effects was associated with a 0.33-point greater decline in the Folstein Mini Mental Status Exam score (95% confidence interval (CI)=0.03-0.64, P=.03) than not taking antimuscarinics. Two-year mortality was also greater for those taking (OR=1.68; 95% CI=1.30-2.16; P<.001) anticholinergics. Many commonly prescribed medications in the elderly possess antimuscarinic properties [Chew et al., 2008], so the results may not be specific to bladder antimuscarinics. Other antimuscarinic medication include, among others, amytriptyline, clozapine, olanzepine, paroxetine, furosemide, hydrocodone, lansoprazole, levofloxacin, and metformin.

Clinicians who remain wary of prescribing antimuscarinic agents for frail older adults with symptoms of overactive bladder are suggested to proceed with caution in prescribing these medications and fully weigh the risk-benefit ratio in light of other therapeutic options that can be equally effective for urgency and mixed incontinence in the elderly. If antimuscarinics are to be prescribed, a short cognitive screen (such as the Montreal Cognitive Assessment http://www.mocatest.org) or even a full neuropsychological test battery for those patients who are concerned or at risk, before and after initiating therapy might reveal whether subtle impairments have been induced. This is especially pertinent because patients are often unaware of their memory deficits [Kay et al., 2006]. A proxy informant, such as the patient's spouse or a relative, may be able to provide more reliable information on possible cognitive changes resulting from the drugs.

A frequently asked clinical question is whether antimuscarinic agents used to treat incontinence should be contraindicated in patients with dementia already taking cholinesterase inhibitors, as the mechanisms of these two medications are diametrically opposed. A number of small studies have shown that cholinesterase inhibitors used to improve cognition in Alzheimer's disease precipitate urinary incontinence [Hashimoto et al., 2000]. A Japanese study followed 94 patients with mild to moderate dementia treated with donepezil [Hashimoto et al., 2000]. Seven patients developed urinary incontinence, although the event was transient in most patients. In Scotland, among 216 patients with Alzheimer's disease initiating treatment with a cholinesterase inhibitor, incontinence was precipitated in 6.6%, and those with existing incontinence worsened [Starr, 2007]. Epidemiologic studies also show associations between cholinesterase inhibitors and incontinence [Gill et al., 2005; Roe et al., 2002]. In a large population-based cohort study of 44,884 adults with dementia carried out in Canada, those who were dispensed cholinesterase inhibitors were more likely to subsequently receive an antimuscarinic drug for incontinence compared to those not receiving cholinesterase inhibitors (hazard ratio 1.55, 95% confidence interval 1.39-1.72) [Gill et al., 2005]. This finding was confirmed by a separate study in the U.S. documenting a two-fold risk of taking oxybutynin in dementia patients treated with donepezil compared to those not treated with donepezil [Roe et al., 2002]. A Japanese study examined

the addition of a 3-month trial of propiverine 20 mg/day to donepezil in twenty-six cognitively impaired older adults, and found improved dryness rates with no deleterious effect on cognition [Sakakibara et al., 2009]. A 6-month study also compared the effects of trospium, galantamine, or trospium plus galantamine in 178 older adults with urge incontinence (n=99), dementia (n=43) or dementia and incontinence (n=36) respectively [Isik et al., 2009]. Treatment with 45-60 mg/day of trospium chloride and combined use of trospium with galantamine 24 mg/day was found to have no adverse effect on cognitive or physical function scores in this group of patients. A larger observational study of 3,563 long-term care residents with dementia also failed to document an increased rate of cognitive decline with combined use of a cholinesterase inhibitor and antimuscarinic therapy (oxybutynin or tolterodine) compared to cholinesterase therapy alone [Sink et al., 2008]. However, a 50% faster rate of physical function decline was observed in higher-functioning participants on dual therapy compared to cholinesterase inhibitor therapy alone. This evidence suggests the competing mechanisms of the antimuscarinics and cholinesterase inhibitors may indeed have clinical consequences in some, but not all patients.

3. Cardiac safety. Another serious side effect of antimuscarinic drugs in the elderly is the risk of cardiac adverse effects and increased mortality, particularly due to increases in heart rate, prolongation of the QT interval, and induction of polymorphic ventricular tachycardia. These have been previously discussed, and it has been noted that studies specific to the elderly are lacking [Andersson et al., 2011]. Only one study prospectively examined the effect of anticholinergic drug use in 400 community-dwelling older people (aged 75-90 years) with stable cardiovascular disease in Helsinki, Finland [Uusvaara et al., 2011]. Bladder antimuscarinic agents were not examined individually, but were considered in a cumulative assessment of all drugs with antimuscarinic properties being taken by the same individual. The unadjusted follow-up mortality was 20.7% and 9.5% among users and non-users of antimuscarinic drugs, respectively ($p = 0.010$). However, the use of drugs with antimuscarinic properties was not a significant predictor of mortality in multivariate analysis after adjustment for age, sex and other comorbidites (hazard ratio 1.57; 95% CI 0.78, 3.15).

4.Drug/drug interactions in the elderly. Rates of polypharmacy (> 5 drugs per patient) are high in the geriatric population, and cause potential for drug-drug interactions that increase toxicity or reduce the efficacy of antimuscarinic agents [Chancellor and Miguel, 2007]. The relationship between the number of drugs and potential drug-drug interactions in the elderly is alarming. Consumption of 5 to 7 and 8 to 10 drugs places older adults at a 4-fold and 8-fold increased risk of potentially serious drug-drug interactions respectively, compared with consumption of 2 to 4 drugs [Johnell & Klarin, 2007]. Drug drug interactions frequently involve isoenzymes of the hepatic cytochrome CYP450 system [Zakrzewski-Jakubiak et al., 2011]. Of the antimuscarinic drugs, tolterodine, darifenacin, solifenacin, and oxybutynin are extensively metabolized by CYP450 and are at greater risk of having altered drug metabolism due to hepatic-based drug-drug interactions. Trospium is eliminated renally as unchanged drug, suggesting that it has lower potential for CYP450 drug-drug interactions [Sand et al., 2011]. Trospium may therefore represent a safer treatment option in the context of polypharmacy in the elderly.

II. DESMOPRESSIN – EFFICACY AND SAFETY IN THE ELDERLY

Desmopressin (DDAVP) (0.1–0.2 mg) reduces nocturia in older persons [Rezakhaniha et al., 2011;Fu et al., 2011; Johnson et al., 2006], but has been associated with significant dose-related hyponatremia in 2-20% of older patients [Fu et al., 2011;Johnson et al., 2006; Weatherall 2004]. Both female sex and increasing age are risk factors for the development of hyponatremia [Callreus et al., 2005; Rembratt et al., 2006; Juul et al., 2010]. A lower starting dose (0.025 mg) for the melt form has been suggested for older women [Juul et al., 2010] but requires further study. Caution is recommended for the initiation of desmopressin in adults aged 65 years and older at the current time.

III. BOTULINUM TOXIN A IN OLDER ADULTS

To date no studies have stratified the results of trials using BoNTA for the treatment of urinary incontinence in patients with neurogenic bladder according to age. The risk of catheterization due to high post-void residual urine volumes following treatment with botulinum toxin may be higher in older adults, as they are at higher risk of elevated residuals, but this requires systematic investigation.

IV. OTHER

None of the other drug classes have undergone rigorous evaluation in the elderly, however a number of general guidelines apply. Use of α1-AR agonists and tricyclic antidepressants are discouraged in the elderly due to blood pressure considerations. Uncontrolled systolic hypertension could occur with the former agents and orthostatic hypotension leading to falls with the latter. There is no evidence that hormonal agents are of benefit for urgency or stress incontinence in older women, although local estrogens may be indicated to treat symptomatic vaginal atrophy. Finally, removal of any offending agents that could be contributing to incontinence should be considered.

Diagnosis and Management of Urinary Incontinence in Childhood

Rien Nijman

Serdar Tekgul, Janet Chase, An Bael, Paul Austin,Alexander von Gontard

A. Introduction

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. In order to understand the pathophysiology of the most frequently encountered problems in children, the normal development of bladder and sphincter control will be discussed.

The underlying pathophysiology will be outlined and the specific investigations for children will be discussed. For general information on epidemiology and urodynamic investigations the respective chapters are to be consulted.

I. NORMAL DEVELOPMENT OF BLADDER AND SPHINCTER CONTROL

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervations which is ultimately controlled by a complex interaction between spinal cord, brain stem, midbrain and higher cortical structures [1].

Achievement of urinary control is equally complex and as yet not fully understood: various developmental stages have been observed [2,3].

In newborns the bladder has been traditionally described as “uninhibited”, and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term foetuses and newborns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification [4]. Foetal micturition seems to be a behavioural state-dependent event: intrauterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the foetus is awake [4].

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 30 times every 24 hours [5].

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. After the first week frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three- to fourfold.

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in newborns the bladder is normally quiescent and micturition does not occur during sleep[6].

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electro-encephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. Sleeping infants are always seen to wake up before the bladder contracts and voiding occurs. This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly afterward go back to sleep. Because this wakening response is already well established in newborns, it follows that the control of micturition probably involves more complicated neural pathways and higher centres than has been appreciated. There is also strong evidence that a pronounced reorganisation of pre-existing synaptic connections and neural pathways

involved in bladder control occurs during the early postnatal period.

In newborns micturition occurs at frequent intervals and may have an intermittent pattern although bladder emptying efficiency is usually good. In over 80 percent of voids the bladder empties completely [7].

During infancy voiding pressures are much higher than in adults. It has also been noted that these pressures are higher in boys than in girls (mean pdet max of 118 vs. 75 cm H2O, respectively) [8,9].

These higher detrusor pressures decrease progressively with increasing age. In up to 70 percent of infants (up to the age of 3 years) with normal lower urinary tracts, intermittent patterns of voiding were observed. They tend to disappear with increasing age, and are thought to represent variations between individual infants in the maturation of detrusor and sphincteric co-ordination during the first 1 to 2 years of life. Videourodynamic studies have confirmed these findings [6,8,9,10,11].

Between the age of 1 and 2, conscious sensation of bladder filling develops. The ability to void or inhibit voiding voluntarily at any degree of bladder filling commonly develops in the second and third years of life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is progressive development towards a socially conscious continence and a more voluntary type of micturition control develops. The child becomes more aware of the sensation of bladder distension and the need to urinate, as well as social norms and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time, then actively initiate urination even when the bladder is not completely full, and allows urination to proceed to completion. During the first years of life, gradual development to an adult type of voluntary micturition control that conforms to the social norms depends on an intact nervous system, in addition to at least three other events occurring concomitantly:

- a progressive increase in functional storage capacity.
- maturation of function and control over the external urinary sphincter.
- and most importantly achievement of volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit a micturition reflex [12].

The final steps are usually achieved at the age of 3 to 4 years when most children have developed the adult pattern of urinary control and are dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and voluntarily initiate micturition at socially acceptable and convenient times and places. This development is also dependent on behavioural learning and can be influenced by toilet training, which in turn depends on cognitive perception of the maturing urinary tract.

It is understandable that this series of complex events is highly susceptible to the development of various types of dysfunction. Various functional derangements of the bladder-sphincter-perineal complex may occur during this sophisticated course of early development of normal micturition control mechanisms. These acquired “functional” disorders overlap with other types of bladder functional disturbances that may have a more organic underlying pathophysiological basis.

II. NORMAL VALUES

1. NORMAL BLADDER CAPACITY

The bladder capacity increases during the first 8 years of life roughly with 30 ml per year, so with an average capacity of 30 ml in the neonatal period, a child’s bladder volume can be calculated as Y = 30 + 30 X, where Y = capacity in ml and X = age in years (**Figure 1**) [13].

Hjälmås described a linear correlation that could be used up to 12 years of age: in boys, Y = 24.8 X + 31.6, in girls Y = 22.6 X + 37.4, where Y is capacity in ml, and X is age in years [14].

It should be noted that these data were obtained during cystometric investigations. Cystometric capacity is generally less than normal bladder volumes. Obviously, the relation between age and bladder capacity is not linear for all ages, nor is the relation between body weight and bladder capacity [15].

Another formula to calculate bladder capacity in infants is: bladder capacity (ml) = 38 + (2.5 x age (mo)) [11].

Kaefer and co-workers demonstrated that a nonlinear model was the most accurate for the relation between age and bladder capacity, and they determined two practical linear equations:

Y = 2 X + 2 for children less than 2 years old, and Y = X/2+6 for those 2 years old or older; Y = capacity in ounces, X = age in years (**Figure. 2**) [16].

None of these formulas have been acquired from a population based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation. Recent work of Rittig et al looked at Maximum Voided Volumes (MVV). 2836 daytime voids showed a reasonably good correlation with the Koff Formula, if first morning voids were neglected [17].

Girls were found to have a larger capacity than boys, but the rate of increase with age was not

significantly different between them. Data on 'normal' bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder.

Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability. (**Figure 3**) [18].

2. NORMAL VOIDING

The micturition frequency of the foetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voidings per day [11, 16].

The normal range for the micturition frequency at age seven is 3 to 7 [19].

By age 12, the daily pattern of voiding includes 4-6 voids per day [20].

Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold [21].

3. NORMAL VOIDING PRESSURES

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children after the age of 2 years are similar to adults, with a mean maximum pressure of 66 cm H2O in boys, and 57 cm H2O in girls [22].

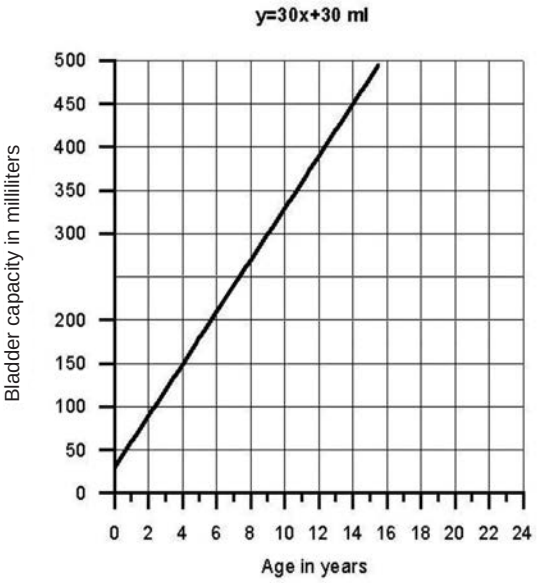

Figure 1: Bladder capacity using the formula
Y = 30 + 30X
(Y = capacity in ml, X=age in years)

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H2O and girls 75 cm H2O [6].

4. NORMAL URINARY FLOW RATES

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children [23].

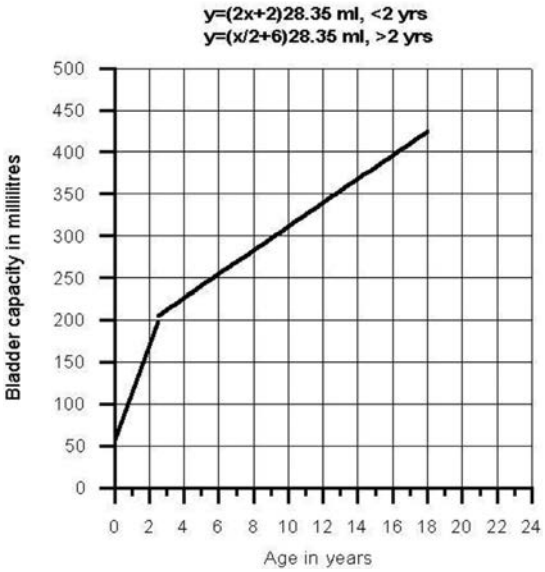

Figure 2: Bladder capacity using the formula
Y = (2X + 2) x 28.35ml < 2 years
Y = (X/2 + 6) x 28.35ml > 2 years
(Y = capacity in ml. X=age in years)

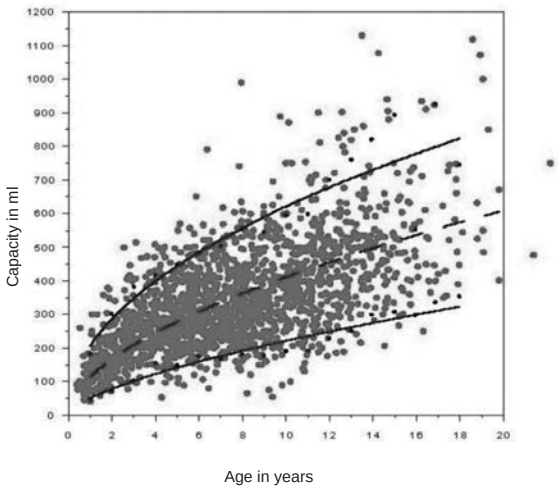

Figure 3: Bladder capacities determined by VCUG in the International Reflux Study.

As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when voiding at a bladder volume approximating the normal capacity for age [21,24].

B. Evaluation in children who wet

Even with clear definitions, the approach to history-taking and physical examination has to be structured. The child's complaints at presentation are not synonymous with the signs and symptoms that have to be checked to arrive at a diagnosis. Also, sociocultural aspects and psychomotor development will distort the presentation.

The International Children's Continence Society has provided two standardization documents on the diagnostic evaluation of children with daytime incontinence as well as on the evaluation of and treatment for monosymptomatic enuresis [1,2].

Standardization reports on urodynamic studies of the lower urinary and on initial diagnostic evaluation, follow-up and therapeutic intervention in congenital neurogenic bladder and bowel dysfunction in children will be available soon.

Validated questionnaires are very helpful in structuring the history-taking; they at least provide checklists [3].

With a structured approach the diagnosis of monosymptomatic nocturnal enuresis can be made with confidence.

When ultrasound imaging of kidneys and bladder, recording of urinary flow, and measurement of postvoid residual are added to history and physical examination, the clinical entities caused by functional disturbances of the bladder and sphincter mechanism (non-neurogenic detrusor and pelvic floor dysfunction) can be diagnosed accurately in the majority of cases, and a high level of suspicion can be maintained towards incomplete bladder emptying in both neurogenic pelvic floor dysfunction and structurally caused incontinence. This is important in view of the potential these conditions have to cause irreversible loss of kidney function.

In a minority of incontinent children the non-invasive assessment yields equivocal results, or results suggesting gross deviations from normal function. Only in these situations is there an indication for invasive investigations, such as:

- Voiding cystourethrography.
- Invasive urodynamics (cystometry, pressure/flow/EMG studies, videocystometry).
- Renal scans or intravenous urography.
- Cystourethroscopy.

I. HISTORY TAKING

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach is recommended, with a questionnaire [3,4].

Level of evidence: 3.

Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child's voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinics. History-taking should also include assessment of bowel function; a similar pro-active process using a questionnaire should be followed for defecation and faecal soiling [5].

The general history-taking should include questions relevant to familial disorders, neurological and congenital abnormalities, as well as information on previous urinary infections, relevant surgery and menstrual and sexual functions (in pubertal and older children). Information should be obtained on medication with known or possible effects on the lower urinary tract.

At times it is helpful to more formally evaluate the child's psychosocial status and the family situation, e.g. using validated question forms such as CBCL (Achenbach) or the Butler forms [6,7].

A short screening instrument for psychological problems in enuresis (SSIPPE) and a disease specific quality of life questionnaire for children with LUTD called PinQ are also validated tools available to the clinician [8,9].

Child abuse is very often signalled first by symptoms of vesico-urethral dysfunction [10].

At present there are no validated questionnaires to diagnose the cause of incontinence in children.

Level of evidence: 4.

Grade of recommendation: C

II. PHYSICAL EXAMINATION

Apart from a general paediatric examination, the physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 (standing on toes, bulbocavernosus) and anal sphincter tone and control. Special attention should be paid to inspection of the male or female genital region, and of the urethral meatus. Asymmetry of buttocks, legs or feet, as well as other signs of occult neurospinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should be looked for specifically [11].

In examining the abdomen for the presence of a full bladder, full sigmoid or descending colon which is a significant finding with a history of constipation.

Detailed questioning of the parents' observation of the child's voiding habits is essential as is direct observation of the voiding, if possible. Children may have their voiding dysfunction ameliorated or even eliminated by correcting anomalies of body position detected when observing the child's micturition. Children may void in awkward positions, e.g. with their legs crossed or balancing on the toilet without proper support of the legs, thereby preventing the pelvic floor relaxation and obstructing the free flow of urine [12] (**Figure 4**).

Figure 4: Improper position for voiding: the feet are not supported (unbalanced position) and the boy is bent forward. Support of the feet will correct this and will allow the pelvic floor muscles to relax properly.

Level of evidence: 4.

Grade of recommendation: D

III. URINALYSIS

In order to be comprehensive, physical examination should include urinalysis to identify patients with urinary tract infection, diabetes mellitus, diabetes insipidus and hypercalciuria if indicated [13].

IV. NON-INVASIVE DIAGNOSTIC TECHNIQUES

1. FREQUENCY / VOLUME CHARTS: BLADDER DIARY

The frequency/volume chart is a detailed diary recording each void by time and urine output over 24-hour periods. The chart gives objective information on the number of voidings, the distribution of day and night voids, along with the voided volumes and episodes of urgency and leakage, or dribbling. In order to obtain a complete picture, defecation frequency and/or soiling are often also recorded: Then, this becomes termed as bladder-bowel diary due to its complexity.

From the frequency/volume chart the child's "functional" bladder capacity may be assessed as the largest voided volume, with the exception of the morning micturition, which actually represents nighttime bladder capacity. Whenever possible, filling out the chart is the responsibility of the child: the parents provide assistance and support. Ideally the chart should cover 3 complete days, but in reality completion over a weekend restricts the record to 2 days.

The frequency volume chart is a reliable non-invasive measure of maximum bladder storage capacity and can be used as an outcome measure in children with bladder dysfunction if care is taken to minimise confounding factors and sources of error during chart completion [14].

The amount of urine voided by a non-supervised child during the day varies considerably since the child's voidings are dictated more by social circumstances and /or bladder activity rather than by

bladder capacity. Children with bladder symptoms void smaller volumes of urine than may be expected from traditional estimates [14].

This is unrelated to either gender, type of presenting incontinence or a positive family history of bladder dysfunction. The only significant influence upon voided volumes recorded on a frequency volume chart is the age effect, and voided volumes, even in incontinent children, increase incrementally with age. The frequency volume chart is useful when comparing the mean voided volume and standard deviation by a child's age 15,16].

Validation and test/retest data on frequency/volume charts whilst scarce indicate that voiding interval is the most variable parameter. Data in normal children and in children with different categories of incontinence are available for comparison [14,17,18].

In order to obtain a complete picture it is better to ask for a bladder diary: fluid intake as well as voiding frequency, voided volumes, incontinence episodes and defecation frequency and/or soiling are recorded.

Test/retest evaluation is not available; trend analyses of frequency/volume charts can be extracted from currently available data.

Level of evidence: 3.

Grade of recommendation: B

2. QUANTIFICATION OF URINE LOSS

Subjective grading of incontinence may not indicate reliably the degree of dysfunction. For objective grading, 12-hour pad test and frequency/volume charts are validated instruments [18-20]. One should be aware that children tend to do their utmost best when filling out diaries and doing padtests: underestimation is more the case than overestimation [21].

In children, the 12-hour pad test should also give information about fluid intake. The pad test is complementary to the bladder diary, which denotes more the frequency of incontinence and the distribution of wetting episodes than the quantities of urine lost.

The amount of urine lost during sleep can be determined by weighing diapers or absorbent pads, before and after sleep. To obtain a measure of the total nocturnal urine output, the volume of the early-morning voiding should be added to the amount lost during sleep.

3 SCORING SYSTEMS

At present three scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% [22-24].

The value of these scoring systems to determine the cause of incontinence seems to be of limited value to the individual patient, but can be very useful in studies to determine and compare treatment outcome.

Level of evidence: 3.

Grade of recommendation: C

4. QUANTIFICATION OF CONSTIPATION

Scoring a plain X-ray of the abdomen (Barr score) yields inconsistent results in grading constipation. [17-19] Reproducibility seems to be best using the method described by Leech [28-30].

A better way to match clues from the medical history with signs and symptoms is the measurement of colonic transit time.

As many children with an overactive bladder habitually use their pelvic floor as an "emergency brake", anomalous defecation frequency and constipation have a high prevalence in this group.

Diagnosing constipation is important: we recommend to use the Rome III criteria listed in the table below [31].

A non-invasive way to determine fecal retention is the estimation of rectal diameter on ultrasound. In children without constipation the mean diameter was 2, 2.1 and 2.4 cm in three different studies respectively [32-34]. In children with constipation the rectal diameter was on average 3.4 cm in the first, 4.9 in the second and 4.2 cm in the third study, significantly different from the non-constipated children. Joensson et al. also re-measured constipated children 4 weeks after treatment with laxatives finding the rectal diameters in the constipation group were significantly reduced ($p < 0.001$) [34].

Finding a dilated and filled rectum on ultrasound while the child feels no need to defecate probably can replace a digital rectal examination.

Overt constipation should be dealt with before embarking on treatment of incontinence or bladder and pelvic floor dysfunction [35,36].

Level of evidence 3.

Grade of recommendation: B

5. URINARY FLOW

Voiding should be analysed in detail in all incontinent children with the exception of monosymptomatic bedwetting where voiding, as far as we know, is normal.

Graphic registration of the urinary flow rate during voiding is a standard office procedure. Flow

patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency.

Approximately 1% of school children have a voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve [37]. It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically means a bladder or voiding dysfunction, as in asymptomatic normal schoolchildren abnormal patterns were also found [38,39].

Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. On the other hand, overdistension of the bladder can result in abnormal uroflow recordings also [40].

A helpful tool in this respect is the use of transabdominal ultrasound (e.g. bladder scan) before micturition in order to assess the bladder volume [41,42]. If the bladder is still nearly empty the child should be asked to drink some water until the bladder is full enough for a reliable flow.

Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or staccato (fluctuating). An intermittent flow pattern shows a interrupted flow, whereas in staccato voiding the flow does not stop completely, but fluctuates due to incomplete relaxation of the sphincter.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency [43,44].

The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or staccato flow patterns (**Figure 5-8**). In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is total duration of micturition, including interruptions.

6. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities requires urological expertise on the part of the ultrasound operator [45].

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity [46,47]. Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with lower urinary tract dysfunction, more studies need to be performed to validate these non-invasive techniques [48,49].

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume / Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment [50].

Functional constipation

Must include ≥ *2* of the following in a child with a developmental age of ≥ *4* years with insufficient criteria for diagnosis of IBS:

- ≤ 2 defecations per week
- ≥ 1 episode of fecal incontinence per week
- History of retentive posturing or excessive volitiotnal stool retention
- History of painful or hard bowel movements
- Presence of a large fecal mass in the rectum
- History of large diameter stools that obstruct the toilet

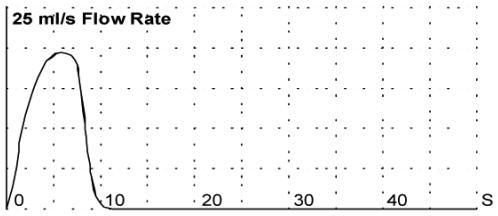
a) Post-void residual volume

Except in small infants, the normal bladder will empty completely at every micturition [51].

The identification or exclusion of post-void residual is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating residual urine, voided volume and the time interval between voiding and estimation of post-void residual should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesicoureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or sphincter / pelvic floor overactivity with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children.

b) Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as post-void residual volumes.



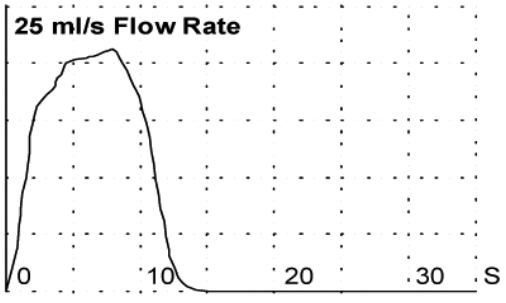


Figure 5: normal urinary flow curves of 2 childtren

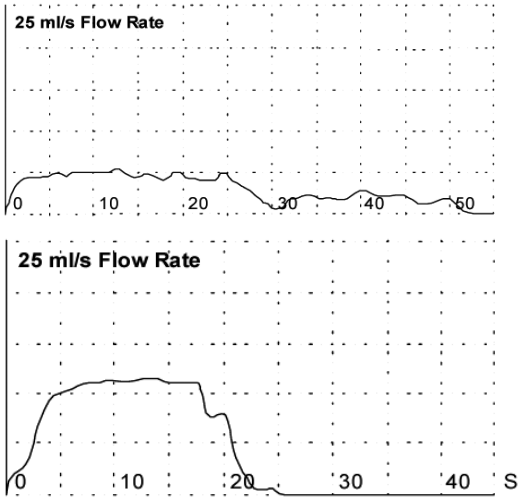

Figure 6: flow curves of 2 children with a static, anatomic obstruction; the curve is continuous but the flow is lower than normal and extended in time

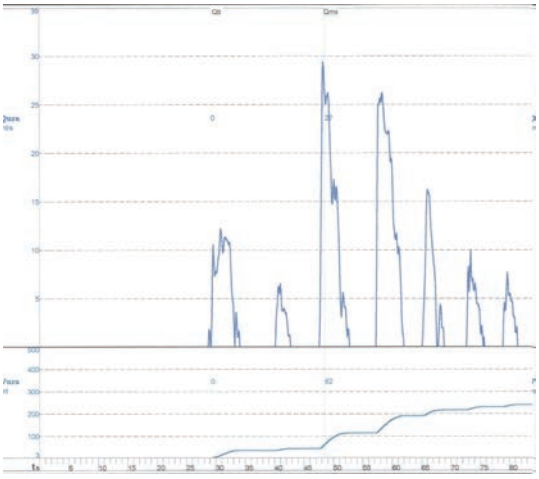

Figure 7: intermittent flow curve in a child voiding with abdominal straining

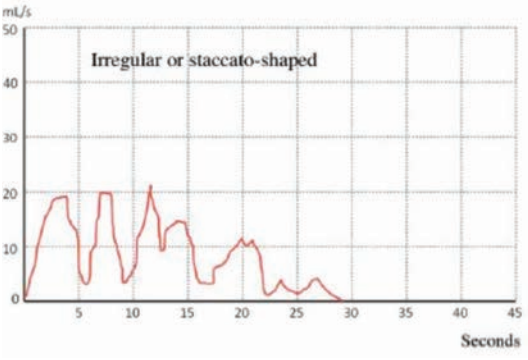

Figure 8: Staccato voiding in a child

With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the functional or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, post-void residual is assessed again.

This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home [52]. For those children who have difficulty voiding in a strange environment, this option can be useful.

7. INVASIVE DIAGNOSTIC TECHNIQUES

The important question (for the incontinent child) "whether invasive diagnostic procedures are necessary" is decided by the results of the non-invasive procedures.

At present there are no studies indicating that a VCUG is useful in children with incontinence, but without urinary tract infections.

In general urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include, straining or manual expression during voiding, a weak urinary stream, previous febrile urinary tract infection, continuous dribbling incontinence or pronounced apparent stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor –sphincter- pelvic floor dys-coordination [43].

A clinically significant post-void residual on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter.

In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (especially posterior urethral valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter- pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant post void residuals.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent urinary tract infections and vesicoureteral reflux, urodynamic studies are needed in only a minority of all children.

a) Voiding Cystourethrogram

1. Technique of VCUG in children

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08) or balloon catheter to catheterise the bladder; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H2O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection, of the complete urinary tract. Upper and lower tract should be visible.

When voiding is imminent, change the position of the child so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary very considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.

Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG urinary tract infection especially in children with an anatomic abnormality.

2. Indications for VCUG

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent urinary tract infections in order to detect reflux, in children with a dilated system on ultrasound and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocele).

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.

In children with non-neurogenic detrusor-sphincter- pelvic floor dysfunction as well as in children with neurogenic detrusor-sphincter dyssynergia, the proximal urethra may show the so-called 'spinning top' configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter. The resulting 'spinning top' configuration used to be seen as a sure sign of distal urethral stenosis, a concept held responsible for recurrent urinary tract infections in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics made it clear that the 'spinning top' will only appear when detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one [53,54].

Women often recall their experience with VCUG as young girls in terms bordering on abuse. The use of VCUG in children should be limited to the absolutely necessary.

b) (Video)-Urodynamics

In children urodynamic investigations should only be performed if the outcome will have consequences for treatment [55-57]. Furthermore like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in children [58-60].

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artefacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the outcome of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding. Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle [61].

Still the results may not always be reproducible and it should be stressed that the primary objective is to treat the child and not a "urodynamic abnormality" per se.

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, unanaesthetised and neither sedated nor taking any drugs that affect bladder function.

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances.

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature [62].

When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute (based on the voiding diary), or < 10ml/min) is recommended in children, as certain cystometric parameters, notably compliance, may be significantly altered by the speed of bladder filling.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures.

The presence of these contractions does not necessarily imply a neurologic disorder. In infants, detrusor contractions often occur throughout the filling phase. (**figure 9**)

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children is it a relevant parameter. Normal desire to void

is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g. wriggling the toes; this usually indicates voiding is imminent. In the older child, the volume may be small with the first cystometry, for fear of discomfort. Also involuntary detrusor contractions occur more often during the first filling cycle [62]. This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.

Maximum cystometric capacity (MCC) is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

Compliance indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage [64].

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) [63].

Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure / flow study, may be anatomical or functional in nature. An *anatomical obstruction* may be present at the bladder neck or in the urethra as a stenosis or a stricture when there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a *functional obstruction,* it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding. This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor, as in clinical practice the urethral sphincter is not readily accessible, and the electromyogram of the external anal sphincter is often used to monitor activity of the striated urethral sphincter. This corresponds to activity of the pelvic floor muscles. Also the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (**Figure 9 and 10**).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability it is a normal developmental feature [65, 66].

c) Cystoscopy

In by far the majority of children cystoscopy is not indicated. In boys with therapy resistant incontinence, an abnormal flow pattern, especially in combination with a history of (recurrent) urinary tract infection is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal [67].

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernosus reflex resulting in dysfunctional voiding [68].

Grade of recommendation: for all diagnostic procedures level B

C. Nocturnal enuresis

I. DEFINITION

Nocturnal enuresis (NE) is involuntary voiding of urine during sleep, at least three times a week, in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [1].

Parental concern and child distress affect the clinical significance of the problem [2]. While most children who wet at night after age five are considered nocturnal enuretics, the child's development level is also important. The age criterion of five is arbitrary but reflects the natural course of achieving bladder control [4]. Verhulst et al argue for flexibility due to different age at which boys develop nighttime continence compared with girls [4]. Extrapolation from Verhulst's figures suggests that the prevalence of nighttime wetting for 8-year-old boys equals that for girls at 5 years [4].

Monosymptomatic NE is bedwetting without daytime symptoms. **Non-monosymptomatic** or polysymptomatic NE describes children with both day and nighttime wetting [5].

II. SEVERITY

Nocturnal enuretics vary in wetting frequency. Although fifteen percent wet each night, most children wet less frequently [4,6]. In a population survey of nearly 1,800 Irish children aged 4 –14 years, Devlin found the frequency of wetting as

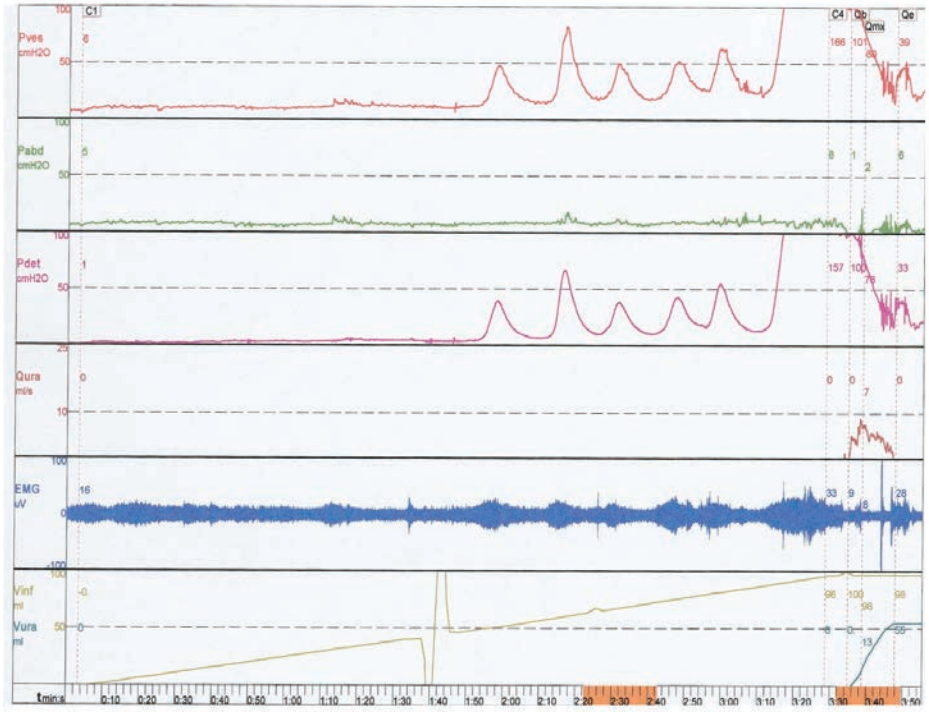

Figure 9: Urodynamic study illustrating involuntary detrusor contractions, counter action of pelvic floor muscles (guarding reflex) and incomplete pelvic floor relaxation during voiding resulting in post void residual urine (detrusor overactivity + dysfunctional voiding) [63]

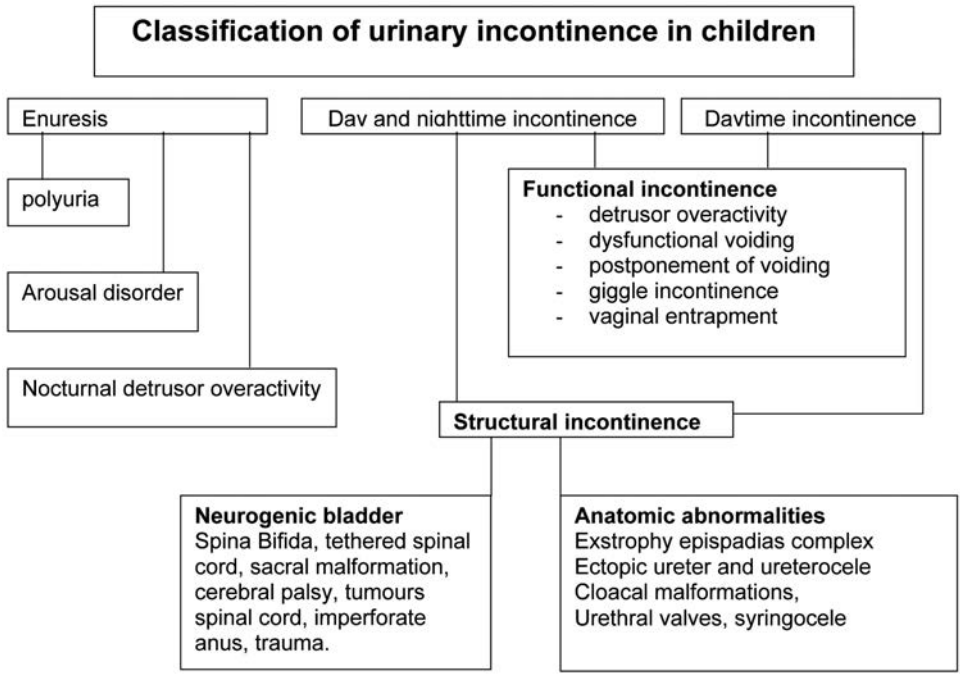

Figure 10: Classification of urinary incontinence in children

(Over)activity of the urethral sphincter- pelvic floor may occur during the voiding contraction of the detrusor in neurologically normal children; this set of events is termed dysfunctional voiding.

Grade of recommendation: for all diagnostic procedures level B

follows: less than once per week in 33 percent, once per week in 11 percent and 2 to 4 times per month in 25 percent [7]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting. Clinically severity can be defined as: infrequent (1-2 wetting episodes per week), moderately severe (3 – 5 wetting episodes per week) or severe (6 – 7 wetting episodes per week) [7].

III. PREVALENCE

Bedwetting is common. In the United Kingdom, estimates approximately 750,000 children and young people over 7 years regularly wet the bed. In the United States 5 to 7 million children regularly experience primary NE [8,9,10].

The prevalence of bedwetting varies regionally. In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. For example, in a large survey from Shandon, the proportion of children attaining nocturnal urinary control before age 2 was 7.7%; by age 3, this had increased to 53.1%, and by age 5 to 93%. The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. There was no additional decrease in the prevalence of enuresis between 6 and 16 years [11]. This suggests that structured awakening and toileting is effective treatment for monosymptomatic NE, even in small children.

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control [12]. By adulthood, bedwetting is rare. Hirasing et al sampled over 13,000 adults [18-64 years] and found an overall prevalence rate of NE at 0.5% [13]. Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 percent of men and 35 percent of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing's study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic boy to remain so for the rest of his life is 3 percent. [12.14]. Many believe adult enuretics represent a "hard core" group with worse symptoms. These individuals are likely to have associated diurnal enuresis or voiding symptoms. One study included 18 males and 29 females with a mean age of 20 years with persistent NE. Of these patients 37 (79%) had moderate or severe symptoms and 17 (38%) also had daytime urinary symptoms. Thirty patients had urodynamics including 12 males and 16 females, and 93% had detrusor overactivity. In addition, 73% of patients had urodynamic evidence of functional bladder outflow obstruction, including dysfunctional voiding and detrusor sphincter or detrusor pelvic floor discoordination. Two male patients (6.7%) had an obstructive pattern on urodynamics and subsequent cystoscopic examination confirmed the presence of congenital urethral stricture/valves. Sixteen patients (53%) had significantly reduced bladder capacity of less than 300 ml. [15-18]. These and other studies suggest that persistent NE after childhood is a serious adult problem requiring some investigation and considerable effort to treat.

IV. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, A positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of grandfathers or (and) mothers. Among the probands the ratio of male to female was 1.3:1 excluding sex-linked inheritance. Autosomal dominant inheritance was in 15%, and autosomal recessive inheritance was consistent in 1.46% of families[19]. Thus, the mode of inheritance is usually autosomal dominant; if both parents were nocturnal enuretics as children, the risk for their children is from 65 to 85 % [20]. If only one parent has NE the risk is about 45 percent [21].

Molecular studies have clearly shown that NE is a complex disease with locus heterogeneity and no clear genotype-phenotype association.

Linkage studies to determine the location of the genetic changes have suggested foci on several genes. Linkage studies to markers on chromosomes 8, 12 and 13 demonstrate both clinical, as well as genetic heterogeneity in nocturnal enuresis [22]. But these have not been consistently reported in other studies [23]. So far, there has been no reported association of the genotype with a particular phenotype of enuresis [24].

V. GENDER AND MONOSYMPTOMATIC NE

Boys suffer nocturnal enuresis more frequently. In a population survey of 706 families in London, Weir found a higher prevalence for boys than girls, at age 3 years, with 56 percent of boys and 40 percent of girls being wet at night more than once a week [25]. More recent studies are consistent [26]. Surveys of monosymptomatic NE undertaken in Great Britain, Holland, New Zealand and Ireland suggest that the prevalence for boys is 13-19% at 5 years, 15-22% at 7 years, 9-13% at 9 years and 1-2% at 16 years. For girls the prevalence rates are reported to be about half that rate: 9-16% at 5 years, 7-15% at 7 years, 5-10% at 9 years and 1-2% in the late teenage years [4,7,27,28]. Although

monosymptomatic NE is more common in young boys, by adolescence the incidence in males is the same as in females [16,29]

VI. CLASSIFICATION

1. PRIMARY VERSUS SECONDARY NOCTURNAL ENURESIS

Children who have never been free of bedwetting for 6 months have **primary NE**. Secondary NE is the re-emergence of wetting after a period of being dry for at least six months. A birth cohort of 1265 New Zealand children studied over 10 years by Fergusson et al found an increased risk of secondary nocturnal enuresis with age [30]. The proportion of children who developed secondary enuresis was 3.3 percent at 5 years, 4.7 percent at 6 years, 6.2 percent at 7 years, 7.0 percent at 8 years, 7.5 percent at 9 years and 7.9 percent at 10 years.

Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent [22, 30,31].

Von Gontard and colleagues found children with secondary enuresis had significantly more emotional difficulties compared to those with primary NE. Their evidence also suggests children with secondary enuresis, compared to those with primary enuresis, are more likely to have behavioural problems, a finding which corresponds to that of McGee et al [32].

Both Jarvelin and Fergusson et al argue that primary and secondary enuretics are similar [30,31]. They believe the two share a common etiological basis. The rate the child acquires primary control influences his or her risk of secondary enuresis. The primary form is the consequence of a delay in maturation of the physiological mechanisms. The child's capacity to sustain and maintain nocturnal bladder control is manifest in the rate at which he or she acquires control. On the other hand, this capacity determines the child's susceptibility to lapsing back to night wetting when exposed to stress.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnea from obstructive airway has been shown to improve or eliminate NE in some children following surgery or medical management [34,35]. Obesity has been associated with nocturnal enuresis both independently [36] and in the context of sleep apnea. [37]

2. MONO-SYMPTOMATIC VERSUS NON-MONO-SYMPTOMATIC NE

Mono-symptomatic NE refers to those children who report no other bladder or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with detrusor overactivity or voiding problems such as urgency and bladder holding during the day [5].

This classification becomes important when considering the most appropriate treatment intervention. Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. Between 10-28% of children with NE have associated daytime wetting. If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resistant to treatment and more vulnerable to relapse [38]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

VII. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of bladder capacity, nocturnal urine output and the ability for the child to arouse during sleep. Night wetting is normal until age 5. Delayed maturation in one or more of the following systems results in NE: a lack of stability in bladder function, a lack of arginine vasopressin (AVP) release or response, or relative increased solute excretion during the night [39,40] , or an inability to wake from sleep to full bladder sensations [41,42]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (**Figure 11**).

1. INCREASED NOCTURNAL URINE OUTPUT

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels [43,44]. In children this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, (AVP) or solute excretion (angiotensin II and aldosterone) and may result from circadian changes in glomerular filtration [45]. In the normal child, this results in increased urine concentration and reduced urine

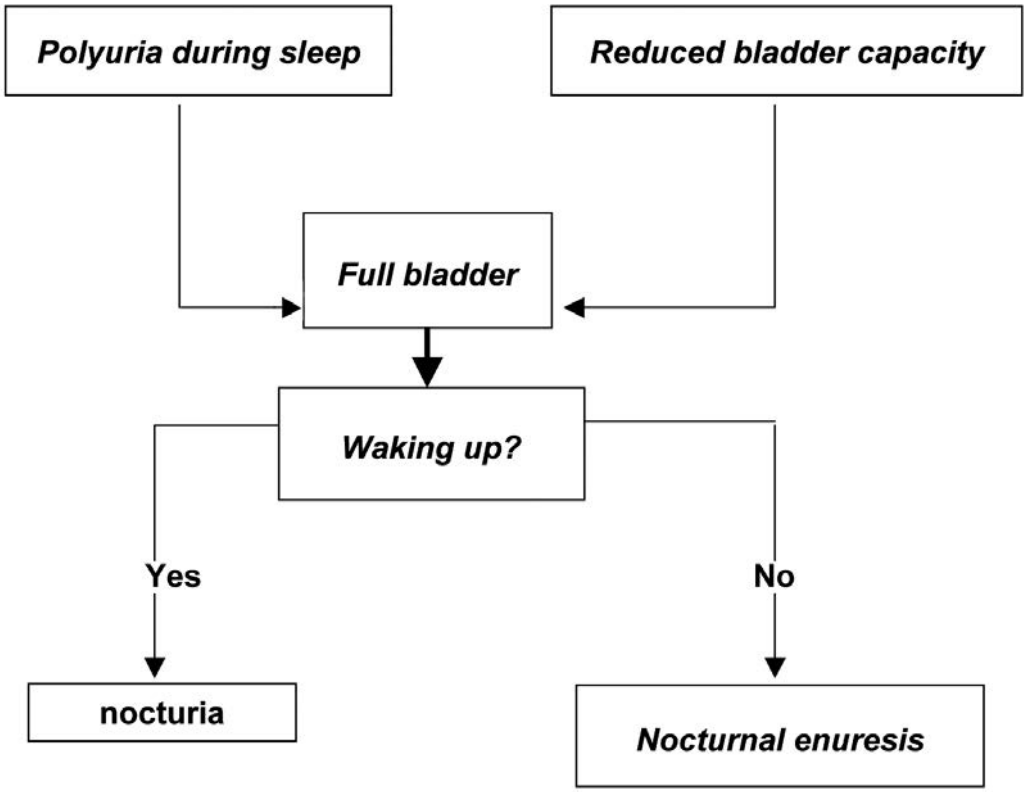

Figure 11: Basic pathophysiology of NE or nocturia. When the bladder is full because of (relative) polyuria and/ or a reduced bladder capacity, the child either wakes up to void (nocturia) or voids while sleeping (NE)

volume during sleep. This is why children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE have been found to have a lack of circadian rhythm of vasopressin, resulting in high nocturnal urine production, which exceeds bladder capacity [46,47,48]. Rittig et al and Norgaard et al demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [46,47]. These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR) [45] or in sodium and calcium excretion[49].

Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are difficult to measure. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. if this total exceeds the child's functional bladder capacity this may indicate nocturnal polyuria. Nocturnal urine output varies appreciably from night to night [50], but seems larger in children with NE who respond best to desmopressin (dDAVP).

By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP [51] with resultant increased urine output [39].

There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [40,52]. Recent work by Devitt et al suggests that 18 percent of children have 'normal' levels of plasma vasopressin release but remain enuretic [48]. These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity. Total urine output during the night could be helpful in differentiating between the two conditions. The subgroup of patients with NE and increased nocturnal urine output generally has a normal func-

tional bladder capacity and a favourable response to dDAVP [53].

2. DETRUSOR OVERACTIVITY DURING THE NIGHT

The detrusor, in order to function appropriately, needs to be relaxed during filling and allow an appropriate functional capacity. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [54].

Watanabe and his colleagues, employing EEG and cystometry recording during sleep, discovered that 32 percent of children with NE had involuntary detrusor contractions that resulted in enuresis [60-62]. These children had smaller functional bladder capacities at the point of wetting, than children with enuresis who did not have detrusor overactivity. Functional bladder capacity – defined as the largest daytime void on a frequency- volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). Reduced functional bladder capacity, when below 70% of predicted FBC for age, is likely to result in poor response to dDAVP treatment [55]. Daytime bladder capacity is smaller than night time capacity in children without NE [56].

The pattern may be different at night. Yeung et al reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [63,64]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children [57].

When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, et al, [58] correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor over activity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favorable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regiments in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, et al. [15] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

3. LACK OF AROUSAL FROM SLEEP/CNS FUNCTION

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (**figure 11**). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor overactivity during sleep. These factors do not fully explain why the enuretic child does not wake up during the night to the sensation of a full or contracting bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child's inability to awaken from sleep to empty prior to the wetting episode.

There is a widely held belief amongst parents and some clinicians that enuretics are deep sleepers. This is logical, since many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Nevéus reviewed by questionnaire 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [42]. Wolfish in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in enuretics than in normals[59]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep [60].

More recently Frietag, et al studied brainstem evoked potentials in 37 children with nocturnal enuresis and compared these aged 8 to 14 years, with 40 controls, mean age 10 years, and found that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggesting that a maturational deficit of the brainstem was present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason behind functional cortical differences in children with family history of nocturnal enuresis [61].

Feittag's study would suggest that a maturational effect is present; however, overnight studies in enuretic children with simultaneous sleep electroencephalographic and cystometry have revealed marked detrusor overactivity, only occuring after sleep at night and not during wakeful periods during the day [62]. Because this pattern has not been observed in normal non-enuretic subjects, even during the newborn period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area in the vicinity of the pontine micturition center, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal center [63].

Another interesting study by Baeyens et al. [64] showed a convincingly significant difference between children with enuresis and control groups, and the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis. Clearly there is considerable work that is required to further unravel the mechanisms behind perceived differences in arousal between enuretic and non-enuretic children.

However a raft of evidence counters such a belief. Sleep patterns of children with NE are no different from children who do not have NE [65].

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is at a volume equivalent to the maximal daytime functional capacity [66-69].

Bedwetting children sleep normally but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness.

Waking becomes easier as the night progresses. However, several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [59,66,67,70,71]. Thus the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep.

Children who do wake up but are afraid to go to the bathroom, and therefore wet their bed should be identified as treatment is completely different for obvious reasons.

VIII. TREATMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. In an important review article, Hjalmas, et al. noted that, "for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment [43]. In order to fulfill the requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age.

Nocturnal enuresis is thought of as a social problem and less of a medical problem; therefore, since the majority of children stop wetting as they mature and since no ill health follows bedwetting in most cases, there is a tendency for many practitioners to take a "wait and see" approach despite the fact that the family and the child in many cases are quite disturbed. In one study, 3803 French school children age five to ten years noted the prevalence of primary nocturnal enuresis to be 9.2%. The majority of the children noted that bedwetting bothered them and hoped that a doctor could help them. In this survey, a questionnaire was addressed to mothers of enuretic children, 100 school teachers and 100 school doctors. The mothers had a relatively tolerant attitude but two-thirds had consulted a doctor. Most of the doctors had proposed no solution or a "wait and see" attitude or treatment with a drug rather than an alarm. From this study, we may conclude that considerable work needs to be done to help educate not only parents but teachers and even physicians about the importance of treatment of nocturnal enuresis as well as supportive care [72].

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. Toilet training age may be different in different societies. For example, toileting in Asia may begin earlier than in North America or other parts of the world [72,73,74]. Toilet training should be started when both the child and parents are ready. Most studies appear to show that children start training between 24 and 36 months of age with a current trend toward later completion than in previous generations. This is markedly different than noted in some Asian cultures where training

appears to begin much earlier. Toilet training should occur in an environment that is comfortable for the child. Unfortunately, toilets in most household bathrooms are adult sized, making it difficult for the child who needs to climb to the top of the toilet to relax. In these cases, a potty chair to toilet train the child, and once the child is old enough, he or she should be transitioned to an over-the-toilet seat with a footstool to allow optimal posture for voiding. Parents should encourage children to relax and take time to completely empty the bladder [43].

It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice such as what to eat and drink and to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertone. Up to 19 percent of children will become dry within the next 8 weeks without any further treatment besides good counselling [43,73,74].

1. EVALUATION

Hjalmas, et al. have recommended a careful history which we will summarize in these next few paragraphs (**Figure 12**). This approach, which has been recommended by the International Children's Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis [43].

a) The frequency volume chart (FVC). Parents are asked to record a two-day three-night record. This includes recording the child's fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday on any weekend.

b) Symptoms of nocturnal enuresis. A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether or not symptoms represent primary or secondary nocturnal enuresis. It is critical to search for new psychological problems that might cause secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternate care givers might have an appreciable impact on voiding habits and will influence management options [43]. Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnea. Other symptoms of sleep apnea include mouth breathing, snoring, and restless sleep [43].

It is important to rule out symptoms of anatomical or physiologic urologic conditions that may lead to

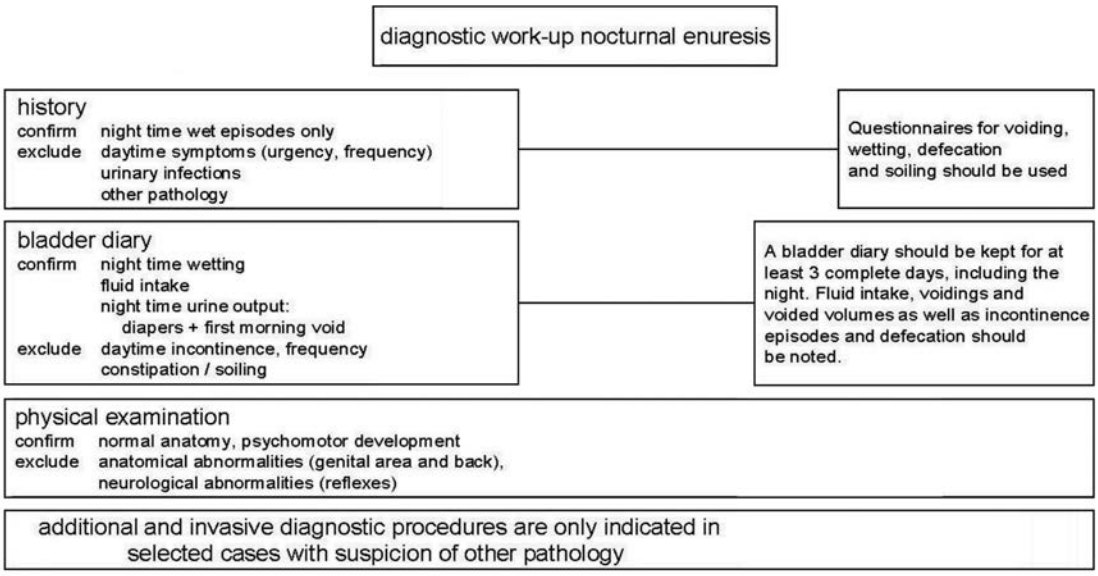

Figure 12 : Schematic work-up in patients presenting with night-time wetting only

nocturnal enuresis. Many of these conditions are covered in other parts of this section, and include a failure to store urine or failure to empty urine. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behavior, daytime incontinence and the sensation to need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Children void four to seven times a day or about every two to three hours [75]. If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder symptoms. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing the genital area with a hand is all suggestive of overactive bladder due to detrusor overactivitiy which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus, which can also cause more frequent voiding [43]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms, or from failing to empty the bladder or sphincter incompetence. Also continous leakage can result from neurologic causes or anatomical causes such as epispadias, or a closed bladder exstrophy or urogenital sinus.

Lastly, children may have incomplete emptying from true dysfunctional voiding which results from the sphincter or pelvis floor contracting at the same time as the detrusor contracts during micturition. In addition, detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as the prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb's collar may also have incomplete emptying. Lastly, the clinician should be alert for symptoms of constipation and faecal incontinence. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the best symptom of constipation is the infrequent or painful passage of hard small pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases [76], this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis.

2. PHYSICAL EXAMINATION

Anatomic and behavioral causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with particular emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult feacal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meatal lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra. Evidence of wetting or irritation of the labia or vagina should be identified, as this could be suggestive of post-void dribbling or incomplete emptying with incontinence due to either detrusor overactivity or sphincter weakness [77].

3. LABORATORY EXAMINATION

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glycosuria and a urine culture if the urinalysis is suggestive of infection.

Urodynamics and imaging are rarely important in the child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring, and then a full evaluation of the daytime problem should precede the evaluation for nocturnal enuresis.

4. THE MANAGEMENT of NE depends on:

- the child's motivation to participate in treatment.
- exclusion of confounding psychosocial factors.
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voidings, and relaxed routines at bedtime.
- regular review of the new intervention.

The therapist should convey a sense of understanding and compassion to both the child and the

family. Education about the problem and a realistic discussion about the prognosis will help instil competence in the treatment offered which may improve both compliance and outcome [78]. What follows is taken in part from the excellent review article by Hjalmas et al [43].

5. EVIDENCE BASED RECOMMENDATIONS FOR TREATMENT

First line treatment and preliminary steps: primary and secondary forms of nocturnal enuresis are treated the same. If faecal incontinence, constipation or daytime wetting is present, these should be treated first [76].

Although treatment modalities like lifting, fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, hypnosis all have been used, there is not sufficient data in the literature to strongly recommend any of these [93-100]. However, non invasive behavioural modifications such as resisting over hydration in the evening are appropriate recommendations at the initiation of therapy. The child must void before bed. Excessive calcium or sodium intake should be avoided as well [79].

During the day the child should be instructed to void regularly, not to hold urine until the last minute, and to relax and take time to completely empty. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family's desire and the child's desire. As a good rule of thumb, children should be six to eight years of age. Some children, however, may want to wait until later. Others may be ready closer to age six. It is important for the parents to know that relapses can occur. The successful treatment of children with nocturnal enuresis has a foundation of realistic expectations and a motivated family [43].

Before starting treatment, a "baseline" meeting with counselling, provision of information, positive reinforcement, reassurance that 15% of children resolve each year, and increasing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomized trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [80].

6. PHARMACOLOGICAL TREATMENT

Based on the three main causes of enuresis, namely nocturnal polyuria, detrusor overactivity, and disorder of arousal, the pharmacological treatment is designed to address these three areas.

a) Desmopressin.

Arginine vasopressin (AVP) or antidiuretic hormone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP by virtue of an independent vasoconstrictor effect is also a potent vasopressor. Desmopressin (or dDAVP) is an analog of vasopressin created by deaminating the cystine residue at position 1 and substituted D-argenine for L -argenine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The half-life of Desmopressin is 1.5 to 3.5 hours. In a larger portion of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production with nocturnal rise of vasopressin is absent. In these cases, dDAVP would seem to be particularly appropriate. Desmopressin is easy to administer and the clinical effects appear immediately. The usual dose is 0.2 to 0.4 mg orally, or 20-40 micrograms intranasally at bedtime. The intranasal form is no longer recommended for nocturnal enuresis in many places around the world. Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosage will become dry when the dose is increased [81].

With meal combination desmopressin melt formulation has a superior pharmacodynamic profile to tablets, making it more suitable for the younger age group with a limited interval between meal and drug administration [82]

Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per month who wants added security on special nights such as a sleepover, etc.

Nocturnal polyuria is a characteristic of children that respond the best to desmopressin [83].

But detrusor overactivity associated enuresis does not easily respond as well to desmopressin treatment. The presence of daytime urgency or daytime incontinence is common in this group, and constipation or faecal incontinence is a regular finding, and these must be treated before offering dDAVP. In the short term, desmopressin is reported to produce more rapid improvement than alarm therapy. The results of various long-term studies which have followed children for six to 24 months after treatment cessation, indicate an annual cure rate in children on long-term treatment of approximately 30% [84,85].

1. Tolerability and Safety

Large amounts of liquid should not be consumed the nights when the drug is taken. There have been several reports that note Desmopressin toxicity [86,87].

This data would suggest that a fairly rigid regimen

of water restriction must be enforced for two hours prior to bedtime and to allow one eight-ounce (300 ml) glass of water at dinner and nothing for the two hours prior to bedtime.

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. In the SWEET study, only six of 242 children (2.5%) withdrew during the long-term treatment because of very mild adverse events following the administration of intranasal desmopressin. With the exception of water intoxication, which can be serious, this drug seems to be tolerated quite well.

In a survey on hyponatremia in patients with nocturnal enuresis, by Robson and Norgard in 1996, it was found that in the majority of children water intoxication was due to considerable intake of water during the time the child was actually taking the desmopressin.

2. Predictors of Response:

The SWEET study found that those who improved or became dry during desmopressin were older (greater than 8 years), had fewer wet nights during baseline, and had only one wet episode during the week and responded initially to the smallest dose of desmopressin used in the study [88,89].

The practical approach, however, is to offer the treatment to enuretic children since it is difficult to absolutely predict those that will respond.

There is considerable evidence that desmopressin works better than placebo. In one study, patients on desmopressin were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo [90].

However, relapse after short-term treatment is common. Sixty-one percent of 399 patients six to 12 years of age recruited from a primary care in one study responded to desmopressin initially [83]. Using intention to treat analysis 19% (77 of the 399) remained dry off medication and 18% were dry while still on desmopressin, thus not significantly better than the spontaneous cure rate. This suggests that desmopressin, by reducing the urine output over night, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous rate.

Although several studies have shown that dDAVP is a well tolerated and safe drug, even during long-term usage, one has to be aware that dDAVP is a potent antidiuretic drug and that there have been reports of severe water retention with hyponatremia and convulsions, but these are infrequent [91-97].

Level of evidence: 1.

Grade of recommendation: A

b) Antimuscarinic drugs for OAB

Antimuscarinic drugs should not theoretically be efficacious in children with monosymptomatic nocturnal enuresis. However, because there is considerable misdiagnosis of monosymptomatic nocturnal enuresis, a number of children with mild daytime symptoms of overactive bladder may have symptoms of overactive bladder at night. Moreover, it has been shown that on Urodynamics, 73% of adults with primary nocturnal enuresis have some form of functional bladder outlet outflow obstruction classified as [1] “primary bladder neck dysfunction” or “detrusor sphincter dyssynergia”. [18]. That would suggest then that antimuscarinic drugs might be a useful alternative in some children who are unresponsive to DDAVP. It is also indicated in combined day and nighttime incontinence [52,98,99].

In general, antimuscarinic drugs are well tolerated but there are some side effects, namely dryness of the mouth, constipation and vertigo (rare). Constipation can also pose a problem since antimuscarinics may lead to constipation and the development of constipation may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Antimuscarinics may also result in increased residual volumes which may make it difficult for the child to empty prior to bedtime. Antimuscarinic treatment in conjunction with desmopressin may have a role in cases with suspected day and night time detrusor overactivity.

Level of evidence : 2.

Grade of recommendation: B.

In those children who have NE due to detrusor overactivity during the night, treatment with an antimuscarinic drug should be considered [100]. Because it is difficult to perform a night time cystometry in these children, it may be tried in children who have more than 2 wetting episodes per night and who do not respond to dDAVP or be given in combination with alarm or dDAVP [101,99]. At present no studies have been performed to demonstrate its efficacy in this circumstance.

Level of evidence: 3.

Grade of recommendation: C

c) Tricyclic antidepressants

Although tricyclic antidepressant drugs, imipramine in particular, have worked in a number of children, most of the studies that recommend this drug are relatively old. The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose.

Because imipramine and other drugs of the same family have potential cardiotoxic side effects they

cannot be generally recommended for treatment of this non-lethal disorder [102].

Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate of only 17 percent restricts the use of these drugs [103].

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) it should be considered [104].

In addition to dDAVP and imipramine, other drugs, such as carbamazine and indomethacin have been investigated as well: based on study design as well as study outcomes, these drugs are not recommended at this stage [105-107].

Level of evidence: 1.

Grade of recommendation: C (due to potential cardiotoxicity).

7. ENURESIS ALARM

The enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat mono-symptomatic NE [107,108]. Intervention with an alarm is associated with nine times less likelihood of relapse than antidiuretic therapy. Relapse rates in the 6 months following treatment are in the order of 15 - 30 %. Alarm therapy has been shown in a meta-analysis to have a 43 percent lasting cure rate [109,110]. Alarm therapy should be considered in every patient. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy.

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy is associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [111-112].

For optimal results, alarm therapy requires a motivated family and child with significant commitment to time and effort. The impact on other family members should be considered. In some families, alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. Close follow-up is important to sustain motivation, troubleshoot technical problems and otherwise monitor the therapy [43].

The exact mechanisms for alarm treatment are not known. The effects are not due to classical conditioning as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning program with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to “nocturia” in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn (vibrating) alarms are as effective as bedside alarms [113].

The family should continue alarm therapy for at least 14 consecutive dry nights – or a maximum of 16 weeks before discarding it as ineffective [114-116]. Compliance remains a problem: drop-out rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child’s preparedness to awake and respond to the signal. Comparison of the different types of alarm did not show significant outcomes.

In general it can be stated that alarm treatment is more effective than other forms of treatment and the lasting cure rate about twice as high [117,118].

Level of evidence 1.

Grade of recommendation A

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioral components. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate [108].

8. DRY BED TRAINING

This is a package of behavioural procedures used in conjunction with the enuresis alarm first described by Azrin et al [119]. It incorporates:

- the enuresis alarm
- cleanliness training (encouraging the child to take responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm)
- waking schedules – to ease arousability from sleep as described above and involving:

  1 for the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether he or she needs to void, and on returning to bed the child is encouraged to have a further drink .

  2 On the second night the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the waking time is advanced by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The waking schedule is restarted if the child begins wetting twice or more in any week, stating again 3 hours after sleep.

High success rates and low drop out have been reported although relapse rates are no different than enuresis alarm treatment alone. Modifications are advocated to remove some of the more punitive elements of the programme but at best, it is a complex, time consuming and a demanding technique [113,120,121]

Hirasing et al found 80 % success with group administered dry bed training. Girls responded better than boys [122]. The majority of parents were satisfied with the programme but opinions of the children were divided. Factors not related to success were the child's age, bedwetting frequency, secondary enuresis or family history.

In another study they found a positive effect on behavioural problems [123].

An important component analysis by Bollard & Nettelbeck found that the enuresis alarm accounted for most of the success achieved through dry bed training. They believe that a large proportion of the components of the procedure can be eliminated without sacrificing much of its overall effectiveness and that the waking schedule coupled with the enuresis alarm is as effective as the complete dry bed-training programme [124].

Level of evidence: 2.

Grade of recommendation D (no more effective than alarm treatment alone)

9. AROUSAL TRAINING

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child's rapid response to the alarm triggering, not on 'learning to keep the bed dry'.

The instructions involve:

- setting up the alarm before sleep
- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and re-sets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker

Van Londen et al first described this procedure with a group of 41 children, aged 6-12 years, with predominantly primary enuresis [125].

They reported 98 percent success [14 consecutive dry nights] compared to 73 percent success with alarm monotherapy. The difference was significant [p<0.001]. Ninety two per cent remained dry after 2 ½ years: a very low relapse rate. An extraordinary aspect of this study was the lack of contact between therapist and parents. All those included were parents who had ordered an alarm from a rental agency and were given the instructions with the alarm. The authors conclude that arousal training is 'definitely the treatment of choice for enuretic children between 6 and 12 years'. Compared with other studies, and considering experience of daily practice, one may question the very high success rate in this particular group of patients.

Level of evidence: 3.

Recommendation: grade C

The enuresis alarm remains the most effective means of facilitating arousal from sleep. The key to success is not the stimulus intensity of the alarm triggering, but the child's preparedness to awake and respond to the signal.

10. ACUPUNCTURE:

In one randomised controlled trial that examined acupuncture, 40 children were allocated either to dDAVP or acupuncture, 75% of children were dry after 6 month of therapy (while still on medication), while 65% of patients were completely dry after a mean of 12 sessions. From this study it is concluded that as an alternative, cost-effective and short-term therapy, acupuncture should probably be counted among available treatment options. Another metaanalysis provides some evidence for the efficacy of acupuncture for the treatment of childhood nocturnal enuresis [126].

Comparison of treatment outcome and cure rates is difficult because of the inconsistent use of definitions, the inclusion of children with daytime symptoms, and the variable follow-up periods in most studies. For a pragmatic approach, see **Figure 3**.

Level of evidence: 4

Recommendation: grade D

11. COMBINED TREATMENT WITH ALARM AND DESMOPRESSIN

Combined treatment may be superior to alarm alone especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of dDAVP is believed to facilitate the child's adaptation to the alarm [127,128]. After 6 weeks the dDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry. Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems.

Combination with full-spectrum therapy may even yield higher success rates [129-130].

Van Kampen et al reported their results of 'full-

spectrum' therapy in 60 patients: they were treated for 6 months with a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training: 52 patients became dry [129].

The combination of alarm with six weeks of 40ug Desmopressin intranasally was better than alarm treatment alone, especially with high micturition frequency and comorbid behavioural symptoms [127]. In a Chinese study comparing alarm, Desmopressin and a combined therapy, the latter had the highest rate of sustained response (40.6%). However, there was a high relapse rate after discontinuing medication [131].

In another randomised-controlled, double blind study, the addition of 3 weeks of 40ug and 3 weeks of 20ug Desmopressin to alarm use, lead to temporary, short-term reduction of wet nights compared to controls on alarm and placebo [128]. The long-term success rate did not differ between the two groups and were low (36% and 37%, respectively). In the subgroup of Desmopressin non-responders, the combination of alarm plus Desmopressin was not more successful (51.5% remission) than alarm plus placebo (48.1% remission), so that this cannot be recommended as a routine strategy [132].

Also, theorectically, the combination of alarm and Desmopressin makes little sense: alarm treatment is an operant type of behavioural therapy that requires a certain number of wet nights to be effective: by reducing the number of wet nights through Desmopressin, the child will have less opportunity to 'practice' and 'learn' continence by the alarm therapy.

Also, the combination of alarm and anticholinergics should be considered if an overactive bladder is suspected. If the alarm is set off several times per night, indicative of overactive bladder, this combination has been proven to be successful. For example, 5 mg of Oxybutinin in the evening combined with alarm could be tried in these cases. If higher levels of anticholinergics are required, several doses should be given over the day.

In conclusion, based on current evidence, alarm treatment alone should be started first. As an adjunct programme, arousal treatment is easy to perform and effective. Also, the combination of alarm and Oxybutinin can be indicated. Alarm and Desmopressin are the two first line alternatives, but their combination cannot be recommended. Other programmes such as 'full spectrum treatment' remain treatment forms that are reserved for therapy-resistant cases. In certain cases, alarm treatment will not be possible: this is the prime indication for desmopressin.

12. INHIBITORS OF PROSTAGLANDIN SYNTHESIS

Because nocturnal polyuria in children with NE may not be entirely attributed to a defect in free water excretion, but rather to an increase in nocturnal excretion of sodium, cyclo-oxygenase inhibitors tlike diclofenac), which reduce urinary sodium excretion, have been tried and in a randomised double blind placebo controlled study proved to be effective [133]. Further studies need to be done to elucidate the role of these drugs.

13. NON RESPONDERS

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from "detrusor dependent NE". These children may void more frequently than their peers or have urgency and day-time urgency incontinence. They are also often constipated. Prescription of dDAVP plus antimuscarinics should be considered, although evidence from the literature is lacking. Most likely, the reduced urinary output during the night leads to a lower filling rate which may reduce the nocturnal involuntary detrusor contractions and enhance the action of antimuscarinic drugs. Treatment success is usually noted between 1-2 months. Treatment should be continued for 6 -12 months, but clinical evidence is lacking.

On the other hand some of these children may have day time incontinence, which was not discovered during the initial workup. They should be given a strict voiding regimen and a combination of dDAVP with the alarm [54].

Some children who remain non-responders to desmopressin in combination with alarm and / or anticholinergic drugs, may have absorptive nocturnal hypercalciuria which may be responsible for the NE in some of these patients. With an appropriate (low calcium) diet these patients can became desmopressin responders [134].

NE is a symptom, not a homogeneous disorder. A really efficient treatment will never become possible until we have clarified all the different pathophysiological subgroups that go under the heading of NE.

14. CONCLUSION

Response and cure of different treatment modalities

Full response (while on medication) and Cure rates (6 months after cessation of treatment) of Nocturnal Enuresis

	Full response	Cure
Alarm treatment	**65%**	**43%**
Desmopressin	**31%**	**22%**
Dry-bed training	**40%**	**18%**
Imipramine		**17%**

- Gaining the confidence of the child and the family is paramount. The development of structure in the child's life, early bedtime, careful diary keeping,

avoidance of fluids late in the day, are critical.

- Secondly, identifying compounding psychological or physiologic factors of the child such as constipation and diurnal enuresis are critical.
- Third, alarm treatment should probably be recommended as the first choice of treatment with the modifications listed above. Single parents have a difficult time with the effort that is required to awaken with the child for the alarm management, and, in some cases, when children are not frequently wet, dDAVP may provide effective therapy for the last few years that they are at risk. In general, those that do the best with the alarm therapy are those with frequent bedwetting, normal estimated bladder volume, parents who are willing to participate, and true monosymptomatic nocturnal enuresis.
- Desmopressin seems to work best in children who are unable to participate in alarm therapy, who have truly monosymptomatic nocturnal enuresis, who are wetting only once on a wet night and are relatively devoid of OAB symptoms.
- If the initial treatment does not provide satisfactory results in two months, the child can switch to another. In some cases, using both the alarm and Desmopressin can be effective [127,135].
- Lastly, combinations of therapy including Desmopressin plus an antimuscarinic can be used in some cases, if detrusor overactivity at night is suspected.

D. Children with both day and night time incontinence

Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder exstrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence and they are referred to as having "functional incontinence."

Becoming continent is a complicated process: there is a progressive development towards normal storage and emptying of the bladder at a socially accepted place and time, mostly achieved by age 3-4.

Bladder control is believed to be under the influence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition (detrusor overactivity control). Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes, However, recent work of CK Yeung suggests bi-directional maturation of both the coordinating influence on the bladder and the pons may be implicated. This implies that a condition such as detrusor overactivity would be the result of loss of cortical control or of deficiency in cortical control, while dysfunctional voiding would be the result of non maturation of the coordination.

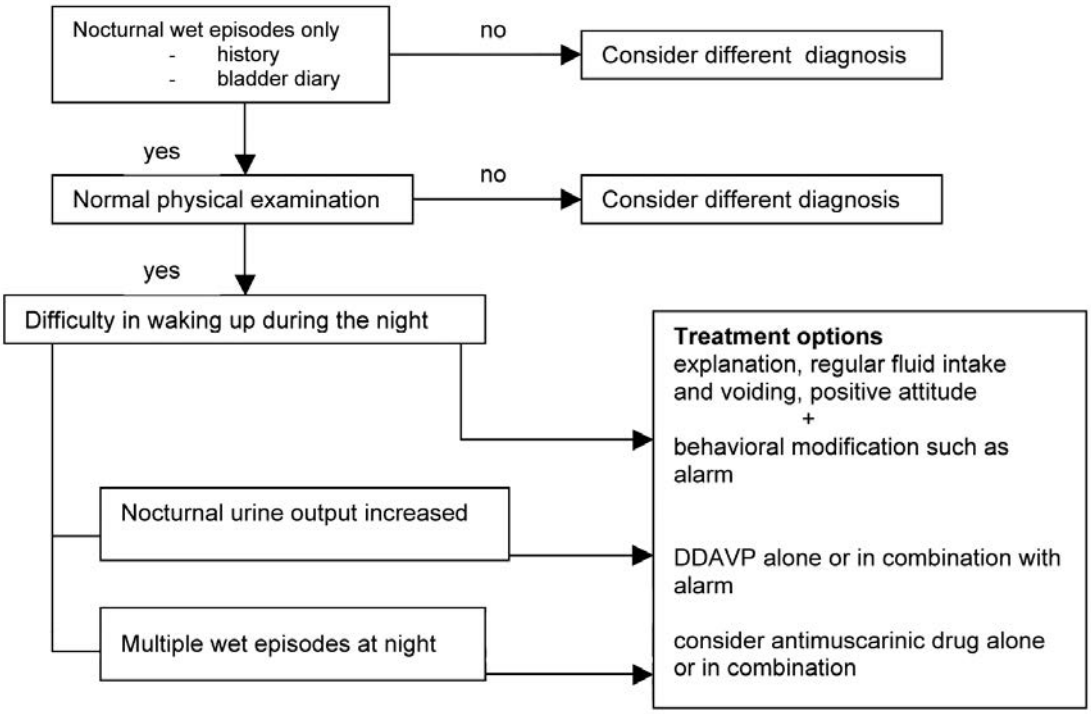

Figure 13. Pragmatic approach to the diagnosis and treatment of nocturnal enuresis

With the emergence of functional MRI, future studies will be able to illuminate this enigma.[1] This opens an era of corticocentric thinking on lower urinary tract dysfunction, moving away from the current trend of vesicocentric thinking. Detrusor overactivity may be a symptom of a centrally located dysfunction affecting bladder, bowel, sexual function and even mood and behaviour.[2] Indeed many studies indicate that there exists a link between lower urinary tract dysfunction and ADHD (attention deficit and hyperkinesia) [3-5].

The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Problems with training or psychological difficulties possibly have a great impact on the results of training: some parents send their child to the toilet many times, though his/her bladder may be empty [6]. Voiding in these circumstances can only be achieved by abdominal straining. The positive reinforcement that the child receives by voiding even a small amount may lead to the development of an abnormal voiding pattern. The same is true when children receive negative feedback related to voiding [7]. Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. . In the ICCS terminology document, these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions. They are divided into either overactive bladder (OAB) or dysfunctional voiding [8]. While the former condition is a filling disorder the latter is considered an emptying disorder. They can of course coincide and one may even be causative of the other.

Detrusor overactivity may lead to disturbances in the filling phase characterized by urgency, frequency and at times urgency incontinence. Girls present with OAB symptoms more often than boys. In addition to the urinary symptoms, children with functional urinary incontinence may also have recurrent urinary tract infections (UTI) and constipation.

Incomplete relaxation or tightening of the sphincteric mechanism and pelvic floor muscles during voiding results in an interupted or staccato voiding pattern, that may be associated with elevated bladder pressures and post-void residuals. Such individuals with dysfunctional voiding are also prone to constipation and recurrent UTIs [9]. Bladder function during the filling phase in these children may be essentially normal, alternatively OAB may be present. In children with a underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals, and incontinence is a characteristic symptom.

I. PREVELANCE

For more detailed information on the prevalence of daytime incontinence the Chapter on Epidemiology should be consulted, where an overview is presented on the currently available data. The main problem is that it is impossible to draw any conclusions from the presented data as different studies have used definitions and criteria that differ from others. Furthermore, it is virtually impossible to identify the prevalence of detrusor overactivity or dysfunctional voiding as the studies tended to look primarily at daytime versus nighttime incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and nighttime incontinence at least once a week seems to occur in about 2-4 percent of 7-year old children and is more common in girls than in boys [10]. Overall the rates of prevalence vary from 1 to 10 percent, but in general for 6 to 7 year old children the prevalence is somewhere between 2 and 4 percent, and rapidly decreases during the following years [11-17]. Sureshkumar et al in a population based survey of over 2000 new entrant primary school children [age 4-6 years] in Sydney, Australia noted an overall prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experienced more than one wetting episode and only 0.7% experiencing wetting on a daily basis [17,18]. Multivariate analysis showed that recent stress, a history of daytime wetting along the paternal line, and a history of wetting among male siblings were independent risk factors for moderate to severe daytime wetting. Because this was a cross-sectional study recall bias may have resulted in an overestimate of risk of daytime wetting being caused by such factors as emotional stress and family history. In addition, urine cultures were not obtained so occult UTIs could not be identified.

Chung comes to the same percentage of OAB (16,6%) in 19,240 Korean children. In this study OAB was differentiated in ‘dry’ OAB and ‘wet’ OAB: children with OAB do not always have incontinence [19].

In a questionnaire based study, supplemented by telephone calls, Hellstrom assessed the prevalence of urinary incontinence in 7 year old Swedish school entrants [20]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was reported in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomitant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2 % of boys and 0.7% of girls. A limitation of this study is its dependency on recall. Children with daytime or mixed wetting were found to suffer from urgency in 50.7 %, with 79.1 % wetting themselves at least once in 10 days [21]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [21,22].

Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier [2.25 years] than boys (2.56 years) [23]. A Turkish study, in 2008, reported day dryness at a mean age of 28 months [24]. The age of commencing toilet training has increased [25].

This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach rather than parent-initiated methods [26]. Children who exhibited elimination signals for voiding became dry sooner than those who did not show such signs. There is huge social and cultural variation in toilet training practices with some of the implicated issues being, availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods [23].

It appears that initiating toilet training after 24 months of age may be associated with problems attaining and maintaining bladder control and that early training is not associated with bladder dysfunction [25,26].

Da Fonseca found no such association between children with combined bladder and bowel dysfunction and the time of toilet training compared to healthy children [27].

Swithinbank et al have found a prevalence of day wetting [including also "occasional" wetting] in 12.5% in children age 10-11 years which decreases to 3.0% at age 15-16 years [28]. Based on these findings, it seems that the prevalence of all kinds of daytime incontinence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incontinence, at least once a week, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not recount the true natural history.

A more recent cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Sweden), daytime urinary incontinence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal incontinence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary incontinence often coexist [29].

The natural history of detrusor overactivity in children is not well understood. It is no longer held that detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the generation of a high pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the growing bladder could be causative. This is in contrast to the adult population, where detrusor overactivity is considered a chronic condition whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult.

There is evidence that genetic influences affect adult urinary symptoms and that suffering lower urinary tract conditions in childhood increases the risk for these conditions in adult woman [30-33]. Recent research points to a link between deficits in the brain and functional urinary problems [5].

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. After this age, night-time and daytime involuntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [37]. A more recent study found no significant differences in the presence of lower urinary tract symptoms between children and adolescents who had experienced sexual abuse and controls [33]. Nevertheless this should be kept in mind, especially when invasive diagnostic and therapeutic procedures are contemplated. One may want to simply ask the parent or caregiver if there were any precipitating events or concerns that they feel may have led to the changes in the child's voiding habits. The appropriate individuals should be contacted if there is a high index of suspicion. Of adult women with complex urinary symptoms, a significant proportion report sexual abuse as a child.

II. INTRODUCTION TO CLINICAL ASSESSMENT

The International Children's Continence Society has published standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the management of dysfunctional voiding in children. They also assessed psychological and psychiatric issues in urinary and fecal incontinence [34-36].

The evaluation of daytime wetting is based on the medical and voiding history, a physical examination, a urinalysis, bladder diaries and uroflowmetry with post void residual. The upper urinary tract should be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate overactivity of the pelvic floor muscles. Urodynamic studies are usually reserved for patients with therapy resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [38-41].

Treatment is usually a combination of 'standard therapy' (see below), behaviour therapy, bladder training, physiotherapy and medical treatment. Surgery is rarely needed for the management of daytime

wetting in the absence of a structural abnormality. The roles of neuromodulation, botulinum toxin and intravesical therapies in the management of pediatric urinary incontinence are less well-defined. Clean intermittent self-catheterization is sometimes necessary in children with poor bladder emptying, due to underactivity of the detrusor and subsequent large residuals, who do not respond to a more conservative approach. The importance of treatment during childhood was pointed out in a general population study of 1333 adult women. Fifty percent reported symptoms of stress incontinence and 22 percent reported symptoms of urgency incontinence. Eight percent noted severe symptoms. Women who at age six years had wet episodes during the day or were wet several nights per week, were more likely to suffer from severe incontinence and report urgency symptoms: occasional bedwetting was not associated with an increased risk in adult life [42].

III. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICOURETERIC REFLUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been confirmed by several authors [43-46]. Koff demonstrated that treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3 fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [46]. Other investigators assessing high grade VUR in newborns noted similar findings. Van Gool et al noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [47].

These studies in infants and the association of combined bladder and bowel dysfunction with reflux and infection in older children support the suggestion that, in some individuals, vesicoureteral reflux is a secondary disorder related more to abnormal detrusor function than to a primary anatomic defect at the ureterovesical junction. It has been shown that increased intravesical pressure, without reflux, may be detrimental for the upper tracts: renal scarring without reflux was described by Vega at al recently [48].

In support of this concept is the common finding of vesicoureteral reflux in children with neuropathic bladders and detrusor-sphincter dyssynergia. In such children, the institution of clean intermittent catheterization and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete emptying of the bladder are the responsible co-factors [49]

Koff et al. evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and compared these children with an age-matched control group with a normal urodynamic study [50]. The overall small sample size and the small number of compliant patients limit the study, however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group [16%] compared to the non-medically treated group [63%] and the age-matched control group [71%]. Several authors have documented the relationship between detrusor overactivity and dysfunctional voiding with recurrent UTIs .

Proposed etiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proximal urethra are “milked back” into the bladder during contraction of the pelvic floor muscles. Alternatively, decreased blood flow and relative hypoxia during periods of increased detrusor pressure such as during involuntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury.

Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [51]. It is a risk factor for recurrent UTIs. Contrary to expectations, findings from the European Bladder Dysfunction Study suggested that symptoms of disordered defecation did not influence the cure rate of treatment for bladder symptoms [52]. In a prospective non-randomized clinical series of day wetting children, a strong correlation was found between recurrent urinary tract infections, detrusor overactivity and detrusor-sphincter dysfunction [53]. In a study by Hansson et al, symptoms of detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacteriuria [54].

In the majority of children with dysfunctional voiding the recurrent infections disappeared following successful treatment of the voiding dysfunction. This finding confirms the hypothesis that dysfunctional voiding is the main factor responsible for the infections [and to a lesser extent vice versa] [55,56],. Additionally, since such children typically have coexistent constipation, attempts at restoring normal bowel habits will also contribute to decreasing the risk of UTIs. At present, current opinion is that vesicoureteral reflux as such does not predispose to UTI: however it may facilitate renal involvement [causing pyelonephritis] once bacteriuria has been established in the bladder. This concept has not been scientifically validated and the incidence of renal scars as a consequence of pyelonephritis is reportedly the same, regardless of whether reflux has been documented

or not [57]. Those children with VUR in association with detrusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylactic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [58-61].

In a recent study evaluating retrospectively a large group of children with LUT conditions it was shown that in patients who had urinary tract infection the presence of reflux increased the rate of renal cortical abnormalities. [62]

IV. CLASSIFICATION

Numerous classifications have been used for children who present with varying degrees of 'functional' urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2006, the International Children's Continence Society (ICCS) released a standardized terminology to provide guidelines for the classification and communication about LUTS in children [8]. Symptoms are classified according to their relation to the voiding and or storage phase of bladder function.

In addition to gaining a comprehensive history, observing micturition and examining the child forms the basis of assessment: the information derived from a 48-72 hour bladder diary, stool record, voiding uroflowmetery and lower urinary tract ultrasonography is also essential in making the initial diagnostic classification [34]. Urodynamic investigations elucidate the basis of clinical findings but are first line evaluation techniques only in tertiary referral centers where children have not responded to previous treatment or have symptoms suggestive of neural involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of underlying pathophysiology. The groups commonly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.

Over active bladder (OAB) including urgency incontinence

Dysfunctional voiding

Underactive bladder

The symptom-specific conditions of

Voiding postponement

Vaginal reflux

Giggle incontinence

Extraordinary daytime urinary frequency

Elimination syndrome

The term 'non-neurogenic dysfunction' is commonly encountered in the literature and describes the whole spectrum, from simple bladder overactivity to severe cases with deterioration of the upper tracts. The fact that a neurologic deficit is not demonstrated at the time of evaluation, does not, however exclude the possibility that a neurologic abnormality was present at the onset of the problem. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [63].

1. OVERACTIVE BLADDER IN CHILDREN

The term bladder overactivity is used to describe the symptom complex of urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage. Recent suggestions describe OAB as a symptom of corticocentral dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [64],.Urgency syndrome is characterized clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one's urine for a prolonged period of time. The symptoms arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimize wetting. The detrusor contractions can be demonstrated urodynamically, as can the increased activity of the pelvic floor muscles during each contraction.

The voiding phase is essentially normal, but detrusor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quickly and may level off ('tower shape'). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition, these children may note suprapubic or perineal pain. A cohort of patients presenting with nighttime pain syndromes based on pelvic floor spasms was described by Hoebeke et al. Good response to pelvic floor relaxation biofeedback is described in this study [65]

Overactive bladder (OAB) should also be considered in "continent" children with recurrent UTI and vesicoureteral reflux. Depending on fluid intake and

urine production, the complaints of incontinence become worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually diminish their fluid intake to minimize wetting, and therefore incontinence may not be the main complaint or symptom, but on careful questioning urgency becomes apparent.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defecation. Constipation and fecal incontinence (soiling) are often found in children with detrusor overactivity [66]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natural history of combined emptying dysfunction of bladder and bowel, using an elimination score in women with and without urogynaecological problems, demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [67].

A careful history, physical examination and scrutiny of the child's bladder diary will identify symptoms of detrusor overactivity. Urine flow rate registration and post-void residual urine measurement help to identify co-exsisting dysfunctional voiding. Thus in the majority of children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurologic defect and those who fail to improve with medical and behavioral therapy, if invasive therapies are being considered.Those children with a history of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child, and the severity of the UTI(s), a voiding cystourethrogram (VCUG) to assess reflux is occasionally performed [68,69]. By adopting a structured approach to history and physical examination, the diagnosis of urgency syndrome can be made in the majority of children without the need for invasive diagnostic procedures.

Treatment:

The treatment of urgency syndrome involves a multimodal approach, involving strategies such as behavioral modification, antimuscarinic medication, adjunctive biofeedback and neuromodulation. Underlying and potentially complicating conditions such as constipation and UTIs are managed prior to intervention.

Level of evidence: 3.

Grade of recommendation: C

2. DYSFUNCTIONAL VOIDING

Dysfunctional voiding refers to an inability to fully relax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunctional voiding usually present with incontinence, urinary tract infections and constipation and demonstrate a intermittent, or fluctuating pattern referred ot as staccato flow (by ICCS definition) during repeated uroflowmetry.

No clear data are available on the possible causes of dysfunctional voiding. It may be that detrusor overactivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [70]. Alternatively, poor relaxation of the pelvic floor muscles during voiding may be a learned condition during the toilet training years, adopted following episodes of dysuria due to UTI, or constipation or occuring secondary to sexual abuse [71]. The child's environment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anomalies [72]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavernosus muscle causing intermittent voiding [73]. Since no true structural obstruction can be identified the intermittent incomplete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dysfunctional voiding:

- Fluctuating (Staccato) voiding: continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.
- Interrupted voiding: characterized by unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-expected capacity. Residual urine is often present. Detrusor overactivity may be seen but it may also be absent [56, 68, 74].

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as phasic detrusor overactivity and inappropriate urethral relaxation [75]. Urinary tract infections and kidney damage are common sequelae[76]. Over time, routine incomplete bladder emptying can progress to detrusor over-distension associated with chronic urinary retention. The child with this presentation is often classified as having poor bladder emptying due to detrusor underactivity .

Urinary symptoms associated with dysfunctional voiding range from urgency to complex incontinence patterns during the day and night [77]. Children with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and also demonstrate increased incidence of higher grades of VUR [63, 78]. Symptoms are significantly more common in children with Attention Deficit Disorder than in 'normal' children [79].

Signs of dysfunctional voiding reflect initial "compensatory" overactivity of the detrusor along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxation of the external urinary sphincter/ pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, secondary vesicoureteric reflux, fecal incontinence or constipation [63, 80,81].

Treatment:

Symptoms are often refractory to standard therapy of hydration, bowel management, timed voiding and basic relaxed voiding education. Effective intervention requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimizing bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Specific goals are:

- consistent relaxation of the pelvic floor throughout voiding,
- normal flow pattern,
- no residual urine and
- resolution of both storage and voiding symptoms.

Strategies to achieve these goals include pelvic floor muscle awareness and timing training, repeated sessions of biofeedback visualization of pelvic floor activity and relaxation, clean intermittent self-catheterization for large post-void residual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in increased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [82]. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described.

Level of evidence: 4.

Grade of recommendation: C

3. DETRUSOR UNDERACTIVITY

Children with detrusor underactivity may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermittent and often augmented with abdominal straining.

Children with this condition usually present with urinary tract infections and incontinence. Urodynamically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contraction during voiding. Abdominal pressure is the driving force for voiding. The previously used term 'lazy bladder' is incorrect and is no longer used.

A correct diagnosis can only be made by urodynamic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to assess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to a non-contractile detrusor. However, no data are available to support this theory.

Treatment:

Treatment is aimed at optimizing bladder emptying after each void. Clean intermittent (self) catheterization is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation [which may be extreme in these patients]. Intravesical electrostimulation has been described, but at this time it is still not recommended as a routine procedure for children.

Level of evidence 4

Grade of recommendation C

4. VOIDING POSTPONEMENT

Voiding postponement is a condition in which children postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [83] . A recent study comparing children with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioral symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioral disorder [83]. In the children with voiding postponement only 20% exhibit a fluctuating voiding pattern. It remains to be determined whether or not voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

Level of evidence 4

Grade of recommendation C

5. GIGGLE INCONTINENCE

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [84]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The etiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurologic abnormalities [85,86]. It is postulated that laughter induces a generalized hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been

demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects further evidence is needed [87]. Since the etiology of giggle incontinence is not known it is difficult to determine the appropriate form of treatment. Positive results have been reported with conditioning training, methylphenidate and imipramine [85- 91]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable evidence that any form of treatment is superior to no intervention.

Level of evidence 3

Grade of recommendation D

6. VESICOVAGINAL ENTRAPMENT

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux [92]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor. Changes in voiding position and treatment of labial adhesions will lead usually to resolution of the urine leakage.

Level of evidence 4. Grade of recommendation C

7. ELIMINATION SYNDROME

This is a term used to describe dysfunctional emptying of bowel and/or bladder presenting with symptoms of OAB, constipation and sometimes infrequent voiding.

The term is misleading as the combined bladder and bowel dysfunction involves dysfunction of both emptying and storage.

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this co-existence was considered coincidental. However, it is now accepted that dysfunction of emptying of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [66,72,93].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

The Elimination Syndrome [ES] is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [94]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with ES when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an etiological factor [84], however, recurrence of UTI in children older than 5 years is associated with the presence of ES [95,96].

Abnormal recruitment of the external anal sphincter during defecation or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops fecal retentive incontinence. If constipation was not present as a predisposing factor, it rapidly develops [93].

Children with elimination syndrome commonly complain of urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) and exceptionally urinary frequency. On investigation, they are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, fecal incontinence, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

Assessment follows the same process as for other aspects of pediatric bladder dysfunction, with the addition of a 2 week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measure, either via the perineum or when assessing the bladder, has been shown to be discriminative for children with elimination syndrome. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of elimination syndrome. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for ES has been developed providing objective assessment for diagnosis and quantification of severity [97].

Treatment:

Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching dynamic elimination skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defecation dynamics. Once stools are being passed regularly, treatment focuses on teaching awareness of age appropriate fullness in the bladder, and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are few studies of the efficacy of treatment in children with elimination syndrome. Several authors have evaluated the outcome of constipation management on bladder symptoms, however the baseline characteristics of subjects were not described adequately enough to allow clear diagnosis of elimination syndromes [66, 97]

A review on the effectiveness of biofeedback for dysfunctional elimination syndrome reports that 80% of children benefited from biofeedback but that the level of evidence was low due to poor study designs [99].

V. PRINCIPLES OF NON PHARMACOLOGICAL TREATMENT FOR ALL DIFFERENT STATES

Treatment of the over active bladder focuses on both the involuntary detrusor contractions and the child's response to these. The initial treatment of daytime urinary incontinence involves a behavioral and cognitive approach. The child and parent[s]/caregiver(s) are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and UTIs and any constipation are managed. Additional treatment involves pharmacotherapy, pelvic floor muscle relaxation techniques and biofeedback, either alone or in combination.

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomized or controlled trials. The paucity of studies evaluating basic standard therapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, patient numbers, objective outcome measures and length of follow-up are sub-optimal.

The main objectives of treatment are to normalise the micturition pattern, normalize bladder and pelvic floor overactivity and cure the incontinence, infections and constipation. Traditional therapy for day-wetting children is cognitive and behavioural. Children learn to recognize the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvers [i.e. immediate voiding without postponement] to generate urethral compression. Children with dysfunctional voiding learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a detrusor contraction rather than via generation of abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation [98]. Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited.

"Bladder training" is used widely, but the evidence that it works is variable [50, 88]. Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment in itself [47] . More active conventional management involves a combination of cognitive, behavioral, physical and pharmacological therapy methods. Common modes of treatment include parent and child reassurance, bladder retraining (including timed toileting), pharmacotherapy, pelvic floor muscle relaxation and the use of biofeedback to inhibit rises in detrusor pressure associated with urinary incontinence [29, 100-102]. Further treatment options include suggestive or hypnotic therapy and acupuncture. A combination of bladder training programs and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary.

1. BLADDER REHABILITATION AND UROTHERAPY

Initial intervention for OAB and dysfunctional voiding uses a non-pharmacologic approach. This is often termed Urotherapy. Despite its use for many years there is no set format to urotherapy and many clinical studies utilize differing combinations of therapies, which makes it difficult to evaluate the results [29, 60, 101]. The aim of urotherapy is to normalize the micturition pattern and to prevent further functional disturbances. This is achieved through a combination of patient education, cognitive, behavioral and physical therapy methods.

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis but was recently used in management of daytime wetting. When a time watch was utilized as a reminder to void at regular intervals 70%

of children became dry. An earlier study of a contingent alarm [which sounded when the child wets] versus a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) over 3 months in 45 children [103] was equally successful for the achievement of continence. Predictors for dryness included a low voiding frequency, larger volumes voided in relation to age-expected storage and fewer incontinent episodes per week [104].

There is evidence that for children who are therapy-resistant, timed voiding assisted by a timer watch added to urotherapy is effective [105].

Following a 3 month training programme, 42.8% of daywetting children were cured at 1 month, 61.9% by 6 months, and 71.4% by 1 year [106]. Allen et al [107] reported that urotherapy patients with good compliance with timed voiding were significantly more likely to improve their continence than those with poor compliance. It has recently been highlighted however, that there is frequently conflict between school rules, routines and toilet facilities and the urotherapy programme components. Adaptive coping techniques added to urotherapy training may enhanced gains in dryness.

In children with OAB and dysfunctional voiding the pelvic floor muscles relaxation is impaired during voiding. Physiotherapy is concerned with re-training of specific muscle groups. Adjunctive physiotherapeutic input offers children different strategies to achieve pelvic floor relaxation during micturition.

Several centers offer intensive urotherapy called voiding schools or even inpatient rehabilitation. A prospective evaluation of 38 Belgian children who underwent this approach showed improvement in 90% of the children with 42% becoming dry, whilst no child on the waiting list improved during the 6 months [108]. Long-term follow-up of 75 incontinent children who underwent intensive urotherapy 16-22 years later showed a good result in 84%and the authors concluded that if the original outcomes of pediatric intensive inpatient urotherapy were good, they tend to remain so over time in most patients [109].

Level of evidence 3.

Grade of recommendation C

2. ADJUNCTIVE BIOFEEDBACK

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback may be utilized for the management of both filling phase (detrusor overactivity) and voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities.

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Training with biofeedback can be used as a single treatment [110,111], or in conjunction with a comprehensive rehabilitation program [112,113]. It may be performed by a cystometrogram during which the child is taught to recognize and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time consuming process with limited application as a routine treatment.

More commonly pelvic floor muscle relaxation is taught through the use of EMG biofeedback and real-time uroflow. The child sits on a toilet with a flow transducer, watching both the flow curve and EMG on a computer display, and attempts to empty completely in one relaxed void. Ultrasound may be used to determine the post void residual and demonstrate complete emptying. Interactive computer games are commonly used to make biofeedback training more attractive to children [114,115], however care should be taken that posture and muscle recruitment approximates that of the voiding position.

The results of biofeedback are commonly reported as case series rather than RCTs. Results are generally positive but overall may not be superior to high quality standard urotherapy. The group receiving adjunctive biofeedback in the Vasconcelos study [106] did not achieve greater continence rates at the study end point, although a greater proportion of subjects achieved earlier dryness. Furthermore, the post void residual volumes were significantly reduced in the biofeedback group compared to the standard therapy only group.

Long duration follow-up, whilst desirable, confounds results of intervention in children who are continually growing and maturing. Hellstrom et al report results of a 6 week bladder rehabilitation program inclusive of biofeedback [101] and note that at 3 years, 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

Level of evidence: 3

Grade of recommendation C

3. CLEAN INTERMITTENT (SELF) CATHETERISATION

In children with an underactive detrusor, bladder emptying can be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterization (CISC) may be tried [116-118]. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the

severity of the problem and may vary between four times a day and once a day before going to bed.

Level of evidence 4.

Grade of recommendation C

4. NEUROMODULATION

Neuromodulation has been used in adults for a variety of lower urinary tract symptoms and has been applied in children. The use of transcutaneous stimulation with surface electrodes stimulating the sacral root (S3) has shown promising results, especially when tested as part of a randomized controlled trial [119]. Transcutaneous and percutaneous neuromodulation delivered over either the sacral outflow or peroneal region of the ankle at a frequency between 10-25 Hz, has proven a useful adjunctive treatment in children with detrusor overactivity. Intravesical stimulation can impact function of an underactive detrusor and potentially improve detrusor contractility and enhance bladder emptying [120,121]].

Electrical current directly affects the central nervous system by artificially activating neural structures; facilitating both neural plasticity and normative afferent and efferent activity of the lower urinary tract. For children with structural abnormalities, for example imperforate anus, electrostimulation is one method of facilitating strength gains in the skeletal muscle and its fascial attachments. Treatment is particularly useful in patients with very little pelvic floor awareness to stimulate muscle recruitment. Once neural efficiency has improved, training is augmented by active pelvic floor contractions.

In 2011, three papers were published reviewing the use of neuromodulation in children [122-124]. This highlights the level of interest in this modality for treating LUTD and also bowel dysfunction. A literature search revealed 18 reports of the use of neuromodulation in children with non-neurogenic bladder dysfunction. Only three of these studies were randomized and controlled, one a randomised crossover study whilst the rest were case series. However parasacral TENS has been shown to be more effective than sham in randomized trials in treating OAB. Use of neuromodulation in children with neurogenic LUT dysfunction has been reported in 9 studies, 3 of which were randomized controlled trials.

Of note is the fact that most studies have looked at the use of electrical neuromodulation in children whose symptoms have been refractory to all other interventions, whereas using it as first-line treatment may prove beneficial. Also studies using intravesical, transcutaneous and implantable electrodes have noted improved bowel function. One randomised placebo-controlled trial using interferential current transcutaneously showed significant improvements in colonic transit times,decreased soiling and abdominal pain and increased quality of life in children with severe constipation [125].

From **Table 1 and 2** it is clear that different modes of application have been trialed in mostly small series of children. There is minimal standardization of populations, application parameters or outcome measures. Thus evidence is largely drawn from low quality studies. Clearly neuromodulation in children warrants larger, controlled and randomized studies, including its use as first-line intervention and in children with combined bladder and bowel dysfunction. Despite the slow pace of research the reviewers of the articles mentioned above agree that there is a positive role for neuromodulation in children with LUTD, and that it is adjunctive to other interventions, with no known predictors of efficacy at the present time, but also rare and minor adverse events. Neuromodulation of the bowel shows promise.

Tables 1: Study parameters in paediatric neuromodulation trials (Neurogenic and Non Neurogenic bladder dysfunction)

Author and year of publication	Population	Design	N	Mode of application	Outcome measure
Guys 2004	Neurogenic (Spina bifida)	RCT	42	Sacral implant	n/s difference from controls for continence
Marshall 1997	Neurogenic (MMC)	RCT	50	Transcutaneous	n/s difference from controls for continence
Johnston 2005	Neurogenic (spinal cord injury)	Series	2	FES implant	Suppression of detrusor overactivity in 1 pt
Han 2004	Neurogenic (MMC)	Series	24	Intravesical	Significant ↓ in faecal incontinence
De Gennaro 2004	Neurogenic and Non neurogenic	Series	6 17	Percutaneous tibial nerve	n/s difference in neuropathic pts 5/9 with incontinence cured
Gladh 2003	Neurogenic and Non neurogenic	Series	20 24	Intravesical	40% cure neurogenic 83% cure non neurogenic
Hagerty 2007	Neurogenic	series	405	IVES	61% gained sensation >UD bladder capacity 77%
Balcolm 1997	Neurogenic	series	29	Transcutaneous	Sensation improved >bladder capacity ($p<0.05$)
Kajbafzadeh	Neurogenic	series	30	Transcutaneous IFT	MMDP, PVR, and DSD improved to sham ($p<0.05$) Also frequency and enuresis ($p<0.05$)

Table 2: Study parameters in paediatric neuromodulation trials (Non Neurogenic bladder dysfunction)

Author and year of publication	Population	Design	N	Mode of application	Outcome measure
Tanagho 1992	Non neurogenic	Series	6	Sacral implant	Resolution 4/6
Trsinar 1996	Non neurogenic	Controlled trial (sham)	73	Anal plug	+ve gains in active group
Bower 2001	Non neurogenic	Series	17	Transcutaneous sacral	73% improved continence
Gladh 2001	Non neurogenic (DI diagnosis)	Series	48	Anal plug	18/48 cured
Hoebeke 2001	Non neurogenic	Series	41	Transcutaneous sacral	56% cured after 1 year
Hoebeke 2002	Non neurogenic	Series	32	Percutaneous tibial nerve	25% cured, 35% improved UD>MVV
Gladh 2003	Non neurogenic	Series	24	Intravesical	Normalized voiding 83%
Lee 2005	Non neurogenic (infrequent voiding)	Series	12	Intravesical	Signif - max flow rate, signif ¯ PVR
Barroso 2006	Non neurogenic (urge syndrome)	Series	36	Transcutaneous sacral	12/19 “complete” improvement
Humphreys 2006	Non neurogenic (severe DES)	Series	23	Sacral implant	Improvements: Day 83% Urgency 75% Freq’y 73% Bowel 80% Retent’n 60%
Malm-Buatsi 2007	Non neurogenic	Series	18	Transcutaneous sacral	13 cured
Roth 2008	Non Neurogenic (DES)	Series	20	Sacral implant	Resolution constipation in 71%
Hagstroem 2008	Non neurogenic	RCT (sham)	25	Transcutaneous sacral	8/13 partial response
Lordelo 2009	Non neurogenic	Series	49	Transcutaneous sacral	2yr later 73% cured
Capitanucci 2009	Non neurogenic	Series	33	Percutaneous tibial nerve	Complete /partial response 78% 2 yrs later
Lordelo 2010	Non neurogenic	RCT (sham)	21 (test) 16(control)	Transcutaneous sacral	62% cured test group. None in control ($p<0.001$)
Haddad 2010	Non neurogenic	RCT crossover	33	Sacral implant	Effective ($p<0.001$) Improvements: 75% for urinary 81% bowel
Lordelo 2010	Non neurogenic (NMNE)	Series	19	Transcutaneous sacral	42% resolved 21% improved

Reported changes on bladder function with neuromodulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infection. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

More recently the first reports on sacral nerve stimulation with implantable electrodes have been published. In a group of 20 patients between 8 and 17 years old followed prospectively. Urinary incontinence, urgency and frequency, nocturnal enuresis and constipation were improved or resolved in 88% (14 of 16), 69% (9 of 13), 89% (8 of 9), 69% (11 of 16) and 71% (12 of 17) of subjects, respectively. Complications were seen in 20% of patients [126] . Due to the uncontrolled design the level of evidence is low. Experience from adults offered this treatment modality suggests future positive development in children to be likely.

Level of evidence: 3.

Grade of recommendation C

5. ALARM TREATMENT

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and has rarely been used for daytime wetting. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday et al compared a contingent alarm which sounded when the child wets with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [103]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3 month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67% of the risk of persistent wetting with the noncontingent alarm, the difference in the reduction in wetting between the groups was not significant (RR 0.67, 95% CI 0.29 to 1.56). In a more recent retrospective review by Van Laecke et al, a cure rate of 35% after the use of a daytime alarm was described[127]. Due to the retrospective design of the study the level of evidence is low.

Level of evidence: 3

Grade of recommendation C

6. CONCLUSION

Most clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Physiotherapy and biofeedback both focus on the pelvic floor. Relaxation of the pelvic floor during voiding is essential for normal voiding and most of these patients are unable to relax their pelvic floor muscles. Biofeedback is important for showing the children the effect of their relaxation efforts. Most studies only state the clinical responses, and do not provide information on urodynamic parameters before and after treatment. A 'normal' flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. In children with a suspected bladder outlet obstruction, endoscopic investigations should be performed. Most often the anatomic abnormality causing abstruction can be treated at the same time. In girls, a meatal web may cause a deflection of the stream upwards [causing stimulation of the clitoris and bulbocavernosus reflex. A meatotomy may cure this problem, though no information on the long-term effects is available [73].

VI. PHARMACOLOGICAL TREATMENT

1. ANTIMUSCARINIC THERAPY

Antimuscarinic therapy remains one of the common forms of therapy for detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of detrusor overactivity. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and urinary tract infections [128]. More commonly, pharmacotherapy is instituted when behavioral therapy has failed to achieve a satisfactory outcome. Some clinicians use pharmacologic therapy as a first line therapy in children with moderate to severe daytime incontinence [60].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioral therapy regimen, the outcome of pharmacologic therapy for daytime urinary incontinence is "unpredictable and inconsistent" and there are few randomized studies available to assess drug safety and efficacy.

a) Oxybutynin

Currently the pharmacologic therapy most widely used in children with detrusor overactivity is oxybutynin [129]. More recently, a long-acting formulation, Oxbutynin- XL, has been approved by the FDA for use in children [130]. Historically, oxybutynin use has been limited by its adverse effect profile with such

side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [131]. The CNS effects are related to the ability for oxybutynin to cross the blood brain barrier. Oxybutynin- XL utilizes a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favorable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterization [132].

There are only a few studies, none randomized and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity in children. Curran et al, in a retrospective review assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamics, who were refractory to behavioral therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years [range 0.2 to 6.6], however patients were not followed frequently [133]. In a study by Van Hoeck et al, holding exercises with and without oxybutynin showed no beneficial effect on bladder volume of adding oxybutynin.[134].

Level of evidence: 3.

Grade of recommendation C

b) Tolterodine

Tolterodine, a nonselective antimuscarinic is currently being used for the treatment of detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be “bladder selective”. It’s affinity for the bladder compared to other organ systems leads to an improved tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [135]. The delivery system of the long acting preparation is such that the capsule may be cracked and “sprinkled” on food. Tolterodine has not been approved for use in children but there are several studies, which evaluate its safety and efficacy in children with detrusor overactivity. Hjålmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [136]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in micturition frequency and a 44% mean decrease from baseline for the number of incontinence episodes in children treated with 1 mg and 2 mg po BID. Bolduc et al reported on a prospective crossover study of 34 children followed for > 1 year who were crossed over from oxybutynin to tolterodine because of adverse effects with oxybutynin [137]. Detrusor overactivity was confirmed in 19/20 who had urodynamic studies performed prior to therapy. Children received either 1 mg or 2 mg po BID and the median treatment period was 11.5 months. Efficacy was assessed by a questionnaire and was comparable for oxybutynin and tolterodine. Sixty-eight percent noted a > 90% reduction in wetting episodes at 1 year and an additional 15% noted a > 50% reduction in wetting episodes. Fifty nine percent reported no side effects with tolterodine and 18% reported the same side effect as with oxybutynin, but felt it was less severe. Eight patients [24%] discontinued tolterodine.

Munding et al reported on the use of tolderodine in children with “dysfunctional voiding” manifested as daytime wetting, frequency or urgency [138]. There was no documentation of uroflow studies to make the diagnosis of “dysfunctional voiding” and from the symptoms these children appeared to have detrusor overactivity. Children were started on behavioral modification for 4-6 weeks and pharmacologic therapy was instituted if they failed or had only slight improvement with behavioral therapy. A minimum of 1 month’s follow-up was needed for inclusion, but the mean follow-up was only 5.2 months. Doses ranged from 1 mg po BID to 4 mg po BID. Assessment of results was made by telephone survey. Thirty three percent had > 90% reduction in daytime and nighttime wetting episodes and 60% had > 50% reduction. Four patients [13.3%] had side effects, constipation in 2, dry mouth in 1 and diarrhea in 1.

Reinberg et al performed an open label parallel group retrospective study of the efficacy and safety of immediate release and long acting tolterodine and extended release oxybutynin [139]. Children started out with the lowest possible dose, 2 mg tolterodine and 5 mg oxybutynin and titrated up according to response and side effects. Children were arbitrarily assigned to therapy based on the formulary restrictions of the health plan and there was an uneven distribution of patients in the treatment groups. Final dose and duration of treatment were not noted. Study nurses asked about side effects and a voiding diary was used to assess efficacy. The authors concluded that extended release tolterodine [$p<0.05$] and oxybutynin [$p<0.01$] were more effective than immediate release tolterodine in improving urinary incontinence symptoms and that extended release oxybutynin was more effective than extended release tolterodine in resolving diurnal incontinence ($p<0.05$) Long term tolerability of tolterodine extended release in a large pediatric population has been shown. [140]

Level of evidence: 3.
Grade of recommendation C

c) Terodiline

One of the drugs which has been investigated in a randomized placebo controlled trial was terodiline [141,142]. Because of serious cardiac side effects terodiline has been withdrawn from the market. Trospium chloride is another agent, which has been used in small series in children. It is currently available in a twice a day dosing formulation. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium's chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies [135]. Lopez Periera et al evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of 'detrusor sphincter dyssynergia' [143]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Level of evidence: 3.
Grade of recommendation C

d) Trospium and propiverine

Like trospium, propiverine has been used in children, but results are variable and inclusion and outcome criteria were not in accordance with ICCS definitions making comparison with other studies difficult. Recently a randomized, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr was performed. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. The primary efficacy parameter showed a decrease in voiding frequency (-2.0 episodes for propiverine versus -1.2 for placebo; p=0.0007). Superiority could also be demonstrated for increase in voided volume (31.4 vs. 5.1ml; p<0.0001) and reduction in incontinence episodes (-0.5 vs. -0.2 episodes per d; p=0.0005. This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence.[144,145] This is the first study with level of evidence 1 that shows beneficial effect of anticholinergic therapy.

Level of evidence: 1.
Grade of recommendation B/C (only single study)

e) Solifenacin

Solifenacin is the last antimuscarinic agent recently used in children with OAB: Hoebeke et al treated 139 children with therapy resistant OAB, with favourable results, and few side effects [146].

Some authors try combinations of anticholinergics for refractory OAB: Bolduc et all treated 33 children with a combination of oxybutinin and solifenacin or tolterodine with good success [147].

f) Botulinum toxin

Botulinum toxin is currently being used in children, mainly with neurogenic detrusor overactivity. Initial results seem promising, but more studies need to be done. In children. 300 Units on average, are injected in 30-40 spots [`148]. The trigone should not be injected, as there is an increased risk of reflux developing. The results last about 6-9 months. Botulinum toxin is not registered for injection in the detrusor or the sphincter in children. It is off label used and further prospective studies are needed before a general recommendation can be made [149].

One prospective uncontrolled study by Hoebeke et all shows beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity [150]. Injection of botulinum toxin is also possible into the external sphincter, but the results are more variable and last only 3-4 months [151] Radojici et al describe excellent results in the treatment of dysfunctional voiding. In 20 children good results are described for 17 patients. [152] In a retrospective study by Franco et al, similar results are described in 16 children, however using a higher dosage. [153]

Less invasively, botulinum toxin can be administered electromotively: a small study in 15 children shows the administration is feasible, safe, and results in considerable improvement on urinary incontinence [154].

Level of evidence: 3
Grade of recommendation C

g) Alpha-adrenergic blockade

Treatment of the overactive pelvic floor and sphincter is much more difficult. Treatment with alpha-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions: as most series are small, not randomized and describe a mixed patient population [155-157].

In a more recent uncontrolled study by Donohoe et al a total of 26 patients with Primary Bladder Neck Dysfunction (20 males, 6 females, mean age 12.8 years) were treated with alpha-blockers. Mean average and maximum uroflow rates improved from 5.5 to 12.6 cc per second and from 10.3 to 19.7 cc per second, respectively, while mean EMG lag time decreased from 24.4 to 5.7 seconds and post-void residual urine volume from 98.9 to 8.9 cc (all p <0.001). Mean follow-up was 31 months and no major adverse side effects were observed.[158] Further randomized controlled studies are needed to define the place of alpha-blockers.

Level of evidence: 3.
Grade of recommendation C

VII. CONCLUSION CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

Because there is much variability in presenting symptoms as well as the underlying pathology an individual approach is advisable: a step by step algorithm has been developed by Marschall-Kehrel, which seems to deal with many of these variables [159].

Level of evidence 3.

Grade of recommendation B/C

The limited number of identified randomized controlled trials does not allow a reliable assessment of the benefits and harms of different methods of management in children. Further work is required in this difficult clinical area. The establishment of outcome measures is needed, to facilitate randomized controlled trials of routine therapy. Interventions that would benefit from further investigations include: bladder and voiding education, bladder retention training, bowel management, hypnotherapy and alternative therapies, psychology, prophylactic antibiotic medication, neuromodulation, biofeedback therapy and pelvic floor muscle awareness and specific relaxation. Only then can the efficacy of new interventions be measured in children with detrusor overactivity or dysfunctional voiding.

In summary, while there is a wide therapeutic choice available to clinicians, many of the commonly used treatments are of dubious value and have not been rigorously evaluated in careful clinical trials with an appropriate study design. Children who suffer this distressing condition, and their families, and those who care for them clinically, need clear guidance as to which treatments are of proven value. They need access to treatments which work, and they need protection from treatments which do not work.

Children who present with urinary symptoms may have been victims of sexual abuse. In these cases, the use of invasive diagnostic procedures (VCUG and urodynamic studies) must be regarded as contraindicated, as must the use of invasive intra-anal treatment devices. Development of less invasive methods of diagnosis and treatment should therefore be encouraged.

E. NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION

I. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop as a result of a lesion at any level in the nervous system. This condition contributes to various forms of lower urinary tract dysfunction which may lead to incontinence, urinary tract infections (UTIs), vesicoureteral reflux (VUR), and renal scarring. Surgery may be required to establish adequate bladder drainage, and potentially, if not managed properly, NDSD can cause renal failure, requiring dialysis or transplantation.

Management of neurogenic detrusor sphincter dysfunction in children has undergone major changes over the years. While the use of diapers, permanent catheters, external appliances and various forms of urinary diversion were acceptable treatment modalities; these are now reserved for only a small number of resistant patients [1]. Initially, long term renal preservation was the only aim of therapy and early diversion had the best long term results for preserving renal function. Despite some of the complications of ileal conduits and cutaneous urostomies requiring secondary surgery, this form of treatment offered the best outcome for renal preservation with socially acceptable continence [2].

Introduction of clean (self) intermittent catheterization revolutionized the management of children with NDSD. It, not only made conservative management a very successful treatment option, but also made surgical creation of continent reservoirs a very effective alternative with a good quality of life [3].

The most common cause of NDSD in children is neurospinal dysraphism and this condition presents with various patterns of detrusor-sphincter dysfunction within a wide range of severity. About 15 % of neonates with myelodysplasia have no signs of lower urinary tract dysfunction (LUTD) when initially studied [4]. However there is a high chance of progressive changes in the dynamics of the neurological lesion in time and even babies with normal LUT function at birth have a 1 in 3 risk of developing either detrusor sphincter dyssynergia or acontractile detrusors by the time they reach puberty [5]. Nearly 60 % of the neonates with neurospinal dysraphism may develop upper tract deterioration due to increased detrusor filling pressures and infections, with or without reflux [6,7].

As our understanding of urodynamic studies has evolved it allowed us to understand the nature and severity of the problems and administer management in a more rational manner differing according to the functional characteristics of each detrusor sphincter unit. Although the last quarter century has witnessed a remarkable progress in understanding pathophysiology, pathogenesis and the management of these children, the main goals of treatment remained the same i.e. the prevention of urinary tract deterioration and the achievement of continence at an appropriate age.

II. PRESENTATION OF NEUROGENIC DETRUSOR SPHINCTER DYSFUNCTION IN CHILDREN

Neurogenic detrusor sphincter dysfunction can develop as a result of a lesion at any level in the ner-

vous system, including the cerebral cortex, spinal cord or the peripheral nervous system. The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion.

The closure of spinal canal in utero takes place in caudad direction from cephalic end and is completed at around 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems. Developmental anomalies that result from defects in neural tube closure are termed as myelodysplasia. This term includes a group of lesions like spina bifida occulta, meningocele, lipomyelomeningocele, or myelomeningocele. Myelomeningocele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children. [8]

The neurologic lesions produced by myelodysplasia are variable and contingent on the neural elements that protrude within the meningocele sac. The bony vertebral level correlates poorly with the neurologic lesions produced. Additionally, different growth rates between the vertebral bodies and the elongating spinal cord can introduce a dynamic factor to the lesion, and scar tissue surrounding the cord at the site of meningocele closure can tether the cord during growth [9-10].

In occult myelodysplasia, the lesions are not overt and often with no obvious signs of neurologic lesion. The diagnosis of this condition has increased since the advent of spinal ultrasonography and magnetic resonance imaging. Yet, in nearly 90% of patients, a cutaneous abnormality overlies the lower spine and this condition can easily be suspected by simple inspection of the lower back. These cutaneous lesions can vary from a dimple or a skin tag to a tuft of hair, a dermal vascular malformation, or an obvious subdermal lipoma. [8] Alterations may be found in the arrangement or configuration of the toes, along with discrepancies in lower extremity muscle size and strength with weakness or abnormal gait. Back pain and an absence of perineal sensation are common symptoms in older children.

Incidence of abnormal lower urinary tract function in patients with spina bifida occulta is as high as 40%. Occult lesions may also become manifest with tethering of the cord later in life. This can lead to changes in bowel, bladder, sexual and lower extremity function.

Sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination. This lesion may produce variable degrees and patterns of LUTD.

Cerebral palsy patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting.

Imperforate anus is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. These children may present with accompanying spinal cord pathology. This is more common when the rectum ends above the pelvic floor muscles and they should undergo a MR imaging for detection. Early detection of this problem in imperforate anus patients is important to improve the child's chance of maintaining healthy kidneys and becoming continent.

III. CLASSIFICATION: PATTERN RECOGNITION

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of the neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurologic disease or injury. Such systems are based on the localization of the neurologic lesion and findings of the neuro-urologic examination. These classifications have been of more value in adults as neurogenic lesions are usually due to trauma and more readily identified.

In children, the spinal level and extent of congenital lesion is poorly correlated with the clinical outcome. Indeed, severe detrusor sphincter dysfunction has been associated with minimal bony defects. Various possible neuropathologic lesions of the spinal cord including syringomyelia, hydromyelia, tethering of the cord and dysplasia of the spinal cord are the causes of these disparities and they may actually extend several segments above and below the actual site of the myelomeningocele. Therefore urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

The detrusor and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder and sphincter dysfunction. Determined by the nature of the neurologic deficit, they may be either in an overactive or in an inactive state. The detrusor may be overactive with increased contractions during filling, with a diminished bladder capacity

and compliance or be underactive with no effective contractions during voiding; the bladder outlet (urethra and sphincter) may be independently overactive causing functional obstruction or paralyzed with no resistance to urinary flow leading stress incontinence.

These conditions may exist in any combination [9-14].

Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible. Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity and
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during 'voiding'.

The urodynamic investigation is considered normal when there is suitable age appropriate capacity, good compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of detrusor overactivity during filling with or without decreased capacity and compliance, is usually seen when there is upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the voiding detrusor contractions are weak or lost and the sphincter is underactive. Urodynamic investigations make it possible to establish a management plan for each individual patient.

Evidence level 3

Grade of recommendation B

For the very young child the combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical filling pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis), whereas an underactive detrusor and a paralysed sphincter is relatively safe, providing a low-pressure reservoir [15-17].

Level of evidence: 2

IV. MANAGEMENT

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals.

1. ASSESSMENT

In the first years of life, the kidneys are highly susceptible to backpressure and infection. In this period, emphasis will be on documenting the pattern of neurogenic detrusor- sphincter dysfunction and assessing the potential for functional obstruction and whether or not there is vesicoureteral reflux [17,18]. Ultrasound studies and a VCUG or video-urodynamics to exclude reflux have to be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or vesicoureteral reflux, and can help identify children at risk for upper urinary tract deterioration and impairment of renal function.

A urodynamic evaluation can be done after some weeks and needs to be repeated at regular intervals, in combination with evaluation of the upper tracts [19].

Level of evidence 3.

Grade of recommendation: B

2. TREATMENT

Overwhelming experience gained over the years with early management of neurogenic bladder in infants has lead to a consensus that children do not develop upper tract deterioration when managed early with CIC and antimuscarinic medication [19-22]. Therefore initial treatment should consist of **oral or intravesical antimuscarinic drugs in combination with clean intermittent catheterisation**, to start soon after birth in all babies and especially in those with signs of possible outlet obstruction [23-27].

Level of evidence 2.

Grade of recommendation: B

The **early initiation of intermittent catheterization** in the newborn period, makes it easier for parents to master it and for children to accept it as they grow older [28,29].

With early management not only are upper tract changes less, but also bladders are better protected and incontinence rates are much lower.

It has been suggested that increased bladder pressures due to detrusor sphincter dyssynergia cause

secondary changes of the bladder wall. These fibroproliferative changes in the bladder wall may cause further loss of elasticity and compliance: resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterization and anticholinergic drugs may prevent this in some patients [30-32].

Level of evidence 3.

Retrospective evaluation of patients has also shown that significantly fewer bladder augmentations were required in patients with early start of CIC [23,24].

Level of evidence 4

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTIs are less common (20%) with CIC when compared to the group without CIC (40%). Since the risk of reflux is similarly lower with CIC the renal scar rates are lower. CIC alone, when begun in infancy can achieve continence at a rate of 60 %. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80%. [33-36]

At present oxybutynin, tolterodine, trospium and propiverine are the most frequently used anticholinergic drugs to treat detrusor over activity in children. Some clinical studies are available, but no randomised placebo controlled studies have been performed [31,37-41].

A prospective controlled trial evaluating trospium in children reports that trospium is effective and safe in correcting detrusor overactvity in children but this study does not include patients with a neurogenic bladder [42].

Two different forms of tolterodine have been investigated in children with neurogenic bladder and extended release formulation of tolterodine is found to be as efficient as the instant release form with the advantages of being single dosage and less expensive [43].

Level of evidence 3. Grade of recommendation: B

Use of medication in children with neurogenic bladder to facilitate emptying has not been studied well in the literature. Few studies investigating the use of alpha-adrenergic blockade in children with neurogenic bladder report good response rates but they are non-controlled studies and long-term follow-up is lacking [44-46].

Level of evidence 4.

Use of **intravesical oxybutynin** in children with poorly compliant neurogenic bladder has been investigated in some studies and incontinence has been shown to be improved significantly in most studies, with “dry and improved” rates ranging from 61% to 83% [47]. Use of lidocain intravesically also has been shown to be effective to improve bladder capacity and compliance and decrease overactivity in children with neurogenic bladder [48]. None of these studies are randomized controlled trials and evidence available is insufficient to strongly recommend this therapy. There are no data available on long term use.

Level of evidence 3.

Grade of recommendation: C

In neurogenic bladders that are refractory to antimuscarinics and still remain to be in a small capacity and high-pressure state, **injection of botulinum toxin** into the detrusor has been introduced to be a new treatment alternative [49-50]. Initial promising results in adults have also initiated its use in children. So far pediatric studies have been open-label studies and prospective controlled trials are lacking [51-53]. Injection of botulinum toxin in therapy resistant bladders seems to be an effective and safe treatment alternative. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment. Dosage in children should be determined by body weight, with caution regarding total dose if also being used for treatment of spasticity, and minimum age [54-57].

Level of evidence 3.

Grade of recommendation C

In a single study urethral sphincter botulinum-A toxin injection has been shown to be effective in decreasing urethral resistance and improve voiding.The evidence is still too low to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases [58].

Intravesical electrical stimulation of the bladder was introduced more than four decades ago and it has been tested in some open clinical trials in children since 1984. Its practice is limited to a few centres who have reported varying results. The nature of this type of treatment (time consuming and very dedicated personal) does not make it attractive for the majority of treatment centres [59].

Level of evidence 3.

Grade of recommendation C

Children with neurogenic bladder also have **disturbances of bowel function.** Fecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum [60].

The majority of children with a neurogenic bladder also have **constipation** and this is managed most commonly with laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel

contents. A regular and efficient bowel emptying regimen is often necessary to maintain fecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemas, the majority of these children's constipation can be managed and they may attain some degree of fecal continence [61-65].

Level of evidence 3.

Grade of recommendation C

Biofeedback training *programs* to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management program in achieving fecal continence [66]. Electrostimulation of the bowel may also offer a variable improvement in some patients [67].

Level of evidence 3.

Grade of recommendation D

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with bacteriuria without clinical symptoms [68-71]. Bacteriuria is seen in more than half of the children on clean intermittent catheterization (CIC), but patients who are asymptomatic do not need treatment.

Level of evidence 3.

Grade of recommendation B

Patients with **vesicoureteral reflux and urinary tract infection** often should be placed on prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage [72].

Sexuality, while not an issue in childhood, becomes progressively more important as the patient gets older. This issue has historically been overlooked in individuals with myelodysplasia. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore counseling patients regarding sexual development is important in early adolescence.

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent in between catheterizations. Bladder pressure and (normal) development of the upper tracts will determine whether additional treatment is necessary.

Children with therapy resistant overactivity of the detrusor, or small capacity and poor compliance will usually need additional surgical treatment such as **bladder augmentation.**

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be **intermittent catheterization** (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. At a later age the outlet resistance has to be increased in order to render them continent [73]. There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Surgical procedures need to be considered for maintaining continence [75-77].

It is important to establish **adequate bowel emptying** before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require **lifelong supervision and monitoring of renal function** is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory. Therefore repeat urodynamic studies are needed more frequently at younger ages and less frequently at later ages. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In case of any apparent changes both in the upper and lower urinary tract or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity in these children.

F. Surgical management of urinary incontinence in children

Intermittent catheterization and drug therapy are usually sufficient in the majority of cases for maintaining continence and preserving upper tracts. Surgical procedures should be considered if conservative measures fail to achieve continence between catheterizations or preserve upper tracts.

Surgical intervention is required for congenital and acquired diseases interfering with the function of the storage function of the bladder, the sphincter mechanisms or which bypass normal sphincter mechanisms. A plethora of different surgical procedures has been proposed to maintain continence by using different mechanisms. Various procedures using different mechanisms for maintaining continence may be used in the same patient.

In many cases measures such as intermittent catheterization and drug therapy are needed in addition to surgery since most of the surgical procedures can achieve 'dry- ness', but rarely restore normal voiding.

Patients with bladder neck incompetence pose a real challenge and require a different approach. All surgical procedures to "reconstruct" the bladder neck have one thing in common; an obstruction is created

to enhance bladder outlet resistance. Even if successful, normal spontaneous voiding with low pressures without external help is not possible in most patients. Considering the long-term outcome, it may be better not to void spontaneously when bladder outlet resistance is increased because longstanding outlet resistance may cause secondary changes of the bladder wall.

The rarity and complexity of the conditions associated with congenital incontinence in children precludes the establishment of higher levels of evidence because of the rarity and spectrum of the pathology. Results are highly dependent on the skills of the individual surgeon. Therefore graded recommendations for specific procedures cannot be provided. There are no randomized controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.

I. ABNORMALITIES OF STORAGE

Bladder Exstrophy*:* The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 2:3.1-6.1). Closure of the bladder is generally performed within the first days of life; pelvic osteotomies facilitate reconstruction of the abdominal wall and may improve ultimate continence [1,2,3]. Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with a poorly compliant small bladders, requiring later bladder enlargement or urinary diversion (ureterosigmoidostomy) [4,5,6,7]. Patients with a good bladder template who develop sufficient bladder capacity after successful primary closure and epispadias repair can achieve acceptable continence without bladder augmentation and intermittent catheterization [8,9,10].

Reconstruction of the bladder neck can either be done at the time of bladder closure or at a later stage. Early reconstruction may facilitate normal bladder function, but should be attempted only at centers experienced with such surgery [11,12]. Continence rates vary from center to center and may range between 43 to 87% [13,14].

Cloacal Exstrophy*:* The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have anomalies of the nervous system, upper urinary tract and gastrointestinal tract that can adversely affect urinary tract reconstruction. Before reconstructive procedures are considered, an extensive evaluation has to be carried out.

Agenesis and duplication of the bladder are both extremely rare. Agenesis is rarely compatible with life. In bladder duplication other associated congenital anomalies are often observed such as duplication of external genitalia or lower gastrointestinal tract.

Abnormal storage function in combination with other anomalies is usually caused by a neurologic deficit or is secondary to bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus [15, 16, 17,18].

Posterior urethral valves may cause severe hypertrophy of the detrusor with a small poorly compliant bladder [19,20] .

Unfortunately, following valve ablation, these bladders may not return to normal function [21,22] .

II. ABNORMALITIES OF SPHINCTERIC FUNCTION

Epispadias (without exstrophy): incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and all females, the sphincteric mechanism is deficient and the child has complete incontinence. Reconstruction of the bladder neck is either performed at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients [23,24].

Malformation of the Urogenital Sinus occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

Ectopic ureteroceles protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

Sphincter abnormalities secondary to spina bifida and other neurologic disorders are of particular importance. The sphincter may be overactive (like in detrusor sphincter dyssynergia) or underactive. Overactivity of the sphincter causes secondary changes of the bladder wall (increased collagen type III with decreased elasticity and compliance). Continence is usually achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence). In cases of incompetence of the sphincter, different types of surgical intervention are possible to enhance the sphincteric mechanism. In general all patients with a neurogenic bladder need Clean Intermittent Catherization (CIC). In patients bound

to a wheelchair a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

III. BYPASS OF SPHINCTERIC MECHANISM

Ectopic Ureter is an abnormally located terminal portion of the ureter. Instead of the ureter opening in the bladder, it opens in the urethra, vagina, or uterus. Ectopic ureters occur more frequently in girls and are commonly part of a duplex system: in girls the ectopic orifice of the upper pole moiety drains into the urethra below sphincteric level or vaginal vestibule, thus causing incontinence [25].

When the ectopic ureter represents a single system, the trigone is usually asymmetrical and not well developed. These children may suffer from continuous incontinence as well as a deficient sphincteric mechanism: this is particularly true in bilateral ectopia of single systems. In these patients the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. When the upper pole ureter opens in the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina) incontinence results. Upper pole nephrectomy or ipsilateral uretero-ureterostomy solves the problem.

A rare and a challenging condition is when there are bilateral ectopic ureters. Since the bladder is hypoplastic, in these children achieving normal bladder capacity and function may require additional procedures to ureteric reimplantation [26,27,28] .

Urethral duplications. Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the urethra bypasses the sphincteric mechanisms, continuous leakage may be present [29] .

Vesicovaginal fistulas. Acquired fistulas may be traumatic or iatrogenic, following procedures on the bladder neck.

IV. EVALUATION AND DIAGNOSIS

A detailed history and physical examination in combination with imaging studies and urodynamic evaluation are the corner stones for successful management. Imaging studies are essential to define the anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord.The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphyseal distance, and fecal retention. The contrast films will show bladder configuration, presence of vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy, and vaginal reflux. Occasionally, an intravenous urogram will provide the clearest assessment of the urinary tract. MRI and CT scanning can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to imaging studies, urodynamic studies (cystometrography, and when needed, electromyography of the sphincters and urinary flow studies) are useful for all patients with neurogenic incontinence, and after surgery in some cases of bladder exstrophy and after posterior urethral valves resection to help define the mechanism of any continued incontinence. However in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

V. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

1. STORAGE FUNCTION

Reduced bladder capacity is the main indication for simple bladder augmentation. Reduced capacity can be congenital (bilateral single ectopic ureters, bladder exstrophy) or caused by previous surgery e.g. bladder neck reconstruction in exstrophy patients, where a part of the bladder is used to create an outlet resistance. Other indications are low functional bladder capacity as it may be present in neurogenic detrusor overactivity, or poor bladder compliance (meningomyelocele), or bladder scarring from previous surgery or obstruction. Bladder scarring from bilharzia remains common in endemic areas and is increasingly common with immigration to the developed world. In all such cases surgery is indicated when conservative treatment has failed.

Several studies suggest that aggressive early intervention with CIC and anticholinergic therapy improves bladder compliance and may protect children from augmentation surgery [30,31].

Yet in a recent survey has reported that there has been no change in augmentation rates during the last 5 years: they demonstrated significant inter-institutional variability [32].

2. SPHINCTER FUNCTION DURING STORAGE

Most of the diseases in childhood requiring surgical repair for incontinence not only have an influence on bladder capacity but also on sphincter function.

Conservative measures to improve sphincter function have limited value and surgery is required in many cases. There are different surgical options; either to increase outlet resistance or to create or implant a new sphincter mechanism. In neurologically normal patients such as classic exstrophy patients, early anatomic reconstruction may allow 'normal' bladder and sphincter function. Sling procedures are indicated when the residual sphincter function is not sufficient to avoid incontinence. This may be the case in patients with neurogenic bladder disturbances and urethral incontinence. If there is no residual sphincter function or outlet resistance, an autologous tape or colposuspension in girls, and an artificial sphincter in boys, may be required. Primary urinary diversion (rectal reservoirs / continent stoma) offers an alternative solution to this problem.

3. PROCEDURES TO BYPASS THE SPHINCTER

If bladder outlet surgery fails or urethral catheterization is not possible, a continent stoma may be constructed. Some patients prefer catheterizing through a continent stoma rather than through the sensate urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. An alternative to such procedures would be the use of the anal sphincter for urinary continence with the use of colon as the storage reservoir.

VI. BLADDER RESERVOIR CONSTRUCTION

1. URETEROSIGMOIDOSTOMY

This type of continent urinary reconstruction may be utilized in reconstruction for bladder exstrophy, an incontinent urogenital sinus or the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter, anal prolapse, previous anal surgery, and irradiation. Because of the potential for electrolyte resorption, renal insufficiency is also a contraindication.

Low pressure rectal reservoirs are superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

There are two techniques which have been utilized:

a) The augmented rectal bladder in which.the rectosigmoid is opened on its antimesenteric border and augmented by an ileal segment. The sigmoid may be invaginated to form a nipple valve to avoid reflux of urine into the descending colon and thus to minimize metabolic complications.

b) The sigma-rectum pouch (Mainz pouch II) in which there is an antimesenteric opening of the recto-sigmoid and a side to side detubularization anastomosis. Ureteral reimplantation of normal sized ureters is by a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated the technique utilizing a serosa lined extramural tunnel may be more appropriate [33,34].

As reported by D'elia et al, the results of these low-pressure rectal reservoirs are excellent with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the sigma-rectum pouch to 34% for the augmented rectal bladder [35]. Late complications for the sigma-rectum pouch range from 6-12.5% and the late complications for the augmented rectal bladder are 17%. Early complications include pouch leakage while late complications are mainly related to the ureteral implantation into the bowel and pyelonephritis. Metabolic acidosis also occurs (69% of the patients had a capillary base excess of –2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloraemic acidosis).

Periodic follow-up studies are important to check the upper urinary tract and prevent metabolic acidosis. Due to the risk of malignancy at the ureterointestinal anastomosis, colonoscopy should be performed annually beginning at postoperative year 10 [30,36,37,38,39].

Grade of recommendation: B

2. BLADDER AUGMENTATION, BLADDER REPLACEMENT AND CONTINENT URINARY DIVERSION, USING INTESTINE

The indication for bladder augmentation, replacement of the bladder, or the creation of a continent urinary diversion, is either the morphological or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and low capacity of the urinary bladder and create a new reservoir with low storage pressures that can be emptied periodically. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and life long intermittent catheterization will be required.

Before deciding on what type of procedure can be performed some significant factors must be addressed. These are:

1. Physical and mental capacity of the patient to do intermittent catheterization.
2. Previous surgery (on urinary tract and bowel)
3. Renal function status (including acid base state)
4. Absence or presence of reflux

5. Outlet resistance

6. The need for a catheterizable channel

The different technical approaches to bladder augmentation or replacement are dependent on the clinical presentation of the patient:

- a simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a catheterizable urethra,

- an augmentation with additional bladder outlet procedures such as bladder neck reconstruction or other forms of urethral reconstruction are required when both the bladder and outlet are deficient. This occurs most commonly in spina bifida or bladder exstrophy. It must be appreciated that bladder outlet procedures may complicate transurethral catheterization.

- augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation a continent stoma will be required. Most urologists however prefer to leave the bladder neck and urethra patent as a safety precaution: when the bladder is very full leakage will occur and it allows transurethral manipulations such as catheterization if the continent reservoir cannot be emptied through the suprapubic catheterizable channel.

- an augmentation with additional continent stoma is utilized primarily following failure of previous bladder outlet surgery. It is advisable also when it can be anticipated that there will be an inability to catheterize transurethrally. An abdominal wall continent stoma may be particularly beneficial to the wheelchair bound spina bifida patient who often can have difficulty with urethral catheterization or who is dependent on others to catheterize the bladder. For continence with augmentation and an abdominal wall stoma, it is essential that there be an adequate bladder outlet mechanism to maintain continence.

- total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urologic reconstruction.

The main contraindications are the inability of the patient to be catheterized, or perform CIC him or herself and the anticipation of poor patient compliance. When there is reduced renal function generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml./min/1.73 m2, there is a relative contraindication to the use of ileum or colon because of metabolic acidosis secondary to reabsorption. The stomach with its excretion of acid may be used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of the severe skin irritation that the acid urine may produce (hematuria-dysuria syndrome).

3. WHICH INTESTINAL SEGMENT SHOULD BE UTILIZED?

a) Stomach

Stomach has limited indications primarily because of the complications that have been seen. It is the only intestinal segment suitable in patients with significantly reduced renal function [40,41,42].

Additionally, when no other bowel may be available, as after irradiation or there exists the physiology of a short bowel syndrome, as in cloacal exstrophy, this may be the only alternative remaining.

b) Ileum / Colon

Clinically these two intestinal segments appear to be equally useful. In children, sigmoid colon is widely used except in those who have been treated for imperforate anus. Use of the ileocecal region can be associated with transient and sometimes prolonged diarrhea. This segment should be avoided in patients with a neurogenic bowel such as in myelomeningocele or who have been subject to previous pelvic irradiation. If the ileocecal valve must be used, it can easily be reconstructed at the time of performing the ileo-colonic anastomosis. The ileum can be satisfactorily used for bladder augmentation: however because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Colon has greater flexibility for ureteral implantation and construction of a continent catheterizable channel.

c) General principles

There are several important principles for bladder augmentation and replacement that should be respected:

- use the minimal amount of bowel and if available use hindgut segments or conduits from previous surgical procedures,

- a low-pressure large capacity reservoir is essential. This requires detubularization of any intestinal segment used.

- for colonic reservoirs a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The

length of the segments can be scaled down in smaller children. Care should be taken not to use more than 50 to 60 cm of ileum in adolescents and comparable lengths in younger children because of reduction of the intestinal resorptive surface.

- the jejunum is contraindicated in intestinal reconstruction of the urinary tract because of its metabolic consequences (hyponatremia, hypercalcemia, and acidosis).
- it is wise to strive to achieve an anti-reflux ureteral anastomosis into the reservoir to avoid the potential for reflux and consequently ascending infection: in high pressure bladders with reflux the reflux usually disappears spontaneously following augmentation [43,44].
- a reliable continence mechanism (continent urinary outlet) must be assured.
- because of the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

d) Bladder augmentation techniques

1. In gastric augmentation a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but can be based on the left one as an alternative. The segment is brought down to the bladder easily in the retroperitoneal space along the great vessels.
2. When using large or small bowel the segment to be utilized is opened on the antimesenteric border and detubularized prior to anastomosis to the bladder remnant. The anastomosis of the intestinal segment to the bladder remnant and to itself is usually carried out in one running layer of inverting absorbable sutures.
3. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults [45,46,47].

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Due to the relatively high morbidity of conventional augmentation there is renewed interest in alternative methods [48, 49,50,51,52,53]. These alternative techniques try to avoid the contact between urine and intestinal mucosa and include gastrocystoplasty, bladder auto-augmentation, seromuscular augmentation, alloplastic or biodegradable scaffolds grafted with autologous urothelium developed in cell culture, and ureterocystoplasty.

e) Auto-augmentation

The principle of auto-augmentation of the bladder is the excision of a great portion of the detrusor while leaving the urothelium intact, creating a large diverticulum for the storage of urine at lower pressures. This urine stored at a low pressure can be drained by intermittent catheterization. The theoretical advantages of this procedure are the low complication rates of the surgery, reduced operative morbidity with shorter stay in the hospital, absence of urine salt resorption, less mucous production in the urine and possibly absence of carcinogenic potential. Although some series showed good results with this procedure [54,55,56,57], most authors have been unable to achieve previously reported success [58].

Long-term results have been rather disappointing: MacNeily et al concluded that of 17 patients with neurogenic bladder following auto-augmentation, 71% were clinical failures and 14 out of 15 were urodynamic failures [59]. Similar findings have been reported by others [60,61]. The inability of this procedure to achieve long-term good results may be due to the regeneration of nerve fibers divided during the surgery as well as the ischemic atrophy of the mucosa.

Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favorable option at this time. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently, some authors have proposed the laparoscopic auto-augmentation as a minimally invasive procedure for the treatment of low capacity/ low compliance bladder. [62,63]. Despite the indifferent results some still suggest its consideration before a standard augmentation because of the reasons listed above [64,65,66].

Level of evidence 4.

Grade of recommendation C

f) Seromuscular patch

To overcome one of the major disadvantages of a conventional augmentation that is mucus formation several techniques have been developed to use intestinal segments free of mucosa. The first attempts at using intestinal segments free of mucosa to improve bladder capacity resulted in viable seromuscular segments covered with urothelial mucosa [67,68]. The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans [69]. Further attempts consisted of using the association between demucosalized intestinal segments and auto-augmentation. In the

initial model using sheep, the animals tolerated the demusculization procedure poorly, reflected by inflamed, hemorrhagic colonic segments in the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals[70] . Follow-up studies in a dog model with previously reduced bladder capacity suggested that the contraction of the intestinal patch in seromuscular enterocystoplasty can be avoided by the preservation of both the bladder urothelium and lamina propria, together with the submucosa and muscularis mucosa of the intestinal patch [71,72] . This form of bladder augmentation was shown to prevent absorption of toxic substances like ammonium chloride [73]. Other authors using the same technique to line de-epithelialized gastric patches in the mini-pig model found it useless due to the fibrotic changes and decreased surface of the patch [74].

The initial experience in treating humans with colocystoplasty lined with urothelium were reported by Gonzales and Lima who developed a slightly different technique independently [75,76] . Bladder capacity increased significantly while bladder pressures decreased. Biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases.

Longer term follow-up is now available and although the results are very encouraging, the results seem to be highly operator dependent and the way the mucosa is removed seems to be a crucial factor. Lima et al do no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients no ruptures were found and only 10% were regarded as failures [77].

Gonzalez et al found seromuscular colocystoplasty in combination with an artificial urinary sphincter successful in 89% of their patients and that it effectively achieves continence with no upper tract deterioration, and concludes that this is their preferred method of augmentation when adverse bladder changes occur after implanting the AUS [78].

Although more authors have now reported their results it still remains a more complex form of augmenting the bladder. This procedure has not receive a general acceptance among the paediatric urological community but is being done in some designated centres [79,80,81,82]. A recent comparison of the long term outcome of this technique with standard intestinocystoplasty has indicated that most of the risks and benefits of augmentation cystoplasty performed using intestine and seromuscular patch appear similar .

Level of evidence 3.

Grade of recommendation C

g) Ureteral bladder augmentation

Another alternative to avoid the morbidity of intestinal bladder augmentation is the use of ureteral segments to improve bladder capacity and/or compliance. Megaureters associated with poorly or nonfunctioning kidneys provide an excellent augmentation material with urothelium and muscular backing, free of potential electrolyte and acid base disturbance, and mucus production [83,84].

Another alternative in patients with ureteral dilation and good ipsilateral renal function, is to combine transureteroureterostomy with ureterocystoplasty [85].Another alternative in bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of bilateral distal ends for detubularized bladder augmentation [86,87].

Bladder augmentation with ureter may be effective in a small sub group of patients with ureteral dilatation and poor bladder capacity. Overall long-term results are good and remain so over a longer period of time [88,89,90,91,92,93].

In a recent evaluation of the long term functional outcome of this technique it is reported that ureterocystoplasty provides durable functional urodynamic improvement, yet some patients (4 out of 17 in this series) would eventually need a standard intestinal cystoplasty [94].

Level of evidence 3.

Grade of recommendation B

It has been shown that this type of augmentation can also be employed in children who require a kidney transplantation [95,96,97].

h) Experimental Methods

The artificial bladder has been the topic of speculation and experiment that remains still outside the bounds of clinical application. Somewhat nearer to clinical application may be the concept of tissue engineering using autologous urothelium and bladder muscle cells. These cells may be grown on biodegradable scaffolds—both naturally derived and synthetic—for the temporary support of growing tissues and then can be used for augmenting the bladder. A number of synthetic materials and natural matrices have been used in experimental and clinical settings and major improvement have been gained in techniques of cell harvest, culture, and expansion as well as polymer design.

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in preclinical trials, recent progress suggests that engineered bladder tissues may have an expanded clinical applicability in the future.

Clinical trials with these methods are not far away [98-110].

Although this field of research may represent the future of bladder reconstructive surgery, currently only few experimental studies are available and it may be some time before all this knowledge can be used clinically. We strongly encourage further research in this field.

VII. BLADDER OUTLET SURGERY

1. URETHRAL ENHANCEMENT

In those children where sphincteric incompetence is the only cause of incontinence or plays a mayor role in association with decreased bladder capacity or compliance, surgical procedures to enhance outlet resistance should be considered. In many cases bladder outlet surgery needs to be combined with other procedures aimed at creating a large low pressure storage reservoir.

2. BULKING AGENTS

The injection of bulking substances in the tissues around the urethra and bladder neck to increase outlet resistance in children dates back to at least 1985. However, concern about distant migration of the injected substance and risk of granuloma formation prevented this technique from gaining widespread acceptance [111,112].

The search for safer, biocompatible substances to create periurethral compression has first led to the use of cross-linked bovine collagen, with initially reported success in about 20-50% of children [113,114,115].

Collagen injection appeared to effectively improve urethral resistance, but this did not always translate into satisfactory dryness, besides, the effect of the injection is of short duration and repeated injections were often necessary [116,117]. Because of this collagen is no longer recommended for this indication.

At present the following substances are available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.

Usually the substance is injected endoscopically in the bladder neck area (finding the best spot is often the most difficult part of the procedure): more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial results of 75% success have been reported, but after 7 years there is a gradual decrease and only 40% remained dry [118,119,120].

Others have reported success rates of 0 - 70% [121-128].

Despite limited success it remains an option for all patients who are poor surgical candidates and those who want to avoid extensive BN reconstruction.

An alternate route may be the injection around the urethra using laparoscopy [129].

Level of evidence : 3.

Grade of recommendation C

3. ARTIFICIAL URINARY SPHINCTER

Since its introduction in 1973 the AUS has undergone major transformations over the years. Different devices are currently in use: one of the most frequently used devices is the AS800-T that has been in use for almost 20 years [130]. It consists of an inflatable cuff, a pressure regulating balloon and a unit containing a pump and control mechanisms. The inflatable cuff can only be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males the bulbar urethral placement is possible but not recommended for wheelchair patients or those who perform intermittent catheterization [131]. In patients who have had extensive urethral surgery (exstrophy and epispadias) it may also not be technically feasible.

Implantation of an AUS requires special training and difficulties may be encountered in the dissection of the space around the bladder neck in obese, post-pubertal males or in patients with a history of previous bladder neck procedures. A 61-70 cm H_2O pressure balloon is used exclusively when the cuff is around the bladder neck and a lower pressure balloon when it is around the bulbous urethra. Although high in cost, the artificial sphincter remains the most effective means or increasing urethral resistance and preserving the potential for voiding.

The ideal candidate for AUS implantation is a patient with pure sphincteric incompetence who voids spontaneously and has good bladder capacity and compliance. Unfortunately only a small proportion of children with sphincteric incontinence meet the criteria. The AUS may also be used in patients dependent on clean intermittent catheterization. The compatibility of the AUS with intermittent catheterization and enterocystoplasty is well documented [132,133,134].

The ability to empty the bladder spontaneously or by Valsalva maneuver may be preserved after AUS implantation. In series reporting children with AUS, the majority having neurogenic incontinence, 25% void spontaneously [135]. When the AUS is implanted before puberty, the ability to void spontaneously may be lost after puberty.

Overall, 40 to 50% of neurogenic patients require a bladder augmentation concomitantly or subsequently to the AUS implantation [133,136,137,138].

The continence rate ranges from 63 to 97% [139-146].

Herndon et al reported a success rate of 86% (of 134 patients): 22% voided, 11% had to perform CIC after voiding, 48% only performed CIC through the urethra, 16% performed CIC through a continent channel and 3% used diversion [147]. Mechanical problems occurred in 30% of patients who had an 800 model implanted (versus 64% in the old model). Revisions (in 16%) were significantly less in the 800 model. Erosion occurred in both groups (16%). A major complication was perforation of the augmented bladder in this group (it occurred in 10 patients). In 28% a secondary bladder augmentation was necessary.

Another interesting aspect of the AUS is that in some children the device is either deactivated or no longer functions but they remain dry: others have reported that placing a cuff only without activation is all that is required to make them dry [148].

The complications most commonly encountered in patients with AUS are mechanical failures. The longevity of the present devices is expected to exceed 10 years, although Spiess et al reported a mean lifetime of only 4.7 years [149].

The second most common problem is the development of reduced bladder compliance with time. This may result from an error in the preoperative evaluation or the reaction of the detrusor to obstruction (a reaction noted in some patients with spina bifida). These changes can be seen after many years of follow-up. The results of decreased capacity and compliance may be incontinence, upper tract deterioration, or the development of vesicoureteral reflux. Therefore long term follow-up with ultrasound, renal scintigraphy and if indicated urodynamics is mandatory in all patients with an AUS.

Infection of the prosthesis should occur in no more than 15% of all cases. Erosions of the tissues in contact with the prosthesis are rather infrequent. Bladder neck erosions are practically non-existent when the sphincter is implanted around a “virgin” bladder neck. When the AUS is used as a salvage procedure following bladder neck reconstruction, the erosion rate may be as high as 30% [137]. Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. For this reason AUS implantation may be better considered as the initial treatment in selected cases [150].

4. FASCIAL SLINGS

Fascial slings constructed with the fascia of the anterior rectus muscle have been used to increase outlet resistance in incontinent children, particularly those with neurogenic dysfunction since 1982 [151]. The sling is used to elevate and compress the bladder neck and proximal urethra. The dissection around the urethra may be facilitated by a combined vaginal and abdominal approach, however, this option is limited to post-pubertal females [152].

Several technical variations of the sling have been reported. The fascial strip may be a graft or a flap based on the rectus sheath on one side. The fascial strip can be crossed anteriorly or wrapped around the bladder neck to enhance urethral compression.

Although the short-term success rate reported by most authors is encouraging, there are no series reporting detailed results at 5 years [153-154]. Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males [155-158]. In patients with neurogenic incontinence postoperative CIC is recommended.

The pubovaginal sling in girls may also be placed through the vagina: in 24 girls with spina bifida this procedure was successful in 19, while another 3 became dry following additional injections with bulking agent around the bladder neck via a suprapubic needle introduction. CIC was possible in all patients. One patient developed a vesicovaginal fistula [159].

Complications of sling procedures include difficulties with intermittent transurethral catheterization, erosion of the urethra and persistent incontinence. Overall, the increase in outlet resistance provided by slings seems less than that provided by the artificial sphincter. Experience with these procedures suggests an overall success between 50 and 80% in females.

Numerous alternatives are being used nowadays: small intestinal submucosa has been used in 20 children and showed equivalent rates of continence. The advantage being that it is available off-the-shelf. Results were better in girls than in boys (85 vs 43% being dry) [160,161,162].

When combining bladder augmentation with a Gore-tex sling in 19 children the results were bad: because of erosion the sling had to be removed in 14 patients, all except one also had a bladder stone. In this respect this type of sling should not be used [163].

From the data published it presently seems that the AUS provides more consistent results in boys and for girls capable of spontaneous voiding who have not had previous bladder neck surgery. Bladder neck slings may be used for the enhancement of bladder outlet resistance in the

majority of patients with neurogenic bladder who need augmentation cystoplasty and whom we do not expect will be capable of voiding spontaneously. Sling procedures are probably equally effective for girls dependant on intermittent catheterization and in conjunction with bladder augmentation. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of the AUS may restrict its use.

Level of evidence 2.

Grade of recommendation B

It is important that one should be aware of the fact that these patients who undergo bladder outlet surgery need long-term follow-up not only because of the complications but also because their bladder behavior may undergo unexpected clinically asymptomatic changes that could negatively affect their upper tracts if augmentation is not performed at the same time[164].

5. BLADDER NECK CLOSURE

In 'desperate' cases the bladder neck may be closed, the indication being persistent leakage despite several attempts to enhance outlet resistance by bulking agents or other surgical procedures. Although initial results are acceptable, long-term results are usually disappointing: persistent urinary leakage, stomal stenosis and leakage or stone formation (in up to 40%) [165,166]. One of the most important factors seems to be compliance with intermittent catheterization and bladder irrigation.

6. BLADDER OUTLET RECONSTRUCTION

Surgical procedures to achieve urinary continence are dictated by functional and anatomic deficiencies and by the ultimate goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterization).

Construction of a functional urethra for continence usually implies an anatomic defect without a neurogenic component (epispadias / esxtrophy) and includes urethral and bladder neck narrowing and urethral lengthening [167-172].

Such procedures may initially require intermittent catheterization or occasional post voiding catheterization, but bladder empting by voiding is anticipated.

Urethral reconstruction for dryness, however, mandates intermittent catheterization. The goal in surgery to achieve dryness is to create a urethra suited to catheterization, which has closure such that intra-luminal pressures always exceed intravesical pressure. The most dependable procedures for dryness utilize a flap valve or tunnel to achieve urethral closure, although urethral slings, wraps and injections have also been used [173].

Level of evidence 3.

Grade of recommendation C

Reconstruction to achieve **continence** is based on the principle that proximal reduction of the caliber of the urethra supports the inherent proximal sphincteric mechanism of the bladder neck and proximal urethra. The narrowing must be dynamic to permit closure for continence and yet permit opening with funneling during voiding. Several techniques have been described to achieve this goal [3, 166-176]. Young [1922] performed a "double sphincter technique" that involved the excision of a wedge of tissue at the anterior bladder neck, as well as removal of a wedge of tissue just proximal to the epispadiac meatus (external sphincter). Dees [1949] added the concept of lengthening the urethral tube to that of narrowing. In his procedure parallel incisions were made through the existing bladder neck area which created a posterior urethral plate from what had previously been the trigone of the bladder. This is tubularized to give added length to the proximal urethra. The added length provides increased potential for urethral closure and moves the bladder neck and proximal urethra into the abdominal cavity. Leadbetter [1964] modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularized by Jeffs [1983] who applied it to a staged repair of exstrophy. He supported a lengthened urethra by a suspension. They report their long term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation [177].

Presently, this represents the gold standard for reconstruction for continence, however, modifications of the technique have reported similar or improved results. Most urethral lengthening procedures utilizing the posterior urethra and bladder neck require ureteral reimplantation and preservation of the posterior urethral plate. Because part of the bladder is used to create the functional lengthening of the urethra, bladder capacity decreases following the procedure. It also remains to be seen whether the created urethra is actually a functioning urethra: in many patients fibrosis around the urethra prevent it from being really 'functional': in these patients it may act as an anatomic obstruction and long-term follow-up is necessary to follow not only the bladder but also the upper tract.

Surgery for **dryness** is dependent on the effectiveness of intermittent catheterization and is usually reserved for patients with neurogenic dysfunction or multiple previous surgeries. Procedures to

achieve dryness usually create a urethral closure pressure that exceeds bladder pressure.

A flap valve can be constructed by using an anterior or posterior bladder flap (full thickness) to construct a tube that is placed in a submucosal tunnel [171,175,176].

The major disadvantage of these procedures (flap valves) is that the valve will not allow leakage with high intravesical pressures, potentiating renal damage. Therefore, these procedures can be dangerous to the patient who is not totally committed to follow catheterization recommendations.

Unfortunately, the ideal procedure for surgical reconstruction of the bladder neck does not exist. The surgical approach to urinary incontinence in the child must be multifaceted because of the inherent complex and varied nature of the problem.

Recent data would support the concept that very early reconstruction in the exstrophy / epispadias group may result in physiologic bladder cycling which facilitates normal bladder and urethral development. This results in higher potential for continence without the need for bladder augmentation and bladder neck reconstruction (Level 3). More work and clinical experience in this area is strongly recommended. (Grade A)

7. ALTERNATIVE CONTINENCE CHANNELS

In the surgical treatment of incontinence in children every effort must be made to preserve the natural upper and lower urinary tract. The bladder is the best urinary reservoir, the urethra the best outlet and the urethral sphincters the best control mechanism. If the bladder is partly or wholly unusable it may be augmented or replaced by a variety of techniques.

Urethral failure may occur either because the sphincters are incompetent or because it is overactive and does not allow spontaneous voiding. It would be preferable for the former to be treated by one of the techniques described above and the latter by intermittent catheterization (CIC). If all of these fail, continent supra pubic diversion is indicated.

a) The Mitrofanoff principle.

Mitrofanoff's name is given to the principle of burying a narrow tube within the wall of the bladder or urinary reservoir whose distal end is brought to the abdominal wall to form a catheterizable stoma suitable for intermittent catheterization [178]. The technique is simple and familiar to all urologists who are accustomed to re-implanting ureters. Several narrow tubes are available for the Mitrofanoff conduit [179,180]. In the original description, the appendix was used. However, even if the appendix is still present, it may be unusable in 31% of patients [181].

If no suitable tube is found, a good tube can be formed by tailoring ileum transversely so that only 2-3cm of ileum can be made into a 7-8 cm conduit. This modification was originally described by Yang in humans and by Monti in experimental animals[182,183]. It is increasingly used though great care must be taken in its construction to avoid an internal fistula [184].

The ureter may be used but there may be some difficulty in achieving sufficient

calibre with a previously normal ureter. Earlier reports that the Fallopian tube could be used have not stood the test of time.

The Mitrofanoff system achieves reliable continence which is maintained in long term follow-up, for a high proportion of patients. Long-term follow-up data shows that in the original series of Paul Mitrofanoff of 23 patients after a mean follow-up of 20 years, 1 patient had died, but in the other 22 patients no metabolic changes were noted. The bladder neck was closed in 21 patients. Secondary bladder augmentation had to be performed in 8, while in 4 children a non-continent diversion was created. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion [185].

The pressure generated within the lumen of the conduit is 2 to 3 times higher than that within the reservoir so that continence is preserved even when the intra abdominal pressure is raised by straining. Conversely, the pressure in the lumen of a Kock nipple is only slightly higher than that in the reservoir so that continence is less reliable[186,187].

The conduit may be buried either between the mucosal and muscle layers of the reservoir, or may be completely imbrocated in the full thickness of the reservoir wall. Any well supported tunnel of about 2- 4 cm will suffice. The choice depends both on the nature of the reservoir and on the conduit [188].

Continence rates of 90-100% with the Mitrofanoff Principle are reported, regardless of diagnosis, reservoir or conduit type [188,189]. Follow-up for at least ten years has shown that the system is resilient [190,191,192].

A modified technique of vesicostomy is described using a gastrostomy button, which could be used as a continent urinary stoma in children with incomplete voiding. Button vesicostomy is a useful addition to the options available for a catheterizable continent urinary stoma in children in the short or medium term [193].

Although perfect continence seems attractive, it may not be in the child's best interests. A 'pop-off' valve may be in the interest of the child if catheterization is impossible or forgotten.

b) The Ileo-cecal valve.

The ileo-cecal valve is an obvious sphincter to combine with cecum and ascending colon as the reservoir and the terminal ileum as the conduit. The early continence rate of 94% was not sustained because of high pressures in the tubular reservoir and weakness of the valve [194,195,196].

The Indiana system is based on the competence of the ileo-caecal valve but with a detubularized reservoir [197]. The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rate is 96% with a 2% rate of catheterization difficulties.

In the complete Mainz I pouch a length of terminal ileum is intussuscepted through the ileo-cecal valve as a Kock nipple [198]. It is impossible to say whether the nipple or the ileocecal valve (or both) produce the continence which is reported in 96% of patients.

Both these systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileo-cecal valve may cause gastro-intestinal complications.

c) Kock pouch

The first workable continent diversion was the Kock pouch [42]. The reservoir is made from 40cm ileum reconfigured to reduce the intrinsic pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which may be more than can be spared from the gastro-intestinal tract.

Although first described as a mechanism for a continent ileostomy in children the Kock pouch is now not commonly used in children because of the problem with large amount of bowel needed, stone formation and mediocre success with dryness of the catheterizable stoma [199,200].

d) Artificial Sphincter

As a last resort, the AUS may be considered to give continence to a reconstructed outlet. Experimental evidence suggests that AUS cuffs can be placed safely around intestine providing the cuff pressure is low [201]. The AUS has been used successfully around large bowel, in three of four children with follow-up to 11 years [202].

e) Where to place the cutaneous stoma

In patients with spina bifida, particularly non-walkers, the site must be chosen with particular care. The natural tendency is for the spine to collapse with time so that the lower half of the abdomen becomes more pendulous and beyond the range of vision. A low site may seem appropriate in the child, but will become unusable in the adult. It is best to use a high, midline site, preferably hidden in the umbilicus. The site should be determined in a sitting position and marked before surgery because in the supine position the position will change dramatically. In some patients the best position may not be in the midline at all: special care must be taken that the patient can manage bladder emptying and irrigation him/herself.

For most other patients, the site of the stoma should be chosen by cosmetic criteria. The umbilicus can be made into a very discrete stoma; the risk of stenosis is low and it is a readily identifiable landmark. Otherwise, the stoma should be as low on the abdominal wall as possible and certainly below the top of the underpants. However, many surgeons find the best results by placing the catheterizable stoma in the umbilicus.

The problem of stomal stenosis remains ever present. It can occur at any time so that only follow up of many years could determine whether any system of anastomosis to the skin is better than any other. The published rate of stomal stenosis is between 10 and 20%. The multi-flap V.Q.Z. stoma is claimed to have the lowest rate but follow up is short and it may well not pass the test of time [203].

VIII. COMPLICATIONS OF CONTINENCE SURGERY IN CHILDREN

1. STORAGE AND EMPTYING COMPLICATIONS

In the short term, it has been shown that the continent diversions can store urine and can be emptied by clean intermittent catheterization (CIC). It is apparent that there is a constant need for review and surgical revision. This observation mirrors the late complications of augmentation cystoplasty for neuropathic bladder where the median time to revision surgery is as long as ten years [204,205].

In general, once continent, they remain continent, although there are occasional reports of late development of incontinence. The problem lies more in difficulties with catheterization, particularly stenosis and false passages which may occur in up to 34% of patients[188]. In a recent retrospective evaluation of 500 augmentations over 25 years with a median follow-up of 13.3 years, the cumulative risk of further surgery at the bladder level was 0.04 operations per patient per year of augmentation and 34 % of the patients needed further surgery for complications. Bladder perforation occurred in 43 patients (8.6%) with a total of 53 events and 125 surgeries done for bladder stones in 75 cases [206].

The principal complications arise because the reservoir is usually made from intestine. Ideally, urothelium should be used and preservation of the bladder epithelium gives fewer complications than enterocystoplasty [207].

Combinations of detrusor myomectomy and augmentation with de-mucosalised colon have given promising results in the short term. The surgery is difficult as the bladder epithelium must not be damaged and the intestinal mucosa must be removed completely. When achieved there are no metabolic problems and many patients can void [207].

When augmentation can be done with a dilated ureter, the results are good and the complication rate low even in children with compromised renal function or transplantation [208].

All intestinal reservoirs produce mucus. The amount is difficult to measure and most estimates are subjective. No regime has been shown to dependably reduce mucus production [209].

2. RESERVOIR RUPTURE

The incidence of spontaneous rupture varies between different units. There may be delay in diagnosis although the history of sudden abdominal pain and diminished or absent urine drainage should make it obvious. The patient rapidly becomes very ill with symptoms of generalized peritonitis [210,211]. A 'pouchogram' may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography and a CT cystogram. If diagnosed early, catheterization and broad spectrum antibiotics may sometimes lead to recovery. If the patient fails to respond within 12 hours on this regime or if the patient is ill, laparotomy should be performed at once. If there is any instability of the patient laparotomy should be considered as an immediate necessity as bladder rupture in this clinical situation can be lethal.

Level of evidence 2.

Grade of recommendation A

Figures are not available on the incidence of this complication in reservoirs made only of bowel but come from patients with intestinal segments in the urinary tract. Most papers report small numbers. In a multicentre review from Scandinavia an incidence of 1.5% was noted. There were eight patients with neurogenic bladder which was said to be disproportionately high [210]. In a series of 264 children with any sort of bowel reservoir or enterocystoplasty, 23 perforations occurred in 18 patients with one death [211]. Therefore, as this complication is more common in children it becomes a very important consideration [212]. A review of 500 bladder augmentation procedures performed during the preceding 25 years, spontaneous perforations occurred in 43 patients (8.6%), for a total of 54 events. The calculated risk was 0.0066 perforations per augmentation-year [213].

Patients and their families should be warned of this possible complication and advised to return to hospital at once for any symptoms of acute abdomen, especially if the reservoir stops draining its usual volume of urine. All young patients with urinary reconstructions including intestinocystoplasty should carry suitable information to warn attending physicians of their urinary diversion in case of emergency.

3. METABOLIC COMPLICATIONS

Metabolic changes are common when urine is stored in intestinal reservoirs and must be carefully monitored. It is uncertain whether they are commoner in children or whether they just live longer and are more closely monitored.

Nurse et al found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable [214]. A third of all patients (but 50% of those with an ileocecal reservoir) had hyperchloremia. All patients had abnormal blood gases, the majority having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed.

In 183 patients of all ages at St Peter's Hospitals who had any form of enterocystoplasty, hyperchloraemic acidosis was found in 25 (14%) and borderline hyperchloraemic acidosis in an additional 40 (22%) patients. The incidence was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found [215].

In a series of 23 patients, Ditonno et al found that 52% of patients with a reservoir of right colon had hyperchloraemic acidosis [216]. In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range [217].

Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0mg% developed hyperchloraemic acidosis within 6 months of enterocystoplasty[218]. It is prudent to monitor patients for metabolic abnormalities, especially hyperchloraemic acidosis, and to treat them when found [219].

With increasing experience, it has become clear that there is a risk of developing vitamin B12 defi-

ciency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which is a metabolite that accumulates in B12 deficiency suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years. In the adults the mean B12 level was significantly lower when the ileo caecal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) [220,221]. In order to avoid the serious neurological complications, regular monitoring of B12 levels is essential.

In a review of 500 augmentations starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low-normal values [222].

Pediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. An annual serum B12 value in children beginning at 5 years following bladder augmentation is recommended.

Level of evidence 2.

Grade of recommendation B

The stomach has had a checkered career as a urinary reservoir. Its non-absorptive role in the gastro intestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastro intestinal function. Metabolically, the acid production leading to hypochloraemic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However about a third of children have had serious long term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acid urine, particularly, have limited its use [223,224].

4. EFFECTS ON THE GASTROINTESTINAL TRACT

Little attention has been paid to the effects on gastro intestinal motility of removing segments of ileum or cecum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected.

Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. It is clear that quality of life may be seriously undermined by changes in bowel habit [225].

It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. Nonetheless, reconstruction should be undertaken with the smallest length of bowel possible. Particular care should be taken in children with neurologic abnormality in whom rectal control is already poor. Poorly controlled fecal incontinence may occur in a third of patients [226,227].

5. RENAL FUNCTION

Obstruction and high pressures in the bladder during storage have devastating effects on the upper urinary tract. Bladder augmentation eliminates these high pressures. Urinary diversion with recurrent urinary tract infections and stone formation also may have deleterious effects on renal function. It is therefore of utmost importance to evaluate renal function in young children who have undergone undiversion or continent diversion. In the follow-up so far available, these procedures do not seem to affect renal function. When function has improved after such surgery it is likely to be the result of eliminating obstruction or high bladder storage pressure.

In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder [228]. This suggests, experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

Clinically, in the longer term, renal deterioration has been related to obstruction, reflux and stone formation. In one long-term study of Kock pouch patients, these complications occurred at the same rate as that found in patients with ileal conduits: 29% at five to 11 years [229]. Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was due to a ‘surgical’ cause in all but one [230].

Although a more complicated procedure, a renal transplant can be anastomosed to an intestinal reservoir with similar long term results as those using an ileal conduit [231,232].

6. INFECTIONS AND STONES

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer et al reported an incidence of 52.5% during a follow-up of four years[233]. Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.

In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs[234]. Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai et al found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch[235]. This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs [236].

It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies[237].

The production of excess mucus has also been blamed. The problem is that the measurement of mucus is difficult.

The finding of a spectrum of stone formation from mucus, through calcification to frank stone lends some support to this aetiology. However, it could be a secondary event, with mucus becoming adherent to a stone that has already formed. Many surgeons encourage patients to wash out their reservoirs vigorously with water two or three times a week. There seem to be fewer stones in those that claim to practice regular washing. In a prospective study a regime of weekly washouts did not improve the incidence of stones in 30 children compared to historical controls [238].

Mathoera et al found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified, while the frequency of irrigation did not appear to be a risk factor [239].

Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals[240]. Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones.

An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self catheterization. There was no significant difference in the incidence of stones with or without an augmentation[241].

Stones are associated with inadequate drainage in the sense that CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most ‘up hill’ drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones [239].

Kronner et al made the observation, that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone)[236].

Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as it is difficult to remove all fragments (and small particles may get trapped in mucus and the pouch wall), which may form the focus of a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended [242,243].

Because of the high incidence of stones following enterocystoplasty several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important [244]. It is unclear whether prophylactic antibiotics are useful, but a clinical infection should be treated adequately. Maybe in the future different types of irrigation fluid may prove helpful.

7. GROWTH

The suggestion that enterocystoplasty delayed growth in height seems to have been ill founded. In a group of 60 children reported in 1992 it was stated that 20% had delayed growth [245]. Current follow up of the same group has shown that all have caught up and achieved their final predicted height. Furthermore, measurements in a group of

123 children from the same unit have shown no significant delay in linear growth [246].

Enterocystoplasty may have an effect on bone metabolism even if growth is not impaired. At least in rats with enterocystoplasty there is significant loss of bone mineral density especially in the cortical compartment where there is endosteal resorption. These changes are not associated with HCA and are lessened by continuous antibiotic administration [247,248].

More recent follow-up data shows either no effect on growth or a decreased linear growth [249-252].

8. PREGNANCY

When reconstructing girls it is essential to have a future pregnancy in mind. The reservoir and pedicles should be fixed on one side to allow enlargement of the uterus on the other.

Pregnancy may be complicated and requires the joint care of obstetrician and urologist [253]. Particular problems include upper tract obstruction and changes in continence as the uterus enlarges.

Pregnancy with an orthotopic reconstruction appears to have a good outcome but chronic urinary infection is almost inevitable and occasionally an indwelling catheter is needed in the third trimester [254]. With a suprapubic diversion, catheter drainage for incontinence or retention may be needed in the third trimester [255].

Except in patients with an artificial urethral sphincter and extensive bladder outlet reconstruction, vaginal delivery is usual and caesarean section should generally be reserved for purely obstetric indications (distorted pelvis in spina bifida patients). During the delivery the bladder reservoir should be empty and an artificial sphincter deactivated. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles.

9. MALIGNANCY

The possibility of cancer occurring as a complication of enterocystoplasty is a constant source of worry. Currently cancer following augmentation cystoplasty is a recognized risk factor. It is known to be a frequent complication of ureterosigmoidostomy after 20 to 30 years of follow up. Animal evidence suggests that faecal and urinary streams must be mixed in bowel for neoplasia to occur. However, if it is chronic mixed bacterial infection, rather than the faeces per se, then all bowel urinary reservoirs are at risk.

In patients with colonic and ileal cystoplasties high levels of nitrosamines have been found in the urine of most patients examined [256]. Clinically significant levels probably only occur in chronically infected reservoirs [257]. Biopsies of the ileal and colonic segments showed changes similar to those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture [258].

In a review by Filmer et al, 14 cases of pouch neoplasm were identified [259]. Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumors were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years old. Cancer was found in bowel reservoirs at a mean of 18 years from formation. This is a few years earlier than the mean time at which malignant neoplasms are seen in ureterosigmoidostomies.

In a review of 260 patients with a follow-up of more than 10 years, Soergel et al found 3 malignancies (all transitional cell carcinoma): 2 following ileocecal and 1 after cecal augmentation. The age at augmentation was 8, 20 and 24 years respectively: the tumors were found when they were 29, 37 and 44 years old. All had metastatic desease and died. The incidence of malignancy in this group was 1.2%: considering that the development of tumors usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8 % [260].

Hussmann et studied a group of 153 patients with a mean follow-up of 27 years (10-52 yrs)after augmentation cystoplasty. In those with a Neurogenic bladder (n=97) they found 2 patients with transitional cell carcinoma (both smokers), in 38 patients with bladder exstrophy 3 multifocal adenocarcinomas in the augmented segment were found and in 2 of 18 patients with urethral valves an adenocarcinoma was discovered. The overall risk of cancer was 4.5% after a median period of 32 years. Of the 7 patients 5 died suggesting that these tumors are very aggressive and metastazise early [261].

This was also confirmed by Sung [262].

Patients who undergo bladder augmentation with a gastric remnant are at increased risk for malignancy, probably similar to that in patients with enterocystoplasty. In a review of 119 patients underwent augmentation cystoplasty with stomach in 2 institutions, three patients had gastric adenocarcinoma, while the other had poorly differentiated transitional cell carcinoma. Each case progressed to malignancy more than 10 years after augmentation [263-265).

If cancer is going to be a common problem, there will be some difficulty in monitoring the patients at risk [266]. Endoscopy with a small instrument through a stoma may not be sufficient. Ultrasound may not be able to distinguish between tumors and folds of mucosa. Three dimensional reconstruction of computerised tomography may be helpful, though the equipment is expensive and not widely

available at present [267]. At present it is advised to perform an annual endoscopic evaluation in all patients following enterocystoplasty starting 10 years after surgery.

10. PSYCHOLOGICAL CONSEQUENCES AND QUALITY OF LIFE

The main justification for performing a bladder reconstruction or continent diversion is to improve the individual's Quality of Life (QoL).

It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments [268]. Our prejudice is that reconstruction does, indeed, improve the lives of children. Supporting evidence is very thin and based on experience in adults.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd et al investigated 200 patients, half with an ileal conduit and half with a Kock pouch: there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently 'happier' were those who had had a conduit and subsequently were converted to a Kock pouch [269].

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QOL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives [270].

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because lack of validated instruments, difficulties in translating from one culture or language to another, and the difficulties in selecting control groups and variations in clinical situations. Gerharz et al have constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance. In addition they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity [271].

IX. CONSENSUS STATEMENT ON SURGICAL TREATMENT OF URINARY INCONTINENCE IN CHILDREN

Forms of urinary incontinence in children are widely diverse, however, a detailed history and physical and voiding diary obviate the need for further studies. These should identify that limited group that may require surgery. Many patients in this group will have obvious severe congenital abnormalities.

Because of the spectrum of problems the specific treatment is usually dictated by the expertise and training of the treating physician. The rarity of many of these problems precludes the likelihood of any surgeon having expertise in all areas. Furthermore, nuances in surgical procedures develop gradually and often are tested without rigorous statistics.

Nevertheless it may be that newer forms of very early aggressive surgical approach to severe complex anomalies such as exstrophy, myelodysplasia and urethral valves may provide a successful model for significant impact on the ultimate continence in such patients. Ultimately this may provide a basis for randomized studies to determine the most specific and effective mode of therapy.

The committee would encourage vigorous research in the molecular basis of bladder development and also support the development of surgical and treatment strategies which would utilize the natural ability of the bladder to transform in the early months of development and immediately after birth. Furthermore efforts to promote bladder healing, and protecting and achieving normal bladder function should be supported. Such studies and research may lead to earlier and more aggressive treatment of many of the complex anomalies now treated by the surgical procedures outlined in this report.

G. PSYCHOLOGICAL ASPECTS OF URINARY INCONTINENCE, ENURESIS AND FAECAL INCONTINENCE

LIST OF ABBREVIATIONS

ADHD	Attention-Deficit/Hyperactivity Disorder
CBCL	Child Behavior Checklist
DSM-IV	Diagnostic and Statistical Manual of Mental Disorders – IV
DW	Daytime wetting (urinary incontinence)
HKD	Hyperkinetic Disorder
ICD-10	International Classification of Diseases – 10
NW	Nighttime wetting (nocturnal enuresis)
ODD	Oppositional Defiant Disorder

Since the publication of the ICI report in 2009 [1] an increasing body of studies has been published on psychological factors of incontinence in children including some comprehensive reviews [2-7]. This part includes an update based on the recent literature and especially the ICCS standardisation document on psychological aspects in urinary and faecal incontinence [8].

I. INTRODUCTION

Children with urinary incontinence, enuresis and faecal incontinence carry a higher risk for manifest behavioural disorders, as well as for subclinical emotional and behavioural symptoms. It is important to assess and integrate psychological factors in treatment for two reasons:

1. As can be seen in **table 3**, the rate of comorbid behavioural and emotional disorders is much higher than possible organic causes [7,8]. The same care used to exclude organic causes should be applied to the assessment of behavioural aspects. Therefore, even paediatricians and urologists should have a basic understanding of psychological principles in order to treat their young patients adequately.

2. In functional elimination disorders, provision of information, cognitive therapy and behavioural modification are the most effective, first-line approaches to treatment. Medication can be helpful in many cases, but are usually not the mainstay of treatment. Surgery is rarely indicated. As most of the techniques used in "urotherapy" are based on cognitive-behavioural psychotherapy, it is essential to be acquainted with the basic psychological principles.

This chapter provides information on comorbid manifest clinical disorders, as well as symptoms which might be emotionally distressing for children and parents, but do fulfil the criteria for a disorder. Often, these will resolve upon attaining continence, while manifest disorders usually do not. In addition, children with psychological disorders are less compliant, and this explains why the failure rate of children's incontinence treatment is much higher. It is recommended that both incontinence and any comorbid psychological disorder are treated separately to ensure effective therapy.

Also, the relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for enuresis and urinary incontinence as well as of the Rome-III classification for faecal incontinence will be used [9,10].

II. CLINICAL BEHAVIOURAL DISORDERS

The rate of clinically relevant behavioural disorders in children and adolescents lies between 12.0% (ICD-10 criteria) and 14.3% (DSM-IV) [11-13]. The rate of comorbid behavioural disorders is increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without making reference to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem,
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis,

Table 3: Organic causes and comorbidity of clinically relevant psychological disorders or symptom scores*

Nocturnal enuresis	
Organic causes	< 1%
Behavioural comorbidity*	20-30%
Urinary incontinence	
Organic causes	<10%
Behavioural comorbidity*	20-40%
Faecal incontinence with constipation	
Organic causes	< 5%
Behavioural comorbidity*	30-50%
Faecal incontinence without constipation	
Organic causes	< 1%
Behavioural comorbidity*	30-50%

- Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD),

- With such common disorders, no causal relationship can be present and the two may co-exist by chance.
