Psychological disorders (synonyms: psychiatric, psychic, mental disturbances) indicate that there is "a clinically significant behavioural or psychological syndrome or pattern (not a variant of normal behaviour) that occurs in an individual, that it is associated with present distress, disability or impairment and carries a risk for the future development of the individual" (DSM-IV)[12].

Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including: history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnoses according to standardised classification schemes: ICD-10 [11] or DSM-IV [12]. Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate:

- externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders and ADHD),

- internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry and depressive disorders),

- and other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders and autistic syndromes.

III. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH ENURESIS AND URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems than non-wetting children, in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher (**table 2**) [7].

1. EPIDEMIOLOGICAL STUDIES

Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups.

Not all epidemiological studies on enuresis actually assess behavioural problems in a standardised form [14]. Only those studies that clearly define the group of clinically deviant children are reported in **table 4**. If a control group is reported, the relative risk for a behavioural problem can be calculated; otherwise the normative data is used.

a) Nocturnal Enuresis

In the Isle-of Wight study, 25%-28% of enuretics were seen by their parents to show problematic behaviour according to the Rutter Child Scale, 3-4 times more often than the controls [15]. Using the same instrument, the longitudinal Study from Christchurch (New Zealand) came to similar rates for the primary children with nocturnal enuresis, while the children with secondary nocturnal enuresis showed a much higher rate of 52% [16]. The same study assessed rates of DSM-III diagnoses at a later age, with marked differences between the primary and the secondary children with nocturnal enuresis [17].

In the Dutch study by Hirasing et al [19], 23% of children with enuresis scored in the clinical range of the CBCL total problem scale. In the cross-sectional Chinese study by Liu et al [18], a third of all wetting children were in the clinical range, 3.6-4.5 more often than controls. The US-Study by Byrd et al [13] used the 32-item-BPI (Behavior Problem Index), which is modelled after CBCL. The rates are lower than in the other studies, but included infrequent wetters, with as few as one wetting episode per year.

In a British population-based study of 8242 children at the age of 7 ½ years, children with enuresis were affected by: separation anxiety (8.0%), social anxiety (70%), specific phobia (14.1%), generalised anxiety (10.5%), depression (14.2%), ODD (8.8%), conduct disorders (8.5%) and ADHD (17.6%) [21,22].

In summary, the epidemiological studies show clearly that, depending on definitions and instruments used, 20-30% of all **nocturnal enuretic children** show clinically relevant behavioural problems, 2 to 4 times higher than non-wetting children.

Children with **primary nocturnal enuresis** were not different from controls in epidemiological studies [17]. **Secondary nocturnal enuresis** was preceded by a higher rate of weighted life-events [23] and was significantly associated with a higher rate of DSM-III psychiatric disorders, which can persist into adolescence [17]. By adolescence, the attainment of dryness after the age of 10 years increased the risk for behavioural problems, independently of the primary or secondary status [14].

The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7 ½ years [24]. Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-monosymptomatic forms), although the differences did not reach significance.

Table 4: Epidemiological studies: Percentage of children with clinically relevant behavioural problems in comparison to controls and their relative risk*

Study	Age (years)	N	Type of wetting	Incontinent children	Controls	Relative risk
				Rutter Child Scale; cut-off > 13		
Rutter 1973 [15]	5-14	4481	NW/DW	Boys: 25.6% Girls: 28.6%	7.9% 7.8%	3.2 3.7
McGee 1984 [16]	7-9	1037	NW	Primary: 30.8% Secondary: 51.9%	21.6%	1.4 2.4
				DSM-III diagnoses		
Feehan 1990 [17]	11-15	1037	NW	Total: 23.4% Primary: 0% Secondary: 42.3%	9.5%	2.5 4.5
				CBCL Total > 90th p.		
Liu 2000 [18]	6-18	3344	NW	30.3%	9.1%	4.3
Hirasing 1997 [19]	9	1652	NW	23.0%	10.0%	2.3
				BPI > 90th p.		
Byrd 1996 [13]	5-17	10960	NW	16.5%	10.2%	1.6
				DAWBA		Odd's ratio
Joinson 2006 [20]	7-9	8213	DW	Separation anxiety: 11.4%	6.8%	1.8
				Attention/activity: 24.8%	13.8%	2.1
				Oppositional behaviour:10.9%	5.8%	2.0
				Conduct problems: 11.8%	6.2%	2.0
Joinson 2007 [21]	7 ½ years	8242	NW	Separation anxiety: 8.0%	6.4%	1.3
				Social anxiety: 7.0%	4.6%	1.5
				Specific phobia: 14.1%	11.5%	1.2
				Generalised anxiety: 10.5%	7.7%	1.4
				Depression: 14.2%	10.9%	1.3
				ODD: 8.8%	4.7%	1.9
				Conduct disorders: 8.5%	5.7%	1.5
				ADHD: 17.6%	11.9%	1.5

b) Urinary Incontinence (Daytime Wetting)

Daytime wetting has been neglected in epidemiological research. Only recently, the first study was published based on a cohort of 8213 children aged 7 ½ to 9 years [20]. Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). Externalising disorders predominate in daytime wetting children which, in turn, will interfere with treatment. In the same cohort, 10,000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression / anxiety were associated with daytime wetting and soiling [25]. In another population-based study, 36.7% of children with urinary incontinence had ADHD symptoms, in comparison to 3.4% of dry children [22].

2. CLINICAL STUDIES

Clinical studies are limited by selection biases, but allow a much more detailed assessment of patients. Overall, children with nocturnal enuresis have lower rates of comorbid disorders (33.6%) than children with daytime wetting (52.6%) [26]. In another study, the rates were 29% and 46%, respectively [27]. Van Hoecke et al could also show that children with daytime wetting (or combined DW/NW) had significantly higher CBCL total problem scores than pure nocturnal enuretics or controls [28]. (**Table 5**)

a) Nocturnal Enuresis

In an early study of Berg et al [29] nearly 30% of children presented in a paediatric clinic were deemed "clinically disturbed". In another study in a paediatric setting, similar rates of 26% were found 20 years later using the CBCL [20]. These rates are almost identical to our own studies in a child psychiatric setting using the same instruments [26]. The rates of a selected group of treatment-resistant children with nocturnal enuresis undergoing Dry Bed Training were 2.2 times higher [31]. In the study of Van Hoecke et al [32], internalizing symptoms predominated in a mixed group of day and night wetting children with significantly higher scores for withdrawal, physical complaints, anxious / depressed, social problems and internalising behaviour scales compared to controls.

According to the ICCS terminology, four subgroups of nocturnal enuresis can be differentiated:

- primary monosymptomatic nocturnal enuresis
- primary non-monosymptomatic nocturnal enuresis
- secondary monosymptomatic nocturnal enuresis
- secondary non-monosymptomatic nocturnal enuresis

Regarding the subtypes of nocturnal enuresis, children with primary nocturnal enuresis showed behavioural problems less frequently (19.5%) than those with the secondary type (75.0%) [26]. The group with the lowest comorbidity – no higher than in the normative population – were those with monosymptomatic nocturnal enuresis (10.0%) without any daytime symptoms such as urgency, postponement or dysfunctional voiding. In a replication study, 29% of children with nocturnal enuresis had at least one ICD-10 diagnosis, 24% of those with monosymptomatic and 33% of those with non-monosymptomatic nocturnal enuresis [27].

Regarding the types of behavioural and emotional disorders, externalising disorders predominate [26]. The most specific comorbid disorders with enuresis

Table 5: Clinical studies: Percentage of children with clinically relevant behavioural problems in comparison to controls and their relative risk*

Study	Age (years)	N	Type of wetting	Incontinent children	Controls	Relative risk
				ICD-10 diagnoses		
von Gontard 1999 [26]	5-11	110	NW	33.6%	12.0%	2.8
von Gontard 1999 [26]	5-11	57	DW	52.6%	12.0%	4.4
Zink 2008 [27]	5-16	97	NW	29%	12.0%	2.4
	5-16	69	DW	46%	12.0%	3.8
				Rutter A questionnaire, cut off > 18 [interview)		
Berg 1981 [29]	6-13	41	NW	29.3% (26.8%)		
				CBCL Total >90th p.		
Baeyens 2001 [30]	6-12	100	NW/DW	26%	10.0%	2.6
von Gontard 1999 [26]	5-11	167	NW/DW	28.2%	10%	2.8
Hirasing 2002 [31]	6-15	91	NW	21%	10%	2.1
Van Hoecke 2004 [32]	9-12	84	NW/DW	20.4%	6.1%	3.3
Zink 2008 [27]	5-16	166	NW/DW	40%	10%	4.0

are ADHD (DSM-IV) or the Hyperkinetic Syndrome (ICD-10). In our own studies, the rates ranged from 9.3% (HKS) to 13.5% (HKS and ADHD) [26, 34]. ADHD is not associated with any specific type of nocturnal enuresis [33].

In a retrospective study of patients with ADHD, 20.9% wetted at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is a nonspecific association of ADHD and both night and daytime wetting [35]. 25% of 140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls [36]. The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens et al. [33], possibly due to selection bias: 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower [37]. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability [37]. Children with ADHD continued to wet at follow-up much more often (65%) than controls (37%) (Odds-ratio 3.17) [37]. At a 4-year follow-up, 64% still had ADHD: of these, 42% continued to wet at night (compared to 37% of the controls) [38].

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of children with ADHD, but only in 22% of the controls [39]. This means that children with both enuresis and ADHD require special attention – and both need to be treated separately.

b) Urinary Incontinence (Daytime Wetting)

Only a few studies have addressed the specific problems of children with daytime wetting. In a study of 418 children aged 5 – 17 years, day wetting children were described as being more stubborn, oppositional and secretive than nocturnal enuretic children[40]. In a subgroup of 58 children, those with and without urinary tract infections were compared: 11 % of day wetting children with urinary tract infections had a CBCL total score in the clinical range, 35 % of day wetting children without urinary tract infections and 16 % of nocturnal wetters. This indicates that children with a higher risk for behavioural problems were day wetting children without urinary tract infections [40]. In another study, 90 girls with recurrent UTI's had significantly more behavioural abnormalities than controls [41], so the issue of behavioural problems in children with and without UTI's remains to be settled.

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria [42]. With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding [39].

Daytime wetting is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated [9]:

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstructive voiding
- Stress urinary incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with **urgency incontinence** have previously been considered to have few behavioural problems [43]. 29 % of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalizing disorder. 13.5 % had a clinical total problem score in the CBCL, again mainly internalizing problems [44, 45]. The children are distressed by their wetting and family functioning is intact [45]. In a new study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis [27]. Children with urgency incontinence have lower rates of comorbid disorders than those with voiding postponement (36% vs. 59%), but higher than controls (9%) [46]. Children with urgency incontinence predominantly have emotional, introversive disorders, while the most typical disorder in voiding postponement is ODD [46]. Comorbid disorders are usually a consequence of wetting in urge incontinence, while ODD seems to be the underlying disorder in voiding postponement in many children. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introversive symptoms predominate.

Children with **voiding postponement**, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8 % fulfilled the criteria for at least one ICD-10 diagnosis [44]. These were mainly externalizing disorders in a third of all children such as Oppositional Defiant Disorder (ODD). Also, 37.3 % of children had a CBCL total score in the clinical range, again, with externalizing

symptoms predominating. In addition, family functioning was impaired [44,45]. In a new sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis [27]. In summary, children with voiding postponement have highly increased psychiatric risks.

Systematic studies on comorbid behavioural problems in children with **underactive bladder** have not been performed, although by clinical impression the rate of associated problems is high. In the original article, the "lazy bladder syndrome" was described as an acquired behaviour: it has "developed from the habitual neglect of the patient to empty the bladder on getting the urge to micturate" [47].

Systematic investigations of psychological aspects of **dysfunctional voiding** are rare. Again, in some children it represents an acquired habit, in others severe psychological disturbances are present [48]. Dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports [49].

There have been no systematic investigations of children with **giggle incontinence**. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends has been observed. It is not known if the rate of behavioural disorders is increased.

Regarding the **other subtypes of urinary incontinence**, not even anecdotal data is available.

IV. CLINICAL BEHAVIORAL DISORDERS IN CHILDREN WITH FAECAL INCONTINENCE

According to the Rome-III classification, two subtypes of faecal incontinence can be differentiated [11]:

• Functional constipation (with or without incontinence)

• Non-retentive faecal incontinence.

1. EPIDEMIOLOGICAL STUDIES

In the large ALSPAC study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (**table 6**) [50]. In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

2. CLINICAL STUDIES

As many studies have used the Child Behaviour Check List (CBCL) [51], the results can be compared easily. As shown in **table 4**, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range. As all studies were conducted in a paediatric setting, this rate cannot be due to selection effects of mental health clinics. Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these behavioural problems are not addressed treatment will be less successful [52].

Children with faecal incontinence and constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, [52] and 37% vs. 39%, [53]). This means that the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there is no evidence that one type (i.e. with constipation) has more somatic aetiology, while the other type (i.e. without constipation) has a more psychogenic aetiology. There is no specific psychopathology typical for faecal incontinence: all types of behavioural and emotional disorders can co-exist.

Internalising clinical behavioural scores (32%) were twice as common as externalizing ones (17%) in one study [58]. In others, single behavioural items, denoting oppositional behaviour and attentional problems predominate [53, 59]. Compared to controls, children with faecal incontinence rated significantly higher regarding anxious/depressed behaviour, attentional difficulties and disruptive behaviour on the CBCL subscales. For example, the rate of children with attentional problems in the clinical and borderline range was 6 - 7 times higher than in controls (20% vs. 3%; norms 5%) [60]. Again, the heterogeneity of behavioural symptoms is apparent.

Only few studies have assessed behavioural and emotional disorders according to standardized child psychiatric criteria. They also show a high general rate and heterogeneity of comorbid disorders. Thus, 34% of 41 children with faecal incontinence had an emotional disorder, 12% a conduct disorder and 10% a hyperkinetic syndrome according to ICD-criteria [61]. In another study of 85 highly selected child psychiatric inpatients with faecal incontinence, 83 % fulfilled the criteria for at least one ICD-10-diagnosis. 32% had a hyperkinetic syndrome, 21% an emotional disorder and 9% a conduct disorder [62]. Children with faecal incontinence and urinary incontinence have an even higher rate of behavioural and emotional disorders than children with wetting problems alone [63].

The co-occurrence of faecal incontinence and sexual abuse has been described by several authors [64]. In one study, 36% of abused boys had faecal incontinence [65], but other symptoms

*Table 6: Epidemiological and clinical studies: Percentage of children with clinically relevant behavioural problems in comparison to controls and their relative risk **

Study	Age (yrs)	N	Type of faecal incontinence	Incontinent children	Controls	Relative risk
Epidemiological studies				DAWBA		
Joinson 2006 [50]	7-8	8242	Not specified	Separation anxiety: 4.3%	0.8%	5.4
				Specific phobia: 4.3%	1.0%	4.3
				Generalised anxiety: 3.4%	0.4%	8.5
				ADHD: 9.2%	1.9%	4.8
				ODD: 11.9%	1.9%	6.3
Clinical studies				CBCL Total >90th p.		
Gabel 1986 [53]	6-11	55	Not specified	49%	10.0%	4.9
Young 1995[54]	5-17	76	Not specified	51%	10.0%	5.1
Nolan 1991 [52]	4-16	169	Not specified	43%	10.0%	4.3
Loening-Baucke 1987 [55]	6-11	38	Functional constipation	42%	10.0%	4.2
Benninga 1994 [56]	5-17	111	Functional constipation	39%	10.0%	3.9
Benninga 2004 [57]	5-17	135	Functional constipation	37%	10.0%	3.7
Benninga 1994 [56]	5-17	50	Nonretentive faecal incontinence	44%	10.0%	4.4
Van der Plas 1997 [58]	5-17	71	Nonretentive faecal incontinence	35%	10.0%	3.5
Benninga 2004 [57]	5-17	56	Nonretentive faecal incontinence	39%	10.0%	3.9

can co-exist [66,67]. However, in a retrospective analysis of 466 children having experienced sexual abuse, 429 children with externalising disorders and 641 controls, the occurrence of faecal incontinence did not differ between groups (faecal incontinence in 10.3%, 10.5% and 2%, respectively) [68].

V. SUBCLINICAL SIGNS AND SYMPTOMS OF WETTING CHILDREN

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions towards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

1. IMPACT ON CHILDREN

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night in one study (40 children aged 5-15 years)[69]. In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits [70]: they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be “really difficult” – ranking 8th behind other stressful life-events [71].

In a clinical study, 70.3% of day and night wetting children aged 5 to 11 years could clearly indicate that the wetting was of disadvantage [72]. The types of disadvantages or negative consequences were: social (I can‘t sleep at friends‘ house, friends can’t stay over night – in 32.1%), affective (I feel sad, ashamed, annoyed – in 16.4%), of isolation (I feel like a baby, nobody is allowed to know about it, I feel different from other children – in 6.7%), of sensation (it feels unpleasant, cold, wet, itchy, nasty – in 32.1%) or referred to direct consequences (I have to take a shower, sleep in pampers, won’t get a bicycle – in 17.6%). Only 4.9% reported any advantages of the wetting at all (I like the wet feeling, I get more attention from mother).

One construct of special importance is that of **self-esteem**. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness [73]. In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls [74] and in yet another, the self-esteem total score was higher among enuretics than norms [75]. Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem [76] – but there can be no doubt that self-esteem can improve upon attaining dryness [75]. Self-esteem increases even if treatment of enuresis is not successful [77], showing that care and “good doctoring” for children and parents is of great help – regardless of outcome. Recently, a focus has been on **quality of life**, which is reduced in children with urinary incontinence [78].

In a population-based study of 75 boys with **faecal incontinence** were compared to 73 matched controls [79]. Specifically, encopretic boys showed higher rates of food refusal, general negativism, strong anxiety reactions, lack of self-insurance, poor tolerance to stress, both inhibited and aggressive behaviour, a strong fixation to their mother and difficulties in relationships. Also, children with faecal incontinence tended to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions [80]. However, in a more recent study, self-esteem did not differ between children with faecal incontinence and controls on the Piers-Harris questionnaire [81]. Although some of these subclinical symptoms will diminish under successful treatment [57,58], it is not known which ones will persist and become chronic.

2. IMPACT ON PARENTS

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little [82]. In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects [83]. Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms [84].

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study [85] and 2.75 years in another [86]. Also, many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead [85,86].

A minority of parents show an attitude that was described as “maternal intolerance” by Butler et al [83]. Convinced that their child is wetting on purpose, the risk for punishment is increased. The reported rates of punishment varied from 37% [89], 35.8% [85], 23% [86] to 5.6% [87]. In other cultures, punishment is even more common: 42% of Turkish children were spanked and 13% beaten [89]. Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child [90]. These parental attributions and experiences have to be taken into account in all treatment plans for enuresis, as they can decisively influence the outcome.

Parents of children with **faecal incontinence** are also stressed and worried the problem [91]. In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls [81]. In another study of 104 families, nearly half (51%) had no unusual family problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event [92]. In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

VI. GENERAL PRINCIPLES

1. ASSESSMENT

a) Screening Questionnaires

Due to this high comorbidity of psychological symptoms as well as disturbances, every child should be screened as part of the routine assessment. The best screening instrument is still a good history and careful clinical observation, which requires some training and experience in addition to a screening questionnaire, such as the Child Behavior Check List (CBCL) [51], which contains 113 empirically derived behavioural items. These are checked on a three-point scale and are formulated in simple wording. From these items, eight specific syndrome scales and three general scales can be calculated.

Recently, even shorter screening instruments have been derived from the CBCL. Thus, Van Hoecke et al. [93] validated a short questionnaire consisting of 7 items for emotional problems, 3 for attention problems and 3 for hyperactivity/impulsivity. This is an extremely useful short questionnaire both for clinical and research uses.

In the recent ICCS document, a general screening for emotional and behavioural problems in all settings (paediatric, urologic, child psychiatric, etc.) with a validated and standardised parental behavioural questionnaire is recommended because of the high rate of comorbid disorders in 30-50% of children [8]. This can be done in two steps (short screening questionnaire such as the SSIPPE [93] first, long questionnaire next) or in one step (validated, long questionnaires such as the CBCL only). If many problem items are checked, a child psychological or psychiatric assessment should follow. If comorbid disorders are present, counselling or treatment, if necessary, is recommended (**see figure 14**).

Also, other useful questionnaires addressing specific aspects of enuresis have been developed [94]. These assess the subjective views and attributions of parents and children, such as parental intolerance. Another potentially useful questionnaire addresses aspects of everyday burden of enuresis on children and their families [95]. Other non-validated questionnaires for the assessment of children with all types of incontinence can be found in von Gontard and Neveus [9]. For children with faecal incontinence, the Virginia-Faecal incontinence-Constipation-Apperception Test (VE-CAT), a validated, picture-based questionnaire for children and parents was shown to be good at differentiating bowel-specific problems [96].

One construct of special interest in children with elimination disorders is that of self esteem. Well-known self-esteem questionnaires include the Piers-Harris Children's self – concept scale [97] as well as others [98]. Another important construct is that of health related quality of life (HQOL). This is a complex construct that tries to assess health related wellbeing in different domains of daily life. Generic HQOL questionnaires allow comparison between children with different medical disorders [99]. These range from short screening to longer, more detailed questionnaires (such as the KINDL-questionnaire)[101]. Recently, the first specific quality of life questionnaire for children with wetting problems was developed by Bower et al. [102]. This has the advantage that the specific, elimination-related effects on daily life can be assessed. For children with faecal incontinence, a health-related quality of life questionnaire with good psychometric properties was described: the Defecation Disorder List (DDL) consists of 37 items and can be used in children with all types of faecal incontinence and/or constipation [103].

b) Child Psychiatric Assessment

A child psychiatric assessment is a professional procedure with the goal of to coming to a categorical decision: to see if a diagnosis, according to the standardised classification schemes (ICD-10 or DSM-IV) is present in the child or not.

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D)[104].

Questionnaires are always an essential part of child psychiatric assessment. They are a time-economical way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behavior Check List, which has been translated into many languages (CBCL/4-18)[51]. In the meantime, Achenbach and co-workers have pro-

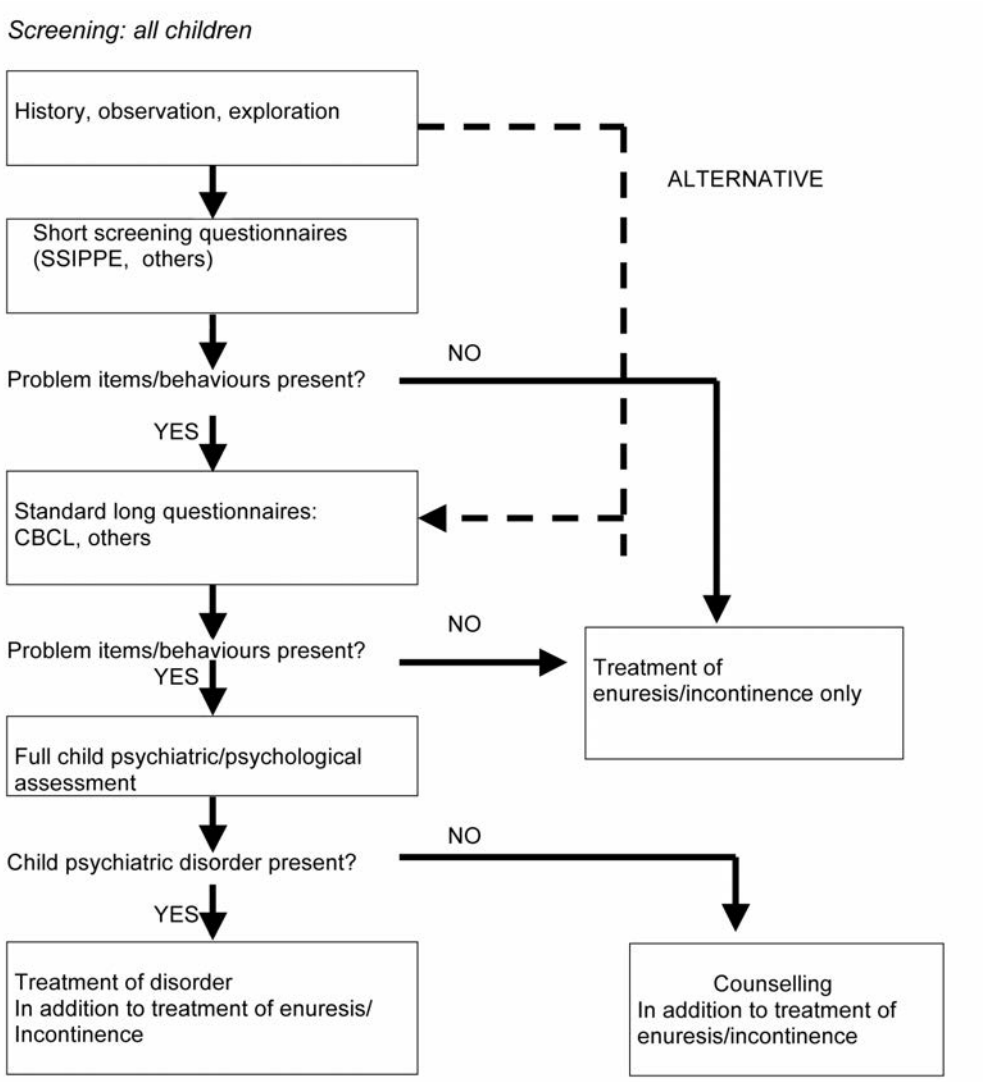

Figure 14: Flow chart for assessment of psychological symptoms (subclinical) or disorders (clinical). The specific treatment for enuresis / incontinence is the same for all children including those with symptoms requiring counselling, and those with disorders needing treatment [8]

duced a whole "family" of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, including those with mental and physical handicap [105-107]. If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist.

Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children or by standardized tests such as the Zurich Motor Tests [108,109].

After the diagnostic process has been completed, the child's disorder is diagnosed according to standardized classification schemes. The two standard classification systems are the ICD-10 [11], which is widely used in Europe and in other parts of the world and the DSM-IV [12] employed in the United States.

In child psychiatry, a multi-axial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intra-familial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

2. OF PSYCHOLOGICAL DISORDER

For most children with elimination disorders, a symptom-oriented approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psycho-therapeutic interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weisz et al. [110] conclude that "psychotherapy with young people produces positive effects of respectable magnitude" (i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone [111]. Of those which have been evaluated, four basic schools of psychotherapy can be differentiated:

1. Depth psychology (or psycho-analysis), which addresses and works with unconscious aspects of the psyche;
2. Client-(or child-) centred-psychotherapy, which focuses on the current conscious experience of the child and the healing aspects of their therapeutic relationship;
3. Family therapy, which focuses on the interaction between family members but not the individual person;
4. Cognitive-behavioural therapy, focussing on cognitions and observable behaviour.

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child's environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality has to be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration have to be addressed: is a short focal therapy focussed on one specific problem needed, or a longer more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also by using speech, occupational, physiotherapy, music and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based "practice parameters" or "guidelines" have been developed in many countries. These interventions are usually performed on an out-patient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

3. UROTHERAPY

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term **urotherapy** is used in some countries. It is an umbrella term which has been defined as a "type of training which makes use of cortical control of the bladder, teaching children to recognize and employ conscious command over their lower urinary tract. Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to

do about it and support and encouragement to go through with the training program" [112].

Although not a psychotherapy in a narrow sense, it employs many psycho-therapeutical techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined.

4. NON-SPECIFIC APPROACHES

The first step in any diagnostic and therapeutical process is to **create a good** relationship with both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the **provision of information** is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

5. COUNSELLING

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of "demonstration", e.g. actively showing how an alarm works. In "coaching", parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include "modelling" and "role-playing". The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

6. COGNITIVE-BEHAVIOURAL THERAPY

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as "self-monitoring" (observation and registration), "activity scheduling" (organisation of activities) and "labelling" (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include "classical conditioning" and "operant conditioning", which basically means learning by success, which can be achieved by different strategies using positive or negative reinforcement.

7. BASELINE AND OBSERVATION

Baseline and **observation** are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration actually has a therapeutic effect and many symptoms actually diminish if they are simply observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and the dry nights symbolically for two to four weeks [113,114]. These non-specific measures have been shown to be successful and are associated with fewer wet nights [3,115]. In one clinical trial, for example, 18% became dry after an 8-week baseline [116]. The authors of the recent Cochrane Review conclude that "simple methods could be tried as first line therapy before considering alarms or drugs, because these alternative treatments may be more demanding and may have adverse effects" [3,5].

In **urgency incontinence**, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart [117,118]. For children with **voiding postponement**, timed voiding 7 times a day and registration in a chart is recommended [118].

For all children with **faecal incontinence**, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after meal-times in a relaxed mode for five to ten minutes [119]. This is documented in a chart and can be reinforced positively. In one study, 15 % of children were cured within six weeks by simple methods such as these [57]. If **constipation** is present and the large amount of faecal masses has accumulated, disimpaction has to be performed at the beginning of treatment. To avoid re-accumulation of faecal masses, maintenance therapy with oral laxatives, such as polyethylenglycol (PEG) is recommended for at least six, and up to twenty-four months [120]. The preferred oral laxatives are osmotic laxatives such as PEG. "These behavioural interventions when used together with laxative therapy may improve continence" according to a Cochrane review of 18 RCT's and 1168 children [6] and other reviews [121].

8. BIOFEEDBACK

Biofeedback has been shown to be effective in some elimination disorders such as **dysfunctional**

voiding [122]. It is defined as a variety of techniques, by which physiological activity is registered, enhanced and presented to the patient in real time by visual and acoustical signals [122]. In **faecal incontinence**, biofeedback is no more effective than standard behavioural techniques in faecal incontinence both with [123] and without constipation [124] and is not recommended in a systematic Cochrane Review [6].

9. ALARM TREATMENT

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experiences and has been shown to be highly effective and was introduced by Mowrer and Mowrer [125].

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-analyses). Houts et al. [126] compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that "urine alarm treatments should not only be considered the treatment of choice, but the evidence from this review suggests that cure rather than management is a realistic goal for the majority of children suffering from nocturnal enuresis".

Lister-Sharp et al [115] provided a systematic review, including only RCT's on nocturnal enuresis. The likelihood for 14 consecutive dry nights was13.3 times higher than without treatment. The authors conclude that "in the long term, alarm treatment would appear to be the most clinically effective, and because the cost of drug therapy, also the most cost effective intervention". Mellon and McGrath's [127] compiled a systematic review on 70 well-controlled outcome studies. With a dryness rate of 77.9%, alarm treatment is deemed clearly efficacious. A comprehensive narrative review was written by Moffat [128] concluding that "all the current evidence suggests that conditioning gives the best long-term outcomes for bed wetters". Finally, a Cochrane review of 50 RCT's involving 3257 children concluded: "Alarm interventions are an effective treatment for nocturnal enuresis. Alarms appear more effective than Desmopressin or tricyclics because around half of the children remain dry after alarm treatment stops" [2].

Therefore, when indicated, alarm has been endorsed as a first line treatment by multidisciplinary European [129], world-wide [130], German [114] and American child psychiatric guidelines [113], as well as various individual authors [131].

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis)[126], so that combinations were considered as "probably effective" [127].

These specific programmes including alarm are all essentially cognitive-behavioural techniques. **Arousal training** is a simply and easily performed [132,133]. Children are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ½ years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively) [132].

Dry Bed Training is a complicated program starting with an intensive night and maintenance treatment and using positive, as well as negative reinforcers [134]. Despite high success rates reported in early studies [134], recent meta analysis have shown that DBT is no more effective than alarm treatment alone [115]. The likelihood to attain 14 consecutive dry nights was 10 times higher than in controls without treatment – but not different from alarm treatment alone. Also, alarm is the most important component of DBT. DBT without alarm showed only a 2.5 times higher likelihood of attaining dryness than controls. The relapse rates were not improved by DBT compared to alarm treatment alone [115]. As it is a cumbersome treatment, it nowadays it is reserved for children and especially adolescents with therapy-resistant nocturnal enuresis, as it "may augment the effect of an alarm" and "might reduce the relapse rate" [3]. Thus, Hirasing et al. [30] could show that behavioural problems were reduced in children with persistent nocturnal enuresis treated with DBT.

Other programmes include the **Full spectrum home treatment.** This is a combination package including a written contract, full arousal, overlearning and bladder retention exercises [126]. 78.5% of children became dry in 2 studies [127], but the alarm exerts the main effect [3]. **Overlearning** is a relapse prevention programme: after attaining dryness, increasing fluids are given before sleep to stabilise the achieved effects [135]. The relapse rate could be reduced from 20-40% to 10% through this "provocation method".

Finally, alarm treatment can be combined with **pharmacotherapy**, although the evidence for combination treatment is conflicting. The combination of **desmopressin** and alarm treatment has been reported in several studies [136-139]. The combination with **anticholinergics** plays an important part in clinical practice, but has not been investigated systematically.

VII. CONCLUSION AND SUMMARY

This review summarised the most important psychological aspects in children with enuresis, urinary incontinence and faecal incontinence.

The rate of comorbid clinical behavioural disorders is increased. Children with urinary incontinence are more affected than those with nocturnal enuresis. Children with secondary and non-monosymptomatic nocturnal enuresis have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD.

Children with daytime wetting have mainly externalising behavioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postponement are characterised by oppositional behaviour. Children with faecal incontinence have the highest rate of associated disorders – both internalising and externalising.

These disorders will not disappear upon attaining dryness. They have to be addressed, as they will interfere with the incontinence therapy due to low compliance.

Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment.

Questionnaires are useful as screening instruments in the assessment process. It is recommended that questionnaires are used as a general screening procedure for emotional and behavioural problems routinely in all settings (8]. If a psychological disorder is suspected, a full child psychiatric assessment and subsequent treatment is needed. The basic principles, including those of psychotherapy, are outlined. Psychotherapeutic techniques are used in urotherapy, especially cognitive-behavioural elements. Non-pharmacological and non-surgical techniques are most effective for most forms of incontinence based on systematic reviews. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

This chapter deals with neurologic urinary and faecal incontinence; it draws on previous ICI reports, and complements information in other ICI chapters. In developing the content, literature searches were undertaken with the keywords; “neurologic”, neurogenic”, “bladder”, “bowel”, “lower urinary tract”, “anorectal”, “incontinence “, “continence”, “urinary”, “faecal”, “paralysis”, “dysfunction”, “retention”, “constipation”. Searches for specific neurologic diseases (section E) were undertaken, looking into selected neurological diseases of particular relevance to neurourology, comprising the more prevalent or more challenging in terms of incontinence diagnosis and treatment.

A. Introduction

Continence relates to reservoir functions of the bladder and rectum, and closure of their respective outlets by contraction of smooth muscle (bladder neck and internal bowel sphincter) and striated muscle urethral and anal sphincters. Expulsion requires relaxation of these latter structures, and contraction of the musculature of the respective reservoirs, to permit a physiological reflex evacuation of urine or faeces.

The lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically, bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lie in close proximity to each other, and to the muscular structures of the pelvic floor. Both are innervated by autonomic and somatic nerves, (**Table 1**) and have similar principles of central control [2, 3]. The LBT differs from the bladder in having an enteric nervous system [4]. Interactions between the two organ systems are increasingly recognised, and their activity is co-ordinated. Voiding can occur without defecation [5], and the initiation of micturition often precedes that of defecation, even if both organs are considered equally full [6]. The filling status of the bladder influences sensation in the rectum and vice versa [7], and the potential for mutual influence in pathology is emerging [8]. Nonetheless, little information is available on co-ordination of both functions in patients with neurological pathology.

The evidence base

Neurogenic lower urinary tract dysfunction (NLUTD) is a term that applies to an extraordinarily diverse spectrum of clinical conditions. This heterogeneity can be appreciated by considering the different challenges faced by the infant born with myelomeningocoele and the elderly patient with dementia-associated incontinence. Some order can be imposed by grouping conditions based on their cause and site of impact on the neuraxis (see **table 2**) [9].

Historical data demonstrates that the management of NLUTD has made huge advances over the last century, largely based on a trial and error approach and the dissemination of expert opinion [10]. Improved outcomes for patients were the result of the development of a urodynamic-based understanding of pathophysiology, the introduction of effective treatments to allow safe and reliable urine storage and intermittent catheterisation, the advent of more effective antibiotics and the development of better catheters and appliances. However, the historical approach is accompanied by significant problems. Dangerous or ineffective treatments can be trialled out-with an appropriate ethical framework and successful therapies can be slow to be introduced because their proponents may not convince their peers of the merits of the new treatment.

There is an inherent risk when an area of clinical practice has not been accompanied by a culture of high quality scientific research, and where the data which is available is used uncritically. For example, there has long been concern that management of NLUTD by indwelling catheter drainage results in excessive morbidity and, at first glance, published data on complication rates between different bladder management systems would appear to confirm that catheters are damaging to upper urinary tract function. However, this is based on cross-sectional data; such studies do not effectively take into account the preceding bladder management methods, the inability to randomise to different management approaches, and that catheters are typically used as a last resort in patients who have already developed problems with their urinary tracts [11]. Prospective longitudinal evaluation accounting for

Sacral spinal cord	Spinal dysraphism, Sacral agenesis, Ano-rectal anomaly	Conus injury	Tumour
Subsacral	Spinal dysraphism, Familial dysautonomia	Cauda equina injury, Pelvic nerve injury	Tumour, Peripheral neuropathy (e.g. diabetic)

**Conditions that can arise in more than one region of the CNS*

antecedent bladder management actually indicates that indwelling catheterisation is protective for the upper urinary tract [12].

The extensive evidence base concerning NLUTD is clearly demonstrated by the content of this chapter, but much of the evidence is contained in reports of studies which fail to meet contemporary standards for high quality evidence. How then should the clinical community respond to the challenge of improving the scientific foundations of our care for patients with NLUTD?

There are many aspects of modern management of NLUTD which will never be tested in definitive clinical trials because they appear to be of self-evident value. As a result, no trial could be conducted because the hypothesis that was to be tested would lack equipoise. For example, it would be impossible to conduct a trial that randomised spinal cord-injured patients between urodynamic-led and clinical-led treatment planning. However, that does not preclude the need to question these standard approaches. For example, such a study could be conducted in the context of multiple sclerosis where different approaches have been advocated [13, 14].

Despite the difficulties of conducting high quality trials in the field of NLUTD, there are an increasing number of studies that demonstrate the feasibility of such studies. Large, industry-sponsored studies have been conducted and are capable of providing near-definitive data on important clinical questions [15, 16]. However, even where high-quality data exists for some patient groups, there may be little or no data for others; spinal cord-injured and multiple sclerosis patients have been shown to respond to intra-detrusor injections of botulinum neurotoxin A but there is a dearth of data on patients with neurogenic detrusor overactivity (DO) due to intracranial conditions. Extrapolation from one condition to another is inevitably going to be needed but would be aided by even small, well-conceived trials that looked at patients with less common conditions.

There are a large number of interventions that have only been assessed by low quality methodologies, typically uncontrolled case-series. In some cases, such as that of the artificial urinary sphincter, there is sufficient data on which to base an evaluation, whereas other procedures still await a more complete assessment; the majority of alternative operations used to treat neurogenic stress incontinence fall in this category.

Finally, there is the question of how to evaluate new investigative and treatment techniques. Drug therapies are tightly controlled by regulatory authorities but

it is common for drugs to be extensively investigated in the non-neurogenic population but not in patients with NLUTD. It is to be hoped that tighter regulation and the demonstration that NLUTD trials are feasible will encourage drug evaluation in this patient group. For devices and surgical procedures, regulation is less tight and it is therefore for the clinical body to resist the premature introduction of techniques that lack an appropriate evidence base. There is a need for multi-centre cooperation in clinical trials that are designed to look, not only at short-term clinical efficacy, but also at long term results, complications and cost-effectiveness of new interventions.

B. Pathophysiology

With a neurologic lesion the type of dysfunction that follows in LUT and LBT will depend on the site, the extent and the evolution of the lesion. Traditionally neurourological pathology has been divided into the upper motor neurone lesions (UMNL), comprising suprapontine (cerebral) and suprasacral (brainstem, and spinal cord); and lower motor neurone lesions (LMNL), comprising sacral and subsacral (cauda equina and peripheral nerve). Brainstem lesions are rarely compatible with more than short-term survival, so they are only infrequently encountered in neurourological practice.

I. SUPRAPONTINE LESIONS

Patients with lesions above the pons usually continue to have reflex contractions of the detrusor. However, they may lose one or more of the cerebral contributions to LUT and bowel function, such as volitional control over timing of emptying, inhibition of reservoir (bladder, rectum) contractility, conscious filling and emptying sensations and some integration functions with other organ systems. This is the case in brain lesions, such as stroke, head injury, etc., which mostly continue to have a normal synergic LUT function. However these patients may purposely increase sphincter activity during an overactive detrusor contraction [1] to prevent urinary incontinence which would otherwise occur. This has been termed “pseudo-dyssynergia” because it is difficult to distinguish from true detrusor sphincter dyssynergia (DSD) on a urodynamic record. Nonetheless, in suprapontine lesions, sphincter activity is synergic with the bladder. Urinary incontinence in suprapontine lesions is due to bladder overactivity [2], or due to disinhibition of the micturition reflex (enuresis).

II. PONTINE LESIONS

Isolated pontine lesions are rare and most often occur in the setting of a neoplasm or vascular event. Urinary retention was described in children with pontine tumours [3] and case histories have been described of patients with retention and focal pontine lesions [4-7]. Amongst patients with brainstem stroke, it was dorsally situated lesions that resulted in lower urinary tract dysfunction [8]. Proximity of the medial longitudinal fasciculus to the pontine micturition centre means that a disorder of eye movements, such as internuclear ophthalmoplegia, is highly likely in patients with pontine pathology causing voiding disorders [9].

III. SUPRASACRAL SPINAL CORD LESIONS

When a lesion is located below the pons in the spinal cord (or medulla oblongata), DSD is a common finding. Incontinence may still be caused by detrusor overactivity, but can be accompanied by retention due to the DSD. For lesions above T6 where the isolated spinal cord below the injury level remains viable, an additional feature can be autonomic dysreflexia. This is a severe, potentially life-threatening, rise in blood pressure precipitated by stimulation in the part of the body supplied by the autonomous distal spinal cord [10]. Clinically, it is characterised by headache, bardycardia, hypertension, and altered cutaneous bloodflow (vasoconstriction in the skin below the level of SCI, vasodilation above).

A spinal cord lesion above the lumbosacral cord level eliminates voluntary and supraspinal control of micturition, leading to DO mediated by spinal reflex pathways. The reflex bladder function is thus very different from normal; (1) it involves different afferent fibres (experiments in cat indicate the relevant afferents are the C-fibres) [11], (2) bladder contractions are poorly sustained, (3) the urethra and bladder become dyssynergic, and (4) previously irrelevant stimuli influence the bladder and/or external sphincter activity. Voluntary inhibition of the micturition reflex is lost, though some consciousness of bladder sensation may be still be present. Of the 269 patients with suprasacral spinal cord injuries investigated by Weld et al., 12.3 % had no dyssynergia, 7.4 % had intermittent and 80.3 % continuous DSD. There was no significant association between the specific level of lesion and the DSD type. Blaivas found that 64.9% of patients with suprasacral lesions demonstrated detrusor overactivity and/or DSD, 41.8 % had low bladder compliance and 40 % had high detrusor leak point pressure. DSD causes a functional outflow obstruction; the clinical impact is impaired voiding, with elevated residual urine, sometimes also prolonged detrusor contractions, structural bladder damage and vesico-ureteric reflux. When combined with recurrent urinary tract infections, renal failure may result. This is more common with continuous than intermittent DSD. More than half of men develop urological complication.

After spinal cord injury, mechano-sensitive C-fibre afferents mediate the abnormal sacral segmental

bladder reflex. The mechanism of this change from chemo-sensitivity to mechano-sensitivity of C-fibres is unclear. In animal models, afferent neurons innervating the bladder increase in size, a change prevented by urinary diversion, perhaps mediated by nerve growth factor (NGF).There is also a change in excitability, mediated by a shift in expression of sodium channels from high threshold to low threshold sensitive channels.

IV. SACRAL (CONUS MEDULLARIS) LESIONS

The intermediolateral nucleus is the part of the spinal cord containing the nuclei of the autonomic nervous system (ANS). In the sacral spinal cord, the intermediolateral nucleus is parasympathetic, and damage to the nucleus renders the detrusor areflexic. Resulting retention of urine can cause incontinence (formerly termed overflow incontinence). Sensation can be impaired as well, affecting LUT filling sensations, and urethral sensation of urine flow during voiding. Constipation occurs due to loss of spinal-cord mediated, though the myenteric plexuses of the enteric nervous system can continue to generate segmental colonic peristalsis.

Onuf's nucleus, located medially in the ventral horn of the sacral spinal cord, is a mixed autonomic/ somatic nucleus containing the motor nuclei for the external sphincters of the LUT and LBT. Damage to this structure affects sphincters (and some pelvic floor musculature), and thus stress incontinence may result. If the pudendal nerve is also impaired, there is an increased risk for incontinence. Loss of function of the puborectalis muscles leads to reduction of the rectal angle.

V. SUBSACRAL LESIONS (CAUDA EQUINA OR PERIPHERAL NERVES)

The same effects as seen with lesions of the conus medullaris can result from lesions of the subsacral nerves (the cauda equina, or the peripheral nerves-including the pudendal nerves). Both parasympathetic and somatic motor function will potentially be impaired; the detrusor can be underactive or flaccid and the external sphincter can be paralyzed. These lesions can also cause a variety of sensory deficits. Some pain sensation can be retained because of intact sympathetic hypogastric nerves [3], which enter the spinal cord in thoracic roots. The bladder neck normally can function independently of the external sphincter, for example closing the sphincter is open at the time of ejaculation in men, while the bladder neck should be closed. Since it is predominantly innervated by sympathetic pathways, it can retain some function in sacral injury. If there is extensive autonomic damage, the bladder neck remains open; this will lead to retrograde ejaculation if ejaculatory function is preserved.

C. Neurological urinary incontinence

I. EPIDEMIOLOGY

NLUTD may be caused by a variety of neurological diseases and/or events affecting the various parts of the nervous systems controlling the LUT. The resultant dysfunction depends grossly on the location, extent, and nature of the causative neurological lesion or lesions. Overall prevalence estimates for NLUTD in the general population are scarce, but data are available on the prevalence of the underlying conditions and, in some cases, the relative risk for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures, due to low level of evidence in most published data and smaller sample sizes.

A Pubmed search was conducted, using the publication range from 2008 until 2011 with search words-epidemiology, neurogenic bladder, neurologic incontinence, neurologic patients, and prevalence, as well as using the specific neurological conditions noted in the discussion below. In general, specific disease states were reported in retrospective analyses, with the prevalence of symptoms and/or abnormal physiological findings in those populations typically highlighted. Only rarely were multi-centre studies conducted and/or prospective analyses performed. Thus, in general, the cohorts studied are small, and the prevalence estimates are typically based on patients referred for the assessment of LUTS. Applying the prevalence estimates to an affected group of neurological patients (who may or may not have NLUTD) therefore may not always be appropriate due to the manner in which most of the data are reported, and due to the possible coexistence of other anatomical or functional abnormalities unrelated to the neurological lesion.

1. NEUROLOGICAL LESION BY DISEASE LOCATION

a) Diseases Affecting Brain/Brainstem

Brain tumours Brain tumours can cause NLUTD in up to 24% of the patients [1]. Case reports and small series note the development of urinary retention and other LUTS in patients with pontine glioma, metastatic oligodendrioma, as well as other lesions [2-5]. In a series of patients with brain tumours voiding difficulty was reported in 46/152 (30 %) of patients with tumours in the posterior fossa, while urinary incontinence occurred only in 3 (1.9 %), though urodynamic data are largely lacking.

Dementia One cannot easily distinguish LUTS caused by age-related changes of the bladder or other lower urinary tract pathology from that due

to dementia [6]. Therefore the true prevalence of LUTS caused by dementia is difficult to estimate. It has been shown that in geriatric patients with dementia, incontinence is much more frequent than in non-dementia patients [7-8]. Additionally, Lewy body dementia (LBD), Binswanger, Nasu-Hakola and Pick diseases have all been associated with NLUTD [9-13]. One recent study found that patients with LBD were much more likely to have urge incontinence (53%) compared to Parkinson's disease (PD; 27%) and Alzheimer 's disease (AD; 12%). With the exception of detrusor overactivity, which was much higher in patients with LBD (92%), all other urodynamic parameters were similar between groups and similar to expected findings for this age group [14].

With regard to AD, the occurrence of incontinence is reported to be between 23% and 48% [15-16]. The onset of incontinence usually correlates with disease progression, and a male to female ratio of dementia-related incontinence was reported to be 1:15 [17].

Mental Retardation Assessing LUTS in the setting of mental retardation is often difficult due to significant cognitive impairment. A NLUTD prevalence of 12 % -65 % has been described, which has been shown to vary with the severity of mental retardation [18-19]. A recent case control study of children with mental retardation noted a much higher prevalence of voiding dysfunction (35.2%) when compared to age matched controls (8.3%), and similarly, a higher prevalence of incontinence [20]. Similarly, adults with severe intellectual disability due to mental retardation appear to be at greater risk for carrying a PVR > 150 ml than those with lesser disability [21].

Cerebral Palsy *A* study of 97 children (mean age 8) with cerebral palsy, who were not necessarily referred for urological evaluation, found a prevalence of NLUTD of 61% and incontinence of 44%. In other populations, LUTD has been reported in 30 – 40 % of patients [22-24].

Normal pressure hydrocephalus (NPH) Case reports have indicated the presence of NLUTD in patients with NPH [25-27] A recent study of 42 patients with idiopathic NPH reported urinary symptoms in 93% of patients (storage symptoms more common than voiding), and detrusor overactivity was noted urodynamically in 95% [28].

Basal Ganglia Pathology – Parkinson's Disease (PD), Huntington, Shy-Drager, Multiple System Atrophy Parkinson's disease is accompanied by NLUTD in 37.9-70% [29-31]. Progressive neurological disability has been associated with greater voiding dysfunction in patients with PD [32]. While there is some disagreement as to whether NLUTD is independently associated with PD progression versus expected age-related pathology, consensus indicates a higher prevalence of symptoms and urodynamic disturbances in patients with PD. Control-based studies noted a prevalence of LUTS of 27-63.9% using LUT symptom questionnaires [33-38].

NLUTD is extremely common in patients with Shy-Drager syndrome (one form of Multiple System Atrophy) [31] while incontinence is present in up to 73 % [34]. LUTS appear to occur earlier in the course of MSA when compared to PD [39].Indolent LUTS may arise in young men with PD, even with relatively minor neurological impairment [37]. Urethral dysfunction appears to be common in patients with MSA, with an open bladder neck at rest noted on VUDS, and external sphincter denervation.

Cerebrovascular Accident (CVA) CVA causes NLUTD in 20-50% of patients [40-41] with decreasing prevalence in the post-insult period [42]. Over half of patients report persistent LUTS at 3 months following a CVA [43] and, without proper treatment, symptoms such as incontinence remain in 20-30% at 6 months. [44]. The most common urodynamic finding is detrusor overactivity, with sphincteric dysfunction relatively uncommon [45-50].

Location of the CVA may impact the likelihood of LUTD. Sakakibara et al. [51] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms; nocturia and voiding difficulty were seen in 28 %, urinary retention in 21 % and urinary incontinence in 8 %. The side of the stroke (dominant hemisphere, non-dominant, bilateral) does not appear to affect the likelihood of developing NLUTD [52].

Traumatic Brain Injury Traumatic brain injury can cause significant NLUTD. In a study of 57 patients, the majority [30] had symptoms of overactive bladder. Urodynamically, 49% were found to have DO, while 32% had detrusor underactivity. DO was found to be associated with the presence of right hemispheric damage, while impaired contractility was associated with left hemispheric damage [53].

b) Diseases of the spinal cord

Demyelinating lesions - multiple sclerosis (ms), transverse myelitis (tm) Multiple sclerosis causes NLUTD in 50-90% of the patients [54-57]. DO (mean 65%), DSD (35%), and detrusor underactivity (25%) are the most common urodynamic findings [58]. There is a very high likelihood of NLUTD when pyramidal dysfunction has been diagnosed neurologically (and progressive gait abnormalities noted on exam). With regard to symptoms, urgency, urgency incontinence, and impaired bladder emptying/ voiding dysfunction are the most common reported. Though controversial, MS severity based on EDSS (extended disability symptom score) does appear to correlate with LUTS overall [59]. It is uncommon for LUTS to be the presenting symptom in MS (2- 12% of the patients), though this may be as high as 34 % depending on the method of symptom assessment [60]. Upper tract impairment is relatively uncommon in MS, perhaps ow-

ing to the fact that detrusor pressures do not appear to be markedly increased, even among patients with DSD [61,62].

Spinal Cord Lesions Spinal cord lesions can be traumatic, vascular, medical, or congenital. Traumatic spinal cord injury (SCI) occurs with an incidence of 10.4 to 83 per million inhabitants per year and a prevalence of 223-755 per million inhabitants worldwide, with a male to female ratio of 3.8:1, and mean age of injury of 33 [63]. Most patients will develop NLUTD [64]. The nature of detrusor and sphincteric dysfunction depends on the location and completeness of the lesion, with suprasacral lesions typically associated with DO and DSD, while those with lower level lesions most commonly have detrusor underactivity and a competent sphincter [64]. Patients with lesions at T10 and below have an increased likelihood of significant sphincteric incompetence which can result in troublesome stress urinary incontinence. Maintenance of low intravesical pressures remains a cornerstone of management, in efforts to reduce the risk of long term upper tract sequelae [65].

For spina bifida and other congenital nerve tube defects, the prevalence in the UK is 8-9 per 10,000 aged 10-69 years with the greatest prevalence in the age group 25-29 years [66]. In the USA the incidence is 1 per 1000 births [67]. The prevalence of NLUTD in patients with myelomeningocele has been estimated to be as high as 90% -97% [68]. About 50% of these children will have DSD, though combination defects - detrusor and sphincteric dysfunction (either incompetence or dyssynergia) are quite common [69-70]. Indeed, the unpredictability of urodynamic findings, often severe ones, is substantial. Risk of upper tract damage and incontinence may be life-long, and ongoing surveillance with urodynamics and renal imaging is typically recommended, particularly in symptomatic patients.

Disc Disease Disc disease, such as prolapsed intervertebral disc, may cause NLUTD in 28-87% of the patients [71-72]. Importantly, data suggesting that NLUTD is clearly reversed following surgical intervention for disc disease is lacking, in most cases, with the exception of patients who develop cauda equina syndrome. Cauda equina due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [73-80]. In this instance, surgical intervention is frequently effective at restoring normal voiding and eliminating incontinence [81].

Spinal Stenosis And Spine Surgery About 50 % of the patients seeking help for intractable leg pain due to spinal stenosis report LUTS, such as sense of incomplete bladder emptying, urinary hesitancy, incontinence, nocturia or urinary tract infections [82]. When evaluated urodynamically, nearly 75% of patients may be found to have LUTD, though this is often an older population with coexisting anatomical abnormalities that could contribute [83-85]. Surgical intervention for stenosis has been shown to improve certain urodynamic parameters (capacity, flow rate, residual volume) while not affecting others (detrusor pressure at maximum flow, compliance). [86].

Spinal surgery itself has been associated with the development of LUTD (most commonly retention) in 38%-60% of patients, depending on the complexity of the surgical intervention [87-88].

c) Peripheral nerve problems

Diabetes Diabetes mellitus has a prevalence of 1-6% in the United States, depending on the specific criteria utilized to identify the disease. Overall, up to 59% of diabetic patients will report urinary symptoms, while 75-100% of those with evidence of peripheral neuropathy will develop NLUTD [89,90]. The classic “diabetic cystopathy” (impaired bladder sensation, increased capacity, ultimately increased post void residual) has been estimated to occur in 43% to 87% of insulin-dependent diabetics, with no sex or age differences, [91], though typically, severely impaired bladder emptying is thought to occur in patients with more long-standing poorly controlled diabetes. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment [92]. More recent urodynamic studies have noted a spectrum of findings in DM; those presenting relatively late with severe LUTS have a higher likelihood of impaired bladder sensation, detrusor underactivity and impaired emptying, while those investigated earlier are more likely to have detrusor overactivity and urgency incontinence [93].

Alcohol Abuse Chronic alcohol use may cause peripheral neuropathy, though its reported prevalence varies from 5% to 64% [94]. No recent studies have confirmed a prevalence estimate of LUTD, though impaired sensation and emptying have been previously noted in patients with chronic alcohol use.

Herpes Virus Infections The incidence of LUT dysfunction is as high as 28 % if only patients with lumbosacral dermatome-involvement are considered. The overall prevalence of NLUTD may be as low as 4% [95,96], and is transient in most patients, typically with symptoms resolving within 2 months.

Guillaine-Barre Syndrome This demyelinating disorder often results in severe autonomic dysfunction [97]. The prevalence of micturition disorders varies from 25% to over 80% [98-99] with severely impaired emptying or frank urinary retention being the most common finding.

d) Other

Systemic Lupus Erythematosis (SLE).Though nervous system involvement occurs in about half of patients with SLE, overt LUTS appear to be only rarely attributable to the disease (1%) [100-101]. An interstitial cystitis syndrome has been described in the setting of SLE, which has been reported to result in asymptomatic hydronephrosis in at least one instance [102].

HIV Voiding dysfunction occurs in 12% of HIV-infected patients, mostly in an advanced stage of the disease [103, 104]. Urinary retention associated with other viral-induced neuropathies has also been reported [105].

Iatrogenic Abdominoperineal resection for rectal cancer has been described to cause NLUTD in up to 50 % [106-108], which results in chronic voiding dysfunction in at least 10%. Surgical prevention with nerve preservation was shown to be important to try to minimize the risk of urinary retention [109,110]. Simple [111] and radical [112-116] hysterectomy, as well as pelvic radiation have been associated with NLUTD (voiding dysfunction, altered compliance) in 8 to 57%. Nerve-sparing procedures have been shown to reduce the risk of altered compliance and improve LUT-associated QOL following radical hysterectomy [117,118].

Conclusions

- **Dysfunction of the LUT occurs in patients with a variety of neurologic diseases but precise epidemiological data is seldom available.**
- **Common manifestations of NLUTD include urinary incontinence, voiding difficulties, and urinary retention.**
- **Because neurological disease is often present in elderly populations, it is frequently difficult to discriminate if LUTS are due to aging alone, or due to the presence of neurological disease. This difficulty is reflected in widely varying prevalence estimates.**

Recommendations

- **Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of lower urinary tract symptoms.**
- **In certain neurologic disease states, NLUTD may be relatively asymptomatic, yet represent a risk of upper urinary tract impairment.**
- **In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic severe LUTS after proper office evaluation for common etiologies.**
- **Prevalence estimates of NLUTD would be improved by multicenter co-operative studies from large tertiary centers utilizing established outcomes and evaluation tools.**

II. SPECIFIC DIAGNOSTICS

Before any functional investigation is planned, all "basic" data should be gathered and used for further interpretation of the NLUTD. Relevant investigations include; voiding diary, urodynamic studies (cystometry, electromyography (EMG), video-urodynamics, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrography and ultrasonography. In this chapter are highlighted some data specially related to NLUTD. Some tests developed for the diagnosis of neurologic dysfunction are considered specifically; the bethanechol supersensitivity test, and the ice water or bladder cooling test. Neurophysiologic studies are discussed in the chapter "Clinical Neurophysiological testing", and only some data for NLUTD is given here.

1. HISTORY

The general history aims at gathering information on the neurological and congenital abnormalities, previous urinary complications or treatments. The use of medication with known or possible effects on the LUT, menstrual, sexual and bowel function, and obstetric history are also important. Hereditary or familial risk factors, metabolic diseases and other must be known. Lifestyle factors such as smoking, alcohol, or addictive drug use should be assessed as well as an evaluation of Quality of Life. Patients with a spinal cord lesion above Th6 may develop autonomic dysreflexia, so a history of severe headaches should be explored.

The signs and symptoms that bring the patient to consultation must be documented. Symptoms related to storage and voiding, continence and /or retention, as well as onset and nature of the NLUTD (acute or insidious) should be determined. If appropriate this information should be compared with the patient's condition before the NLUTD developed. Bladder sensation and mode and type of voiding (catheterization) should be considered. Warning signs and symptoms that warrant early further investigation include; fever, pain, hematuria, catheterization problems, clinical infections and signs of autonomic dysreflexia. Individuals with NLUTD may not be accurate at determining whether they have a UTI based on their symptoms [3]. UTI management is not standardised and clinical practice suffers from a weak evidence base [4].

A urinary diary can be used to capture information on the number of voids (frequency and nocturia), the sensation at each void, volumes voided, incontinence, and volume/ time of fluid intake. Little information is available on optimal diary duration in NLUTD, considering information captured balanced against

inconvenience to the patient [5]. Nonetheless, such diaries deliver useful assessment for evaluating treatment outcomes [6].

2. PHYSICAL EXAMINATION

A general impression of patient's physical and mental possibilities is relevant to the choice of investigations and treatment. Severely impaired mobility, extreme spasticity, severe mental disorder or general weakness are all important in this respect. The physical examination evaluates the lower abdomen, external genital organs and perineal skin. Palpation per vagina or per rectum is done in search of pelvic organ descent, or cervix-uterus/ prostate disease. The strength of the pelvic floor muscles should be assessed. Cardiovascular function should be considered. Patients with very high neurological lesions may suffer from a significant drop in blood pressure when changing position.

Specific examination of the lumbo-sacral innervation includes: sensation of fine touch and pin-prick in the different perineal dermatomes (**figure 1 and 2**), evaluation of bulbocavernosus/ anal/ cremaster reflexes, tone of anal sphincter and voluntary contraction of the anal sphincter / pelvic floor muscles. Clinical neurological findings correlate well with NLUTD in some types of neuropathy such as single level traumatic spinal cord lesions [7] but less in other types like meningomyelocoele or combined traumatic spinal cord lesions [8,9]. Urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment in infantile cerebral palsy [10].

3. URODYNAMIC TESTS

Urodynamic techniques evaluate multiple functional parameters in NLUTD [11]. The International Urodynamic Basic Spinal Cord Injury (SCI) Data Set sets out data to be included in the urodynamic evaluation of patients with spinal cord injury. Variables included are; bladder sensation during filling cystometry, detrusor function and compliance during filling cystometry, detrusor function during voiding, detrusor leak point pressure, maximum detrusor pressure, cystometric bladder capacity and post-void residual [12].

Often, the nature of NLUTD is impossible to anticipate from clinical assessment alone, exemplified by CNS tumours in children [13]. Likewise, severity of NLUTD does not necessarily correspond with severity of neurological lesion.

a) Electromyography (EMG) during cystogram

The basis of EMG has long been a question of debate [13a]. Sundin and Petersen [14] used cystometry (EMG) investigation in NLUTD for patients with an active detrusor contraction associated with

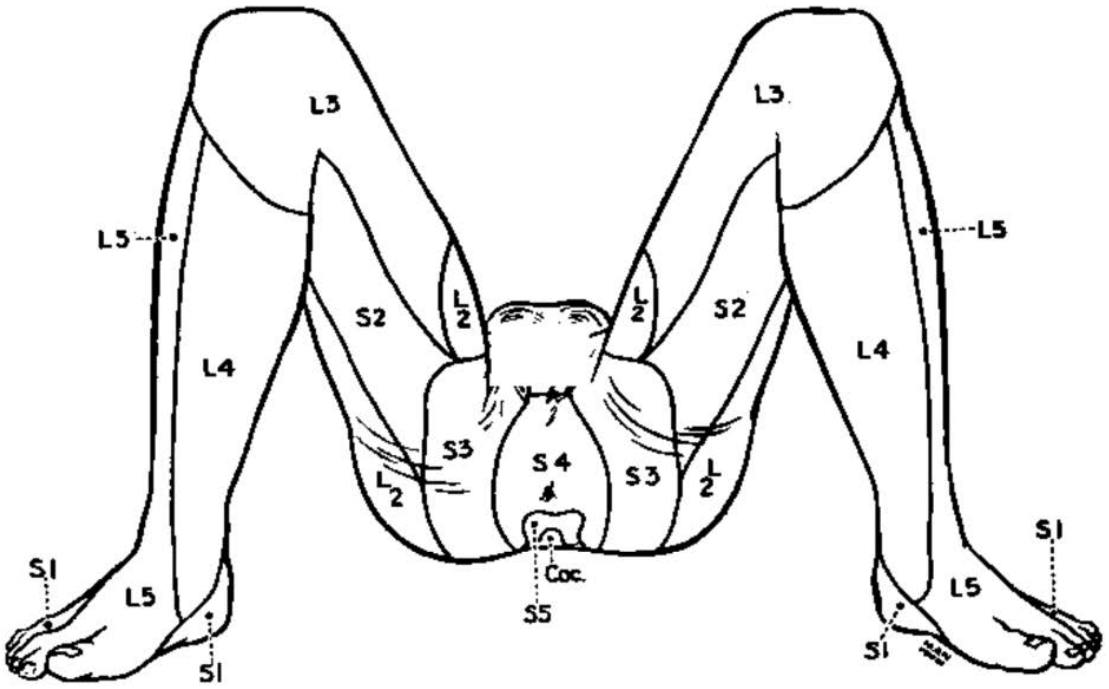

Figure 1: Dermatomes of spinal cord levels L2-S4

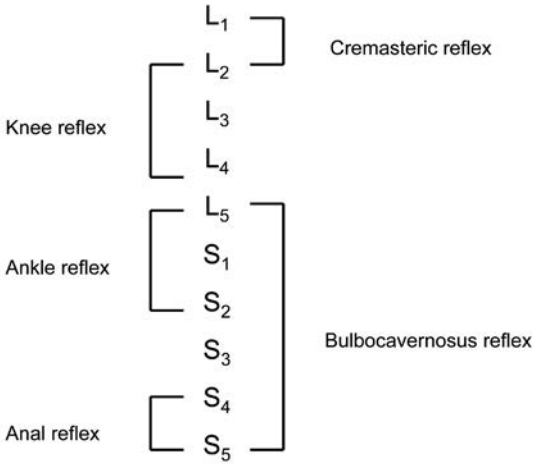

Figure 2: Urogenital and other reflexes in lower spinal cord

impaired bladder emptying. A voluntary control of external urethral sphincter relaxation was found in most of the healthy volunteers, and cystometry-EMG gave reliable information on DSD in patients. Perkash [15] found rhythmic detrusor contractions on cystomanometry with associated marked increase in EMG activity on attempted voiding to be relevant characteristics of patients with DSD. Rodriquez et al. [16] used EMG-gas cystometrogram to select SCI patients for removal of a Foley catheter. Important factors governing success were the amplitude of the detrusor contraction, the presence of detrusor-sphincter synergy and the presence of a flaccid sphincter. Mayo and Kiviat [17] used multichannel urodynamic studies in patients with incomplete bladder emptying secondary to suprasacral spinal cord lesions. They found that bladder pressure and sphincter EMG measurement during voiding, combined with fluoroscopy, are ideal methods to identify the factors responsible for incomplete emptying in problem cases. Perlow and Diokno [18] and Koyanagi et al. [19] found cystometry-EMG informative in SCI patients.

Blaivas et al. [20] described three types of dyssynergia. Type 1 had a crescendo increase in EMG activity that reached a maximum at the peak of the detrusor contraction, type 2 had clonic sphincter contractions interspersed throughout the detrusor contraction and type 3 was characterized by a sustained sphincter contraction that coincided with the detrusor contraction. There was no correlation between the clinical neurologic level and the type of dyssynergia. In DSD, Rudy et al. observed clinically that increases in EMG activity and external urethral sphincter pressure were associated clearly with a positive slope of the intravesical pressure trace, whereas decreases in both parameters were associated with a negative slope [21].

Simultaneous recording of intravesical pressure, sphincter electromyography and uroflowmetry was compared by Aoki et al. [22] with cystometry EMG. They found some influence of the catheter in the urethra. Micturition pressure and opening pressure were larger with cystometry EMG, and incidence of DSD was greater. The authors also found that the Credé manoeuvre exaggerated the DSD. Urodynamics with EMG permitted Kirby [23] to differentiate between patients with pelvic nerve injury, distal autonomic neuropathy, progressive autonomic failure - multiple system atrophy, and idiopathic Parkinson's disease. This influenced the selection of patients for transurethral surgery. Pavlakis et al. [24] studied cystometry concomitant with perineal floor and rectus abdominis EMG and were able to improve the recognition of intravesical pressure elevation owing to voluntary contraction of the abdominal musculature. EAS motor unit potential (MUP) analysis and EMG cystometry were used to differentiate multiple system atrophy (MSA) from Parkinson's disease in the first five years after disease onset. It showed that involvement of Onuf's nucleus in MSA is time-dependent; before the fifth year of illness, the prevalence of neurogenic change does not seem to be high, so a negative result cannot exclude the diagnosis of MSA [25]. Rapidi et al. used combined urodynamic and electrophysiological study of diabetic cystopathy [26].

b) Filling parameters

The importance of detrusor pressure has been acknowledged for many years. Filling rate is important in NLUTD, and slow filling is recommended by the International Continence Society to minimise artefactually affecting compliance [27].

Bruschini et al. [28] undertook clinical, urodynamic and imaging evaluation of the upper and lower urinary tract in inadequately managed myelomeningocele patients. The urodynamic data correlated with the status of the upper urinary tract (UUT). The cystometry showed detrusor overactivity (DO), poor compliance, increased bladder capacity and normal cystometry in 48, 49, 2 and 1% of the patients, respectively. Detrusor leak point pressure (DLPP) over 40 cm H2O was associated with UUT damage. Patients with decrease of functional bladder capacity (FBC) had more renal scars than their counterparts. Incomplete SCI patients with neurogenic DO should be evaluated with the same caution as complete SCI patients, as there can be little difference in cystometric capacity and leak point pressure between complete and incomplete spinal cord injury patients [29].

The importance of urodynamic tests for diagnosis and follow up was demonstrated in the study by Abrahamsson et al. [30] on urodynamic changes with untethering in myelomeningocoele children. After untethering, 35% experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward,

and 90% of those who were stable preoperatively continued to be stable postoperatively. Regular evaluation of bladder function in children with myelomeningocele is recommended. Kang et al. [31] used urodynamic tests to determine prognostic factors affecting urological outcome after untethering surgery for lumbosacral lipoma.

Perkash and Friedland [32] found simultaneous transrectal ultrasonography helpful. They recommended not to irritate the bladder when introducing the urodynamic catheter, and to examine the entire curve of the CMG, not simply the initial rise [33].

c) Filling technique

In SCI patients with neurogenic LUT dysfunction, Ko et al. [34] determined whether cystometry performed by filling using diuretics (FMCG) reveals different findings compared with conventional CMG. Significant differences between the two techniques were found in pressures and compliance in neurogenic DO, but not in hyporeflexic or areflexic bladders. Natural filling by the production of urine can change the results of cystometry considerably, and should be considered when performing urodynamic investigations and interpreting the results.

De Gennaro et al. [35] performed continuous urodynamic monitoring over six hours in children and compared this with standard urodynamics. They found continuous monitoring feasible, permitting a better diagnosis than standard cystometry in some cases. Zermann et al. [36] investigated the diagnostic value of natural fill cystometry (NFC) in children with neurologic bladder in comparison to conventional videocystometry. In 45%, NFC detected additional findings. The extra value of ambulatory urodynamics as compared to conventional urodynamics in spinal cord injury patients was investigated by Martens et al. They concluded that ambulatory urodynamics do not seem necessary for diagnosis and risk assessment in SCI patients suspected for DO when conventional urodynamics are done properly [37].

d) The outlet during voiding

Pressure-flow study can demonstrate an obstructive pattern (high pressure voiding) in neurologic patients due to urethral relaxation failure [38,39]. Videourodynamics (VUDS) offers visualisation of bladder neck and urethral sphincter activity during filling and voiding [40,41]. Accordingly, VUDS is a test that can determine the site of obstruction. Zerin et al. [42] found that the urographic position of the bladder neck in relation to the pubic symphysis was correlated with lower motor neuron (LMN) denervation of the urethral sphincter as detected with electromyography in infants and children with myelodysplasia. They concluded that, although not as precise as urodynamic testing, significant descent of the bladder neck is a reliable urographic finding of complete LMN denervation of the external urethral sphincter in infants and children with myelodysplasia. In men with SCI, some cystometric variables and detrusor overactivity may remain consistent over sequential studies [43].

e) Bladder sensation

In a large cohort study it was shown that impaired perception of bladder filling during CMG is a sign of neuropathy [44]. Nonetheless, despite spinal abnormality, patients can experience bladder filling sensation, signifying the presence of afferent pathways joining the spinal cord at higher levels. In 52 SCI patients, 26 % of those with a supposed complete lesion had sensation of bladder filling during cystometry [45]. In 41 patients with myelodysplasia the perception of bladder filling was present in a majority [46]. In a study of 26 SCI patients, bladder sensation was reported by 73% of patients in daily life. However, only 41% of patients had analyzable bladder sensation concomitant with detrusor overactivity during ambulatory Urodynamics [47].

Ersoz and Akyuz [48] investigated bladder filling sensation in 73 SCI patients with complete lesions above T11 and below T10 and with incomplete lesions. Bladder filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and in 38.9% of the patients with complete lesions above T11. Bladder-filling sensation investigations were reproducible in terms of bladder filling sensation category in 36 SCI patients who had a second CMG. The authors concluded that presence of bladder-filling sensation in many SCI patients reveal the potential for sensation-dependent bladder emptying, especially in the ones with complete lesions below T10 and the ones with incomplete lesions. The safe use of sensation-dependent bladder emptying was shown to be dependent on the urodynamic situation [49].

The amplitude of the first overactive contraction and the maximal detrusor contraction were found to be statistically greater in female patients with multiple sclerosis and neurogenic detrusor overactivity compared to women with idiopathic overactivity. The threshold volume for detrusor overactivity was greater, likely secondary to the elevated post void residual urine volume in the MS patients. In this study using a cut off value of 30 cm H2O for amplitude of the first overactive contraction achieved a positive predictive value of 88% for identifying multiple sclerosis [50].

f) Complications of urodynamic testing

Complications of cystometry include hematuria due to the urethral catheter, the development of oedema in the urinary bladder wall and urinary bladder spasm as a result of catheter irritation. One case report of twist and knot formation in the double lumen urethral catheter after cystometry of a patient with a hypocompliant bladder has been published [51]. Another case report describes bladder rupture during filling cystometry many years after bladder augmentation in a girl with meningomyelocoele [52].

Symptomatic urinary tract infections after cystometry are not infrequent and antibiotic prophylaxis has been advocated [53]. Randomised controlled trials (RCTs) comparing effectiveness of prophylactic antibiotics with placebo or nothing in reducing bacteriologically proven UTI after invasive cystometry for all patients, including NLUTD [54]. The use of prophylactic antibiotics in urodynamics reduced the risk of significant bacteriuria.

Conclusions

- **Findings of Urodynamic tests can be difficult to anticipate from clinical assessment alone in NLUTD (LOE 2).**
- **A combination with EMG and /or imaging adds to the diagnostic possibilities (LOE 2).**
- **Filling rate can influence the outcome of several urodynamic parameters (LOE 2).**
- **Pressure development in the bladder is one of the important parameters to be studied and high leak point pressure is a risk factor for renal deterioration (LOE 2).**
- **Sensation of filling may be preserved despite spinal abnormality (LOE 2).**
- **Complications of urodynamic testing are rare, but antibiotic prophylaxis can be advocated (LOE 2).**

Recommendations

- **Urodynamic tests should selectively be employed to supplement clinical assessment in determining management in NLUTD.**
- **Methods of Urodynamic testing in NLUTD should follow International Continence Society recommendations.**

4. SPECIAL TESTS

a) Bladder-cooling reflex; the ice water test (IWT)

The ice water test (IWT) is a C-fiber mediated reflex, first described as a way to differentiate upper from lower motor neuron lesions. It is based on the principle that mucosal temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. An upper motor neuron lesion interrupts these inhibitory pathways, resulting in manifestation of the reflex, whereas a lower motor neuron lesion does not. A positive test should therefore theoretically occur in patients with upper motor neuron lesions, whereas those with lower motor neuron lesions and neurologically normal patients should have a negative test. Simultaneous measurement of intravesical pressure with cold fluid instillation enables evaluation of the response. Patients without neurogenic disease have a greater perception of cold during the IWT than neurogenic patients; this must be considered when evaluating test results [55]. The bladder cooling reflex was blocked in 16 out of 17 neurogenic patients when 30 mg intravesical oxybutinin was instilled [56].

There is a significant correlation between a positive IWT with abnormal sensation of bladder filling and inability to inhibit micturition voluntarily. A negative IWT also corresponded with the occurrence of phasic detrusor contractions during cystometry. The IWT may be useful for functional subdivision of overactive bladders. In patients with voiding dysfunction in the absence of LUT inflammation, a positive test is an indicator of a silent or overt neurological disorder. Geirsson [57] reported positive or a false negative IWT in a large cohort study. Geirsson and Fall [58] used the IWT in patients suspected of DSD (cystometry and needle EMG). A positive test with a high detrusor pressure was stated to indicate DSD, whereas the contrary applies to the negative test. All patients who responded to cold stimulation with detrusor contraction but without fluid leakage (called positive non-leakage IWT), manifested DSD on EMG. The authors concluded that the simpler IWT could substitute for a needle EMG study.

Ishigooka et al. [53] evaluated urinary bladder sensation to ice water instillation in patients with diabetes mellitus. There was no apparent relationship between prevalence of peripheral neuropathy and that of negative sensation of IWT. Impairment of ice water perception was less frequent than that of mechanoreceptor sensation in patients with diabetic cystopathy.

Ronzoni et al. [60] studied the IWT in 148 patients with neurologic bladder dysfunction resulting from a traumatic lesion and in 130 patients with neurologic bladder dysfunction and multiple pathogenic disorders. IWT was positive in 95% of patients affected by complete and in 86% of patients with incomplete medullary lesions. The IWT in patients with lower motor neuron medullary lesions was always negative. The test was used diagnostically in patients with lower motor neuron lesions. In those with upper motor lesions it was used as a rehabilitation method during the medullary-shock phase to accelerate the appearance of the micturition reflex. In 9% of patients it was used to induce micturition during cystography. The authors consider IWT as a useful complement to urodynamic examinations in patients with neurological bladder disease.

Chancellor et al. [61] determined the clinical utility of IWT during urodynamic evaluation in SCI patients and found that it did not contribute to their management because of the insensitivity and non specificity. Autonomic dysreflexia can occur during evaluation.

Repeating the IWT has been shown to increase its positivity [62]. Combining the IWT and electrical perception threshold (EPT) testing will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurologic pathologic

finding in patients with idiopathic DO. In multiple sclerosis it may have pathophysiological value, indicating a spinal rather than cerebral mechanism of overactive bladder, and diagnostic value, indicating multifocal demyelination [63].

Conclusions:

- **The literature results from IWT show value in the diagnosis of NLUTD and in the differentiation between reflexic and areflexic neurologic bladder (LOE 2).**

Recommendation:

- **The ice water test is an optional test which should be interpreted in the context of all data from the diagnostic evaluation (B).**

b) Bethanechol supersensitivity test (BST)

Bethanechol is a muscarinic agonist which may improve bladder emptying in some non neurologic patients, and correspondingly increase bladder sensitivity [64]. The BST was developed by Lapides et al. in 1962 [65] to try to distinguish between a neurologic and a myogenic etiology in an acontractile bladder. It is based on the observation that after an organ is deprived of its nerve supply, it develops hypersensitivity to the normal excitatory neurotransmitters. A neurologically intact bladder should have a pressure increase of less than 15 cm H2O above the control value, whereas a denervated bladder shows a response greater than 15 cm H2O. The clinical utility has not been studied in detail recently.

The test is considered unreliable by some [66]. Penders [67] considered the test reliable when the indications are good (large capacity, hypotonic bladder, clinical suspicion of lower neuron lesion) and when the interpretation is based on a right understanding of its mechanism. Pavlakis et al. [68] suggest that the BST is more sensitive and more specific than perineal floor electromyography in corroborating bladder neuropathy. Sidi et al. [69] studied patients with neurologic or non-neurologic detrusor areflexia with the BST, EMG of the urethral rhabdosphincter and bulbocavernosus reflex latency and found the sensitivity of these tests in detecting neurologic mechanisms to be 90, 87.5 and 78.1%, and the specificity 96, 76 and 80%, respectively. When all three tests were performed together, the combined accuracy approached 100 %. They conclude that these combined tests are useful in the diagnosis of patients with equivocal bladder neurologic conditions and in those with subtle neurological lesions. Denervation supersensitivity to bethanechol was demonstrated in acute idiopathic autonomic neuropathy [70].

Wheeler et al. [71] found the positive BST not diagnostic of neurologic detrusor areflexia because of the many variables that can influence the test. In a later study, the same group [72] suggested that flow rate, surface electromyography, and bethanechol supersensitivity test cannot help differentiate neurologic from non-neurologic detrusor failure. Although no test can accurately differentiate neurologic from non-neurologic female urinary retention, careful neurourologic evaluation will help guide to more appropriate management.

Conclusion:

- **The literature on the value of the bethanechol test for the diagnosis of neurologic pathology is contradictory. The test may contribute to overall evaluation of neurologic LUT dysfunction. (LOE 2)**

Recommendation:

- **The bethanechol supersensitivity test has limitations, and result should be interpreted in conjunction with established diagnostic results. (B)**

c) Electrodiagnostic tests

1. EMG of the Urethral Sphincter

EMG of the urethral sphincter has been used for decades in the diagnosis of NLUTD; its value in practice remains uncertain. Use of needle or surface electrodes is debated. Urethral concentric needle electrodes were found to be superior to surface patch electrodes for evaluating relaxation of the muscle during voiding in neurologically intact women [73]. Nordling and Meyhoff [74] used cystometry in combination with urethral and anal sphincter EMG in patients with suspected NLUTD and found anal sphincter EMG to be highly unreliable. Koyanagi et al. [75] also found discordant activities between the anal and the external urethral sphincters in 39 % of male patients with SCI. The degree of bladder dysfunction was related more to the degree of dyssynergia of the urethral than the anal sphincter. Nevertheless, Podnar states that anal sphincter EMG is the most useful diagnostic test, particularly for focal sacral lesions, and atypical Parkinsonism [76]. Fowler et al. [77] introduced a technique of recording EMG activity of striated muscle in the urethral sphincter by using a concentric needle electrode and an oscilloscope with a delay line and trigger. Individual motor units were isolated and measured. Vodusek also studied individual motor units [78]. Both conclude that quantitative EMG may be a helpful technique in the investigation of patients with disorders of micturition.

Ziemann and Reimers [79] found the sphincter EMG the most sensitive technique in the diagnosis of chronic pudendal lesions. However, pure afferent lesions cannot be detected by the sphincter EMG. In this case, the BCR, using unilateral stimulation of the dorsal nerves of the penis, provides the opportunity to distinguish between afferent and efferent lesions of the sacral innervation. Fowler [80] concluded that sphincter electromyography (EMG) has is valuable for identifying patients with Parkinsonism who have multiple system atrophy.

Tests which examine aspects of nerve conduction velocity have proved to be of lesser value both because such investigations test conduction of nerve fibres rather than levels of innervation. Furthermore, they examine large myelinated fibre conduction, rather than the unmyelinated fibres which comprise the autonomic innervation. Sphincter EMG is a diagnostic test of Fowler's syndrome in young women with urinary retention [81]. Sphincter EMG can be used in gauging timing of stimulation for suppressing DO [82].

De E J et al. [83] found a significant disagreement between needle EMG and voiding cystourethrogram (VCUG) for diagnosis of DSD. A combination of EMG and VCUG may identify more cases of DSD than either modality alone and underscores the need for more strict criteria when defining this entity from a urodynamic standpoint.

Anal sphincter EMG as well as external urethral sphincter EMG can be used to detect the onset of detrusor contractions in patients with both neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) opening a door for the use of triggered devices to inhibit unwanted contractions through continuous electrical stimulation of sensory nerves [84, 85]. Light et al. [86] found in patients with detrusor areflexia and a high spinal cord lesion, EMG of the pelvic floor muscles is the neurophysiological test which best predicts detrusor contractility.

EMG of the urethral sphincter has been used to investigate retention in multiple-system atrophy [87], LUT function in Machado-Joseph disease [88], the impact of pregnancy and delivery on vesico-urethral disorders in patients with multiple sclerosis [89] and children with cerebral palsy [90].

2. EMG of Detrusor Muscle

Detrusor EMG has not been widely studied in neurologic patients. La Joie et al. [91] recorded simultaneous EMG recordings from the bladder detrusor muscle and the inferior rectus abdominis muscle in 6 normal subjects, in 4 patients with LMN bladder disease and in 2 patients with an UMN type of bladder lesion. The bladder electrodes did not appear to record muscle activity remote from the abdominal muscles so that any increased detrusor electrical activity with abdominal contraction must have some other explanation. Kaplan and Nanninga [92] analysed detrusor EMG in upper motor neuron type NLUTD. Kinder et al. did not advocate detrusor EMG [93]. Recent data are lacking and so the technique cannot be considered a standard diagnostic test.

Conclusion

- **Sphincter EMG can be valuable in the diagnosis of patients with neurologic bladder dysfunction (LOE 2).**
- **Detrusor EMG is not established as a diagnostic test.**

Recommendation:

- **EMG of the urethral sphincter can be considered as a diagnostic method in patients with neurologic LUT dysfunction and neurologic urinary incontinence (B B).**

3. Dynamic Bulbocavernosus Reflex (BCR).

Walter et al. [94] studied dynamic BCR during micturition induced by using periodic dorsal penile nerve stimulation; the evoked reflex response was recorded with an anal sphincter pressure sensing balloon. Results indicate that an enhanced BCR is a factor contributing to increased urethral resistance during micturition.

Kaiho et al. [95] recorded the evoked potential of the BCR (BCR-EP) with a concentric needle electrode at the periurethral striated muscle. They found was BCR-EP suppressed during voluntary voiding in normal subjects, but it was insufficiently suppressed in the patients with NLUTD. It was suggested that the measurement of BCR-EP could distinguish involuntary voiding caused by pathological urethral sphincter relaxation from voluntary voiding. The same group [96] investigated the change of sacral reflex activity of the striated urethral sphincter in the urine storage phase with BCR-EP in normal male subjects and male patients with NLUTD due to suprasacral spinal cord injury. Sacral reflex activity was accelerated by bladder filling in both the normal subjects and SCI patients, particularly in the latter. In addition to the conventional evaluation of the integrity of sacral reflex arc by BCR examination, the observation of changes of BCR affected by bladder filling may provide information on the continuity of sacral segment and supraspinal micturition center. Niu et al. showed that in 8% of patients with SCI and in 70% of patients with peripheral nerve lesions the BCR was abnormal [97].

4. Motor Evoked Potentials

Motor evoked potentials (MEP) has been used to assess neurogenic lesions affecting the urethral compressive musculature with simultaneous recording of evoked pressure curves [98]. MEP recording is an accurate and easily applicable test for the diagnosis of lumbosacral spinal cord lesions [99].

5. Nerve Conduction Studies

In patients with diabetes mellitus, conduction velocities are decreased [100]. Vereecken et al. [101] found urethral and anal responses produced by electrical stimulation of penis, bladder neck and anus were delayed and the duration reduced. Carbone et al. [102] assessed the effect of urinary bladder filling on the excitability of somatic spinal motor neurones in patients affected by neurogenic and non-neurogenic DO and proposed that H-reflex modulation may be considered a tool in the differential diagnosis of voiding dysfunctions.

6. Somatosensory Evoked Potentials

In the committee's literature search, no recent publications were found on somatosensory evoked potentials (SSEP). Badr et al. [103] described techniques of recording evoked potentials in humans in response to stimulation of the urinary bladder. Galloway et al. [104] described a method of sacral evoked response to measure the integrity and function of the lower sacral segments by stimulation at the urethral and anal sphincters.

Mochida et al. [105] studied evoked spinal cord potentials (ESCP) in surgical patients with cervical myelopathy. The presence of NLUTD was closely correlated with severe limb symptoms and relatively slow ESCP velocity. However, for 47% of the patients with urinary complaints, findings of urodynamic examinations were negative; these patients may have had pathologic or psychosomatic factors other than neurogenic bladder due to cervical myelopathy.

Curt et al. [106] studied the significance of SSEP recordings in predicting the recovery of bladder function in acute, traumatic spinal cord injury (SCI). They found a good correlation with the recovery of the external urethral sphincter function, but not with the urodynamic impairment. SSEP in response to stimulation of the tibial nerve have been studied in patients with hyperactive urinary bladder to clarify their role in prognosis of tibial neuromodulation efficacy [107].

7. Afferent Nerve Recording on Sacral Roots

Afferent nerve activity from the sacral dermatome, bladder and rectum can be recorded using cuff electrodes placed on the extradural S3 sacral root in humans, but improvements in recording quality and sophisticated signal processing methods are needed for chronic application. The applicability in clinical practice is very limited [108,109].

Conclusions:

- **Detrusor EMG, BCR-EP and MEP are techniques of experimental interest, but with insufficient basis for use as standard clinical diagnostic tests.**
- **There are some arguments that nerve conduction studies can be useful in the further differentiation of the nerve deficits in cases of neurologic pathology of the bladder (C).**
- **Direct measurement of sacral afferent nerve activity is still experimental**.

Recommendation:

- **Somatosensory evoked potentials can be of use in the further diagnosis of nervous deficits related to LUT dysfunction (C).**

8) Electrosensation in the LUT

Measurement of the sensory threshold of the LUT towards electrical stimulation was attempted as early as 1899 [110]. After re-introduction of the technique by Markland et al. [111] several authors have studied its value in neurologic bladder dysfunction. Kieswetter [112], and Powell and Feneley [113] demonstrated abnormal electrosensation in patients with NLUTD. Frimodt- Möller [114] described pathological electrosensation in patients with Parkinson's disease, multiple sclerosis and meningomyelocoele. He also found abnormal electrosensation in half of patients with diabetes and generalized sensory neuropathy, but only in 10% of the diabetic patients with a neurologic bladder. Electro sensation was present in many meningomyelocoele patients with absent skin sensation and absent reflexes, and in many patients with suspected complete spinal cord injury on clinical evaluation [44, 46].

Wyndaele [115] determined the threshold of sensitivity to electrical stimulation in several parts of the LUT in 436 consecutive patients. In the groups with different patterns of disturbed sensation a higher incidence of neuropathy was found than in the group with a normal sensation. Further neurological investigation revealed abnormal innervation in 29% of patients who lacked electrosensitivity in one or more parts of the LUT but who had no previous evidence of neuropathy.

Standardization is necessary to develop the technique and achieve reproducible results [116]. While it is a constructive concept to be able to determine threshold of different fibre types selectively [117], so far no such fibre selectivity has been demonstrated in the bladder [118]. In the committee's literature search, no recent publications were found.

Conclusion:

- **To determine the electrosensation in the LUT might be valuable to evaluate the afferent innervation in cases of neurologic bladder.**
- **Absent electrosensitivity might guide further neurologic tests in patients with LUT dysfunction (LOE 2).**
- **Further development and standardisation is needed for the use of electrosensation test to become established as a clinical test.**

9. Sympathetic Skin Response

Schurch et al. [119] assessed the descending sympathetic spinal tract and correlated these findings with bladder neck function in SCI patients. Evidence was presented that the integrity of the descending sympathetic spinal tract is necessary for a synergic function of the vesicourethral complex and that sympathetic skin responses (SSR) are of value in the diagnosis of bladder neck dyssynergia. SSR's

are absent in case of bladder neck dyssynergia. For lesions below the T12 level, other investigative methods to exclude bladder neck dyssynergia are necessary. Rodic et al. [120] found that recording the perineal SSR in addition to that of the hand and foot represents a sensitive diagnostic tool for assessing sympathetic nerve function within the thoracolumbar spinal cord, representing a reliable and accurate diagnostic tool for assessing bladder neck competence and incompetence.

SSR recordings above a spinal lesion level after urethral electrostimulation might provide a useful and technically simple objective diagnostic tool to assess integrity of autonomic (visceral) afferent nerves from the LUT. Somatosensory deficits are not always paralleled by viscerosensory loss and vice versa. SSR may be superior to visceral sensory evoked potentials, which are more difficult to record. The clinical utility needs to be further studied.

Conclusion

- **Sympathetic skin responses may help evaluate the integrity of LUT-related sympathetic function, including bladder neck competence and synergia (LOE 2)**

III. CONSERVATIVE TREATMENT

Therapeutic principles in different patterns of NLUTD depend on the underlying processes: dysfunction of the detrusor, dysfunction of the sphincter or a combination of both. Neurogenic detrusor overactivity leads to reflex-incontinence, detrusor areflexia to incontinence with retention (overflow incontinence). An areflexic (incompetent) sphincter causes neurogenic stress-incontinence, a hyperreflexic (spastic) sphincter overflow-incontinence. Quite often detrusor and sphincter are affected simultaneously by the neurogenic lesions. In most patients the storage problem, leading to incontinence, is associated with an emptying problem; therefore both aspects have to be considered at the same time. Therapy of neurogenic incontinence is primarily a conservative one. Timed bladder emptying, by whatever means, controlled fluid-intake and avoidance of urinary tract infections are the prerequisites for successful treatment.

If incontinence persists, and if operative procedures are not indicated or possible, containment products will be needed. The indwelling catheter remains an option for conservative therapy, and can offer acceptable quality of life outcomes [1] and long-term protection of the upper urinary tract [2, 3]. Most experts regard indwelling catheterisation as being associated with significant problems [4]. While suprapubic catheters are generally preferred over urethral, there is little evidence on which to base practice [5]. Urethral leakage can persist despite continuous drainage with a SPC, so additional steps such as bladder neck closure may need to be considered [6].

1. OVERVIEW ACCORDING TO TYPE OF LESION

a) Supraspinal lesions

In supraspinal lesions, neurogenic DO is mostly combined with normal sphincter function; overactivity incontinence is the main symptom and antimuscarinic therapy together with behavioural treatment is the method of choice, especially in patients with cognitive impairment.

b) Suprasacral lesions

Spinal lesions mostly cause simultaneous dysfunction of the detrusor and the sphincter. In suprasacral lesions, the spinal reflex bladder manifests the combination of DO with an overactive/ dyssynergic sphincter. For these patients, spontaneous reflex voiding may be possible. However, detrusor contractions may inadequate, and detrusor striated sphincter dyssynergia is present, both potentially leading to inefficient voiding. Triggered reflex voiding is recommended only if it is urodynamically safe and reflex incontinence is manageable; accordingly, careful support is needed to achieve adequate symptom control [7] and long-term renal safety [3]. Treatment to lower tone and spasticity of the urethral sphincter can be used to aid emptying, such as sphincterotomy [8], stenting [9] or botulinum toxin injections into the sphincter [10]. Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia. Sphincterotomy may help in reducing episodes of autonomic dysreflexia [11a].

The mainstay of treatment in current practice is intermittent catheterization (IC) [12], undertaken by the patient or carer. However, to achieve low pressure LUT urine storage and continence between catheterisations, additional pharmacotherapy may be necessary. If bladder relaxing agents fail or are not tolerable, electrotherapy is an alternative in incomplete lesions: ano-genital electrostimulation (penile, clitoral, vaginal and anal) can inhibit neurogenic detrusor overactivity by stimulating pudendal nerve afferents.

c) Lower motor neuron lesions

For complete conus lesions, areflexia of the detrusor with areflexia of the sphincter is characteristic. Sphincter incompetence causes neurogenic urinary stress incontinence and may be combined with dribbling incontinence if adequate emptying is not achieved. Conservative treatment to achieve continence is often unsuccessful. Bladder expression is potentially dangerous, and pharmacotherapy is not helpful in this situation. Accordingly, appliances and condom catheters are often necessary, and consideration of suitability of surgery may be needed [10].

Areflexia of the detrusor combined with overactivity of the sphincter may occur in epiconal lesions. This pattern may also result from decompensation of a neurogenic overactive bladder after chronic urinary retention. With this combination, overflow incontinence can be controlled by intermittent catheterization- mostly without adjunctive additional pharmacotherapy. If intermittent catheterization is not possible, an indwelling catheter, preferable suprapubic, may be needed. If overactivity of the detrusor is combined with areflexia of the sphincter, reflex incontinence is combined with neurogenic stress incontinence. This pattern is sometimes found in epiconal lesions, especially in myelomeningoceles. Bladder relaxant agents may diminish neurogenic detrusor overactivity. In incomplete lesions, electrical stimulation of the pelvic floor musculature may improve sphincter function. However, with this type of neurogenic LUT dysfunction, conservative treatment alone is generally unable to restore continence; therefore either appliances or operative treatment must be considered.

Cauda equina and peripheral nerve lesions are often incomplete. Hypoactivity or areflexia of the detrusor may be combined with a normally functioning external striated sphincter, a combination which can be seen after intrapelvic surgery, when the pudendal nerves remain intact. Conversely, pudendal nerve lesions in which the pelvic plexus remains intact, a combination of a normally functioning detrusor with a hypo- or areflexic external sphincter may be present. If there is DO, pharmacotherapy is the first choice treatment. For some lesions, intravesical electrotherapy has been reported to increase detrusor contractility [13]. Injection of botulinum toxin in the striated sphincter has created a potential new treatment option, but more research is needed.

2. SPECIFIC INTERVENTIONS

During the acute period of spinal or cerebral shock, bladder management comprises proper bladder drainage. For the post shock period, or for non-acute neurogenic dysfunctions, several conservative treatments are in use [14, 15]:

a) Behavioral therapy

1. Triggered Reflex Voiding

"Automatic" or "reflex" bladder behavior can occur following recovery from spinal shock in spinal cord lesions not involving the conus or cauda equina. This can be used as a means to empty the bladder, using voluntary approaches to provoking a bladder contraction by stimulation of the sacral and lumbar dermatomes. The most commonly used manoeuvres are suprapubic "tapping", thigh scratching and anal/rectal manipulation. A quadriplegic patient who is unable to perform ISC may choose this option because it gives more independence. If the efferent branches of the pelvic nerve are impaired, reflex emptying is much less complete, and considerable voluntary straining is additionally required to empty the bladder to a satisfactory degree. Integrity of the sacral reflexes predicts the potential to use this approach. The aims of regular triggered reflex voiding are to achieve "balanced voiding", decreasing incontinence but ensuring safe (low pressure) urodynamic function. The possibility of collecting the urine in a socially acceptable way and a reasonable time period for bladder emptying are needed. Frequency of emptying has to be specified for each patient. Whether bladder outlet obstruction is present also has to be considered; this is not often considered in published literature. To improve emptying, control autonomic dysreflexia related to bladder filling and contraction, and avoid upper tract damage, alpha-blockers or botulinum toxin sphincteric injections should be tried; sphincterotomy and/or bladder neck incision may sometimes be needed. Regular follow-up is essential, though the frequency of check-up appointments is not validated.

Triggered voiding should not be recommended as first line management; in current practice, IC is the accepted standard for continence, upper urinary tract protection and improvement of quality of life.

Conclusions

- **Reflex voiding is based on an unphysiological sacral reflex. It is potentially dangerous and has a limited role in managing the reflex bladder (LOE3).**
- **Costs of appliances and of adjuvant therapies (pharmacotherapy, surgery, urethral prosthesis etc) have to be evaluated (LOE 2).**
- **Treatment of co-existing sphincteric spasticity/ bladder neck obstruction and co-morbidity should be taken into consideration (LOE 1 and 2)**

Recommendations

- **Triggered voiding could be recommended only for patients whose situation has proven to be urodynamically safe and stable, and who can manage reflex incontinence.**
- **Triggered voiding can be considered for patients after sphincterotomy and/or bladder neck incision and/or alpha-blockers and/or intrasphincteric botulinum toxin injections, in order to improve spontaneous reflex voiding (C).**
- **Reflex voiding can be recommended only if an adequate follow-up is guaranteed (C)**
- **Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia.**

2. Bladder Expression (Crédé and Valsalva)

Bladder expression comprises various techniques aimed at increasing intravesical pressure in order

to facilitate bladder emptying. The most commonly used are the Valsalva (abdominal straining) and the Crédé (manual compression of the lower abdomen). It has been recommended for a long time for patients with a combination of an areflexic detrusor with an areflexic sphincter or with an incompetent urethral closure mechanism of other origin (e.g. after sphincterotomy). Difficulties in emptying the bladder by expression may be due to an inability to open the bladder neck. However, especially in men, these techniques may induce a functional obstruction at the level of the striated external sphincter despite complete paralysis of the musculature of the pelvic floor. Over time, a high proportion of patients manifest problems such as reflux into the prostate and seminal vesicles, or epididymo-orchitis. Moreover, the high pressures could cause reflux into the upper urinary tract. The stress to the pelvic floor with these techniques several times a day also can make incontinence worse, and causes additional genital-rectal prolapse and haemorrhoids.

Adjunctive therapy to decrease outflow assistance includes alpha-blockers, sphincterotomy or botulinum toxin injections. If effective, they usually cause or increase neurogenic urinary stress incontinence. Expression of the bladder for voiding by Crédé and Valsalva can be effective. To empty the bladder, the pressures measured may be high and potentially dangerous for the upper urinary tract. Bladder expression is often not safe. Sphincter-hyperreflexia and detrusor-sphincter dyssynergia are contra-indications for bladder expression.

Conclusions

- **Bladder expression by Valsalva or Credé is potentially hazardous for the urinary tract due to functional obstruction at the level of the pelvic floor (LOE 3).**
- **It is contraindicated if it creates a high intravesical pressure, particularly in association with reflux into the ureters or seminal vesicles. Hernias, pelvic organ prolapse, haemorrhoids and urethral pathology (strictures) are relative contraindications (LOE 3).**
- **Bladder expression may adversely affect a flaccid pelvic floor, potentially exacerbating incontinence (LOE 3).**
- **Alpha-blockers, sphincterotomy or botulinum toxin may reduce the outflow resistance, but may also induce or increase urinary stress incontinence (LOE 3).**

Recommendations

- **Before recommending bladder expression by Valsalva or Credé, it must be proven that the LUT is urodynamically safe. (B)**
- **Exclude contraindications, such as vesicoureteric reflux, pelvic organ prolapse, hernias, urethral pathology and symptomatic UTIs before recommending this type of bladder emptying. (B)**
- **In general, bladder expression should be replaced by CIC in most patients with neurogenic bladder-sphincter dysfunction. (B)**
- **Adjunctive therapy of outflow obstruction can be considered. (B).**

3. Toileting Assistance: Timed Voiding, Habit Retraining, Prompted Voiding.

See also the chapters on adult conservative treatment and frail elderly.

Adaptation of the drinking and voiding regimen requires education and can be implemented by the patient and/or caregivers. The aim of the behavioural process in adults is to re-establish the control of urinary continence. The goals include correcting faulty habit patterns of frequent urination, improving ability to control bladder urgency, prolonging voiding intervals, increasing bladder capacity, reducing incontinent episodes, and building a patient's confidence in controlling his/her bladder. In dependent patients all these techniques can be proposed and tried, provided that caregivers (physiotherapist, nurse, family members, etc.) are supportive.

Timed voiding is characterized by a fixed interval between toileting. It is a passive toileting assistance program, initiated and maintained by caregivers. It is considered appropriate for patients who cannot participate in independent toileting. It has been used where incontinence is associated with cognitive and/or motor deficits. Its aim is more to avoid incontinence than to restore a normal bladder function. For neurologic patients it has also been considered as an adjunct to tapping and/or Crédé manoeuvre and/or intermittent catheterisation. Timed voiding can be recommended in management of patients with excessive bladder volumes, exemplified by diabetic patients with impaired bladder filling sensation.

Habit retraining and prompted voiding have to be initiated and maintained by caregivers. They are more suited to patients with brain diseases than spinal cord diseases, and for patients with cognitive and/or motor deficits. The aim of habit retraining is to help patients to avoid incontinence by decreasing voiding intervals. Such program has to be adapted to each patient and needs a specific analysis of voiding patterns to select a good individual schedule for voiding. Such a program is very useful for institutionalised patients. Prompted voiding is used to teach people to initiate their own toileting through requests for help and positive reinforcement from caregivers. There are no specific evaluations on neurologic patients in the literature.

Conclusions

- **Behavioural techniques should be used in conjunction with other therapies (pharmacological treatment, catheterisation) (LOE 2).**
- **When appropriate, toileting assistance should be used to improve continence of neurologic impaired patients (LOE 3).**
- **Prompted voiding may be able to decrease incontinence episodes. Patients likely to benefit from the technique are those with less cognitive impairment and higher dependency (LOE 2/3).**

Recommendations

- **Behavioural techniques are a suitable component of the rehabilitation program for each individual. (C)**
- **There are no guidelines or consensus on suitable intervals for bladder emptying. They should ideally be derived from the voiding diary and other related factors (bladder volume, fluid intake, post-void residual urine volume, urodynamic parameters). (C)**
- **The mental status of a patient must be taken into consideration, and a rehabilitation program realistically tailored to the patient's possibilities. (B/C).**

b) Catheters and appliances

1. Intermittent Catheterization

Intermittent catheterization (IC), including intermittent self-catheterization (ISC), aims to resume normal bladder storage and regularly complete urine evacuation. They avoid some of the complications of indwelling catheterization (IDC). IC can improve incontinence, or make patients with neurogenic bladder continent, if; bladder capacity is sufficient, bladder pressure is kept low, urethral resistance is adequate, and fluid intake is balanced with frequency of catheterization. In children with SCI, IC used with anticholinergic drugs appears to minimise upper urinary tract deterioration, improve continence and decrease infections; safe increase in capacity appears to increase with growth [16, 17]. Post-void residual signifying the need to institute IC remains to be clarified. However, Dromerick et al. [18] (LOE 2) demonstrated in a series of stroke patients that a post-void residual greater than 150ml is an independent risk factor for development of UTI.

Most appropriate technique and catheter depend on individual anatomic, social and economic possibilities [19] (LOE 1). Two main techniques have been adopted, sterile IC (SIC) and clean IC (CIC). The sterile non-touch technique involves the use of sterile materials handled with sterile gloves and forceps. In an intensive care unit, some advocate wearing a mask and a sterile gown as well [20]. De Ridder et al. [21] compared SpeediCath hydrophilic-coated catheters versus uncoated polyvinyl chloride (PVC) catheters, in SCI patients. This 1-year, prospective, open, parallel, comparative, randomised, multi centre study included 123 male patients injured within the preceding 6 months. Primary endpoints were occurrence of symptomatic UTI and hematuria. Secondary endpoints were development of urethral strictures and convenience of use. The results indicate a beneficial effect regarding UTI when using hydrophilic-coated catheters. Bjerklund-Johansen et al. evaluated patient willingness to change and satisfaction with catheters for IC in neurogenic bladder dysfunction. They also compared patient response to conventional catheters and a packaged hydrophilic catheter: LoFric Primo [22]. 409 neurogenic patients were recruited and 378 (283 males, 95 females; mean age 43.5 years) completed a short-term trial. Patient satisfaction was expressed on a Visual Analogue Scale for seven topics covering use and general satisfaction. Differences regarding satisfaction, handling, time spent, and ability to cope with daily life were reported. Kovindah and Madersbacher investigated whether a silicone catheter reused over years for clean IC was safe for men with SCI [23]. Reused silicone catheter appeared to function as well as disposable. However, to reuse urinary catheters, one should consider the increased risk of infection. The authors suggest that for SCI patients in developing countries, CIC with a reusable silicone catheter may be a suitable and safe choice if one cleans and applies it. In the same way, Getliffe performed a systematic Cochrane review summarizing current evidence on the relationship between sterile single-use catheters or clean reused catheters and the incidence of UTIs [24]. 13 trials met the inclusion criteria. There was considerable variation in length of follow-up, definitions of UTI, and numbers of subjects. Attrition was a problem for several studies, and all were underpowered. Several studies were more than 10 years old, and outcome measures were imprecise, making it difficult to draw conclusions on the benefit of one catheterization method over another. They concluded that there are no definitive studies illustrating that incidence of UTIs is affected by sterile single-use or coated catheters compared to clean reused catheters. However the current research base is weak and design issues are significant. Based on the current data, it is not possible to state that one catheter method is better than another and further research is needed (LOE1). Research to evaluate clean vs. sterile PVC catheter use, and hydrophilic vs PVC use (both sterile and reused), is needed.

Frequency of catheterization depends on many factors, e.g. bladder volume, fluid intake, post void residual, and urodynamic parameters (compliance, detrusor pressure). Usually it is recommended to catheterize 4 – 6 times a day during the early stage after spinal cord lesion. Some will need to keep this frequency if IC is the only way of bladder emptying. Others will

catheterize 1 – 3 times a day to check and evacuate residual urine after voiding. To overcome high detrusor pressure, adjunctive therapy with antimuscarinic drugs or other bladder relaxants can be indicated. For those who develop a low compliance bladder, upper tract deterioration or severe incontinence, injection of Botulinum toxin in the bladder wall or surgery, such as bladder augmentation, may be necessary.

If catheterization is begun by patients with recurrent or chronic UTI and urinary retention, the incidence of infection usually decreases. If symptomatic infections occur, improper CIC or misuse should be considered. Chronic infection persists if the cause of the chronicity remains. Treatment of UTI is necessary if the infection becomes symptomatic. Lindehall et al. evaluated the rate of complications associated with catheterization and the risk of urethral lesions in myelomeningocele treated with clean IC for a minimum of 10 years. They found that there were remarkably few problems [25]. The incidence of major urethral lesions did not increase during puberty. Larger catheters seemed to be protective against major lesions [26] (LOE3). In contrast, Chen et al. found that the incidence of urethral strictures increases with a longer follow-up, and bladder stone formation is associated with long-term use of CIC in SCI patients [27] (LOE3).

Oh et al. evaluated health-related quality of life (HRQOL) with IC in neurogenic bladder. They conducted a prospective trial involving 132 patients (81 men and 51 women, mean age 41.8 years, range 18 to 80 years) with SCI [28]. Patients using IC have a reduced quality of life in all health domains, as assessed by the SF-36 (LOE2) [29].

Conclusions

- **IC in the neurogenic bladder is effective and safe in short- and long- term use. (LOE 1)**
- **Complications such as UTI are regularly seen and seem to be related to both the catheterization itself and the pre-existing LUT condition (LOE 2).**
- **Urethral and bladder complications seem to increase in the long- term (LOE 3).**
- **In order to reduce and prevent complications, appropriate materials and correct techniques should be taught and performed (LOE 3).**
- **Adequate frequency of CIC, a non-traumatizing technique and suitable materials are the key factors for a successful outcome (LOE 2).**

Recommendations

- **IC is the first choice treatment for those with inability to empty the bladder adequately and safely in neurogenic voiding dysfunction. It is a valuable tool for achieving continence. (A)**
- **Proper education and teaching are necessary to achieve a good outcome. (B)**
- **To prevent and reduce complications, a non-traumatizing technique (external lubricant or lubricant coated catheters) with adequate frequency of catheterization and complete emptying should be achieved. (B)**
- **Annual follow-up is needed. (B/C)**
- **It is not currently possible to state whether any IC method is advantageous (Grade D) and further research on the topic is strongly recommended.**

2. Indwelling Catheter (IDC)

The Foley catheter was developed in the early 20th century. After the World War I, most SCI and other neurologic patients were treated with indwelling urethral catheterization (IDUC) or suprapubic catheterization (SPC) due to difficulty in voiding or urinary incontinence. While IC is nowadays recommended for neurologic patients, many still choose IDC due to difficulty in performing IC, or persistent leakage between catheterizations. In developing countries, IDC can still be the method of choice for those with urinary retention or incontinence.

IDUC placement requires meticulous technique. More frequent catheter changes may be needed in patients with recurrent UTIs. IDUC can cause various complications, such as; urethral trauma and bleeding, urethritis, bladder stones, cystitis, acute and chronic UTI, bladder neck incompetence, meatus and urethral sphincter erosion, and bladder carcinoma. Fistulas can result from pressure effects, caused by improper catheter size and inadequate securing technique, particularly with long-term use. Therefore many experts advocate removal of an IDUC as soon as possible, and usage of other methods such as IC or SPC. Nowadays the complications of IDC seem less, presumed due to better materials, judicious size selection and a proper technique of securing the catheter. For CIC wet patients, overnight IDUC self-placement seems to decrease risk of febrile episode due to UTI, as compared to CIC alone [30]. In the morning, the catheter was removed, washed with tap water and stored in disinfectant (LOE3).

The study by Pannek (LOE 3) reported an incidence 0.11% for bladder cancer in catheterised SCI individuals (48 out of 43,561 patients), similar to that observed in the general population [31]. However, more than 60% of the patients with SCI initially presented with muscle-infiltrating bladder cancer. Hypothetically, the expression of inducible nitric oxide synthase with IDC [32] might predispose to formation of potentially carcinogenic nitrosamines in the bladder. Hamid et al. [33] did not find bladder cancer on bladder biopsies in patients with SC I and a mean IDC use of 12.1 years.

Routine antibiotic prophylaxis for patients with IDC is not recommended. Attempts at eliminating bacteriuria associated with indwelling or intermittent catheters are generally unsuccessful [34, 35] (LOE 4). For prevention of UTI, general cleanliness and local hygiene should be encouraged. In symptomatic UTI, it is important to consider catheter blockage and problems such as urinary stones. Symptomatic UTIs have to be treated with the most specific, narrowest spectrum antibiotics available for the shortest possible time. Guidelines for selecting antimicrobial agents in SCI patients are similar to guidelines for the treatment of complicated UTIs in the general population. Characteristics of the quinolones make them well suited for treating UTI in SCI patients [36] (LOE 4). Recommendations of the local microbiology department should be sought.

The benefit and risks of SPC are similar to IDUC, including the risk for UTI, stone formation and maintenance cost of catheter and bag. Advantages include: minimized risk of urethral trauma and pain- in neurologically impaired women with even relatively short-term IDUC, urethral destruction is a significant risk. The key disadvantage is that SPC placement requires a minor 'surgical' produce to insert the suprapubic catheter, with potential to injure nearby organs [37]. While most centres favour SPC use, complications are well-recognised and literature is limited. Most publications are old, there are no prospective studies and no RCTs on SPC.

Conclusions:

- **Long-term IDUC use in neurologic patients can predispose to complications. (LOE 2)**
- **Catheters should have as large a lumen as possible to maximise time to blockage by encrustation, and 5-10 ml self-retaining balloons to minimise the pressure effect on the bladder neck. (LOE 4)**
- **Closed drainage systems are associated with lower infection risk. (LOE 1)**
- **Frequency of change largely depends on time to blockage, which is influenced by catheter materials and lumen, patient factors and infection. (LOE 3)**
- **SPC is a reasonable alternative to IDUC, but IC is the first line intervention (LOE 3).**
- **SPC is a safe and effective short-term management of urinary retention. (LOE 3)**

Recommendations:

- **Silicone or hydrogel-coated catheters are preferable. (A/B)**
- **Use sterile materials and aseptic technique, and routine catheter care in the context of a closed drainage system. (C/D)**
- **Catheters should be changed regularly, to try to pre-empt obstruction or infection. (C/D)**
- **Bladder irrigation and antibiotic prophylaxis are not recommended as a routine infection-control measure. Symptomatic UTI should be treated with narrowest spectrum antibiotic possible, according to local microbiology practice. (B)**
- **Patient education on daily cleanliness and hygiene care are mandatory. (C)**
- **Short-term IDC during the acute phase of neurological injury is a safe management for neurologic patients. (B)**
- **Long-term IDC may be safe only if a careful check-up of urodynamic, renal function, and upper and lower tract imaging are performed. (B)**
- **Bladder screening for bladder cancer is strongly recommended, especially those with IDC more than 5-10 years. (C)**
- **Annual cystoscopy and biopsy may be necessary for those with gross hematuria, or chronic symptomatic UTI refractory to therapy. (C)**
- **Consider the use of antimuscarinic drugs in individuals with suprasacral lesions using chronic indwelling catheters. (C)**
- **Patient comfort, convenience, sexuality and quality of life need to be considered. (C)**

3. Condom Catheters and External Appliances

Male patients with neurogenic bladder and chronic urinary incontinence can be candidates for a condom catheter connected to a collection bag. However, some men have difficulty in applying condom catheters, e.g. due to obesity, penile atrophy or retraction.

Conclusions

- **Condom catheters facilitate urinary containment in neurologic male patients (LOE 3).**
- **Long-term use does not increase the risk of UTI when compared to other methods of bladder management. (LOE 3)**
- **Complications may be less if technique, hygiene, replacement and maintenance of low bladder pressures are optimised. (LOE 3)**

Recommendations

- **Size selection should consider control of leakage, and prevention of penile compressive effects. (B)**
- **Regular bladder emptying with low bladder pressures and low post void residual should be confirmed (B).**

IV. PHARMACOTHERAPY

This chapter deals only with specific issues of continence pharmacotherapy in neurologic patients. For a fuller description of the drugs in use, see chapter 8. The principal causes of urinary incontinence in this subpopulation are neurogenic DO and/or incompetence of urethral closing function. Accordingly, treatment aims to decrease storage-phase detrusor activity, increase bladder capacity and/or increase bladder outlet resistance. This picture is blurred by the occurrence of DSD, which can be present concomitantly with DO. Pharmacologic therapy is particularly helpful in relatively mild degrees of neurogenic bladder dysfunction. Patients with more profound neurogenic bladder disturbances may require pharmacologic treatment to improve results of other forms of management, such as IC.

The two most commonly used classes of agents are antimuscarinics and alpha-adrenergic antagonists. However most drugs have not been evaluated specifically in neurogenic bladder dysfunction.

1. DRUGS FOR NEUROGENIC STORAGE DYSFUNCTION

a) Bladder relaxants

General indications of pharmacological treatment in neurogenic DO are to improve reflex incontinence, ameliorate high intravesical pressure and support other interventions e.g. IC and IDC. Antimuscarinic therapy is a symptomatic treatment. In neurogenic DO, antimuscarinics may increase post void residual urine.

The evidence base for the use of antimuscarinics in patients with a neurogenic bladder is limited. In fact, in a recent Cochrane review performed on all current literature regarding anticholinergic therapy for MS-related incontinence, only five usable studies were found, and no conclusion supporting benefit could be drawn from the analysis [1].

1. Oxybutynin

Oxybutynin hydrochloride is a moderately potent antimuscarinic agent with a pronounced muscle relaxant activity and local anesthetic activity as well-the clinical relevance of the latter is debatable. In a prospective, 12-week dose titration trial of controlled release oxybutynin (OXY-XL), Bennett et al. [2] evaluated the efficacy and tolerability of higher dose oxybutynin chloride in patients with neurogenic bladder and multiple sclerosis, spinal cord injury or Parkinson's disease. A 7-day washout period was used before initiation of the starting dose of 10 mg OXY-XL. Doses of OXY-XL were increased by 5 mg at weekly intervals to a maximum dose of 30 mg per day guided by patient perception of efficacy versus side effect. At the end of the study statistically significant decreases in the number of voids in 24 hours, episodes of nocturia and incontinence episodes were observed. Residual urine remained unchanged. No patient experienced serious adverse events (LOE2). In a prospective, open label trial of 3 formulations of oxybutynin (tablets, syrup and extended release tablets), Franco et al. [3] evaluated the efficacy and safety of oxybutynin in children with neurogenic DO. The effect of treatment on average urine volume per catheterization and on secondary urodynamic outcomes was evaluated. Maximal cystometric capacities increased, and mean detrusor and intravesical pressures were significantly decreased at week 24. Improvements in bladder function were consistent across all oxybutynin formulations (LOE 2). Gajewski et al. demonstrated in a prospective randomized study that oxybutynin was more effective than propantheline in the treatment of DO in patients with multiple sclerosis (LOE 1) [4].

2. Propiverine

In a randomized, double-blind, prospective multicenter clinical study, Stöhrer et al. [5] compared the efficacy and tolerability of propiverine and oxybutynin in patients with neurogenic detrusor overactivity. Propiverine and oxybutynin were equally effective in increasing bladder capacity and lowering bladder pressure. The trend for better tolerability of propiverine compared to oxybutynin achieved significance for dryness of the mouth (LOE1). Propiverine hydrochloride has also been shown to be effective in neurogenic detrusor overactivity in children and adolescents, even in some of those cases unresponsive to other anticholinergics [6, 7]. The low incidence rate of adverse events evidenced a favourable risk-benefit profile of propiverine hydrochloride (LOE3).

3. Trospium

Trospium is a quaternary ammonium derivative with mainly antimuscarinic actions. Trospium has been shown to significantly reduce the number of urinations, increase cystometric capacity and mean effective volume of the bladder, and reduce the incidence of urgent voids in neurogenic patients [8, 9] (LOE1).

4. Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist. Tolterodine has a high selectivity in vitro and exhibits selectivity for the urinary bladder over the salivary glands in vivo. Several phase II studies have demonstrated the efficacy and safety of tolterodine in patients with overactive bladder [10]. Ethans conducted a prospective, randomized, double-blind, crossover trial plus open-label comparative stage, aiming at comparing tolterodine with oxybutynin and placebo in people with neurogenic DO. Tolterodine, when used at self-selected doses (SSDs) was comparable with oxybutynin at SSDs in enhancing bladder volume and improving continence, but with less dry mouth. It seems that larger

doses of tolterodine are needed to achieve best effect on neurogenic bladder [11, 12] (LOE3).

5. Solifenacin succinate

Solifenacin has been extensively studied in OAB [13, 14] (LOE1). In a prospective, open-label study of solifenacin for the treatment of OAB in MS patients, van Rey et al. demonstrated a significant improvement in number of micturitions, number of pads used per day and severity of urgency compared to baseline following eight weeks of treatment [15] (LOE 2).

6. Darifenacin

Dariferacin has a higher relative selectivity for the M3 receptor compared with other anticholinergics. Dariferacin has been extensively studied in OAB, but not in neurogenic bladder dysfunction.

7. Fesoterodine

Fesoterodine acts functionally as a prodrug, hydrolysed by nonspecific esterases to 5-hydroxymethyl tolterodine (5-HMT). This active metabolite, responsible for the antimuscarinic activity of fesoterodine is also an active metabolite of tolterodine. Phase 3 trials have evaluated fesoterodine in OAB, but there is no current data on the effect of fesoterodine in neurogenic LUT dysfunction.

8. Dual therapy with antimuscarinics

Dual therapy (between combinations of oxybutynin, tolterodine and trospium) has been shown to be effective and well tolerated in a few patients with neurogenic bladder dysfunction [16] (LOE 2).

9. Antimuscarinics in neurological patients with cognitive impairment

In the cognitively impaired, antimuscarinics should be prescribed with a warning about possible deterioration in memory or the onset of confusion. It would appear sensible to recommend the use of antimuscarinics that are likely to have less impact on cognition, either by lower propensity to cross the blood–brain barrier (e.g. trospium chloride) or by relative selectivity for the M3 receptor (e.g. darifenacin) which is not known to be involved in cognition; evidence affirming these considerations is limited. No studies have specifically evaluated patients with neurological disease. In a randomised, double-blind, parallel group, multicentre study of 3 weeks treatment with darifenacin in the healthy elderly, no significant effects on memory compared to placebo was observed, in comparison to oxybutynin ER which caused significant memory deterioration [17] (LOE 1). In a single-centre, non-comparative, pre-post dose intervention phase IV study of healthy elderly that was primarily designed to evaluate CSF trospium levels after orally dosed trospium , no decline in performance on tests of learning and memory was observed following ten days [18] (LOE 2).

Recommendations

• The evidence demonstrating the efficacy of antimuscarinics in the management of overactive bladder symptoms in patients with a neurogenic bladder is limited. Randomised control studies are needed to evaluate this further.

b) Intravesical bladder relaxants

1. Antimuscarinics.

Since the first use of the intravesical application by Brendler et al. 1989 [19], there have been several articles reporting successes of intravesical oxybutynin to treat OAB and neurogenic DO. The main findings were, at least at short term follow up; improved LUTS, fewer incontinence episodes, an increase of maximum bladder capacity and decreased DO. George et al. 2007 compared the therapeutic response of intravesical oxybutynin, propantheline, and capsaicin in the treatment of neurogenic DO [20]. Oxybutynin 5 mg in solution or propantheline 15 mg in solution and capsaicin were instilled intravesically in each patient. Urodynamic studies were done before and after the intravesical instillation of each drug. There was a significant difference in therapeutic response between intravesical oxybutynin, propantheline, and capsaicin in the treatment of detrusor overactivity for leak volume (LV) and leak frequency at 2nd week. When comparing responses of oxybutynin and propantheline, more subjects demonstrated improvement with intravesical propantheline than oxybutynin for reflex volume, detrusor leak point pressure, clean intermittent catheterization volume, and LV (LOE3). However, there is no standard instillation protocol concerning the use of intravesical oxybutynin; doses used range between 5-30 mg, diluted in 30-40 ml saline [20, 21]. Also the instillation frequency is not standardized and varies between 1 to 3 times /d. Small case series report on long-term success of intravesical oxybutynin (up to 3 years in adults, up to one year in children with NDO (LOE4) [22, 23]. Despite favourable results on urodynamic parameters, there is also a low level of evidence for the use of intravesical oxybutinin in low-compliance neurogenic bladders [24]. Modulation of the ice-water test and suppression of the electrical perception threshold by oxybutynin has been studied [25]. An animal experiment suggested that early administration of oxybutynin might have a protective effect on structural bladder alterations, at least in obstructed animals [26].

Fader et al. 2007 [27] tested the efficacy and side effect profiles of intravesical atropine compared to oxybutynin immediate release (IR) in MS. They performed a study to determine the most effective dose of atropine. Eight participants used increasing doses of intravesical atropine (2 to 6 mg in 20 ml saline) during a 12-day period. Bladder diary data

showed that the instillation of 6 mg atropine 4 times daily was most effective for increasing bladder capacity (voided/catheter volumes). Afterwards they performed a randomized, double-blind crossover trial. Participants received 14 days of treatment with oral oxybutynin IR 5 mg twice daily (range 2.5 twice to 5 mg 4 times daily) or with intravesical atropine, followed by 14 days of alternative treatment. Participants recorded a bladder diary and rated side effects and quality of life. The primary outcome variable was bladder capacity. 57 participants with MS completed the study. Average change in bladder capacity was higher in the atropine arm. Changes in incontinence events and voiding frequency were not statistically different between the arms. Changes in total side effect and dry mouth scores were significantly better in the atropine treatment arm. These findings suggest that intravesical atropine is as effective as oxybutynin IR for increasing bladder capacity and has less antimuscarinic side effects (LOE2). However, no further results of clinical trials with intravesical atropine have been published since.

2. Nociceptin/Orphanin FQ (N/OFQ)

Nociceptin is a peptide that exerts several physiologic actions at both the central and the peripheral level by activating a specific G-protein-coupled receptor named nociceptin orphan peptide (NOP) receptor. Animal studies have demonstrated that N/OFQ inhibits the micturition reflex in the rat [28]. Lazzeri et al. recently studied the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of the endogenous peptide N/OFQ in a selected group of patients who performed CIC for neurogenic DO [29]. A total of 18 patients were randomized to receive 1 mg nociceptin/orphanin FQ in 10 ml saline or placebo (saline) at the first catheterization for 10 days. Mean daily urine leakage episodes significantly decreased from 2.18 at baseline to 0.94 during nociceptin/orphanin FQ treatment, while no significant changes were reported in the placebo group. The bladder capacity significantly increased in patients receiving nociceptin/orphanin FQ. The urodynamic parameters showed an increase in cystometric capacity and a decrease in maximum bladder pressure. Although these findings supported the use of nociceptin/orphanin FQ peptide receptor agonist as an alternative approach for controlling NDO incontinence (LOE2), no further study results have been published in five years.

3. Compounds Acting Via the Transient Receptor Potential (TRP) Channels

The vanilloids, capsaicin (CAP) and resiniferatoxin (RTX), desensitize afferent nerves by binding TRPV1 receptors. CAP has been the subject of small, short-lasting placebo-controlled trials in patients with SCI or MS [30] (LOE1-2). Thus, the use of CAP is still largely experimental and limited by the fact of prolonged and painful excitation of the sensory c-fibers. The alcoholic solvent may be a major factor in the poor tolerability of alcoholic CAP instillation, as suggested by the result of one placebo controlled study showing that side effects appeared to be the same after intravesical instillation of CAP diluted in 30% ethanol as after instillation of ethanol alone (LOE2).

RTX acts without the potent neuronal excitatory effect of capsaicin, and therefore elicits less discomfort. The difference in tolerability of the 2 vanilloids (CAP vs. RTX) was usually attributed to the differential pungency of the 2 agents. Nevertheless, because we know the role of the solvent in the irritative effect on bladder mucosa, it is reasonable to assume that differential effects could be related to the use of different vectors. From a technical point of view the choice of the solvent is limited because of the poor hydrosolubility of CAP, imposing the use of an alcoholic, lipidic or glucidic vector. The safety of the lipidic solution could be imperfect because of difficulty of achieving complete elimination of lipidic solution from the bladder. On the contrary, a glucidic solution may represent a safe and valuable alternative to the alcoholic vector. De Seze et al. [31] compared the efficacy and tolerance of intravesical instillations of CAP and RTX using a glucidic solvent for CAP and the 10% ethanol solvent for RTX in a controlled randomized, double blind study in patients with severe urinary incontinence due to spinal cord injury. On day 30, improvement was found clinically and urodynamically in 78% and 83% respectively of patients treated with CAP vs. 80% and 60% treated with RTX. No significant difference between the 2 groups was observed. The benefit remained in two-thirds of the 2 groups on day 90. There were no differences in regard to incidence, nature or duration of side effects in CAP vs. RTX treated patients. These results once more strongly argue for the importance of accounting the role of vanilloid solute when interpreting efficacy and tolerance of vesical vanilloid instillation in neurogenic DO cases. They suggest that a glucidic solution is a valuable solvent for CAP instillation (LOE2).

RTX seems to have a beneficial effect on neurogenic DO (LOE 2). However, good randomized controlled studies are needed to determine its place in the treatment of NDO. Also the optimum doses (concentration) as well as the inter treatment intervals need to be determined. Moreover, the long-term safety of vanilloid agents, particularly concerning mutagenic and carcinogenic effects on the bladder wall is not perfectly known. RTX belongs to the family of tumor promoting phorbol esters, strengthening the need to ensure the safety of RTX before extending its therapeutic applications.

Initial interest in RTX has declined following the introduction of intradetrusor Botulinum toxin injections in the treatment of intractable neurogenic DO. In a randomized trial comparing onabotulinumtoxinA injection to resiniferatoxin intravesical instillation in 25 patients with spinal neurogenic DO [32] there was

a significant decrease in catheterization and incontinence episodes for both treatments at 6, 12, and 18-months of follow-up. However, onabotulinumA injections provided superior clinical and urodynamic benefits as compared to intravesical resiniferatoxin, although RTX did not necessitate subsequent intermittent catheterisation (LOE1-2).

Transient receptor potential channels are being increasingly investigated as targets for the treatment of detrusor overactivity. Piperine, a novel vanilloid compound, was found to have both acute and prolonged in vitro effects [33]. In an animal model of chronic spinal NDO, systemic administration of GRC-6211, a novel TRPV1 antagonist, could abolish DO [34]. An antagonist of another TRP channel, the ankyrin-repeat transient receptor potential 1 channel (TRPA1), could decrease the number and amplitude of non-voiding bladder contractions in SCI rats [35]. Finally, nitro-oleic acid, an electrophilic fatty acid nitroalkene derivative which modulates gene transcription and protein function via post-translational protein modification demonstrated TRP-agonist actions affecting both the TRPV1 and the TRPA1 receptors in rat bladders [36].

4. Botulinum Neurotoxin Type A

Efficacy: The past decade saw the emergence of the most successful intravesical treatment for refractory neurogenic DO to date, namely Botulinum neurotoxin (BoNT) intradetrusor injections. Following several publications from increasing numbers of centres worldwide and multicentre registration studies, BoNT type A (BoNT/A) in the OnabotulinumtoxinA (BOTOX™) format has become the newest approved treatment for urinary incontinence in adult neurological patients with inadequate response to (or reduced tolerance of) an anticholinergic medication (U.S. Food and Drug Administration approval). Similar approval has been granted or is awaited in a number of European countries. Several systematic reviews [37-40], a number of randomized, placebo-controlled trials (LOE1, four fully published studies [41-44], one active comparator-controlled trial (LOE1-2) [32], three LOE2 studies [45-47], and several LOE3 studies have confirmed the efficacy of BoNT/A in the treatment of refractory neurogenic DO incontinence. Clinical improvement is accompanied by significant ameliorations in bladder function, as urodynamic parameters that matter in the management of NDO, namely maximum cystometric capacity, maximum detrusor pressure and reflex volume, appear to gain substantial benefits in most published patient series [37-39]. Almost all studies have published on two BoNT/A preparations, onabotulinumtoxinA (Botox) and abobotulinumtoxinA (Dysport) [39]. The two formats are not interchangeable and there are no direct comparisons for dose, efficacy and safety, at least in urological indications. Although both products appear to be efficacious in NDO, onabotulinumtoxinA has been more comprehensively studied than abobotulinumtoxinA [39]. An LOE1 study has been published reporting abobotulinumtoxinA [46]. An LOE3 study suggests that onabotulinumtoxinA may be more efficacious than a novel BoNT/A preparation, Prosigne, in the treatment of refractory NDO [48].

The mean duration of efficacy of a single injection is 6-16 months for onabotulinumtoxinA and 5-12 months for abobotulinumtoxinA [39]. The FDA regulatory trials (275 and 416 patients, respectively) demonstrated a mean duration of effect of [37-42 weeks for onabotulinumtoxinA compared to 13 weeks for placebo [43, 49]. Complete continence was achieved in 36-38% and 40-41% respectively with the 200U and 300U doses of onabotulinumtoxinA as opposed to 7.6-10% with placebo. Interestingly, significantly higher post-treatment continence rates have been reported in single-centre studies with both preparations (a mean 71% with onabotulinumtoxinA and 65% with abobotulinumtoxinA) [39]. The concomitant use of anticholinergics did not appear to provide additional benefit, although this needs to be confirmed in specifically-designed studies. Several retrospective studies now attest to the sustained efficacy of repeat treatment sessions with either of the two formulations [50-58].

Reported failure rates range was 5-25% for onabotulinumtoxinA and 10-32% for abobotulinumtoxinA [39]. Clinical predictors of success/failure in NDO have not been studied. A study of patients with MS proposed that longer duration of MS may be a predicting factor for treatment failure [59] (LOE3). To date there is no robust evidence to link treatment failure with the formation of neutralizing BoNT/A antibodies, but a wide range of antibody formation rates following treatment has been reported (0-35%) [60-63] and its clinical significance needs further investigation. A small, controlled study in children (LOE1-2) found no association between antibody formation and treatment failure, but reported an increased rate of antibody formation in those receiving repeat versus single injections (71% versus 38%) [64] in the mid-term (up to 4 months post treatment). In the long-term, antibody titers returned to control levels.

Patient populations: The majority of the studies involved participants with neurogenic bladder due to SCI or MS, often mixed, while only small case series investigated efficacy in patients with Parkinson's disease, multiple system atrophy or cerebrovascular accident (CVA) [65-68]. Comparisons of efficacy between neurological subpopulations are generally lacking, although a small LOE3 study suggested better continence outcomes and more significant improvements in maximum detrusor pressures in SCI patients compared to those with CVA [68]. The largest RCTs which involved MS and SCI patients conclude that the toxin is highly efficacious in both subpopulations [43, 49]. A lower placebo effect

in the SCI subpopulation could be noted, although the studies were not designed for head-to-head comparisons. The same studies demonstrated a similar efficacy and adverse event profile for the 200U and 300U onabotulinumtoxinA (BOTOX) doses, suggesting a plateau in the efficacy of the toxin. Similar conclusions had been drawn by the results of an earlier study in the IDO population (plateau dose 150U onabotulinumtoxinA) [69]. Providing the best benefit/risk ratio, the 200U onabotulinumtoxinA dose was recommended for the treatment of refractory NDO incontinence [43, 49]. A LOE2 study suggested a trend towards better clinical and urodynamic improvements with 750U as opposed to 500U abobotulinumtoxinA [46]. Other, non-randomised and inadequately powered studies (LOE3) [45, 56, 70] could not identify a clear dose-response for higher doses of abobotulinumtoxinA, although 1000U abobotulinumtoxinA might produce a beneficial effect of greater duration than that with 500U [45].

Little data exists on lower doses. A pilot LOE3-4 study suggests that 100U onabotulinumtoxinA could be effective in MS patients and minimize unfavourable side-effects, particularly the need for IC [71], while a LOE1 dose-response study still in abstract format confirms a more significant clinical benefit of the 200U dose as opposed to the 50U and 100U doses of onabotulinumtoxinA in patients with SCI [72].

Effect on quality of life (QOL): Both preparations have been shown to improve patients' QOL in RCTs. A single injection of 500 units abobotulinumtoxinA, diluted in 25 ml saline and injected into 25 injection sites, was compared to placebo in 31 patients with NDO-associated incontinence. At 26 weeks follow-up, patients in the abobotulinumtoxinA group had a more significant change in clinical QOL and urodynamic parameters, and anticholinergic use [42]. Similarly, 200U and 300U onabotulinumtoxinA administered into 30 injection sites improved QOL scores significantly more than placebo in all LOE1 studies [43, 44, 49, 73]. The I-QOL questionnaire has been used in the majority of LOE1 studies.

Administration technique: A large variance in the number and volume of injections has been described. However, in the majority of studies onabotulinumtoxinA was given at 30 injection sites (range 10–40) at a dilution of 10U/1ml per injection site (total volume of 30 ml, range 3–30 ml), as described in the original publication by Schurch et al. [74]. The same dilution and number of injection sites was used when administering either 300U or 200U onabotulinumA in the regulatory trials. Administration of abobotulinumtoxinA is less standardized (10–30 injection sites, total volume of 5–30 ml), but a total 30 ml given at 30 injection sites appears to be the most common again [39]. The effect of these variables on outcomes has little been studied. In a LOE3 study, Karsenty et al. compared 10 versus 30 injection sites (300 U Botox) [75]. They reported no significant difference in efficacy measured by number of incontinence episodes or cystometric capacity, but a significant reduction in post-procedure pain was noted in the 10 injection-sites group.

The majority of studies reported injections into the detrusor muscle sparing the trigone, as in the original technique [74]. There is, however, LOE2 evidence to suggest that trigonal injections may produce better continence rates than detrusor injections alone; urodynamic parameters were affected to a lesser extent, as only reflex volume was improved more significantly in patients who received trigonal injections [47].

Alternative delivery techniques are being investigated in preclinical studies and include intravesical instillation of BoNT/A encapsulated in liposomes [76] or via electromotive drug administration (EMDA) [77]. The latter method has also been tested in a pilot LOE3-4 study in children with myelomeningocele and significant improvements were reported in maximum cystometric capacity, detrusor pressure, urinary incontinence, vesicoureteric reflux and even fecal incontinence [78], but these conclusions need to be confirmed in controlled trials.

Safety: The treatment appears to be overall safe in currently used doses and techniques. The most common adverse event is the significant increase in postvoid residual in patients not using CIC prior to treatment. In onabotulinumA placebo-controlled trials, 12-22%, 30-47%, and 42-49% of patients in the placebo, 200U, and 300U groups, respectively, initiated CIC post-treatment. Although earlier studies had reported a reduced incidence of UTIs in NDO patients treated with BoNT/A [55, 79, 80], recent large RCTs suggest a higher incidence of UTIs in those treated with onabotulinumtoxinA as opposed to placebo-treated patients [43, 49]. This might be associated with the increased rate of de novo CIC in the Botox-treated population. Prospective, long-term trials are needed to clarify this apparent discrepancy.

Haematuria, constipation and flu-like symptoms have also been described [39, 43, 49], while inclusion of trigonal injections does not appear to produce vesicoureteral reflux (LOE2-3) [47, 81, 82]. A study in SCI male patients found a post-treatment decrease in the volume of ejaculate accompanied by improvements in semen quality, sperm mobility and vitality, as well as semen culture [83]. Further research is needed to confirm these results and explore whether they are due to a local re-organisation of autonomic function which also affects the reproductive system.

The most serious adverse event is generalised paraparesis/ fatigue, which has been described in 0.005% of patients receiving onabotulinumtoxinA and in 0.026% of patients receiving abobotulinumtoxinA [39]. The effect resolves spontaneously after 4-6 weeks and appears to be dose-related, with

most cases reported in those patients injected with 750-1000U abobotulinumtoxinA or 300U onabotulinumtoxinA [49, 53, 84].

As BoNT/A studies in skeletal muscles have identified autonomic, histological and other secondary effects [85, 86], further investigation is needed on safety issues, especially after repeat injections [38]. A single study to-date prospectively examined distant effects post-BoNT/A bladder injection using single-fibre EMG; one-third of the patients had findings of neuromuscular jitter post-treatment, but there was no placebo arm or pre-treatment data for comparison [87] (LOE3). Other studies produced histological evidence of reduced or no additional fibrosis after one or multiple injections, including in children [88-90].

Future research should highlight the gaps in our knowledge of long-term treatment, overall safety and different techniques of application.

5. Potential Intravesical Treatments with Cannabinoid Modulators

While orally administered cannabinoid modulators appear to improve neurogenic OAB symptoms, particularly in MS patients [91], the identification of functional cannabinoid receptors (CBs) in the human bladder urothelium [92, 93] has intensified research in intravesical cannabinoid agonists for bladder dysfunctions. To date, only preclinical studies exist, and in non-neurogenic bladder models. Cannabinor, a selective CB2 receptor agonist, was found to affect bladder function in both normal rats as well as rats with bladder outlet obstruction, by increasing intervals between bladder contractions as well as flow pressures [94, 95]. In rats, but not humans, a Cannabis sativa extract enriched in cannabidiol drug substance reduced cholinergic-mediated bladder contractility in vitro [96]. Intravesical application of a non-selective cannabinoid agonist suppressed afferent activity via activation of CB1 receptors [97]. Finally, intravesical administration of the fatty acid amide hydrolase, the enzyme responsible for the degradation of the endocannabinoid anandamide, altered afferent-related urodynamic parameters in normal rats [98]. In a single study using a spinal cord injury model, systemic administration of a CB2-selective agonist could improve spontaneous voiding, possibly via a positive effect on inflammatory responses in the spinal cord [99].

c) Drugs for sphincter deficiency

Several drugs, including alpha-adrenergic agonists, estrogens, beta-adrenergic agonists and tricyclic antidepressants, and duloxetine have been used in an effort to increase outlet resistance. No adequately designed controlled studies of any of these drugs for treating neurogenic sphincter deficiency have been published.

2. DRUGS FOR TREATING VOIDING DYSFUNCTION

a) Alpha-adrenergic antagonists

Alpha-adrenoceptors are present in the bladder base, posterior urethra and prostate. Alpha-blockers have been already reported to be useful in neurogenic bladder by decreasing urethral resistance during voiding. Tamsulosin has been shown to improve bladder storage and emptying in MS and SCI [100]. Abrams et al. [101] evaluated the efficacy and safety of tamsulosin in patients with neurogenic lower urinary tract dysfunction secondary to suprasacral spinal cord lesions in a 4-week randomized controlled trial (RCT) followed by a 1-year, open label, long-term study. A total of 263 patients were randomized to 4-week double-blind therapy with placebo, or 0.4 or 0.8 mg tamsulosin once daily. The primary efficacy parameter was maximum urethral pressure (MUP). In the long-term study, but not in the RCT trial, there was a statistically significant mean decrease in MUP from baseline to end point. In the long-term study tamsulosin also improved several cystometry parameters related to bladder storage and emptying, e.g. decreased maximum urethral closure pressure. It also increased mean voided volume based on the micturition diary. There was statistically significant improvement for the International Prostate Symptom Score Quality of Life. Both doses were effective and well tolerated. (LOE1).

b) Botulinum toxin

Sphincter injections were historically the first application of BoNT/A in the lower urinary tract [102], but there is still inadequate evidence to support its use. The most commonly injected volume is 4ml of either the onabotulinumtoxinA or the abobotulinumtoxinA preparations. Usually 100U onabotulinumtoxinA or 150U abobotulinumtoxinA have been delivered transperineally or transurethrally [103, 104]. There exists no direct comparison of injection techniques; there is LOE4 to suggest the two delivery approaches are equally effective [105].

In a LOE1 study, the effects on DSD of botulinum toxin versus placebo was studied in 86 multiple sclerosis (MS) patients [106]. The study employed a single transperineal injection of onabotulinumtoxinA, 100 U in 4 ml normal saline, or placebo, into the striated sphincter with EMG guidance. The primary endpoint was post void residual volume at 30 days. The secondary endpoints included voiding and urodynamic variables. OnabotulinumtoxinA failed to decrease post-void residual volume in this group of MS patients, although it increased voided volume and reduced pre-voiding and maximum detrusor pressures. These findings differ from those in patients with spinal cord injury and may be due to lower detrusor pressures in MS patients. A small LOE1 study showed a superior effect of onabotulinumtoxinA over lidocaine 0.5% injected in the urethral sphincter in MS patients [104]. In MS patients

there is also LOE3 to suggest that a combination of detrusor and sphincter injections may facilitate bladder emptying [105]. In children with NDO and DSD due to myelomeningocele there is LOE1-2 to suggest that sphincter injections additional to the detrusor injections accomplish significant improvements in post-void residuals, as well as more significant benefits in urinary incontinence, constipation, vesicoureteral reflux and creatinine levels [107].

c) Cholinomimetics

In general, bethanechol chloride seems to be of limited benefit for detrusor areflexia and for elevated residual urine volume. Elevated residual volume is often due to sphincter dyssynergia. It would be inappropriate potentially to increase detrusor pressure when concurrent DSD exists.

Conclusions

- **Antimuscarinic drugs improve storage function (LOE 1).**
- **Antimuscarinic drugs have a high incidence of side effects (dry mouth, constipation, urinary retention, etc.). Tolterodine, propiverine, trospium and controlled-release oxybutynin have significantly less side effects compared to immediate-release oxybutynin (LOE 1).**
- **High doses of oxybutynin have been used to treat patients with neurogenic bladder dysfunction (LOE 3).**
- **Intravesical instillation of oxybutynin may be an alternative route of administration (LOE 4).**
- **Intravesical instillation of capsaicin/resiniferatoxin has been reported to improve spinal reflex incontinence. Resiniferatoxin is preferable (LOE 3). Recent results supporting their use are lacking.**
- **Botulinum neurotoxin A (BoNT/A) injection into the detrusor muscle improves clinical and urodynamic parameters (LOE1), and has been approved as second-line treatment for urinary incontinence associated with neurogenic detrusor overactivity in patients with inadequate response to or intolerance of an anticholinergic.**
- **Repeat intradetrusor injections of BoNT/A provide sustained clinical benefits (LOE3)**
- **Treatment with intradetrusor BoNT/A is considered overall safe, with increased post-void residual and need for post-treatment CIC being the most common adverse event (LOE1).**
- **Long-term alpha adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1).**
- **BoNT/A is probably safe and effective for the treatment of DSD in spinal cord injury patients (LOE2). However, on the basis of one LOE1 study, BoNT/A does not provide significant benefit for the treatment of DSD in MS patients.**
- **There is no adequately designed controlled study of any drug for neurogenic sphincter deficiency.**

Recommendations

- **Antimuscarinic drugs should be recommended for the treatment of neurogenic detrusor overactivity (A). Titration of the dosage of these drugs individually should be done to optimal balance of therapeutic and adverse effects. If one drug is not tolerated, another drug should be tried (C/D).**
- **BoNT/A should be offered as a treatment option for incontinence associated with neurogenic detrusor overactivity (A).**
- **Further research is needed on long-term outcomes and safety, administration techniques, the bio-equivalence of the various preparations, the concomitant use of anticholinergic drugs, mechanisms of action, and wider effects (A).**
- **Vanilloid intravesical therapy still remains experimental and therefore is not recommended except within clinical trials (C/D).**
- **For decreasing outlet resistance in neurogenic bladder a-adrenergic antagonists may be used (B/C).**
- **BoNT/A may be considered for DSD in spinal cord injury patients (B).**
- **For neurogenic sphincter deficiency, no effective drugs are available up to now; further research is needed (D).**
- **For detrusor areflexia no effective drugs are available up to now; further research is needed .**

V. ELECTROSTIMULATION

1. ELECTRICAL NEUROMODULATION

In the last decade, sacral nerve neuromodulation (discussed in the Surgical Treatment section of this chapter) has been established as a treatment option for patients with OAB. The success with sacral neuromodulation has increased the interest in other neuromodulation techniques. Additional methods include; (a) anogenital stimulation (b) pudendal nerve stimulation, (c) dorsal genital nerve stimulation (d) percutaneous tibial nerve stimulation, (e) magnetic stimulation and (f) deep brain stimulation. It is not really known how neuromodulation works, but there is evidence that sites of action are spinal and supraspinal [1]. Firstly the non-surgical ways of neuromodulation will be presented, followed by the surgical techniques.

a) Anogenital Stimulation

This has been applied in children with OAB complaints. Gladh et al. found a response for anogenital stimulation in 53% of the children [2]. Trsinar and Kralj used an endoanal electrode and reported a complete or partial response to the treatment in 75% of the patients [3]. In a control group of patients who had the endoanal electrode introduced but not activated, no patient had the symptoms resolved completely. No recent publications could be found.

b) Pudendal Nerve Stimulation

Pudendal nerve stimulation and electrode positioning can be carried out under neurophysiological monitoring (using a St. Mark's electrode) in order to guide the electrode in Alcock's Canal as close as possible to the pudendal nerve [4]. Electrode implantation can also be carried out by a rear approach under local anesthesia according to the method described by the same team [5, 6]. On the other hand, an anatomical study demonstrated that the technique for implanting electrodes at the pudendal level may carry some risk [7].

Direct pudendal nerve stimulation has beneficial effects on numerous pelvic floor function impairments such as urinary and/or fecal incontinence, retention, and constipation. In preceding literature the implant technique required a fairly complex and invasive procedure, although recent advances with percutaneous placement of the lead through an introducer have made the procedure much less invasive. Electrical stimulation of pudendal nerve afferents can inhibit bladder contractions in patients with SCI, and bladder capacity can be increased [8] (LOE3). Implants such as the InterStim system have made this treatment modality commercially available (see sacral nerve stimulation). Common to these implantable systems is that they use continuous stimulation. Detrusor inhibition is in principal only necessary during an involuntary contraction and, thus, stimulation could be turned off between contractions (i.e. conditional stimulation) [9]. Such a stimulation scheme could have a number of advantages. Power consumption may be decreased and, thus, extend battery lifetime. Furthermore, continuous stimulation of a reflex may lead to habituation, which would be minimized or prevented by conditional stimulation. Hansen et al. [10] examined the effect of the automatic, event driven electrical stimulation of pudendal nerve afferents on bladder capacity in patients with SCI. The study included two women and 14 men older than 18 years with NDO, bladder capacity below 500 ml and complete or incomplete suprasacral SCI. Detrusor pressure (Pdet) was recorded during natural bladder filling. In a similar subsequent recording Pdet was used to trigger electrical stimulation when pressure exceeded 10 cm H2O. Of the 16 patients enrolled in this study, 13 had increased bladder capacity and reduced storage pressure decrease achieved by event-driven electrical stimulation. During stimulated filling, Pdet never exceeded 55 cm H2O. An average bladder capacity increase of 53% was achieved (LOE 3). Ohlson et al. treated eight patients with NDO in whom vaginal/rectal stimulation failed, with acute pudendal nerve stimulation. Five achieved a decrease in urinary frequency and four had an increase in cystometric capacity [11].

Spinelli et al. [5] performed a staged procedure similar to that of sacral neuromodulation (SNM) to place a tined lead near the pudendal nerve, using neurophysiological guidance. They named this approach chronic pudendal nerve stimulation (CPNS). Fifteen neurogenic patients (eight male, seven female) with urgency incontinence underwent CPNS. All patients had complete neurophysiological and urodynamic evaluation at baseline and follow-up and were asked to complete a voiding and bowel diary for 7 days. During screening, the average number of incontinent episodes per day decreased from 7+/-3.3 to 2.6+/-3.3 ($P<0.02$, paired t-test). Eight patients became continent, two improved by more than 88% (from 9 to 1 daily incontinence episodes) and two patients reduced the number of incontinence episodes by 50%. The implantable pulse generator (IPG) was subsequently implanted in those 12 patients. Three patients without improvement did not continue to second stage. In implanted patients with 6 months follow-up, urodynamic evaluation showed an objective improvement in the maximum cystometric capacity which increased from 153.3+/-49.9 to 331.4+/-110.7 ml ($P<0.01$, paired t-test). The maximum pressure decreased from 66+/-24.3 to 36.8+/-35.9 cmH2O ($P=0.059$, paired t-test). Eight patients reported significant improvement in bowel function (LOE3).

c) Dorsal Genital Nerve (DGN) stimulation

DGN stimulation can be continuous or conditional. Goldman et al. used continuous stimulation for one week [12]. They found a 55% increase in cystometric capacity. In 47% there was >50% reduction in incontinence episodes, and in 81% there was >50% reduction in number of urgency events. Increases in cystometric capacity vary significantly between studies using continuous stimulation (range 11-177%) and also conditional stimulation (range 37-144%). Horvath et al. and Oppisso et al. showed that DO was suppressed conditionally, with a subsequent increase in bladder volume and postponement of incontinence [13, 14]. Martens et al. found with conditional stimulation that increase in stimulation current results in a more pronounced detrusor inhibition [15]. Besides DO suppression, increases of the pressure at the bladder neck and the urethral sphincter contribute to continence [16]. In general, patients tolerate conditional stimulation well and they adapt to the sensation in long-term use [17]. Stimulation effectively suppresses urgency and decreases urgency episodes. Suppression of urgency

during stimulation might contribute to tolerance of stimulation. This might enable stimulation at higher current to increase effectiveness when stimulation is applied conditionally.

d) Posterior tibial nerve stimulation

Percutaneous posterior tibial nerve stimulation (PTNS) was described 20 years ago as a minimally invasive treatment for urge incontinence due to neurogenic detrusor overactivity (NDO) in spinal cord injury (SCI) patients. Interestingly, the location where the tibial nerve is stimulated is in the same area as the Sanyinjiao (SP6) point used in Chinese acupuncture to treat pelvic floor organ dysfunctions. The PTN is derived from the L4-S3 nerve roots and therefore shares common roots with those serving bladder functions. SCI and Parkinson patients with neurogenic DO have been treated with PTNS. PTN seems to increase cystometric bladder capacity and bladder volume at which DO and associated leakage occurs [18, 19] (LOE3). Gobbit et al. looked at the effect in 21 MS patients. Eighty-nine percent of patients reported a treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King's Health QoL questionnaire [20]. Kabay et al. looked at the clinical and urodynamic effects in MS and Parkinson's disease [21, 22]. They found significant clinical and urodynamic improvements, although it was impossible to completely suppress DO. De Seze et al. looked at transcutaneous PTNS in 70 MS patients [23]. With daily stimulation sessions, they showed clinical improvement in urgency and frequency in more than 80% of patients at three months. They also observed an initial acute cystometric response in > 50% of the patients without correlation with clinical efficiency. There still is debate about the possibilities to really influence voiding behavior via the posterior tibial nerve [24]. PTNS is a stimulation technique that allows for sham comparison. It should therefore be tested in this fashion.

e) Repetitive transcranial magnetic stimulation

Repetitive transcranial magnetic stimulation (rTMS) of the motor cortex induces a long-lasting modulation of spinal cord excitability [25]. Thus, it represents a potentially useful tool for the treatment of neurogenic urinary disturbances. Centonze et al. [26] investigated the effects of high frequency (5 Hz) excitatory rTMS over the motor cortex on LUT dysfunction in a population of 10 MS patients complaining of urinary symptoms. All but one of the patients reported an improvement of voiding phase LUT symptoms and a significant reduction of post void residual volume. In patients with pure detrusor underactivity, there was increase of PdetQmax and Qmax. In patients with DSD, on the other hand, rTMS produced negligible effects, although the observation of a reduction of PdetQmax in this context seems to suggest a better relaxation of the urethral sphincter (LOE3). Brusa et al. also observed positive effects lasting 2 weeks after rTMS in 8 patients [27].

f) Deep brain stimulation

1. Subthalamic Nucleus Deep Brain Stimulation (ST-MN-DBS)

A large proportion of patients suffering from Parkinson's disease present with urinary dysfunction including urgency, increased frequency or incontinence [28]. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been established as a surgical treatment of motor symptoms in Parkinson's disease patients [29]. However, data from experimental urodynamic measures in men [30] and animal models [31] have also demonstrated a significant influence of STN-DBS on urinary bladder function. In these studies, the main effect of STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity. Herzog et al. investigated the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. Using PET to measure changes in regional cerebral blood flow (rCBF), 11 patients with bilateral STN-DBS were studied during urodynamic bladder filling in STN-DBS ON and OFF condition. A filled bladder led to a significant increase of rCBF in the anterior cingulate cortex, which was further enhanced during STN-DBS OFF. A significant interaction between bladder state and STN-DBS was observed in lateral frontal cortex with increased rCBF when the bladder was filled during STN-DBS OFF [32, 33] (LOE3).

2. Thalamic Deep Brain Stimulation

The precise mechanisms underlying cerebral regulation of lower urinary tract function are still poorly understood. Essential tremor (ET) is not known to induce lower urinary tract symptoms (LUTS) or neuropathological changes in the thalamus. Consequently, DBS in patients with ET offers the unique opportunity to investigate the role of the thalamic ventral intermediate nucleus (VIM) nucleus in lower urinary tract function. Kessler at al. [34] evaluated the effect of thalamic DBS on urodynamic parameters in patients with ET. Seven patients were examined (two females, five males) with ET 15–85 months after implantation of DBS leads into the VIM. They compared urodynamic parameters during thalamic DBS (ON state) and 30 min after turning the stimulator off (OFF state). In the ON compared with the OFF state, there was a significant decrease in bladder volume at first desire to void (median, 218 ml vs. 365 ml, $p = 0.031$), at strong desire to void (median, 305 ml vs. 435 ml, $p = 0.031$), and at maximum cystometric capacity (median, 345 ml vs. 460 ml, $p = 0.016$). No significant differences between the ON and OFF state were detected for changes in detrusor pressure during filling cystometry, bladder compliance, maximum detrusor pressure, detrusor pressure at maximum flow rate, maximum flow rate, voided volume, and postvoid residual (LOE3).

Conclusions

- **Electrical neuromodulation is not first line treatment for neurogenic DO. There are some limited reports showing that it may be beneficial (LOE 3).**
- **Automatic, event-driven electrical stimulation in the treatment of neurogenic DO is feasible (LOE 3).**
- **Chronic pudendal nerve stimulation is feasible. Neurophysiological guidance seems to be mandatory to place the lead near the pudendal nerve (LOE3).**
- **Percutaneous Tibial Nerve Stimulation gives improved clinical and urodynamic parameters. (LOE3), but its role is not established.**
- **Enhancing corticospinal tract excitability by rTMS might be useful to ameliorate detrusor contraction and/or urethral sphincter relaxation in MS patients with bladder dysfunction (LOE3).**
- **Thalamic deep brain stimulation resulted in an earlier desire to void and decreased bladder capacity, suggesting a regulatory role of the thalamus in lower urinary tract function (LOE3).**
- **STN-DBS appeared to tend to normalization of urodynamic parameters in the storage phase, with a delayed first desire to void and an increased bladder capacity (LOE3).**

Recommendations

- **If pharmacotherapy fails to relax the hyperreflexic detrusor, electrical neuromodulation may be optional in patients with neurogenic DO (C/D).**
- **Although the setup for conditional, event-driven electrical stimulation is not suitable in a clinical setting, the treatment modality is promising and it warrants further investigation (D).**
- **Further studies on chronic pudendal nerve stimulation must be carried out to identify the best stimulation parameters and to verify the long term results (D).**
- **The thalamus may be a promising target for the development of new therapies for lower urinary tract dysfunction. Further investigation on this matter is needed before its potential role can be elaborated.**

2. ELECTRICAL STIMULATION OF THE PELVIC FLOOR MUSCULATURE

The aim of electrical stimulation in patients with neurogenic urinary stress incontinence is to improve key functions, namely the strength and/or timing of the pelvic floor muscle contraction. Electrical stimulation is provided nowadays mostly by portable battery powered stimulation, offering a wide combination of wave forms, frequencies, intensities, electrode placements etc.

In patients with incomplete denervation of the pelvic floor muscle and of the striated sphincter, electrical stimulation via anal or vaginal plugs performed over months, may improve pelvic floor function, and may thus improve incontinence. The incompleteness of the lesion should be as such that the patient is able to contract voluntary the pelvic floor to some extent, even if such contraction is weak.

Conclusions

- **There is no study published which deals with electrical stimulation via anal or vaginal plugs could be able to improve the strength of pelvic floor musculature (LOE 4).**

Recommendations

- **In patients with incomplete denervation and some voluntary contraction of the pelvic floor muscle and the striated sphincter, electrical stimulation may be an option to improve pelvic floor function, thus improve incontinence (C/D).**

3. INTRAVESICAL ELECTRICAL STIMULATION (IVES)

The technique involves a catheter with a stimulation electrode, introduced into the bladder and connected to the stimulator. Saline (0.9 %) is used as the current leading medium within the bladder. The neutral electrode is attached to the skin in an area with preserved sensation, usually in the lower upper abdomen. The afferent stimuli induced by IVES travel along afferent pathways from the LUT to the corresponding CNS structures. This “vegetative afferention” results in sensation of bladder filling/urge to void, with subsequent enhancement of active contractions, and possibly also in voluntary control over the detrusor. Feedback training is mediated by enabling the patient to observe the change of the detrusor pressure on a water manometer, which enables the patient to notice when a detrusor contraction takes place. This also facilitates voluntary control.

Intravesical electrical stimulation of the bladder (IVES) is still not established as a therapy for patients with neurogenic detrusor dysfunction. IVES may help to verify function of afferent pathways, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, proved by the evaluation of viscerosensory cortical evoked potentials. Intravesical electrotherapy may be able to improve neurogenic bladder dysfunction. Studies about IVES were reviewed in previous consultations [35].

Conclusions

- **Basic research during the last decade supports the underlying working concept of IVES (LOE 3).**

- **The results reported in the literature are controversial, mainly because of varied inclusion and exclusion criteria (LOE 3).**
- **In the only sham-controlled study the treatment period was short and the inclusion and exclusion criteria were not fully defined (LOE 3).**

Recommendations

- **Intravesical electrotherapy may improve neurogenic bladder dysfunction, inducing bladder sensation and the urge to void (B/C).**
- **IVES is the only available option to induce/ improve bladder sensation and to enhance the micturition reflex in patients with incomplete central or peripheral nerve damage, but corroborating controlled evidence is needed (B).**
- **Selection of patients is crucial and IVES should be applied only if afferent fibers between the bladder and the cortex are still intact and if the detrusor muscle is still able to contract (B).**
- **The ideal indication is the neurogenic hyposensitive and hypocontractile detrusor (C).**

VI. SURGICAL TREATMENT OF URINARY INCONTINENCE

1. SACRAL NEUROMODULATION

Two indications for neuromodulation are clearly valid in urology: overactivity/ urgency urinary incontinence and chronic urinary retention (aside from vesicosphincteric dyssynergia) [1], as discussed elsewhere in the consultation. This section focuses on the possible application of sacral neuromodulation in patients with neurological bladder dysfunction. The literature survey was undertaken with the key words: neurogenic bladder; spinal cord injury; spina bifida; meningomyelocoele; multiple sclerosis, sacral neuromodulation.

a) Hypotheses on the modes of action of neuromodulation

The first effects of electricity on the bladder were reported during electro stimulation treatment of pelvic floor muscles (with the aid of electrodes situated in the anus, the vagina, on the penis...) during urinary incontinence reeducation [2-5]. Inhibition of bladder contractions by electrostimulation was seen. Tanagho and Schmidt, the pioneers of neuromodulation, attributed the benefits of neuromodulation in urinary incontinence to a hypertrophy of the pelvic muscles, allowing better control [6]. Voluntary contractions of the pelvic floor muscles can cause reflex relaxation of the bladder. However, the most widely held hypothesis currently is that neuromodulation allows a restoration of normal vesical reflexes [7-9] (LOE4). This hypothesis explains that the stimulation can inhibit the guarding reflex pathway and restore normal urination or turn off supraspinally mediated overactivity by blocking ascending sensory pathways. The role of cortico-subcortical structures was recently emphasized in studies of patients with incontinence [10, 11] (LOE4) or retention [12] (LOE4). Somatic afferents as the vectors for neuromodulation mechanism of action is supported by the observation that visceral nerve fibers are not activated by the parameters normally used [13] (LOE4). Despite data obtained in animals [14] (LOE4), it seems that neuromodulation cannot be effective in patients with a non functional peripheral nerve circuit.

b) Treatment of neurogenic detrusor overactivity incontinence

There is little in the literature concerning sacral neuromodulation (SNM) in this specific indication. Many studies recorded results for incontinence and for retention at the same time, without always separating the results. Since the technique's first stages, Vodusek [5, 6] (LOE4) reported that non-muscular electrical stimulation of the sacral somatic afferents can induce bladder inhibition in patients who present with DO secondary to a medullary lesion, be it due to trauma or to multiple sclerosis (MS).

Two points must be kept in mind when treating patients with neurological bladder:

- The disappearance of wettings between catheterizations can be considered a success by itself in patients using IC. In contrast, in able-bodied patients, treating retention with IC is most often considered a failure.
- On the other hand (contrasting, for example with botulinum toxin injections), neuromodulation does not systematically require the use of IC. Furthermore, reversibility of neuromodulation is a strong point that must be considered when devising a therapeutic plan.

The main published series are summarized in T**able 3**. Author definitions for neurological pathology differed widely: some authors considered a history of pelvic surgery as a possible etiology while others included only patients with medullary neurological lesions. Despite this, several points considering the neurological etiology of the bladder dysfunction can be discussed;

- MS is not a contra-indication for neuromodulation [10, 15, 16] (LOE3-4). However, it seems important to propose this treatment only in patients who present with a stabilized form of multiple sclerosis. In addition, patients must be clearly informed that the results of neuromodulation may be altered by the evolution of their underlying illness.
- Patients with incomplete medullary lesions, whether of traumatic or other origins, may benefit from neuromodulation [10, 17-22] (LOE3-4). On the other hand, all authors agree on excluding

Table 3: Results of sacral neuromodulation (test and implantation) in neurogenic patients.

patients with complete medullary lesions. Clinical data, especially from the Hohenfellner series [19] (LOE3), support among others those reported by Schurch et al. in 2003 [23] (LOE4). These authors published a study in which they recorded external anal sphincter (EAS) electromyographic activity caused by stimulation of the S3 sacral root during a percutaneous needle evaluation (PNE) test in three patients who presented with neurogenic DO and DSD secondary to a complete traumatic medullary lesion. They describe a reflex response with early and late latency in the three patients. They also demonstrated that the EAS contraction observed during the PNE represented an indirect motor response mediated by the afferent nerves towards the spinal cord. Despite the recording of an EAS motor response in the three patients, they did not obtain any urodynamic or clinical benefit. This suggests the participation of supraspinal neuronal centers— presumptively a spino-bulbar spinal pathway—in the SNM mode of action. However, these data are contradicted by an experimental study using bilateral neuromodulation in the cat [24] (LOE4).

- Guys et al. [25] demonstrated significant but limited urodynamic differences in children (LOE3). However, the clinical translation of these modifications has not been reported. It must be emphasized that, in the absence of electrodes adapted to paediatric sizes, the study was carried out without the usual percutaneous evaluation phase.

- Encouraging short term results in neurological bladder dysfunction do not necessarily translate into long-term efficacy [19] (LOE2). Despite a positive test in about half of the patients tested, long term (54 months) results were poor in almost all patients (1/12 had neuromodulation efficacy).

- Sievert et al. [26] performed acute bilateral sacral S3 nerve stimulation in 10 patients with complete spinal cord lesions (SCLs) during the spinal shock phase, with six patients as controls. After a mean follow-up of 26 months, the cystometric capacity increased and IDC were abolished in the stimulation group. Further studies should look into this technique and question the ideas about the working mechanism in sacral nerve stimulation since afferent stimulation effects are unlikely in complete SCI.

- One of the largest and latest series is from Chaabane et al. [27]. They looked at the results of PNE testing and SNM implants with a mean follow-up of 4.3 years in 62 patients (34 with DO, 28 with chronic urinary retention). DSD was present in nine cases. 41 patients (66.1%) had more than 50% improvement on urodynamic evaluation and bladder diary with PNE, and 37 were implanted. At follow-up results remained similar to the evaluation phase in 28 cases (75.7%). In six cases (16.2%), clinical response had been lost; in these six cases, neuromodulation failed on average 12.0 months after implantation.

Scheepens et al. [20] reported two prognostic factors for poor response (the study population was six incomplete medullary injuries, five patients with cauda equina syndrome, six with multiple sclerosis, and one with myelomeningocele) (LOE3): duration of the symptoms (more than seven months in this study) and the existence of a neurological cause for bladder dysfunction. Neurological patients with a very localized and incomplete nervous condition were the most successful. Patients with herniated disc surgery had a greater chance of good response. Patients with complete medullary or large sacral lesions were poor neuromodulation candidates.

Clinical results of neuromodulation do not necessarily correlate to urodynamic results. Bosch indicated in his series [17] that almost half of the patients considered to have had a good outcome clinically in reality retained some overactivity. One publication reported correspondence between urodynamic test data and clinical data [10] (LOE4). In 2001 Chartier-Kastler [28] et al. published the results of a prospective study concerning the evolution of urodynamic parameters during the acute phase of the PNE test in 14 patients with neurogenic DO. The authors concluded that the acute phase of PNE was accompanied by a significant change in urodynamic parameters in more than 2/3 of the patients, and that this should be a possible means for selecting patients.

c) Sacral neuromodulation for urinary retention in neurological bladder dysfunction

The only study which reported specific results for neurogenic urinary retention is from Hohenfellner et al. [19] (LOE3), reporting on 11 patients. Of these patients, three were implanted and there were temporarily satisfactory results in only two. Thus, it seems that neuromodulation has a marginal place in retention patients with neurological bladder. Patients need to be clearly informed of the high risk of failure. In this respect the bladder contractility test can be helpful in order to predict a successful outcome of sacral nerve stimulation in acontractile neurogenic bladders [29]. It is also necessary to be especially prudent in patients with cauda equina problems, who may have the illusion of recovering urination, but actually may be enhancing abdominal straining to evacuate their bladder. In reflex incontinence, patients with complete spinal cord or cauda equina lesions are poor candidates (LOE4). While a few studies have reported on SNM in specific contexts [30-33], patients should be informed that IC is the first-line therapeutic option for neurogenic urinary retention.

Recommendations

- **Sacral neuromodulation can have an inhibitory effect on neurogenic DO (C).**

- **While sacral neuromodulation has a place in the care of neurological urinary incontinence or neurological urinary retention, the proportion of patients whose condition is improved is much less than in non-neurological pathologies (B).**
- **Indications for sacral neuromodulation in the care of DSD in neurological urinary dysfunction are still not established (D).**

2. DENERVATION PROCEDURES FOR TREATING REFLEX URINARY INCONTINENCE DUE TO DETRUSOR OVERACTIVITY

a) Peripheral bladder denervation

Various techniques of peripheral bladder denervation, such as prolonged hydrodistension or bladder trans-section, are no longer used. Some authors have reported transient improvement in certain patients after prolonged hydrodistension, but DO recurs rapidly and the procedure is not straightforward. There are no reports for patients presenting specifically with neurogenic DO [34]. Bladder transsection was briefly popular at the end of the 70s [35-37]. It involved complete section of the bladder wall from one ureteric orifice to the other. The technique was indicated for urgency incontinence. However, a lack of anatomical and physiological information to support the mechanisms of efficacy of the procedure, and a lack of reproducible results from the initial series, explains why it is no longer used.

Another bladder denervation technique was developed by Ingelman-Sundberg [38, 39], by resection of the inferior hypogastric plexus in contact with the bladder through an inverted U-shaped vaginal incision, dissecting the bladder laterally and posteriorly, as widely as possible. In the most recent paper [39], the authors report up to 54% recovery over a mean follow-up of about three years. Each published series is from the same group, is retrospective and reports only a small sample size (LOE4). It has only occasionally been used in neurogenic DO.

b) Isolated rhizotomy of ventral and/or dorsal sacral roots

Historically, attempts at sacral root surgery first focused on cutting the motor (ventral) sacral roots. It was soon clear that this method failed within six months. With a different objective, Brindley [40] developed a technique involving stimulation of ventral sacral roots to obtain controlled and complete bladder voiding in cases of SCI. He realised that patients only acquired continence if the stimuli causing reflex bladder contraction could be blocked [41]. Early techniques consisted in selective destruction of the dorsal sacral roots that evoke detrusor contractions. These selective rhizotomies did not, however, give the best results. Only after complete de-afferentation of the sacral micturition centre by intradural rhizotomy were better results obtained [42-45] (LOE2-3).

The technique of “selective” dorsal sacral rhizotomy has been studied more extensively. It involves making an extra-dural approach to the sacral roots (S2-5), isolating and stimulating the dorsal (sensory) contingent whilst monitoring changes in urodynamic pressure within the bladder in order to cut only those fibres responsible for overactivity. To retain reflex erection, S2 must be preserved, at least on one side. This treatment may be proposed for patients with neurogenic DO, and also those with urgency incontinence. The literature records only case series without control groups. Preliminary results were promising but were based on a small number of cases with short follow-up times [46-49] (LOE4). The outcome seems to deteriorate over time. Opsomer et al. [50] reported deterioration after one year for all treated patients (n=8)(LOE4). Torrens, one of the first to use the technique, was led to re-evaluate his long-term results [51]. The most recent article by Lucas et al. [52] concerning 22 patients (LOE3), also reported a significant, but less marked, deterioration at four years. At the mean follow-up of 4 years, 39% of patients retained a urodynamically stable bladder with satisfactory clinical response. The authors ascribe these improved results to a more extensive rhizotomy. However, it should be noted that there was a marked heterogeneity of patients in this series, three out of the eight, considered to be “successes”, were IDC patients with leakage due to DO.

Mertens et al. [53] applied a technique previously used for limb spasticity, namely microsurgical DREZotomy, the aim of which is to destroy the dorsal root entry zone (DREZ). This zone, first defined in 1972 by Sindou [54], is a functional anatomical entity that groups together the proximal portion of the dorsal root, the medial portion of the dorso-lateral tract and the superficial layers of the dorsal horn. The technique involves making a micro-surgical lesion (by micro-coagulation) on the ventro-lateral portion of the entry zone, near the apex of the dorsal zone. The effect of DREZotomy is to selectively block nociceptive afferents, and their relays, and myotatic afferents. The benefit of the limited lesion is to avoid complete abolition of tactile and proprioceptive sensitivity and to prevent the development of deafferentation phenomena. To treat neurogenic DO, the lesion must be made on both sides from S2 to S3, or even S4. The results from the first series concerned 38 patients treated for incapacitating lower limb spasticity, treated by extended DREZotomy from L2 to S1. 58% of these patients were permanently catheterized. At six months, DO had disappeared in 82%, with 63% having significantly improved bladder capacity. At 18 months post-surgery, leakage had disappeared in 89% of cases. In the last 8 years, no publications on DREZotomy for neurogenic LUT disorders were found.

Hohenfellner [55] following Brindley’s experience,

proposed “neurogenic bladder augmentation”. This involved completely destroying the ventral and dorsal sacral roots, possibly followed by continent cystotomy and simplified urinary catheterization. The author reported his experience with eight patients retrospectively (LOE3). After surgery in all patients, bladder capacity increased from about 177 ml to 670 ml, with complete disappearance of detrusor overactivity. No updates have been published since 2001 on this technique.

Percutaneous sacral root block

Sacral root block is an old technique, since Dogliotti [56] proposed it as early as 1931 to relieve vertebral cancer pain by chemically sectioning several dorsal roots. An injection of alcohol causes denervation due to the fragmentation of myelin in the endoneurium. In the 1950s, Bors [57] applied the technique to the bladder, standardized the procedure and described preliminary results. Later authors reported on a few series (LOE3) [58, 59], but always with the same result; the benefit disappeared after a few months. Phenol, considered to be “selective” for C fibers was then tried but the results were no better [60-62]. Chemical destruction of the sacral nerve roots has proved ineffective and is accompanied by a high rate of minor complications (pain), resulting in significant discomfort and prolonged hospitalization (LOE3) [58, 59]. Mulcahy et al. [63] proposed sacral rhizotomy by percutaneous radiofrequency for neurogenic bladder (LOE4). A recent study was published by Ferreire et al. [64]. In 8 SCI patients they performed a bilateral block of S3 with bupivacaine. These 8 responders had an increased bladder capacity and for 3 out of 4 patients autonomic dysreflexia (AD) improved.

c) Rhizotomy of posterior sacral roots and stimulation of the anterior sacral roots

Electrostimulation to improve micturition in patients with spinal cord injury has been extensively researched since 1954. Direct stimulation of the detrusor, the spinal cone, the splanchnic and sacral nerves have not produced reliable results. Since 1969, G.S. Brindley has developed a set of electrodes for stimulating the spinal roots in the cauda equina. The technique, first tested in baboons, led to the development of an implanted stimulator to induce micturition in paraplegic patients. Sacral rhizotomy performed during implant surgery makes it possible to control bladder hyperactivity and ensure continence. The energy source and the microprocessor for adjusting the stimulation parameters are not implanted. The transmitter transforms the electric current from the energy source into electromagnetic waves, which are picked up by the implanted receptor and re-transformed into an electric current that circulates to the electrodes in contact with the nerve. Depending on the surgeon’s decision, the implant is placed within the membranes of the dura mater or outside them, so as to stimulate the sacral roots from S2 to S4. At the same time, it is essential to perform posterior rhizotomy from S2 to S4 to remove any detrusor overactivity, though this is difficult to perform [65] (LOE4). This technique can only be performed in those with spinal damage who are para- or tetraplegic. The sacral reflex arc must be preserved.

Micturition is not continuous: the detrusor cannot be stimulated without also stimulating the sphincter. The parasympathetic fibers and the fibers destined for striated muscles are stimulated together. The response of detrusor smooth muscle fibers causes a gradual increase in pressure, which continues after stimulation has ceased. The “on-off” response to stimulation of striated muscle fibers is different. When stimulation stops, the striated sphincter immediately relaxes, whilst the detrusor continues to contract. A new wave of stimulation increases and maintains sufficient detrusor pressure to cause micturition after stimulation stops. The careful selection of stimulation and stopping times results in a discontinuous, but satisfactory, micturition. Sphincter fatigue due to electrical stimulations, blocking of pudendal nerve motor fibers [66] (LOE4) or use of specific detrusor stimulation by performing an anodal block [67] (LOE 4) have been reported, together with poor efficacy.

Stimulation can also help defecation and erection, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Induced erection is a secondary benefit but not an indication for the procedure, and men should be warned that they would lose reflex erection after posterior rhizotomy.

The results of the intervention are summarized in **Table 4**. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by additional placement of an artificial sphincter [44, 45] (LOE3). Incomplete rhizotomy can be surgically completed [44, 45, 68] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of ≤ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can resolve the problem of pre-operative reflux [68, 69] (LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [68] (LOE3) reported twelve cases of upper urinary tract impairment, ranging from grade I reflux to upper urinary tract dilation.

Table 4: Results of series on Sacral anterior root stimulation technique + Sacral deafferentation

	Patient numbers	Sex ratio (M/F)	LOE	Mean follow-up (extremes)	Pre-op. conti-nence (%)	Pre-op. Post-op. Continence (%)	Pre-op. bladder capacity (ml)	Post-op. bladder capacity (ml)	% complete micturition (PVR < 50ml)	Pre-op. dysreflexia (%)	Post-op. dysreflexia (%)	Pre-op. UTIs (%)	Post-op. UTIs (%)

Vignes et al. (2001) [75]	32	-	3	8 years (4-11)	0	90	220 (50-600)	550 (350-600)	80	18	2	100	30
Kutzenberger (2005) [45]	464	244/220	2	6.6 (6-17)	-	83	173	470	81	-	-	6.3/yr	1.2/yr
Martens (2011) [70]	46	36/10	3	13(1-19)	-	52	-	-	-	-	-	-	50 (>1 yr)

Martens et al. looked at patients in the Netherlands who underwent a Finetech-Brindley procedure [70]. They investigated the effects on quality of life in a group of 46 patients that still used the implant. They also looked at the presumed beneficial effects of the rhizotomy only, comparing with a group of 70 matched controlled patients that had optimised standard care. The patients had a significant better Specific Impact of Urinary Problems score, general QoL index (Qualiveen), and continence rate, and less urinary tract infections compared to the Control Group. If the stimulator was not used anymore, patients still benefited from the rhizotomy with regard to QoL and continence rate. The subscales of the SF-36 had better scores for the patients who used their stimulator as compared to those who did not use the stimulator and compared to the Control Group. The conclusion was that the active group had a better QoL than the rhizotomy group, and both groups had advantages over optimized standard care.

Schurch [71] focused on the specific problem of dysreflexia and recorded its persistence during stimulation in all patients who had suffered prior to surgery, but with marked improvement in symptoms.

Conclusion

- **Bladder denervation is mainly reserved for those suffering complete spinal cord injuries.**

Recommendations

- **No peripheral bladder denervation technique has passed the test of time (D).**
- **Injections of neurolytic products to treat detrusor overactivity should be abandoned, since they are ineffective in the medium and long term and expose patients to morbidity (A).**
- **Sacral dorsal rhizotomies need to be quite extensive to treat successfully neurogenic DO. So they may be performed only in patients with lower limb neurological impairment (B).**
- **In certain situations, dorsal rhizotomies can be undertaken in association with ventral root stimulators (Brindley's technique) or even with continent cystostomy (B).**
- **Electrostimulation of the anterior sacral roots is a valid option for managing neurogenic bladder in patients with spinal lesion, with long-term follow-up (B).**
- **It must be combined with destruction of all or part of the posterior sacral nerves, and cannot therefore be performed in patients with conserved lower limb motility (B).**
- **The reflex arc must be intact(B).**
- **Posterior rhizotomy exposes men to loss of reflex erection and women to a loss in reflex vaginal lubrication(B).**
- **It is vital to assess the patient carefully before implantation so as to determine whether he/she will be able to mount a toilet or grasp a urinal handrail (B).**

3. SURGERY FOR INCONTINENCE ASSOCIATED WITH POOR BLADDER EMPTYING DUE TO DETRUSOR UNDERACTIVITY

Incontinence in neurological patients can be aggravated by deficient bladder emptying and retention. Two mechanisms can be involved: detrusor sphincter dyssynergia (DSD) or bladder hypocontractility. A literature search was undertaken for the terms: neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; sphincterotomy; stent.

a) Surgical treatment of detrusor external sphincter dyssynergia

DSD is a characteristic feature of suprasacral and infrapontine lesions. The aim of sphincterotomy is to produce reflex micturition into a condom catheter, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to do IC. It is invasive, irreversible and the patient has no adaptation period [76, 77] (LOE3). Prosthetic sphincterotomy using a urethral endoprosthesis (or stent) is an alternative.

Sphincterotomy recommendation supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesicoureteral reflux, autonomic dysreflexia or repeated urinary infections secondary to poor bladder voiding. Patients should have failed or refused IC. Main contra-indications are [78, 79]:

- Impossibility to retain a condom catheter. All sphincterotomy techniques, including stenting, are contra-indicated for men who cannot retain a condom catheter (hence also for women). A semi-rigid penile prosthesis can be placed to help retain the condom catheter [80] (LOE3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with SCI, as opposed to only 2.7% in the general population [81, 82] (LOE3).
- Detrusor acontractility or hypocontractility. Patients with spinal cord injury and no reflex detrusor contraction during urodynamic tests are poor candidates for the various techniques of sphincterotomy.
- Patients who wish to father children and are candidates for vibro/electro-ejaculation and an artificial insemination program.

1. Endoscopic Sphincterotomy

Emmett [83] first described endoscopic sphincterotomy in 1948. He performed cervico-prostatic incisions

in patients with SCI, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross et al. [84]. They carried out cold-blade surgery and placed a catheter (Ch 22-26) for tamponade, since nearly all patients required transfusion (one of the ten patients in the series died after surgery). A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later. Complexity and frequent serious complications explains why these approaches were abandoned [85, 86]. Sphincterotomy with electrocoagulation was finally found to be the best technique.

Endoscopic sphincterotomy morbidity includes hematuria, which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (LOE2-3). Incision at the twelve o' clock position seems to offer the lowest risk of hemorrhage, with three and nine o' clock sphincterotomies entailing the highest risk [87] (LOE4).

Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series [88-91] (LOE3). More recent series (**table 5**, LOE 2-3), most using a median, or slightly deviated incision, have not affected sexual function. However, it should be noted that the population concerned may have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction. When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. The fear of this sequel sometimes causes the patient to decide against surgery; use of an incontinent prosthesis as first-line therapy can enable the patient to gain insight into this potential consequence of endoscopic sphincterotomy.

If striated sphincter section fails, the possibility of bladder neck stenosis should be investigated. This is seen in from 2 to 21% of patients (LOE 2-3). Section of the bladder neck may then improve voiding, but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

Results of endoscopic sphincterotomy are summarized in **Table 5** (LOE2-3). Any analysis is made difficult by the absence of unequivocal criteria of success. Some patients are improved by sphincterotomy, even with a 200 ml residue. Most authors use indirect urodynamic criteria to evaluate success (decrease in bladder pressure during micturition, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic UTIs. However, chronic bacteriuria is not improved [92]. The reported results concerning resolution of hydronephrosis and vesicorenal reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients [77, 93, 94] (LOE3). Riccotone et al. (LOE3) [94] reported 82% recurrence of symptoms after ten years of follow-up. Juma et al. [77] (LOE3) report similar results after eleven years, with patients undergoing an average of 1.7 sphincterotomies. Pan et al. reported a mean duration of benefit of almost seven years, which could be sustained with a repeat procedure [95]. A single study has tried to address predictive factors for a successful sphincterotomy. In this retrospective study, although detrusor leak point pressure and retrograde perfusion pressure were found to be superior to residual urine volume in predicting sphincterotomy success, results were not statistically significant [96]. 30-68% of patients eventually develop some impairment of the upper urinary tract [77, 95]. Patients who have undergone this surgery must therefore be regularly monitored to detect any distension of their upper urinary tract.

2. Prosthetic sphincterotomy

In 1990, Shaw et al. proposed using a wire mesh stent (Urolume) to treat patients with spinal injury presenting with DSD [97] (LOE3). Since then, various stents have been used. **Table 6** lists the types of stent used for DSD, according to classification criteria [98, 99]. They can be placed in various sections of the urinary tract: prostatic urethra, through the striated sphincter or more distal in the subsphincteric urethra. Our review is limited to placement through the striated sphincter.

• *Temporary prosthetic sphincterotomy*

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheter use, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this trial period, it is possible to study how the bladder empties in the seated position, and assess the necessity of additional treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. Moreover, as this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition and leaving the possibility to discuss any fertility and sexual issues, and considering the possibilities of preserving sperm. For patients with SCI, early temporary stent placement (within six months of trauma) theoretically has the added advantage of waiting for recovery of upper limb motility to enable IC, decrease the risk of nosocomial infection during rehabilitation by reducing carer-assisted catheterization, and relieve nursing load during rehabilitation. The last two points, though logical, are yet to be proved by relevant studies. After using a temporary stent, the patient may choose his mode of micturition; i.e. return

Table 5: Results of endoscopic sphincterotomy

	Number patients	LOE	Mean Follow-up (months)	Success criteria
Chancellor *et al.* 1999 [92]	26	2	24	- PVR decrease - Hydronephrosis, VR reflux decrease (100%, 100%) - Improved micturition comfort (80%) - Improved autonomous hyperreflexia (100%)
Catz *et al.* 1997 [132]	32	3	NP	- Significant decrease in PVR - Decrease in infections (74%) - Decrease in hydronephrosis, reflux (66%, 40%) - Improved autonomous hyperreflexia (100%)
Perkash *et al.* 1998 [121]	37	2	9	NK
Fontaine *et al.* 1996 [133]	92	2	20.6	- Decrease in hydronephrosis, reflux (100%, 90%) - Significant decrease in PVR, micturition pressure - Decrease in infections (74%) - Improved micturition comfort (73%) - Improved autonomous hyperreflexia (93%)
Noll *et al.* (1995) [76]	105	3	59	No statistical study, but: - Improved autonomous hyperreflexia (42 to 17%) - Decrease in mean PVR (180 to 70 ml) - Decrease in micturition pressure (from 97 to 37 cm H2O) - Decrease in frequency of symptomatic urinary infections (8.1 to 3.6 per year)
Rivas *et al.* 1995 [120]	22	2	12	- Improved autonomous hyperreflexia (44%) - Significant decrease in PVR, micturition pressure - Decrease in hydronephrosis (40%)
Juma *et al.* 1995 [77]	63	3	132	- Renal function (creatinine): normal in 97% of patients - on X-ray, 30% of patients showed upper urinary tract impairment. - 2/3 patients had more than one sphincterotomy
Vapnek *et al.* 1994 [93]	16	3	39	- 31% required repeated sphincterotomy - 50% failure rate (sub-pubic catheter placed)
Namiki 1984 [134]	9	4	3	- PVR < 50 (100%)
Ruutu *et al.* 1982 [135]	11	4	NS	- Subjective improvement in micturition comfort (56%) - Improved autonomous hyperreflexia (100%)
Carrion *et al.* 1979 [136]	60	3	12	- Reflux disappeared (86%) - Significant decrease in reflux: 75%

LOE: Level of evidence; NK: Not known; PVR: Post-Void Residue

Table 6: Urethral stents used in neurogenic DSD

Temporary stents					
Stent	Expansion method	Size		Material	Maximal duration (months)
		Caliber (F)	Length (mm)		
Not specific to the striated sphincter First-generation					
Urospiral [137]	Non expandable	21	40-80	Stainless steel	<12
IUC [138]	Non expandable	16-18	25-80	Polyurethane	<6
Second-generation					
Memokath [139]	Heat	22/34	30-70	Nitinol	<36
Specific to the striated sphincter					
Diabolo [100]	Self-expansion	18	38	Medical steel	>12
Permanent stents					
Stent	Expansion method	Size		Material	
		Caliber (F)	Length (mm)		
Urolume Wallstent [140]	Self-expansion	42	20-40	Steel alloy	
Titan [141]	Balloon	43	19-58	Titanium	
Memotherm [142]	Heat	42	20-80	Nitinol	
Ultraflex [144]	Self-expansion	42	20-50	Nitinol	

to his former state, change to another temporary stent, replace it by a permanent stent, or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Only the temporary stent Diabolo [100] is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series [101] (LOE3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean ten month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequelae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. During the study, the authors abandoned the first used stent (Nissenkorn), replacing it with Diabolo.

Memokath is another device that has been studied in neurological patients [102-107] (LOE3-4). Several authors report complications (32-100%) using this stent, which seems to induce a lot of bladder stones and to be quite difficult to remove, especially if it is left longer than 18 months. When used as second-line treatment following failed sphincterotomy, Memokath successfully reduced post-void residuals, but failed to improve urodynamic parameters including bladder capacity, detrusor leak point pressure, bladder compliance, and maximum detrusor pressure [102].

• *Permanent prosthetic sphincterotomy*

Permanent stents are designed to integrate with the urethral wall [108]. They resist the striated sphincter and prevent its closing during reflex contraction. They can be removed if necessary, or at the patient's request, with recovery of striated sphincter contraction [109, 110]. Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single thread (e.g. Urolume) or several threads (e.g. Ultraflex). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume, Memotherm and Ultraflex. All can be placed under local anesthesia. **Table 7** summarizes the principal series published on these devices. Only Urolume was studied according to strict prospective criteria [92] (LOE1-2). Using stringent clinical and statistical methods, they classified the stent as LOE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with SCI (mean age 36.3 years) in 15 North American centres, were treated prospectively with Urolume for DSD. Urodynamic parameters for micturition pressure, PVR and functional bladder capacity were measured before treatment and then annually up to 5 years afterwards. Mean micturition pressure, the primary criterion, was significantly lower 5 years after stenting. PVR decreased significantly and was maintained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the others. Autonomic dysreflexia resolved in 70% of cases. The indwelling catheters of 63 of the 86 (84.9%) patients catheterized before surgery could be removed. The percentage of positive urine cultures remained unchanged after stenting. No case of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. One case of prosthetic encrustation occurred during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic section in 20 cases). In the mid-term, prosthetic sphincterotomy using a Urolume stent appears to be satisfactory. However, the situation is not so clear over the longer-term. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis [111-114] (LOE3). A small study (n=12) following patients up to twenty years after insertion, suggests a high rate of complications, as 5/6 patients who completed the 20-year follow-up developed bladder neck dyssynergia requiring incision, 2 patients developed obstructive encrustations within the first year of insertion and another patient developed bladder cancer [115]. However, in those patients who completed the 20-year follow-up, sustained significant improvements in maximum detrusor pressure and duration of detrusor contraction were recorded.

Whether patients should be offered prosthetic or endoscopic sphincterotomy is not yet agreed. Endoscopic sphincterotomy is the preferred standard treatment for DSD, where IC cannot be performed. Two prospective studies carried out in the US in 1994 indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with SCI, and offered advantages in terms of morbidity, duration of hospitalization and cost [116, 117]. The two studies were not randomized. Follow-up was short (mean 15 months), with a potential risk of bias, since the conclusion that external sphincter balloon dilatation is as effective as endoscopic and prosthetic sphincterotomy is not borne out by long-term outcomes [118].

Table 7: Results of the main series on sphincterotomy using urethral stents

	Stent	Year	LOE	n	Efficacy (%)	Mean follow-up (Months)	Migration (%)	Complications

Hamid et al. 2003 [103]	Urolume	2003	3	12	77	144	NR	16
Abdul-Rahman et al. 2010 [115]	Urolume	2010	3	12	80	144	0	80

A prospective, multicenter, randomized study comparing endoscopic sphincterotomy with prosthetic sphincterotomy was published in 1999 by Chancellor and Rivas, using the Urolume stent [119]. Fifty-seven patients in three specialist spinal cord injury centers were included. The study concluded that prosthetic sphincterotomy was as effective as endoscopic sphincterotomy and required shorter hospitalization. These findings are relevant only for the short and medium-term. The long-term outcome of prosthetic sphincterotomy for incontinence remains unreported. At present, it is vital that stented patients be monitored carefully at least once a year during the years following implant surgery.

3. Other sphincterotomy techniques

Two authors reported using Nd-YAG lasers for sphincterotomy [120, 121]. Although no randomized study has been conducted, comparison with results from the literature (with very short follow-up), suggests that these techniques are not as good as standard endoscopic sphincterotomy. However, the reported morbidity (particularly hemorrhage) was reduced (LOE2). External sphincter balloon dilatation was recommended by Chancellor et al. [122], with short-term results similar to those of surgical sphincterotomy. However, the technique has been abandoned by its sponsors and the device has not been distributed, probably indicating poor efficacy in the medium and long-term, compared with other mini-invasive methods such as stenting.

b) Bladder neck incision (BNI) for detrusor-bladder neck dyssynergia (DBND)

The rationale to use BNI was that sympathetic overactivity might inhibit detrusor contraction and transurethral incision of bladder neck might interrupt the inhibitory reflex arc and result in restoration of detrusor contractility. In a single retrospective study BNI was performed in 22 patients with high-level SCI and DBND demonstrated upon video-urodynamics, who were previously managed by either IC or indwelling catheter [123]. Voiding symptoms were complicated by autonomic dysreflexia in 17/22 patients. Deep incisions were carried out at the 5 and 7 o'clock positions, sparing the external urethral sphincter. A satisfactory surgical outcome, defined as greater or equal to 2-point reduction in the AUA/IPSS quality of life index was recorded in 86.4% of the patients 3 months post-op (LOE3). Presentation of urodynamic results is not, however, clear. Significant reductions were reported in those patients with preoperative Pdet >15cm H2O and significant increases in those with preoperative Pdet <15cm H2O, but it was not clarified whether detrusor pressures refer to filling or voiding Pdet. Post-void residual improved significantly in both patient subgroups. While all patients additionally suffered from DSD preoperatively, an open urethral sphincter during voiding was reported in 86.4% of them following BNI, and autonomic dysreflexia became less severe or resolved in 88.2% of sufferers. The authors hypothesized the presence of a urethra-to-bladder neck reflex pathway to explain additional improvements in DSD, but this theory as well as the clinical results need to be verified in further studies.

BNI, however has been used as supplementary treatment in patients who were originally managed with a urethral stent. It is not clear whether in those cases BDND was an overlooked primary dysfunction or developed secondary to the use of the stent. It is recognized in a large percentage of patients with a permanent stent [92, 115, 124], and is reported to be treatable with BNI although detailed results are missing (LOE 3-4).

Recommendations

- **Where clean intermittent catheterization is not possible, the long-term use of indwelling catheters should be avoided (B).**
- **Whatever type of sphincterotomy is chosen (surgical or prosthetic):**
  - **Patients must think carefully about the different modes of micturition possible for them (A).**
  - **The few studies reporting long-term results of sphincterotomy demonstrate the vital importance of regular patient monitoring for the recurrence of DSD or blockage (B).**
  - **This mode of micturition is contraindicated in women, and in men with difficulty in maintaining a condom catheter (B).**
  - **Men who wish to have children should be warned of the risk of ejaculatory duct obstruction (B).**
- **For patients who have chosen surgical sphincterotomy:**
  - **The reference technique involves an elective 11, 12 or 1 o'clock incision of the urethral sphincter (B).**
  - **Although surgical sphincterotomy is the accepted reference treatment for neurogenic DSD, analysis of the literature highlights the lack of reliable efficacy and reproducibility criteria for the technique (B).**
- **For patients who have chosen prosthetic sphincterotomy:**
  - **Different types of stent are used, depending on whether sphincterotomy is temporary or permanent. Stents are complementary, and different designs can be used for different situations (B).**

- **o Surgical complications depend as much on the surgeon's competence as on the material and may be reduced by experience (C).**
- **o Clinical studies have demonstrated that neurogenic patients prefer prosthetic sphincterotomy because it is reversible, even when permanent stents are placed (C).**
- **o Careful follow-up, using yearly cystourethroscopy is mandatory when leaving a permanent urethral stent (B).**
- **o Published data is inadequate to support a recommendation on the use of bladder neck incision in patients with inadequate bladder emptying due to detrusor-bladder neck dyssynergia, either as a first-line procedure or as a complementary approach to DBND recognised following permanent urethral stenting. Further studies are needed.**

4. SURGERY TO INCREASE DETRUSOR STRENGTH

For some patients, the cause of bladder hypocontractility lies in the bladder wall. In this case, the control circuit functions but the bladder muscle is too weak. At present there is no medical treatment for this situation. The general objective is to reduce peripheral resistances as much as possible and where this fails, to propose IC. However, some teams have suggested placing rolled strips of muscle around the bladder. Some authors have also suggested a strip of rectus abdominis muscle. This is easier to perform and may be used essentially for reconstructive surgery, such as in bladder exstrophy [125-127] (LOE4). The only team to have published results on bladder hypocontractility in man is that of Ninkovic et al. [128] (LOE2). They reported interesting results from twenty patients suffering from neurogenic detrusor underactivity and requiring self-catheterization. They reported a technique that they had designed in animal experiments [129, 130] (LOE4) and which consisted of transferring a free strip of latissimus dorsi muscle, which was anastomosed to the epigastric vessels and the lowest branch of the intercostal nerve. Out of twenty patients, with a mean follow-up of 44 months, 60% no longer required IC, with PVR below 100 ml. After complementary surgery on the bladder neck, there was a 90% success rate that was stable over time. The authors reported no heavy morbidity, particularly with regard to the donor site. These promising results were largely confirmed in a multicentre trial involving 24 patients with a median follow-up time of 46 months [131]. Complete spontaneous voiding (mean PVR 25ml) was restored in 71% of the patients, while frequency of CIC was reduced in another 13%. Recurrent UTIs ceased in 91% of patients. A critical increase in bladder contractility index may be required to achieve complete bladder emptying, but the number of patients was too small for safe conclusions. Future development could use tissue-engineering techniques to construct vascularized and contractile strips implanted around the bladder with the same procedure. Reduction cystoplasty, previously used in Prune Belly syndrome has not been reported in neurogenic LUT dysfunction.

Recommendations:

- **Latissimus dorsi myoplasty on the bladder is a promising technique that needs to be validated further (C).**

5. STRESS URINARY INCONTINENCE (SUI) DUE TO SPHINCTERIC INCOMPETENCE

Some patients with neurogenic lower urinary tract dysfunction will suffer from incontinence due to sphincter weakness. In general, patients with lesions affecting the brain or suprasacral spinal cord will not suffer from this problem, as the sacral sphincter guarding reflexes will be intact. However, patients with lesions of the conus medullaris, the cauda equina or peripheral sacral nerves are at risk of developing neurogenic stress incontinence. Patients with neurological disease may also suffer from stress incontinence due to direct sphincter injury from urethral catheter trauma or as a result of previous interventions such as sphincterotomy or dorsal rhizotomy. In women, SUI may be present for non-neurogenic reasons such as urethral hypermobility due to previous pregnancy and childbirth.

People with neurogenic lower urinary tract dysfunction and SUI may also have impaired bladder storage function. If this is the case, a surgical procedure that treats the stress incontinence in isolation might put the patient at risk of upper urinary tract deterioration (as the upper tracts become exposed to the full force of the bladder dysfunction, having lost the "safety valve" effect of a weak sphincter) or of persisting incontinence. Pre-operative urodynamic evaluation of bladder function is therefore mandatory before undertaking surgery for neurogenic SUI.

The question as to when it is safe to treat neurogenic SUI while leaving bladder dysfunction uncorrected has been studied most intensively in the paediatric age group. Most series relate to children with spinal dysraphism/myelomeningocoele and, typically, authors report the necessity to proceed to bladder augmentation in at least a third of patients. Even with a thorough urodynamic and radiologic preoperative evaluation, some patients will have late bladder compliance deterioration [148-165]. However, the issue continues to generate debate and studies have not reached total consensus; for example, Snodgrass et al. [166] (LOE3) published a retrospective analysis of 30 children (mean age: 8.6 years) who had a bladder neck sling procedure and appendico-vesicostomy without augmentation. At 22 month of mean follow-up, only one patient had

had to undergo a bladder augmentation. In a subset of 16 patients who had urodynamics at 24 months, 13/16 had an increase of their maximum bladder capacity. However, 67% of the patients required anticholinergic therapy. In contrast, Dave et al. [167] (LOE3) strongly advocate the case for simultaneous bladder augmentation. The authors report a series of 15 children followed for at least five years after an isolated bladder outlet procedure (5 Pippi-Salle, 5 slings and 5 artificial urinary sphincter). At a mean follow-up of 11.25 years, all the patients underwent surgery to increase bladder capacity, either for recurrent incontinence or for upper urinary tract deterioration. At present, no definitive conclusions can be drawn as to advisability of routine prophylactic bladder augmentation, but many authors recommend a concomitant bladder augmentation when performing a bladder outlet procedure [168] (LOE4). The option of using detrusor injections of botulinum toxin in children offers a further therapeutic approach in circumstances where there is uncertainty.

A further important consideration when contemplating neurogenic SUI surgery is the means of bladder emptying following treatment of the sphincter weakness. In particular, patients who are emptying their bladders using an element of straining will not be able to empty in this way post-operatively. Patients will therefore need to consider how they will empty their bladder once continence is achieved. The options available to patients will include: IC (either via the urethra or a continent catheterisable abdominal conduit) or the use of a suprapubic catheter (either on free drainage or with a catheter valve). There will be some patients, who have only limited neurological damage, who will continue to be able to empty their bladder using voluntary voiding post-operatively but, even in this group, it is necessary to warn patients of the possible need for post-operative IC and to make sure that they are capable of using the technique before embarking on treatment.

a) Bulking agents

There have been some studies reporting on the use of bulking agents in neuropathic patients (**table 8** and 20-27). Most of the published series relate to the use of periurethral injections in children. Various agents have been used. Polytetrafluoroethylen (TEFLON) was one of the first [169, 170]. It was once popular for treating vesico-ureteric reflux, but it has been progressively abandoned after several authors reported possible particle migration and granulomatous reaction to this product [171, 172] (LOE2). Collagen has also been used, although collagen lysis can lead to the loss of the bulking affect over time [170, 173-180]. Other synthetic products that have been used include polymethylsiloxane (MACROPLASTIQUE) and dextranomer hyaluronic acid copolymer (ZUIDEX) [169, 181-187]. Zuidex is no longer used in SUI, but is in use for vesico-ureteric reflux. Henly et al. [188] demonstrated that distant migration of particulate silicone was observed in animals after periurethral injection with polymethylsiloxane (LOE4). This was not demonstrated with dextranomer acid copolymer injections [189] (LOE4).

One of the main advantages of periurethral injections of bulking agents is that they are minimally invasive and can even be carried out as an outpatient procedure. The product is usually injected in the region of the bladder neck using a retrograde endoscopic approach. The bulking agent is injected at up to four sites with the aim of achieving urethral coaptation. Dean et al. [187] have suggested using an antegrade approach whereby the bladder neck is accessed using a percutaneous puncture into the bladder.

The results of periurethral injection surgery are summarized in **Table 8.** There are difficulties in comparing results from different series, because patient populations and definitions of treatment success differ. In particular, the criteria for defining “improvement” and “social continence” vary. Therefore, it seems appropriate to consider the proportion of “dry patients” as defining clear-cut success (even if some authors add to this result a notion of “dryness for some hours” between voiding or catheterization). Using this definition, 0 to 36% of the patients are considered to be cured using bulking agents (LOE2-3). Moreover, these results are observed after a mean follow up that rarely exceeds 2 years (LOE2-3), although one series has reported long-term improvement up to 7 years after the last injection [190].

There are other important considerations to be made when interpreting the results of periurethral bulking agents. The first is that the studies in children generally contain patients with two types of problems: congenital urinary tract malformations (epispadias, bladder exstrophy) and neurogenic lower urinary tract dysfunction (mainly myelomeningocoele). This is of importance because there is some indication that, in children, bulking agents work slightly better in patients with malformations than in those with neurological problems [169, 176, 184, 190]. The global results of the series are therefore probably more optimistic than the results that might be observed in a population of only neurological patients. A second point is that these children have frequently already undergone various surgical procedures, which could modify the results of the injection procedure. Although a high proportion of the patients in these studies use IC, some have satisfactory outcomes while continuing to void spontaneously.

Although the use of bulking agents does not appear to cause any severe complications, there is the suggestion that the presence of deposits of inert material might lead to greater difficulty in performing future bladder neck surgery [184, 197, 190]. It is also important to acknowledge that the failure to correct

incontinence is in itself a complication of the operation [168]. Most authors agree that no more than two injections should be undertaken since further injections are unlikely to produce a long term improvement. Gender and previous bladder/sphincter surgery do not seem to be reliable prognostic factor regarding the success of the injections.

b) Autologous Sling Procedures:

In women with neurogenic lower urinary tract dysfunction, the use of an autologous fascial sling to support the urethra (usually close to the bladder neck) has been widely used to treat stress incontinence. A sling can either be used in isolation or in conjunction with other procedures such as bladder augmentation. **Table 9** summarises the results of published case series. Complete continence is observed in 83 to 89% of the patients (LOE3). Once again it should be emphasised that many patients will be dependent on bladder emptying using IC or an SPC, because the patient's neurological dysfunction may preclude voluntary voiding and because the sling may have to be inserted under tension in order to provide sufficient outflow resistance in the face of neurogenic intrinsic sphincter deficiency. All of the series report a low morbidity rate from the procedure. In particular, the risk of urethral erosion is very low when fascial slings are used. Synthetic sling materials have generally not been advocated when significant sling tension is

(LOE: level of evidence, NS not stated)

required because of the risk of secondary urethral erosion [170, 197-199] (LOE3). However, there is a lack of studies that compare the use of autologous tissue and synthetic material. Bladder neck slings appear to be capable of providing good results in children. Some series suggest that girls have better outcomes [166, 191-193].

c) Suburethral tapes

Midurethral tape operations, such as the tension-free vaginal tape procedure, have taken a major role in the management of stress incontinence in the non-neuropathic population but have not been adopted for the treatment of neurogenic stress incontinence; concerns about the risk of urethral erosion have been discussed already. Furthermore, intrinsic sphincter deficiency represents the usual pathophysiology in neurogenic SUI, contrasting with urethral hypermobility in non-neuropathic women.

There is very little published data available on the efficacy of midurethral tension-free tape operations in adult women with neurogenic LUTD. In a retrospective series of 12 women treated by TVT [200] with a mean follow up of 10 years, 9 patients were available for assessment of which 7 were dry and 2 were improved. The authors did not report any urethral erosions on follow up.

For male patients with post-prostatectomy incontinence, the use of synthetic tapes is increasing but, there is very little data for patients with a neurological cause to their incontinence, other than case reports. The use of this type of device in patients with underlying neurological illness should clearly be very cautious until further data emerges from clinical trials (LOE4).

d) Artificial urinary sphincter (AUS)

Since it was introduced in clinical practice [201], the AUS is recognized as one of the most effective treatments for urinary incontinence. It has the inherent advantage that it provides an adequate urethral closure pressure during the urine storage phase of the micturition cycle but then allows voiding to take place in the face of a low bladder outlet resistance. In patients with SUI, it is able to deliver either complete or “social” continence in 75 to 87% with satisfaction rates ranging between 85 and 95%. These rates are provided by published case series that contain a majority of patients with post-prostatectomy stress incontinence (PPI), along with some neuropathic patients. However, outcomes are probably similar for patients with neuropathic stress incontinence and a low-pressure bladder reservoir (LOE4) [202]. It should be noted that most of the published data on the use of the AUS in neurogenic SUI relates to men, although the device is also used in female patients with neurological disease.

Before using the AUS in neurogenic SUI, several factors must be considered:

• Firstly, the risk of implant infection and erosion is probably higher than in the PPI population. It is generally recommended that patients undergo

pre-operative urine culture and sterilisation of the urine before surgery [203] (LOE4).

• Manual dexterity must be sufficient to allow the patient to use the AUS pump- either to open the cuff to urinate, or to allow IC [202]. They must also accept the need for IC should the bladder have reduced contractility. However, some studies seem to indicate that the cycling activation of the pump could be avoided in patients performing IC (LOE3) [204, 205]. Bersch et al. [204] have described a modified technique.

• The cuff implantation site in adult patients with a neurologic bladder dysfunction is debated. The cuff can be implanted via a retropubic approach at the level of the bladder neck or around the prostatic apex. Alternatively the cuff can be implanted around the bulbar urethra using a perineal incision. Proponents of the retropubic approach argue that perineal incisions may cause cicatrisation problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS [160] (1 to 5.5% in contemporary series) and, although it is recognized that IC is possible in AUS implanted patients [206], the risk of traumatic catheterization and subsequent cuff erosion might be higher when the bulbar urethral site is used. On the other hand, inserting an AUS cuff around the bladder neck is technically more difficult in adults in comparison with peri-bulbar implantation (LOE4). Some investigators are now exploring the possibility of using a laparoscopic technique for sphincter implantation [207].

• It is necessary to know the ejaculatory status of males in order to discuss the possible impact of the device on ejaculatory function. Cuff implantation around the bladder neck may allow patients to achieve antegrade ejaculation [208, 209] (LOE4).

As previously stated, a thorough urodynamic evaluation of the bladder is mandatory in order to evaluate the potential impact of bladder compliance following AUS implantation. This has been reported in several retrospective series (LOE3) [152-165]. The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with myelomeningocoele [157, 159, 161,162, 164]. In the event of any doubt about the quality of the bladder reservoir, bladder augmentation should be performed. The main results of published series are summarized in **table 10**. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients). The older series include some patients with the previous version of the AMS 800 (AMS 792). Therefore, it is possible that the long-term outcomes for patients being implanted today may be better than those seen in the past as a result of technical modifications of the device. Device infection, cuff erosion into the urethra and loss of fluid from the implant are the main causes of loss of an AUS. Infection and erosion typically occur in the early months after implant but late erosions are seen [156] (LOE3). The average "survival" for AUS is ten years. This particular point has to be explained to the patient, especially when they are very young. However, it is important to stress that sphincter replacement is usually possible so that continence can be restored. The majority of the authors consider AUS to be the "gold standard" procedure to treat neurogenic sphincter deficiency in men.

e) Surgery of the bladder neck

Three main procedures have been described. Historically, the technique of Young [210], later modified by Dees [211] and Leadbetter [212] came into use, essentially for reconstruction in cases of exstrophy and epispadias. The principle was to mobilise the trigone (after ureteric reimplantation) in order to resect bladder neck tissue, so as to reconstruct the trigone around a small catheter. Although some authors [213, 214] described its use in neurogenic patients, the procedure has rarely been used in this patient group. However, a recent paper describes an interesting hybrid procedure whereby a bladder neck reconstruction was combined with implantation of a fascial sling in neuropathic children with a post-operative continence rate of 82% [77]. Tanagho [215] (LOE3) described a variation of this technique which can be used in difficult situations in incontinent adult patients, when the implantation of an AUS is not possible [216].

The Kropp procedure [217] involves the use of a tubularised flap of the anterior bladder wall, which is used to extend the bladder neck and create an intravesical conduit. The tube is secured to the posterior bladder wall between the ureteric orifices. In the initial technique, the tube was tunnelled submucosally, but this manoeuvre was thought to increase the risk of tube stenosis [218, 219] (LOE3).

A third technique is that described by Pippi-Salle [220]. It is considered to be a variant of the Kropp procedure (also called a Kropp-onlay), with an anterior bladder wall flap that is not tubularised. Initial descriptions involved routine ureteric reimplantation but this was abandoned in later patients as long as there was an absence of reflux [221, 222] (LOE3). In a systematic review, Kryger et al. [168] (LOE4) stated that only data on 83 patients for the Kropp technique and 25 with the Pippi-Salle procedure have been published. Since that review there has been a lack of further significant data concerning the outcomes of these procedures. The continence results are good (50-69% for the Pippi-Salle procedure, 78-81% for the Kropp procedure) [218, 219]. However, several problems exist with the two techniques. Firstly, the techniques do not allow easy endoscopic access to the bladder. This is a major problem because it prevents or limits future endoscopic

procedures (especially ureteroscopy, botulinum toxin injections and litholopaxy). Secondly, 28-45% of patients (especially male) report catheterisation difficulties following a Kropp procedure. For the Pippi-Salle procedure, continence rates are lower than for the Kropp procedure, but fewer cases of catheterisation difficulty have been reported [168]. However, a revision procedure is necessary in significant numbers, and it has rarely been used in male patients.

f) Complete bladder neck or urethral closure

Closure of the bladder outlet may be required if alternative approaches to managing stress incontinence are inappropriate or have failed. In women, closure can be achieved either via a vaginal or an abdominal approach while in men, either the bladder neck or the bulbar urethra can be the site of closure. Bladder drainage is maintained using a continent catheterisable abdominal conduit (e.g. using the Mitrofanoff principle), an SPC or (rarely) an ileo-vesicostomy. Bladder neck or urethral closure can be technically difficult and a secondary operation to close a persistent fistula may be needed in some cases [224]. Interposing vascularised tissue between the bladder neck suture line and the urethral or vaginal closure is a well-described aid to the avoidance of closure failure; a flap of rectus abdominis can be used for this purpose. Bladder neck closure has also been used in children where other means of correcting SUI have failed or are felt to have a limited chance of success. The published series of cases provided some reassurance that children with closed bladder necks do not suffer from excessive complications in the form of renal deterioration, bladder rupture or stone formation.

As a general principle, urethral closure should not be undertaken in cases where it is possible to maintain urethral patency using alternative approaches to treat SUI. For example, patients with neurogenic lower urinary tract dysfunction are at high risk of stone formation in the bladder or upper tracts and it is desirable to maintain easy endoscopic access to the bladder in order to allow potential endoscopic treatment. Finally, preserving the natural urethra may constitute a safety measure if high bladder storage pressures are present or in the event of any complication with bladder access via a continent catheterisable abdominal conduit or suprapubic catheter [225].

Recommendations:

- **Patients with stress incontinence in association with neurogenic lower urinary tract dysfunction require careful assessment in order to plan appropriate management. Video-urodynamic study must be used to evaluate both bladder and sphincter function (C).**
- **The clinical assessment must also evaluate the degree of patient handicap in order to determine whether they can perform self-catheterization, or whether an alternative means of emptying the bladder will be required. (D).**
- **Patients require careful preoperative counselling with respect to the benefits and risks of different operative approaches**
- **Autologous slings can be used to treat neurogenic stress incontinence. (B). The use of synthetic slings and tapes is not supported by an adequate evidence base at present. (C).**
- **Artificial urinary sphincter can be used to treat neurogenic stress incontinence (A).**
- **Bladder neck reconstruction can be used to treat neurogenic stress incontinence (D).**
- **Bulking agents can be used to treat neurogenic stress incontinence when there is a demand for a minimally invasive treatment (D). The patient should be aware that the technique has a low success rate.**
- **Bladder neck closure should be offered to patients who have persistent neurogenic stress incontinence where alternative treatments have either failed or are likely to fail (B).**

6. SURGICAL ALTERNATIVES EXCLUDING DENERVATION PROCEDURES TO TREAT REFLEX INCONTINENCE DUE TO NEUROGENIC DETRUSOR OVERACTIVITY

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; bladder augmentation; enterocystoplasty; gastrocystoplasty; sigmoidocystoplasty; colocystoplasty; ureterocystoplasty; autoaugmentation; detrusorectomy

a) Bladder augmentation using intestinal segments

The aim of bladder augmentation is to provide long-term protection to the upper urinary tract by reducing the risk of impairment due to high bladder pressure, as well as to improve storage function [231]. First performed in man by Von Mickulicz [232] who used a segment of small intestine, the technique has regained popularity since the 1970s after the introduction of IC [233]. Unlike complete bladder replacement, enterocystoplasty preserves the integrity of the trigone of the bladder with the urethra and ureters, and reimplantation is not necessary. A segment of the gastrointestinal tract is taken out of continuity from the rest of the gut, and sutured onto the bladder. Various augmentation techniques using different segments of the gastrointestinal tract (caecum, colon, and ileum) have been described. Bladder augmentation is indicated wherever bladder capacity and compliance is reduced, or in the event of detrusor overactivity, when all conservative treatments (medical treatments, detrusor injections

of botulinum toxin and/or neuromodulation of the posterior sacral roots) have failed [231, 234].

Before performing bladder augmentation, it is essential to ensure that:

- There is no malignant disease or lithiasis in the bladder.
- Renal function is normal and the upper urinary tract is unimpaired (screen particularly for lithiasis).
- There is no gastrointestinal tract disease (Crohn's disease, hemorrhagic rectocolitis, short gut syndrome, etc.).
- The patient is willing and capable of self-catheterization. This can be combined with continent cystostomy.

Technical principles:

There are two stages to the surgical procedure: first bladder preparation and then augmentation. Usually open surgery is performed, but recently laparoscopy has been reported [235, 236] (LOE3). At present, except for technical articles on laparoscopy, there are no publications comparing this technique with open surgery.

The bladder can be prepared either by clam cystoplasty or by supratrigonal cystectomy. The preferred preparation depends on the quality of the detrusor, and more particularly on whether the bladder has retained its visco-elastic properties. Where the detrusor is very fibrous and thick, supratrigonal cystectomy should be envisaged, since otherwise exclusion of the ileal patch may occur.

1. Clam Cystoplasty

Clam cystoplasty involves freeing the anterior/ posterior surfaces and dome of the bladder. The bladder can be opened either in the transverse plane or sagittal plane, the incision starting and ending about 2 cm above the bladder neck. If the lateral surfaces are not mobilised, the vesical arteries can be preserved to maintain vascularization of the bladder dome. Robot-assisted laparoscopic augmentation cystoplasty has been recently introduced. Preliminary results have been reported in children with spina bifida [237].

2. Supratrigonal Cystectomy

Supratrigonal cystectomy involves resection of the body of the bladder, but retaining the trigone. The bladder is freed under the peritoneum and the superior vesical arteries ligated and sectioned. The bladder pedicles are ligated and sectioned laterally up to the trigone, which is preserved. The body of the bladder is excised 1-2 above the trigone. During the bladder dissection, care must be taken to spare the ureteric vascularization.

3. Ureteric Reimplantation

Ureteric reimplantation must be carefully discussed in the event of vesicoureteric reflux (VUR). Several authors have reported that improved bladder compliance precludes the need for reimplantation (LOE 3) [238-241]. They have reported a resolution rate of about 85% for VUR, classified below grade IV. For grade V reflux, improvement was observed in 2/3 of patients. Except for the work of Simforoosh [238], these results were obtained in small heterogeneous series of children (neurogenic bladders and congenital anomalies), and after relatively short mean follow-up times (1 to 5 years).

Hayashi et al. [242] reported on 22 patients treated by ureteric reimplantation during bladder augmentation (LOE 3). Their work was original in that it gave detailed account of renal function after long-term follow-up (mean 12 years). Ureteric reimplantation during bladder augmentation did not result in greater morbidity and 97% of patients recovered. Renal function was preserved and satisfactory. The case for ureteric reimplantation during augmentation cystoplasty was supported by a small non-randomised study (LOE2-3), where Wang et al. demonstrated that lack of ureteric reimplantation during cystoplasty in children with neurogenic bladder was a risk factor for residual high-grade reflux, which, in turn, was a risk factor for febrile UTIs [243]. A larger non-comparative non-randomised study (LOE3-4) reported equal success rates for the two methods, but ureteric reimplantation had been mostly reserved for the higher grade reflux cases [244]. These results were presented as part of a literature review which was inconclusive as to the superiority of the results of either method [244]. Accordingly, the need for ureteral reimplantation during bladder augmentation should still be considered, especially for cases of grade V reflux. However, improved bladder compliance will reduce some VUR.

4. Intestinal Segments

The choice of intestinal segment depends on patient's history and the local conditions. All segments of the gastrointestinal tract may be used, except the jejunum because of the risk of water-electrolyte disorders. The most frequently used segment in adults is the ileum, because it is easy to remove, is close to the bladder and may be shaped easily into a reservoir. Colon segments are used more often in children. The removed intestinal segment must always be detubularized to reduce peristalsis to a minimum and to obtain a reservoir with low pressure. The segment is then placed and sutured onto the bladder in the form of a patch. For supratrigonal cystectomy, the intestinal segment needs to be longer and fashioned into a neo-bladder [234].

Technical variations aim to reduce mucus secretion and reduce the reabsorption of urine by the intestinal mucosa that leads to metabolic acidosis. A number of variant techniques have been proposed but not developed extensively. Seromuscular colocystoplasty lined with urothelium involves removing the detrusor,

leaving the bladder mucosa intact, and then covering it with a demucosalized sigmoid patch [245]. Seromuscular enterocystoplasty necessitates removing the mucosal membrane of the intestinal segment surgically, or destroying it argon beam [246], before placing it onto the prepared bladder [247].

A third technique uses an appendicular-based cecal flap, aiming for a less invasive form of augmentation cystoplasty [248]. The technique involves isolation of a 10-12 x 3 to 5-cm cecal flap on the base of the appendicular pedicle, by which the bladder was augmented and the appendix was brought out through the abdominal wall for catheterization. Without any bowel anastomosis, the cecal anterior wall was repaired.

An experimental technique tested only pre-clinically is the reversed seromuscular ileocystoplasty, where the seromuscular layer of the ileal loop from its antimesenteric aspect was sutured to the bladder mucosa of the previously bivalved bladder. Complete epithelialization of the ileum's serosal surface with transitional epithelium was confirmed 4 weeks postoperatively [249].

5. Results of Enterocystoplasty

The main published series for patients undergoing surgery for neurogenic bladder are summarized in **Table 11.** Peri-operative mortality is estimated between 0 and 3.2% (LOE 2-3). The most frequently reported early morbidity (LOE 2-3) is prolonged post-operative ileus in up to 11.7% [250-253]. A nasogastric catheter is no more justified in neurological patients than in the general population (LOE3) [254]. Other common complications include episodes of febrile UTI (4.8-9%), urinary fistula (0.4-4%), that usually resolve, and thrombo-embolic complications (1-3%). When the pelvis has been irradiated, the patient must be warned of the increased risk of entero- or colovesical fistula. Stoma revisions (up to 50% in a small series) and wound infections have also been reported [253].

Chronic bacteriuria always occurs with IC and should not be considered a complication [203] (LOE4). Cases of late urosepsis have, however, been reported [255]. The risk of calculus in the enlarged reservoir ranges from 10-50% [255-9] (LOE 2-3). There may be a higher risk of developing upper urinary tract lithiasis than in the general population [260-2] (LOE3).

After bladder augmentation, intestinal transit disorders are frequent and probably underestimated (0- 30% [263-5]). Several explanations have been proposed (ileocecal valve not preserved, biliary salt malabsorption, etc.). Somani et al. conducted a cohort study (LOE2) focusing on this particular problem [266]. They report a high rate of intestinal transit disorders, affecting almost 50% of patients treated for neurogenic bladder. These complications distressed patients and nearly 10% regretted having undergone surgery. Although transit disorders cannot be attributed to surgery alone (patients with neurogenic bladder may have intestinal transit disorders unrelated to surgery), patients should be informed of this risk.

Since the gastrointestinal tract mucosa resorbs urine, water-electrolyte disorders may occur. Hyperchloremic acidosis is reported in up to 15% of cases (LOE 2-3). These water-electrolyte disorders may be accompanied by anomalies of calcium metabolism that do not appear to have any significant long-term effect, for example on growth in childhood, but the subject is still under debate (LOE 3) [267-270]. However, care must be taken when treating patients with a marked decrease in creatinine clearance, since metabolic acidosis is no longer compensated [234] (LOE4).

In theory, diversions performed using the ileocaecal junction and the end segment of the ileum would expose patients to a risk of vitamin B12 deficiency (with possible onset of megaloblastic anemia). The fact that the intestinal segments measure less than 50 cm would explain why few patients suffer clinically overt vitamin B12 deficiency.

The risk of cancer development of the newly formed reservoir is particularly important, since neuro-urological surgery is often indicated in patients with long life expectancy, many being children. The general consensus today is that patients with a bladder reservoir are at higher risk of developing a tumour than are the general population, but this risk has not as yet been clearly defined. The figures usually given for the risk of tumour development range from 1 to 4.6% [271-274] (LOE 3-4). Most of the published cases concern adenocarcinoma at the junction of the intestinal mucosa with the urothelium. These usually developed long after the initial surgery (over 10 years in most cases). Some patients developed urothelial tumours with the typical risk factors. Two facts should be emphasised with regard to neurogenic bladder (augmented or not):

- The sensitivity and specificity of the routine bladder tumour diagnostic and monitoring tools (urinary cytology, BTA test, simple cystoscopy, etc.) may be reduced. Patient monitoring can only be envisaged by regular cystoscopy with biopsy of suspect areas.
- Monitoring is essential, since many patients develop tumours without symptoms and may not be diagnosed until late.

Monitoring frequency needs further investigation. A review of a series of cystoplasties performed in patients with congenital abnormalities including neurogenic bladder found comparable risk of bladder cancer, compared to control patients managed only by IC (4.6% vs 2.6%, p=0.54) [274]. In addition, a projected

cost-analysis based on post-augmentation malignancy and cost estimates from published reports or US government sources concludes that annual screening with cytology and cystoscopy of children with spina bifida subjected to augmentation cystoplasty is unlikely to be cost effective at commonly accepted willingness-to-pay thresholds, but would be justified if the annual rate of cancer development were more than 0.26% (12.8% lifetime risk) or there were a greater than 50% increase in screening effectiveness and cancer risk after augmentation [275].

The most serious and possibly life-threatening complication is cystoplasty perforation (LOE3). This can happen whichever gastrointestinal segment is used, but occurs more often after ileocystoplasty [276] (LOE3). It is estimated to occur in 5-13% of cases [250] (LOE3). Perforation usually occurs on the graft or at the junction of the bladder with the enterocystoplasty, and often results from high pressure within the enterocystoplasty, or more rarely from traumatic catheterization or urodynamic investigations [277] (LOE4).

6. Functional Outcome

The functional outcome of bladder augmentation by enterocystoplasty is given in **Table 11.** Only series of patients undergoing bladder augmentation for neurogenic bladder were retained in our analysis. Given the wide range of indications, surgical techniques and enteric segments used, and retrospective nature of studies, it is difficult to draw any clear conclusions. Nonetheless, all authors reported an improvement in bladder capacity and compliance (LOE2-3). More than 90% of patients achieved nocturnal continence, and 91-100% achieved diurnal continence (LOE2-3).

Two quality-of-life studies (LOE2) reported improvement rates exceeding 90% [252, 281]. A 92% satisfaction rate was reported by a long-term follow-up study (mean 14.7 years) and patients would recommend the treatment to a friend [255]. However, a potential bias might arise due to the heterogeneous population analysed in some of these studies, including a mixture of patients with neurogenic and idiopathic DO.

If the bladder compliance defect persists, exclusion or ischemia of the intestinal patch must be investigated [272, 280]. Sometimes urinary leakage is related to sphincter deficiency and may be treated by an AUS [283] or other means of urethral pressure reinforcement [272, 282]. However, most authors consider that this type of adjunctive treatment should not be performed routinely since most patients have a good functional outcome after bladder augmentation, and only those with marked sphincter deficiency prior to surgery require these measures.

7. Possible Alternatives to Enterocystoplasty

• Gastrocystoplasty and ureterocystoplasty

The use of a pedicled segment of stomach (gastrocystoplasty) or ureter (ureterocystoplasty) as an alternative to enterocystoplasty has been reported mainly for children with a neurogenic bladder. In theory, its advantage lies in the absence of metabolic acidosis, but in adults this is very theoretical. Moreover, both these intestinal segments secrete less mucus than the small and large intestines [284-288]. Abdel-Azim et al. [286] reported gastrocystoplasty in adults (LOE3). In the light of their experience with children, they decided to use this technique in a set of young adults (mean age: 23 years, range: 4-32 years). Their paper records that the short-term results (3 years mean follow-up) of gastrocystoplasty were satisfactory, with increased functional bladder capacity and no impairment of the upper urinary tract (LOE3). However, two disadvantages are reported. First, a hematuria-dysuria syndrome requiring occasional use of antacids sometimes accompanied gastrocystoplasty. Second, the maximum bladder capacity was lower than that observed with enterocystoplasty. This may have a benefit for easier bladder voiding, but if the bladder were to lose some capacity, further surgery would potentially be required. The outcome in the very long-term for patients who have undergone this procedure remains unknown.

8. Kidney Transplantation and Augmentation Cystoplasty

The general notion is that augmentation cystoplasty should be beneficial in patients with chronic renal failure and performed prior to transplantation, as a low-pressure reservoir might delay the native kidney's death and optimize graft survival rates. However, published studies suggest otherwise. In a small series (n=11) of neurogenic bladder patients, augmentation cystoplasty did not affect progression to end-stage renal disease (LOE2-3) [289]. More strikingly, prior cystoplasty was found to be associated with higher risk of graft rejection compared to non-cystoplasty transplants, up to 7 years postoperatively (LOE2-3). Although the authors suggest this may be due to higher rates of febrile UTIs and chronic rejection, it might also be due to a more severe underlying pathophysiology which resulted in the necessity of a cystoplasty in those children [291]. The same group of authors conclude that the timing of augmentation cystoplasty in relation to the transplant surgery (before or after) has no significant effect on the outcome of the transplantation, with respect to graft acute rejection, graft survival (up to 7 years) and incidence of febrile UTIs (LOE2-3) [292]. In terms of serious complications, patients with augmented bladders and a history of renal transplant on chronic immunosuppression were found to have a significantly higher incidence of bladder cancer compared to patients who were not immunosuppressed (15% vs 2.8%) [274] (LOE3).

b) Autoaugmentation by detrusor myotomy

Bladder autoaugmentation without any associated gastrointestinal tract surgery as an alternative to enterocystoplasty was proposed as early as 1972

by Mahony and Laferte [293] who performed detrusorotomies (detrusor incision without resection) to increase bladder capacity and reduce incontinence. With Cartwright and Snow [294], the technique then evolved to detrusorectomy (myectomy). This involves excising a thick segment of muscle from the dome of the bladder, leaving only the mucosal membrane in place. Bladder pressure gradually dilates the "demuscularized" area resulting in bladder augmentation. The intervention, initially described by extra-peritoneal laparotomy, can be performed by video-assisted surgery [295, 296] or by robot-assisted surgery [297] (LOE4). The detrusor can be dissected by laser [298] (LOE3). The area around the detrusorectomy can be protected using the omentum [299] or a striated muscle [300] (rectus abdominis muscle) to prevent perforation and retraction(LOE4).

Techniques using free-graft or pedicled de-epithelialized gastric patches [301, 302] require gastrointestinal tract surgery and were therefore not included in the present work. Furthermore, most of the previously published studies concerned children. All the studies are retrospective and with few patients. For children, most authors [299, 304-7] report poor results after surgery, both symptomatic and urodynamic, together with a risk of upper urinary tract impairment (LOE4). Two authors recently reported better results with certain technical adjustments, namely an extensive detrusorectomy [308] (LOE4) and rectus muscle hitch and backing [300] (LOE4). The last technique supposes a large dissection of the rectus muscle. Urothelium is then sutured to this muscle in the theoretical objective to prevent its retraction and shrinkage.

Only three retrospective series are available for adults. The first, published by Stöhrer et al. in 1997 [309] (LOE3), reports interesting results for efficacy, with increased functional bladder capacity. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The two other published series concerning adults [303, 304] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). Detrusor myectomy achieves better results for idiopathic DO; nearly all patients (5 of 6) with neurogenic DO were not improved, with a mean follow-up of 79 months [303] (LOE3).

There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious, digestive and parietal complications) against only 3% for detrusorectomy [304]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus potentially exposing the patient to an increased risk of rupture [310] (LOE4).

c) Bladder augmentation using biomaterials

Research interest in the role of tissue engineering in bladder reconstruction is growing. This research appears to evolve along three axes [311]:

a. use of acellular natural or synthetic biomaterials: an acellular biomaterial graft is used as a tissue implant which becomes incorporated through the ingrowth of cells of the native host bladder

b. use of biomaterial scaffolds which have been preincubated with autologous cultured human urothelial and smooth muscle cells

c. composite cystoplasty, which combines the use of autologous cultured urothelial cells with a host pedicled and de-epitheliased smooth muscle segment.

Most publications concern preclinical studies [312-326] (LOE4). Several biomaterials have been used which can be grouped in 3 categories: (a) decellularized natural matrices produced from a variety of tissues; (b) matrices produced from natural extracted polymers (e.g., collagen, alginate, chitosan and hyaluronan); and (c) synthetic polymers including polyglycolic acid (PGA) and poly-caprolactone (PCL) (see reviews [311, 327]). These biomaterials can only be used after performing clam cystotomy since the area to be colonized should not be too large. It also appears that the use of biomaterials is associated with higher incidence of bladder lithiasis. The best studied natural materials are porcine intestinal submucosa (SIS, Cook) and bladder-derived acellular matrix [318, 328-33].

Results from only two pilot human studies have been fully published to-date [331, 332].The former reported on neurological patients, the latter on non-neurogenic OAB patients. In a small prospective study of 7 young myelomeningocele patients (LOE 2-3), Atala [332] describes his technique, which consists of seeding patient's urothelial and muscle cells on a biodegradable scaffold. After 7 weeks, this engineered artificial bladder could be implanted in patients. Although the small number of patients doesn't allow definitive conclusions, a trend towards an improved bladder capacity and compliance was observed. It was also implied that patients who received cell-seeded collagen-coated PGA scaffolds wrapped in omentum as a vascular bed had the best outcomes. Encouraging results were also reported in 12 women with intractable non-neurogenic OAB who were submitted to bladder augmentation using an acellular matrix of porcine dermal collagen and elastin fibres (Pelvicol, Bard) [331] (LOE4). Significantly improved or cured incontinence was achieved in 67% of them at a 12-month follow-up. Finally, a recent review article [327] claims results in short report form from two small Phase II trials on patients with neurogenic bladders due to either spina

bifida (paediatric patients) or SCI (adults). Success rates of 60% and 67% are reported for up to 2-year follow-ups, depicting patients with preoperative 'normal bladder cycles' as the best candidates for bladder augmentation with a tissue-engineered scaffold. Further studies, including larger trials are necessary to evaluate routine use of biomaterials.

Recommendations

- **Any segment of the gastrointestinal tract may be used for bladder augmentation, but the ileum seems to give the best results in terms of ease of use, risk of complications and efficacy (B). Few data are available concerning gastrocystoplasty and ureterocystoplasty in adults (D)**
- **When the bladder suffers a significant compliance defect, supratrigonal cystectomy and reconstruction is preferable to clam cystoplasty (B).**
- **Bladder augmentation may solve low-grade vesicoureteric reflux. In the event of grade IV or V reflux, ureteric reimplantation may be necessary (C).**
- **Patients should be informed that the most frequent and serious complications are bladder calculi and perforation at the bladder/bowel junction, usually caused by over-pressure (B).**
- **Bladder augmentation may have sequelae such as intestinal transit disorder, and patients should be informed of this before surgery (C).**
- **The body of evidence concerning detrusor myomectomy in neurological patients is controversial. Therefore, detrusor myomectomy should not be recommended in these patients with impaired bladder function (D).**
- **Bladder augmentation using biomaterials or tissue engineering is promising, but the preliminary results need to be confirmed by larger studies (D).**
- **Due to risk of complications, regular follow up is needed (B).**

d) Cutaneous continent urinary diversion

For certain patients, urethral catheterization can be or become, unacceptable or even impossible. The following list is not exhaustive, but describes the more frequent reasons:

- Functional limitations of the upper limbs (tetraplegia [346] unilateral or bilateral plexus problems, musculoskeletal trauma problems).
- Cognitive disorders (forgetfulness, lack of comprehension, refusal).
- Difficulties in terms of mobility and/or undressing (spasticity, upper SCI resulting in difficulty in maintaining the equilibrium of the trunk and or limited control of the upper limbs, obesity).
- Failure to reach the urethra independently (more common in women, compounded by the tilted pelvis and all other factors that cause mobility difficulties.)
- Urethral injuries (stenosis, fistulas, hyperesthesia), urethral pain.

In these situations, management requires careful consideration; in some, a continent cystostomy may be an option. The general principle is to permit the emptying of a full bladder, independently and easily, by IC through an efferent tube attached to the wall of the lower half of the abdomen. The absence of any leakage from the cystostomy is controlled by its own watertight system, associated with the return process of a capacitive and compliant reservoir. This will require careful selection of patient candidates, especially when there is any function impairment of the upper limbs (trauma to the spinal cord) [347-9] (LOE3).

Assessment is essential, and must include the motivation of the patient, capabilities for dressing and undressing, capability of catheterization in the planned stomal area, and tolerance for the time and potential discomfort involved. In the case of cognitive difficulties that are too significant, if a severe upper limb dysfunction exists [346], or if compliance of the patient remains an impossible obstacle, continent diversion is not indicated. Impaired renal function can also be a contraindication [350].

In neuro-urology, techniques for heterotopic continent neo-reservoir (e.g. Koch pouch, Benchekroun, Mainz, Miami pouches) are seldom used initially. They can be offered to patients with VUR, with incontinence through the native urethra despite bladder enlargement, or when closure of the bladder neck will be needed (e.g. uretero-vaginal fistula).

1. Results of the Different Types of Cystostomy:

The series are mainly retrospective (LOE 3) and frequently combine several techniques. This makes the analysis of the results difficult, but some major facts can be gleaned from them. The catheterizable tube must be able to penetrate the intact or enlarged bladder and it must be able to reach the abdominal wall through a direct pathway with easy access for the patient that has already been predetermined by pre-operative research. The pathway of the tube must be direct in order to facilitate self-catheterization. Techniques can be grouped in two major categories : simple tubes implanted with an anti-reflux system and intestinal loop invaginations.

Simple tubes

Virtually any anatomical structure that is tubular or that can be tubularized and that is vascularized can be used to make a continent catheterizable tube

[350] (LOE4). The two structures that are the simplest to use are:

- The appendix: Trans-appendicular cystostomy according to Mitrofanoff's procedure [351] has long been the most used technique (LOE3). Different modifications have been proposed, especially to gain more length by removing a cecal cuff.
- A short, remodeled intestinal segment (small intestine, less frequently the sigmoid or right colon). Yang and Monti simple [352] (LOE3) or double technique and the Yang-Monti technique modified according to Casale in order to gain length by avoiding a double tube [353] (LOE3).

Other structures have been used in a more anecdotal manner, primarily in children: cecum and appendix monobloc [354] (LOE4), bladder [355] (LOE4), stomach [356] (LOE4), distal ureter [357] (LOE4), Meckel's diverticulum [347, 358] (LOE4), or the preputial or clitoral skin [359] (LOE4).

For most authors, continence of the tube was achieved by implantation in the native bladder or in the augmentation via a submucosal path similar to that used in ureteral reimplantation for VUR. (LOE4). The submucosal path length must be at least 2cm, and is adapted to the bore of the tube (two to three times the diameter) [349] (LOE4). A posterior or posterolateral bladder flap (kept in case of a supratrigonal cystectomy) should allow a more solid implantation of the tube in the bladder [360] (LOE2). Direct implantation into the cystoplasty has also been reported. The cutaneous anastomosis is made in the lower half of the abdomen, at the umbilicus, or in the right or left iliac fossa. It seems essential that the site of the stoma would be determined preoperatively in patients with functional limitations of the upper limbs. The site is chosen based on the patient's capabilities and the position during self-catheterization (seated in a chair, supine, other). The surgical technique used in this particular case must allow access to any point on the lower half of the abdominal wall [361-3]. Most authors recommend the interposition of a skin flap in the distal end of the tube in order to minimise stenosis of the circular orifice scars. Several techniques have been proposed: flap in V, VQZ [364] (LOE3), and VR [365] (LOE3). However, at present, the results published do not confirm that the risk of stenosis is avoided by any of the techniques.

Table 12 summarizes the results in terms of stoma continence and complications, specifically pertaining to the continent stoma. The necessity of reservoir augmentation (80% of published cases) and techniques allowing reinforcement of ureteral continence are addressed elsewhere. Continent stomas are obtained overall in 75 to 100% of cases (LOE3). Seven studies indicate significant improvement in quality of life after the procedure related to improved autonomy in bladder evacuation, to continence, and to improved sex life [348, 360, 362, 363, 366-368] (LOE2-3).

The rate of stoma complications (16-60%) is dominated by the risk of stenosis, which is most often treatable by a simple dilation [369] (LOE3). Many authors emphasize the fact that this complication occurs most often in the year following surgery. However, Liard et al. [370] (LOE3) reported an elevated (65%) intervention rate at 20 years of monitoring. For most authors the rate of complications related to the tube continence was lower when the segment used was the appendix or intestines remodeled according to Yang-Monti (LOE3). However, these two plasties seem to have equivalent complication rates. Only Narayanaswamy et al. [371] (LOE3) reported higher rates for catheterization difficulty and reintervention with the Yang-Monti tube in comparison to the appendix. The Monti tubes in this study were double tubes in 68% (17/25) of cases, and the majority of the complications were related to the junction area for the two hemi-tubes and not to stoma stenosis. Therefore it seems that this lengthening method should be used with caution. If there is a problem with tube length, the method proposed by Casale [353] (LOE4) has the theoretical advantage of avoiding an anastomosis on the tube or a bent pathway at the junction of the two tubes.

The umbilical anastomosis site for the stoma may be related to an increased frequency of stoma stenosis [355, 372] (LOE3). The poorer vascularization of the umbilicus has been proposed as an explanation [372]. However, results on this point are contradictory with more recent studies [360].

Other types of continent urinary stoma:

Techniques are extremely varied. Two technical approaches can be broadly outlined here:

- Invaginated valves (Koch pocket, Benchekroun, Mainz), in which the continence mechanism is tied to the flattening of the invaginated valve by urine accumulated in the neo-reservoir;
- Ileal-caecal reservoirs, in which a portion of the ileum and the ileal-caecal valve are used as a continence mechanism (Indiana pouch, Charleston pouch, Miami pouch).
- A new technique using a pedicled cutaneous flap which is surgically elevated from a hairless area on the abdomen, tubularized and passed through the anterior abdominal wall directly into the bladder (The Daoud technique) [373].

Data in the literature do not allow a determination to be made as to the superiority of one type of stoma over the others. However, the catheterization difficulties seem to be lower with stomas that use the appendix, and the risk of lithiasis seems to be higher with the stomas constructed using metal staples [374] (LOE4). Several authors have also specifically

reported results in neurological patients [363, 373, 375-380] (LOE3). Continence rates for the stoma vary between 63 and 100%. Complication rates for the stoma are between 10 and 23%.

Bladder outlet management; although prospective studies are missing, evidence from retrospective analyses (LOE2-3) suggest that continent diversion combined with bladder neck closure is superior in terms of functional outcomes to continent diversion with an open bladder neck, whilst having similar morbidity [381]. Another series reports primary continence rate following bladder neck closure and continent vesicostomy of 82% [382]. Both series report however on a mixed patient population.

Recommendations:

- **Indication for cystostomy presumes a multidisciplinary evaluation involving the urologist and a neurologist or a reeducation doctor, as well as stomatherapy nurses or occupational therapists for estimating patient catheterization capabilities (A)**
- **Use of the appendix to carry out continent cystostomy is the standard method in children, but few long term data are available in adults (C). The appendix may have a short mesentery, so a reconfigured ileal segment is often needed.**
- **If the patient has undergone an appendicectomy, the use of a segment of the small intestine can be proposed, with slightly poorer short term results (C).**
- **Long term follow up of after continent cystostomy is needed to have a better idea of the long term results of the various procedures (C).**

e) Non-continent cutaneous urinary diversion

Non-continent cutaneous diversion refers to all methods used to divert urine, and where incontinence remains or where a system of extra-physiological continence is created, i.e. urine flow is continuous and requires a means of collecting urine attached to the skin. In the context of neurogenic bladder, these diversions make it possible to obtain low bladder pressure and to preserve the upper urinary tract. This type of surgery is a last resort for the many complications related to neurogenic bladder (and congenital anomalies of the lower urinary tract), in patients for whom other therapies have failed to help. Urinary diversion techniques, however, have been largely replaced by augmentation cystoplasty in the treatment of refractory neurogenic bladder, at least in some groups of neurological patients. The analysis of the US national database of patients with spina bifida between 1998-2005 demonstrated that 3,403 patients were submitted to augmentation cystoplasty as opposed to 772 treated with urinary diversion. Moreover, patients undergoing urinary diversion required more healthcare

resources, with significantly longer hospital stays, higher total charges and more use of home health care after discharge home [393].

Four techniques are described for non-continent urinary diversions for patients with neurological vesico-sphincter disorders. In order of frequency these are: ileal conduit urinary diversion, ileovesicostomy, cystostomy and cutaneous ureterostomy.

1. Ileal Conduit Urinary Diversion

Ileal conduit urinary diversion is the type of diversion most frequently performed on neurological patients with bladder dysfunction. Pre-operative location of the intended stoma site is crucial and must be adapted to the patient's main position (wheelchair or bed); the stoma site must be easy to access for management. The ileal segment must be as short as possible to prevent stasis [394] (LOE3). There is a variant to this technique whereby a segment of jejunal loop is removed and a stoma made on the left hemi-abdomen. This technique can be proposed after irradiation of the pelvis minor, if the ileum has been impaired and a short loop must be used (about 10 cm) to avoid metabolic disorder (jejunal conduit syndrome: hyperkalaemia, hyponatraemia, hypochloraemia, acidosis) [395] (LOE3).

In neurological patients, ileal conduit urinary diversion by laparoscopy and by robot-assisted laparoscopy have been described [396-400] (LOE4). Patients seem to benefit from the procedure, though this remains to be confirmed in the medium and long-term [401] (LOE 2). Uretero-ureterostomy on conduit diversion has also been described in neurological transplant recipients in whom the donor ureter is too short to achieve a tension-free ureteroileal anastomosis [402]. Graft survival rates at mean 5.3 years follow-up was 83%.

Some series of neurological patients were evaluated to determine the onset of early and late complications [401, 403-408] (LOE2-3). The first study to use the recently introduced Clavien system reported on a series of multiple sclerosis patients (n-53), of whom 43% developed minor complications (Clavien grades I-II) and 11% major complications (Grades III-IV) [409]. Early series of children can be evaluated to determine the morphology of the upper urinary tract and renal function after urinary diversion over a long period (up to 20 years) [410-415] (LOE3). Despite complications, significant improvements in patients' quality of life were recorded, in both retrospective [410] and prospective studies [401]. The latter, however, noted that only aspects of QOL associated with the limitations and constraints induced by urinary problems were improved, not the overall QOL.

Mortality is estimated between 0 and 3.4% (LOE2-3). The commonest early complication is intestinal occlusion (4 to 12.6%), usually reversible after prolonged intestinal drainage [401, 403, 404, 406-408] (LOE2-3). The risk of gastrointestinal fistula should also be taken into account (0 to 3.3%). As for enterocystoplasty, the current trend is to try to reduce nasogastric tube drainage time to a few hours [416] (LOE3). The most frequent medical complications encountered (3 to 8%) are febrile urinary infections and thrombo-embolism (2 to 3%; LOE2-3). Other major complications include: urinary fistula in 0.3 to 3.4% of patients which may be prevented by placing a ureteric catheter for about ten days (LOE3). This complication could be a risk factor for later ureteroileal anastomosis stricture (LOE4).

The risk of long-term intestinal occlusion ranges between 5 and 7% (LOE3). Even when a short intestinal segment is used, some patients can experiment transient constipation or diarrhoea, which could adversely affect their quality of life [417] (LOE2).

Complications affecting the bladder left in situ. For the particular indication of neurological patients with bladder dysfunction, several authors have proposed not carrying out cystectomy so as to avoid potentially morbid surgery. At present, this is debatable for several reasons:

- There is a risk of pyocystis formation in the unused bladder (21-50%) [403, 404, 408, 418] (LOE3). Even where conservative treatments have been attempted (combining vesicular irrigation with antibiotherapy) [419] (LOE3), secondary cystectomy is then necessary in a high proportion [404, 410, 412]. For women, a surgical alternative is vaginovesicostomy, which appears to be effective [405, 412] (LOE4).

- The unused bladder frequently becomes infected and may become an "irritative thorn", especially in patients with spinal injury or multiple sclerosis (LOE 4) [404, 420].

- The risk of bladder neoplasia is higher in neurogenic patients, the principal risk factors being long-term indwelling catheterization (more than 8 years), bladder calculi and smoking [421-423] (LOE3). Moreover, screening by cystoscopy-biopsy is not effective [424, 425] (LOE3).

- Improvement of the cystectomy technique (noticeably laparoscopic cystectomy) has considerably reduced related morbidity [401, 426] (LOE2-3). Supratrigonal cystectomy can be performed in men, preserving the prostate and preventing any genital and sexual sequelae.

Upper urinary tract complications. Stenosis of the uretero-ileal anastomosis may occur in the medium and long term. This is very damaging to the upper urinary tract and requires regular monitoring. In contemporary series, it occurs in 2 to 7.8% of cases within 10 years [403-408] (LOE3). For cases followed for more than 10 years, the finding of 16.5 to 50% stenosis is essentially that of early paediatric series

[410-415] (LOE3). Impairment of the upper urinary tract and renal function seems to be correlated mainly with stenosis of the uretero-ileal anastomosis, but also with a long ileal graft and stomal stenosis leading to poor voiding and pyelonephritis [411] (LOE4). In the event of poor functioning of the uretero-ileal anastomosis, some authors suggest endoscopic dilation before further surgical repair of the anastomosis (LOE3) [407, [407, 427-429]. Surgery however remains the reference treatment [427] (LOE3).

The risk of upper urinary tract lithiasis (3 to 31%) is always present in these patients (even without stenosis of the uretero-ileal anastomosis) [403, 404, 407, 408] (LOE3). Patient monitoring should include regular screening of the upper urinary tract to detect any lithiasis and to implement timely treatment (LOE 4). Chronic bacteriuria is frequent but should not be treated if asymptomatic. Both patients and attending physicians must be informed so as to avoid the administration of unnecessary antibiotics. However, the risk of febrile infection persists over the long term and may be predisposed by uretero-ileal stenosis (12 to 34%) [403, 404, 407, 408].

Stoma complications. These are relatively frequent (18.6 to 30%) and varied [404, 407, 408]. The risk of peristomal herniation is the most frequently reported (between 7.7 and 10%). Stomal stenosis may also occur. Stoma complications appear to occur more often in obese patients (LOE3) [430].

Some patients, usually adults who underwent surgery as children and who subsequently to recover a continent system, or who have had complications with their non-continent urinary diversion could ask for undiversion [431-435] (LOE3-4).

2. Ileovesicostomy

This technique was first described by Cordonnier in 1957 for treatment of three children suffering from myelomeningocele [436, 437](LOE4). Its theoretical advantages are relative simplicity, the absence of dissection and suture of the ureter, thus preventing ureteral complications and the potential of restoring the integrity of the bladder (only one case described) [438] (LOE4). The surgery consists in removing a 10 cm ileal segment from about 15 to 20 cm above the ileocecal valve. One side of the segment is anastomosed to the dome of the bladder and the other to the skin halfway between the iliac spine and the umbilicus. A partial cystectomy is performed to reduce reservoir volume and possible urine stagnation. Surgical variants have been described with simple partial detubularization of the ileum before vesico-ileal suture [439], or the creation of a modified Boari flap on the bladder associated with partial detubularization of the ileum [438, 441-444] (LOE3). These improve drainage by reducing the ileal segment. Laparoscopic ileovesicostomy seems to be feasible [440, 445] (LOE4), and robotic ileovesicostomy has been described. A small, retrospective comparative study (LOE3) reported similar results in terms of continence and complications with the open surgery group, although a trend for less blood loss and shorter hospital stays was noted in the robotic group [446, 447].

One of the problems with ileovesicostomy, particularly in women, is the need for further surgery to prevent residual urinary leakage. All authors agree that this significantly prolongs surgery time. This further surgery may consist in closing the bladder neck or placing a suburethral tape [436, 438,443, 448, 449] (LOE3). Some authors propose performing this surgery later, where necessary [439] (LOE3).

Early complications are related to the underlying condition of these patients, which is often poor. No case of post-operative mortality has been reported in the published series [436, 438, 439, 441-444, 446-451] (LOE3). Other early complications were related to poor results of the surgery performed to render patients continent (**Table 12**). Patients with this type of problem are the most likely to resort to cystectomy with ileal diversion (3 to 6%) [438, 448] (LOE3).

Late complications are summarized in **Table 13**. Only one series to date has more than five years of follow-up [451]. It should be noted that, despite reduction in complication rates, particularly those related to chronic upper tract infections and stone formation, none of the patients in this series remained complication-free [450]. The largest series to-date also report high complication rates (up to 74%), albeit reduced in comparison with preoperative rates [448].The most frequent new adverse events appear to be poor emptying related to stenosis of the stoma or the ileovesical anastomosis. Only one group of authors specifically mention problems related to stoma equipment that occur in about 38% of patients [448] (LOE3). The incidence of renal or vesicular lithiasis can be as high as 25% in some series, and several authors report that affected patients had a history of lithiasis [450].

Renal function appears to be preserved with this procedure at least with a mean follow-up of five years (LOE 3) [438, 439, 441-444, 448, 449, 452]. No case of impaired renal function, or even post-operative uretero-hydronephrosis was reported. Two patients in a series with long-term follow-up developed a bladder tumour [444] (LOE4).

3. Vesicostomy

Vesicostomy was described by Blocksom in 1957 [453] and detailed subsequently by Lapides [454, 455]. The technique consists in constructing a bladder tube anastomosed to the skin by making a transverse suprapubic incision to reach the space of Retzius. The stoma is located half way between the umbilicus and the incision. The principal benefits simplicity and reversibility, particularly in children [456-462], making it possible to envisage temporary surgery to treat an acute urological problem. In

pediatric series, an improvement in the symptoms of infection was reported, with 6 to 20% of patients suffering bladder calculi and 6 to 18% stomal stenosis. Hydronephrosis improved or stabilized in most cases. The rate of end-stage renal failure varied between 6 and 18% for mean follow-ups of 6-7 years.

Nowadays, it is rare to conserve a vesicostomy long term. The long-term results of Lapides [455] (LOE3) are therefore all the more interesting. At two years of follow-up, there was no urinary infection, 16% poor drainage, 12% calculi, and renal function was preserved. At 10 years, however, end-stage renal failure, mainly due to calculi and repeated infection of the upper urinary tract, and mortality were reported [455, 463] (LOE3). Follow up at intervals ranging up to 20 years, showed the rate of chronic renal failure is around 16.6% [453-464] (LOE3).

Recently, percutaneous button vesicostomy placement under endoscopic control was proposed as a temporary continent alternative to Mitrofanoff in a series of 10 children with neurogenic bladders. The authors only discuss the feasibility of the procedure, not its efficacy [465].

4. Cutaneous ureterostomy

Cutaneous ureterostomy was first performed in the 1960s, to treat children with spina bifida and severe upper urinary tract impairment [466, 467]. The technique was also developed to treat malformative uropathies (exstrophy of the bladder and the posterior urethral valves) [467-470]. During this procedure, the ureters are anastomosed direct to the skin without using intervening gastrointestinal tract tissue. It is only feasible in the context of significant ureteric dilatation, and even then chronic stenting is often needed. The absence of gastrointestinal resection/ anastomosis avoids a major source of morbidity and mortality, but successfully achieving urine containment with appliances can cause considerable problems. In the absence of cystectomy, two short lateral incisions are made in the iliac fossa, at approximately 3-4 cm from the anterosuperior iliac spine. Direct retroperitoneal access is made and the two ureters located on the internal border of the psoas muscle or above the iliac vessels. It is important that the peri-ureteral region be spared and the ureter sectioned as low as possible. The ureter is then catheterized and raised to the skin. The stoma is formed by attaching the ureter to the skin, or by spatulating the sutured ureter on a V-shaped cutaneous incision (separate sutures with fine resorbable thread). Variants are described so as to obtain only one stoma: Y-transuretero-ureterostomy, implantation of both ureters in a single stoma, and implantation of a single ureter (ureter of the less functional kidney ligated, or even nephrectomy). The use of cutaneous plasties may remove the need for ureteral catheterization [471].

The main inconveniences are: cutaneous stenosis if the stoma is left unstented, upper urinary tract infections, and calcification around catheters. Moreover, it is frequently necessary to construct a double stoma. It is used in adults, usually in the context of palliative urinary diversion for those with obstructive pelvic cancer (bladder, uterus, rectum), and rarely in neurological patients [467-472]. Long-term results with a mean follow-up of 8 years are given hereafter: rates of stenosis between 8.7 to 11%, infections from 6.6 to 10% and calculi from 10 to 15.5%) [470, 472] (LOE3). Renal function was preserved for short follow-up times, but fatal end-stage renal failure occurred in up to 26.6% of children during long-term follow-up [469] (LOE3).

This technique is almost never used for neurological patients with bladder dysfunction anymore because conservative treatments (intermittent catheterization, urological endoscopy) have improved and the number of children suffering from spina bifida or presenting with complex malformation of the lower urinary tract has gradually lowered. Moreover, new urinary diversion techniques have been developed.

Recommendations:

- **Non-continent urinary diversion is the last resort for patients with neurogenic bladder (A).**
- **Bladder should be removed during the procedure because of the risk of later complications at this site (B).**
- **It may be indicated for urological dysfunction or in the event of a motor handicap that prevents other modes of micturition (C).**
- **Ileal conduit urinary diversion has the best long-term results for non-continent diversion, if the following pre- and peri-operative precautions are taken (B):**
  - **o Pre-operative identification of optimal location for the stoma site, with wheelchair test, if necessary.**
  - **o Utilization of a short intestinal segment (10 cm maximum).**
  - **o Minimal dissection of the ureters.**
- **There are several reports of good results for ileovesicostomy, but the medium-term results need to be confirmed in the long term. Quality-of-life studies should also be performed (C).**
- **Vesicostomy may be a useful temporary solution, particularly for children (D).**
- **Cutaneous ureterostomy shouldn't be used for non continent urinary diversion in adult patients because of the rate of long term complications (B).**

D. Neurological faecal incontinence

I. EPIDEMIOLOGY

Disorders of the central nervous system (CNS) are common, with worldwide estimates of the prevalence of spinal cord injury (SCI) at over 2.5 million, multiple sclerosis (MS) considerably greater than 1.5 million and Parkinson's disease (PD) approximately 3 million [1-3]. Whilst mobility, pain and bladder dysfunction has been relatively well studied, the bowel and pelvic floor dysfunction has been neglected by comparison. This is doubly unfortunate, as a large proportion of patients with CNS dysfunction experience frequent bowel symptoms, and these symptoms are amongst the most physically, socially and emotionally disabling [4-6]. Most of the literature deals primarily with the bowel dysfunction associated with three common CNS diseases – SCI, MS and Parkinson's disease. The literature on the most common of all CNS diseases – stroke – is more patchy and often directed towards acute post-stroke problems, as opposed to chronic neurogenic bowel dysfunction. With rapid advances in rehabilitation medicine resulting in increased survival of patients, these individuals are experiencing bowel symptoms for ever-longer periods.

Spinal cord injuries are common, with an estimated 50 people per million sustaining a traumatic spinal injury every year in the Western world [7]. Non-traumatic injury (vascular, infection, tumour) is more common, and cancer alone is estimated to cause more SCI than trauma [8]. Traumatic injury mostly affects young men, and advances in rehabilitation medicine mean that the longevity of paraplegics is similar to the general population while that of tetraplegics is 10 years shorter [9]. Bowel dysfunction affects almost all patients with a chronic SCI – up to 95% report constipation, faecal incontinence is experienced at least once per year by 75% and daily by 5%, with 33% experiencing regular abdominal pain [4, 10, 11]. Inevitably, given the nature and chronicity of the bowel symptoms, they represent a significant contributor to reduced quality of life in SCI individuals [4]. Patients with SCI reported bowel dysfunction as more problematic than bladder dysfunction, sexual dysfunction, pain, fatigue and body image [4].

Bowel dysfunction is less studied, but almost as prevalent in other neurological conditions. The prevalence of MS is approximately 1 per 1 000 [2]. About one-third of MS patients suffer from constipation and one-quarter are incontinent at least once per week [5, 12]. In patients with Parkinson's disease, constipation, in particular difficulty with defaecation, occurs in 37% [13]. One quarter of stroke survivors experience constipation, and 15% suffer with faecal incontinence [14].

II. NEUROPHYSIOLOGY OF BOWEL DYSFUNCTION

The pathophysiology of pelvic floor and colorectal dysfunction is broadly similar in patients with both SCI and MS. The extent of injury is the most important factor in determining bowel symptoms in both SCI and MS. However, in chronic SCI patients the lesion is usually sharply defined and unchanging, while in patients with MS the lesions typically occur at multiple levels and tend to vary with time.

Gastrointestinal transit is under the complex regulatory interplay of the enteric nervous system and extrinsic autonomic innervation. Parasympathetic innervation accelerates transit, proximally provided by the vagus and distally by the lower sacral roots (S2-S4). The vagus provides parasympathetic input up to the distal transverse colon, so in spinally injured patients, the dysfunctional gut segment is the distal colon. The sympathetic innervation (T9-L2) retards intestinal transit. Standard clinical classification of SCI relates to this, in that lesions are classified as supraconal (above the conus medullaris, where inhibitory input is lost), within the conus or being located in the cauda equina (where excitatory sacral parasympathetic supply is lost).

In supraconal SCI, an "upper motor neurone" type injury of the bowel results; there is slowed whole gut transit [1, 2] and hypertonia and hyperreflexia of the hindgut (i.e. distal to the splenic flexure) [3, 4]. The slowing of transit is autonomic-mediated, but also contributed to by reduced mobility and attenuation of the gastro-colic response [5]. The rectal hypertonia results in reduced rectal compliance and predisposes to reflex defaecation and incontinence. In cauda equina lesions the efferent limb of the reflex arc to the hindgut is interrupted, resulting in a "lower motor neurone" type bowel dysfunction with hypotonia and hyporeflexia [6]. Complete SCI has been shown to result in the most severe degree of bowel dysfunction [7]. However, in incomplete injuries, the relationship is more variable. The ASIA classification of severity of the lesion has not been convincingly shown to relate to magnitude of bowel symptoms, which may relate to the influence of the enteric nervous system in moderating gut-function post-injury.

Anal continence rests on an interplay between rectal musculo-sensory function and the internal and external anal sphincters. The internal anal sphincter is a condensation of the circular smooth muscle of the colon. As such, it is not subject to voluntary control but receives an autonomic (excitatory sympathetic and inhibitory parasympathetic input) [8]. Nevertheless, supraconal injury tends not to alter anal tone, whilst the reduced tone of cauda equina lesions may relate to faecal bolus impaction as much as loss of sympathetic input. The striated external anal sphincter is under voluntary control from Onuf´s nucleus in the ventral horn of the sacral

spinal cord via the pudendal nerves. Thus, in complete SCI the voluntary control of the external anal sphincter is lost [9].

Faecal incontinence relates not only to motor factors affecting the sphincter, but also to anorectal sensation. The anal mucosa has a dense network of sensory receptors, and loss of sensation can result in anal incontinence. Rectal hyposensation occurs in both supraconal and cauda equina lesions, and predisposes to faecal impaction (especially in the flaccid rectum of patients with cauda equina lesions) [9].

The pathophysiology of bowel dysfunction in patients with Parkinson´s disease (PD) is quite different from that of SCI or MS. Dystonia of the striated muscles of the pelvic floor and external anal sphincter explains the defecatory dysfunction [10]; this aetiological factor is supported by the observation that pelvic floor dysfunction is alleviated with L-Dopa [11]. In addition to the pelvic dysfunction, colonic transit time is usually prolonged in patients with idiopathic PD [10]. Two important pathophysiological factors contribute to this: firstly, the number of dopamine producing cells in the colonic wall is reduced in idiopathic PD [12] and secondly Lewy bodies, typical of PD, form in the enteric ganglia [13]. Recent observations have identified that men with a bowel opening frequency less than every 24 hours have an almost threefold risk of developing PD in later life compared to men with a daily or more often bowel frequency [14], suggesting that PD is not just a degenerative disorder of the CNS but also of the enteric nervous system.

III. ASSESSMENT

Patients with PD, where bowel dysfunction can long pre-date neurological diagnosis, often report decades of bowel symptoms. Current bowel symptomatology is next assessed, regarding bowel frequency, stool consistency, faecal incontinence and manoeuvres needed to achieve bowel management. This information is usually gathered from standard patient and carer history, but scoring systems exist which may supplement this. There are standard instruments (Cleveland Constipation score, St Mark's incontinence score [1, 2], and recently a condition specific score has been developed for neurologic patients [3]. This Neurogenic Bowel Dysfunction (NBD) Score is validated in SCI, but not PD; it is currently being assessed in patients with MS.

Digital rectal examination is an essential component, allowing assessment of rectal filling, resting anal tone, ability to generate a voluntary contraction and it also gives a crude assessment of anal sensitivity. The place of more interventional physiological or radiological transit investigations is not established, but may be appropriate if there is any co-morbidity (prior anal surgery, obstetric history, pelvic organ prolapse). Plainly, patients with alarm symptoms should have necessary colonic imaging performed. Alarm symptoms in this patient group are more difficult to recognise, but any worsening of established bowel dysfunction, weight or blood loss warrants investigation.

IV. CONSERVATIVE TREATMENT

The primary aims of bowel care are twofold: to achieve bowel evacuation in a timely manner and to avoid fecal incontinence. The first step of this bowel care consists of optimizing stool consistency with adequate fluid and fiber intake, and stimulating evacuation of stool on a regularly scheduled basis with digital rectal stimulation. A range of other non-invasive interventions may supplement this: Valsalva or manually-generated external pressure, oral medications – stool softeners, stimulant laxatives and prokinetic agents; diet modification; biofeedback; electrical stimulation and functional magnetic stimulations. The key to successful bowel management is intensive patient education and training. If conservative bowel management fails, surgical management may be necessary.

Search strategy; in updating previous consultations [1, 2], Pubmed items from 2007-2011 were searched with the key words: faecal incontinence, neurogenic, neuropathic, neurologic, neurogenic bowel, bowel management, bowel care, conservative treatment, practice guideline, incontinence, constipation, cisapride, colonic, dietary fibre, laxative, suppositories. From such searches, resulted a number of papers of various levels of evidence described below.

1. BOWEL PROGRAM /BOWEL CARE

Krassioukov et al. [3] in a large literature review found 57 studies on bowel care in SCI. They concluded that multi-faceted programs are the first approach to neurogenic bowel and are supported by lower levels of evidence (LE). There is level 4 evidence (from three pre-post studies) that multifaceted bowel management programs reduce gastrointestinal transit time, incidences of difficult evacuations and duration of time required for bowel management. Coggrave et al. described bowel management in community-dwelling SCI individuals [4]. In 1334 SCI individuals, median 52 years old and with duration of injury of 18 years, the most common intervention was digital evacuation (56%). Less than 30 minutes was spent on each bowel care episode by 58% of respondents, the others needed more time. Reported problems included constipation (39%), haemorrhoids (36%) and abdominal distension (31%). Reduced satisfaction with bowel function was associated with longer duration of each bowel care episode, fecal incontinence, greater number of interventions used and more problems reported. Impact of bowel dysfunction on the

respondent's life was rated as significantly greater than other aspects of SCI. Emmanuel has summarized the evidence base [5]. Initial management for all subjects is medication review (especially bladder drugs such as antimuscarinics, baclofen, ditropan, codeine analgesia, non-steroidal anti-inflammatory drugs (NSAIDs) and antibiotics) and addressing any unusual dietary habits.

In general, scheduled defecation should be attempted once a day or on alternate days. However, knowledge of bowel frequency prior to injury is important in deciding on the bowel program. The bowel regime approach used at the UK's National Hospital for Neurology and Neurosurgery [5] includes

- For patients with an upper motor neuron type bowel lesion and normal or minimally impaired anorectal sensation: aiming to have a stool consistency soft enough to be passed after rectal stimulation, but not so loose as to risk incontinence in between bowel actions; stool softened by regular use of gentle osmotic laxatives and stool softeners titrated in dose to obtain a stool of the desired consistency; stimulant laxatives are best used on an as-and-when basis rather than regularly; rectal stimulation is achieved by the simplest means possible (from digital stimulation to suppositories to enemas).

- For patients with an upper motor neuron type bowel lesion and absent or grossly impaired anorectal sensation: aiming as above, but there is less room for adjusting stool consistency, since loose stools will always result in incontinence; fiber-based laxatives are occasionally recommended alongside osmotic ones, although use should be cautious to avoid worsening abdominal distension and flatulence; rectal stimulation is performed as above.

- For patients with a lower motor neuron type bowel lesion: aiming to have a formed stool which is manually removed or irrigated from the rectum; bulking agents can be helpful in this situation, along with softening agents or gentle osmotic laxative use to get the correct consistency of a formed stool. Stimulants are not helpful; manual extraction, enemas or rectal irrigation are required to remove the stool. On rare occasions tiny doses of loperamide syrup may be given after bowel care to minimize the risk of subsequent soiling. The emphasis is on avoiding becoming constipated.

2. SPECIFIC TECHNIQUES

a) Diet

Patients with an upper motor neuron type bowel will tend to have slow whole-gut transit, and a high-fiber diet will tend to cause bloating and flatulence. In general reducing the fiber intake – especially of insoluble (i.e. cereal) fiber – is helpful in improving these symptoms. Patients with lower motor neuron type bowel may find that a higher fiber diet helps improve stool consistency and therefore prevent fecal soiling. The most important aspect of diet is to get into a pattern of regular eating, which helps optimize bowel motility. Excessive quantities of caffeine, alcohol and foodstuffs containing the sweetener sorbitol can cause the stools to become looser and hence more difficult to manage [5].

b) Toileting

Patients need to have a sense of privacy and comfort to achieve a successful bowel regime. Bowel contractions are maximal on waking up and after a meal or warm drink (the gastro-colic response), therefore many patients should optimize this with scheduled defecation after a warm drink and breakfast. Where possible, it is best to exploit gravity to evacuate the bowel, so sitting on a toilet or commode chair is preferred. When this is not practicable, toileting has to be done on the bed. There are previous case reports on positive effects of using a standing table or a washing toilet seat with visual feedback [3]. Valsalva maneuver (breathing hard against a closed glottis) may help, but should be avoided in patients with significant autonomic or cardiorespiratory problems [5].

c) Digital rectal stimulation

Digital rectal stimulation (DRS), involves circular motion of a finger in the anal canal with the intention of causing a reflex contraction of the colon and rectum, and hence a bowel action. A lubricated, gloved finger is gently inserted into the anus and rotated for 20–30 seconds before being withdrawn. If there is no result within 5 minutes the procedure can be repeated at that point. This process also serves as a useful check to see if there is any stool present in the rectum [5]. It was demonstrated that DRS contributes to bowel evacuation in individuals with SCI in part by increasing left-side colonic motility. Mechanical stimulation must be done with caution as it may cause local trauma and induce autonomic dysreflexia (AD) in SCI individuals [2].

d) Manual stool extraction

Manual extraction of stool differs from DRS, attempting physical removal of the stool from the rectum with a gloved finger hooking stools out. This technique is only possible when the stools are formed. Manual extraction can be combined with a Valsalva maneuver to improve effectiveness [5]. In a randomized, controlled trial, systematic use of less invasive interventions could not reduce the need for oral laxatives and manual evacuation in individuals with chronic SCI [6]. It provided evidence of acceptability of the technique.

3. CHEMICAL STIMULANTS

Suppositories and enemas may supplement the above by causing a reflex contraction of the rectum. Implicitly, there is little point in using these agents when the rectum is empty on digital checking [5].

Stimulants range in potency, from glycerine suppositories, through micro-enemas, to larger volume stimulant enemas. Ideally, these agents should be retained for at least 10 minutes.

Krassioukov et al. gave an extensive overview of publications on medications. There is LoE 1 evidence to support polyethylene glycol-based suppositories for bowel management. Cisapride did significantly reduce colonic transit time for chronic constipation but did not seem to have clinically useful effects in people with SCI. It has now been withdrawn because of cardiac side effects. Psyllium did not alter colonic transit time but was associated with increased stool frequency in people with Parkinson's disease. Prucalopride increases stool frequency, improves stool consistency and decreases gastrointestinal transit time in chronic constipation, and has shown some benefit in this patient group [7]. The time schedules for administration of rectal medication may influence bowel responses. The clinical significance of any of these results was difficult to interpret because of the limited number of papers and the quality of the research. During the last three years there has been no research study on the effectiveness of such medications in patients with neurogenic bowel dysfunction.

4. ASSISTIVE TECHNIQUES FOR DEFECATION

a) Abdominal massage

Abdominal massage with the heel of the palm, in a circular motion from right to left may help increase bowel transit and movement of content towards the rectum [5]. In small controlled trials, positive effects were seen in patients with multiple sclerosis [8] and with spinal cord injury [9].

b) Anal stimulation with water streams

Pulsed water irrigation consists of supplying intermittent, rapid pulses of warm water into the rectum to break up stool impactions and to stimulate peristalsis. Pulsed irrigation evacuation would be a safe and effective method for individuals with SCI who develop impactions, or do not have an effective bowel routine [3].

c) Transanal / Transrectal irrigation (TAI)

Several studies have been published comparatively recently on this technique. Christensen et al. [2009] described how 163 of 348 patients (47 percent) had a successful outcome from treatment with TAI after a mean follow-up of 21 months. Success rates varied between patients with different underlying pathology: for neurogenic bowel dysfunction, the success rate of 67 of 107 (63 percent) was higher than in patients with anal insufficiency, sequela to anorectal surgery, idiopathic constipation, and miscellaneous [10]. Amongst factors correlating with positive outcome were neurogenic bowel, low rectal volume at urge to defecate, low maximal rectal capacity, and low anal squeeze pressure increment. Two non-fatal bowel perforations were found in approximately 110,000 irrigation procedures.

Faaborg et al. studied long-term application of TAI and found a drop-off in effect, with successful outcome in 46% of neurologic patients after a mean follow-up of 19 months. The rate of success was 35% after 3 years and remained almost unchanged thereafter. TAI was relatively safe, with a perforation rate of about 1 in 100,000 [11]. Whether this perforation rate is cumulative or seen only at the initiation of treatment remains to be determined in long-term studies.

Ausili et al. treated 60 children with myelomeningocele with TAI for three months. Sixty percent (36/60) reported relief from constipation and 75% (12/16) for fecal incontinence. Wheelchair-bound and walking patients showed similar improvements of bowel habit. There was a clear improvement in quality of life. They observed a reduction of urinary tract infections during the course of treatment and few complications [12].

Neel prospectively evaluated the efficacy and durability of combined intradetrusor botulinum-A toxin, endoscopic treatment for vesicoureteral reflux, with anal irrigation in a small group of young (5.3 +/- 2.5 years), incontinent, treatment-refractory myelomeningocele children. Ten of 13 patients achieved stool dryness with anal irrigation 1 to 2 times weekly. Three patients who were stool continent on standard enemas did not require this irrigation system [13].

TAI using a self-administered system results in a lower total cost to society than conservative bowel management [14]. Building on the positive data reported for patients with SCI, continued evaluation in the clinical trial setting is required to further define the utility of TAI in other populations with NBD [15].

5. APPLIANCE/ASSISTIVE TECHNIQUES FOR FAECAL INCONTINENCE

a) Anal plug

Previous studies employing anal plugs have yielded conflicting results [3]. Bond et al. undertook a randomized controlled trial with the Conveen anal plug (Coloplast Limited) used for 12 months in patients, including a number with neurologic bowel. The anal plug proved of benefit to the majority of patients. It did not suit all eligible patients, with in situ plug retention being a problem for some [16].

b) Neuromodulation /Electrostimulation/Magnetic stimulation

Tsai et al. state that functional magnetic stimulation, featuring broad-spectrum application, can be incorporated successfully into other therapies as an optimal adjuvant treatment for neurogenic bowel dysfunction resulting from SCI- both with supraconal and conal/caudal lesion [17]. Kajbafzadeh et al. applied transcutaneous interferential (IF) electrical

stimulation for constipation symptoms in children with myelomeningocele (MMC). They found sphincter pressure and rectoanal inhibitory reflex significantly improved compared with sham stimulation and pretreatment measures. In 73% of patients, the characteristics of constipation decreased immediately after IF therapy, while in 53% patients, they persisted for 6 months. Frequency of defecation increased statistically significant [18].

In a small pilot study Fu et al. explored the efficacy of neuromodulation. One patient with permanent sacral electrode and neurostimulator implantation was overall successful. Four out of 8 with dorsal penile/clitoral nerve neuromodulation had decrease in Wexner constipation score. Patients also showed a significant improvement in their symptoms and quality of life during follow up. If confirmed, sacral neuromodulation and dorsal penile/clitoral nerve neuromodulation may be effective for some neurogenic constipation. However, there are no predictive tests to anticipate the candidates with the best chance of benefit with the procedure [19].

In the previous literature [4], one good quality RCT, with only a few study subjects, showed that external electrical stimulation of the abdominal wall muscles can improve bowel management for individuals with tetraplegia. In a prospective controlled trial, 25 minutes of electrical stimulation of the abdominal muscles per day, five days a week, for eight weeks, resulted in accelerated colonic transit times when compared to the placebo control group. In a case study, posterior tibial nerve stimulation improved bowel management in incomplete SCI. Functional magnetic stimulation on the thorax and lumbosacral nerves (simulation placed at T9 and L3 spinal processes) reduced colonic transit times and self-reported symptoms of constipation [4].

c) Quality of life

No specific new study has been published, but in several studies mentioned above an improvement of QoL was shown.

Conclusions

- **In reflex bowel, digital rectal stimulation relaxes the external anal sphincter and increases peristaltic contractions by facilitating an excitatory anorectal (ano-colonic) reflex, and enhances bowel movement and evacuation (LOE 3).**
- **Abdominal massage has beneficial effects on neurogenic bowel dysfunction, including defecation function and fecal incontinence (LOE 3).**
- **Transanal irrigation is a safe method to improve constipation and faecal incontinence in individuals with neurogenic bowel dysfunction (LOE 2).**
- **An anal plug can help control fecal incontinence in selected neurological patients (LOE 3).**
- **Different forms of electrical stimulation seem promising for fecal incontinence and defecation management in neurologic patients (LOE 3).**
- **To increase adherence rate with bowel care program/clinical practice guideline, implementation strategies should be addressed to care providers (LOE 3).**

Recommendations

- **Multi-faceted programs are the first approach to neurogenic bowel management and are supported by lower levels of evidence (B). They may consist of toileting, rectal stimulation (digital or with water stream), manual feces extraction, transanal irrigation and other assistive techniques (B).**
- **Diet can help but multi fibre is not necessarily indicated in patients with upper motor neuron lesion (B).**
- **Autonomic dysreflexia when using mechanical stimulation and assistive techniques can occur in neurologic patients with a high spinal cord lesion (B/C).**

Recommendations for research

- **Development of sensitive and valid instruments to quantify bowel dysfunction in neurogenic conditions other than spinal cord injury.**
- **Well-designed controlled trials with adequate numbers and clinically relevant outcome measures of bowel management are needed, including for administration of stimulants.**
- **Larger and good quality randomized crossover trials are needed to confirm the effects of neuromodulation and other forms of electrical therapy for controlling fecal incontinence and reducing constipation in neurologic patients.**
- **Transanal irrigation needs to be studied in patients with causes of neurologic bowel different from spinal cord lesion and meningomyelocoele. Long-term follow up of TAI populations is important to determine the safety, and factors predicting poor outcome.**
- **Given the prevalence of bowel dysfunction in Parkinson's disease (which is increasing in prevalence), specific studies in this population are required.**

V. SURGICAL TREATMENT

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to December 2011, looking for the keywords; neurogenic constipation and faecal incontinence, surgery,

sacral nerve stimulation, antegrade continent enema procedure, dynamic graciloplasty, artificial anal sphincter and colostomy.

The mainstay of current treatment in neurogenic fecal incontinence is adopting a conservative approach towards reversing the systemic effects and optimizing the mechanics of defecation through the use of laxatives and irrigation approaches. Surgery should be normally reserved for patients who have failed conservative therapy. This section focuses on specific aspects of faecal incontinence surgery in neurogenic patients. Although traumatic lesion of the external anal sphincter in neurologically intact patients is treated by reconstruction, functional impairment of anal sphincter without mechanical defect of the sphincter in neurogenic patients can not be treated by this simple surgical approach. Thus, options for surgical treatment of neurogenic bowel dysfunction are limited. They consist of; 1) sacral nerve stimulation, 2) antegrade continent enema procedure, 3) dynamic graciloplasty, 4) artificial anal sphincter, 5) elective colostomy, 6) postanal repair.

1. SACRAL NERVE STIMULATION

Electrical stimulation of sacral nerve roots has been reported to restore continence in patients with intact muscle structure. The procedure includes a test phase: acute percutaneous testing, today mostly using tined lead electrodes as part of a two stage operative procedure, or temporary percutaneous nerve evaluation, prior to permanent electrostimulation with an implanted neurostimulation device. An electrode inserted into the S3 sacral foramen provides low grade stimulation. If patients respond to acute or temporary percutaneous sacral nerve stimulation tested for 2 to 3 weeks, permanent stimulation can be considered. Thus is achieved with a chronic stimulator implanted under the anterior abdominal wall or subcutaneously in the gluteal region. The first case report with this technique was published by Matzel et al. [1] in 1995 who described a successful outcome in three patients with faecal incontinence. Since then, ten articles have been published [2-11] (**Table 14**). Matzel et al. [2] reported a multicentre, prospective trial with chronic sacral nerve stimulation in a series of 34 patients at a median follow-up of 23.9 months. At least 83 % of patients had a 50 % or greater improvement in total number of incontinent episodes per week and at least 71 % of patients a 50 % or greater improvement in total number of days per week with continence during the course of follow-up. Continence was fully restored in at least 12 (37 %) patients. Quality of life improved in all four ASCRS (American Society of Colon and Rectal Surgeons) scales ($p<0.0001$) and in seven of eight SF-36 scales, though only social functioning was significantly improved ($p=0.0002$). Although 12 patients had 19 device-related adverse events including pain (ten episodes in 9 patients), lead breakage in one patient, recurrent infection needing device removal in one patient and deterioration of bowel symptoms in three patients, resolution rate was 63.2 % and 100 % for all and severe complications, respectively. However, this study excluded patients with neurological diseases.

Similar success rates (73-100%) with this technique have been reported from other centres [3-5, 7-11]. Among these reports, only one case-series by Rosen et al. [12] mainly evaluated faecal incontinence in patients with neurological lesions. In that study, 20 patients (15 neurogenic, 5 idiopathic) with severe faecal incontinence were initially treated by temporary external stimulation over a period of 10-14 days. Sixteen patients (11 with neurogenic causes, including SCI, spinal cord surgery, myelomeningocele and MS) who had shown a positive response to the temporary stimulation subsequently underwent permanent implantation. The median follow-up was 15 months (range, 3-26 months). All patients who had received a permanent implant revealed a marked reduction in their incontinent episodes, as well as an increase in retention time. In the neurogenic subpopulation, the median numbers of incontinence episodes decreased significantly ($p<0.01$) from 7 (4-15) to 2 (0-5), and a median retention time significantly ($p< 0.01$) increased from 2 minutes (0-5) to 7 minutes (2-15) after chronic stimulation. Assessment of QOL scales using ASCS questionnaires after 6 months treatment showed significant improvement on all scales. Three patients (2 neurogenic and 1 idiopathic) had severe infections needing explantation of the device and wound drainage 0-3 months after implantation. Another one patient had dislocation of the permanent electrode. No complications were observed in the remaining 12 patients (60 % of total series). All of those patients with functioning systems showed improved incontinence during the follow-up period. Although the mechanism of SNS in improving faecal incontinence is uncertain, rises in anal resting and squeezing pressures and changes in rectal sensitivity and motility have been proposed. Particularly in neurogenic patients, neuromodulation of sacral reflexes and regulation of rectal sensitivity appear to be the major reasons for the functional improvement [7]. Where the diagnostic stage is performed as a staged implant, a tined lead is employed with four active electrodes (compared with a single electrode used in PNE) and has self-retaining flanges, which reduce risk of lead migration. Usage of the tined lead has the benefit of minimizing false-negative results.

Jarrett [2005] [14] reported on experience with sacral nerve stimulation for faecal incontinence in patients with previous partial spinal injury including disc prolapse: the spinal insults were disc prolapse (six), trauma (four), spinal stenosis (one) or occurred during neurosurgery (two). Temporary SNS was performed in thirteen patients (median age 58,5, range 39-73 years). Twelve patients had successful temporary stimulation and proceeded

Table 14: Published data on sacral nerve stimulation for fecal incontinence

Authors, year	No. of patients (neurogenic patients) with chronic stimulation	No. of patients underwent test stimulation	Median follow up (months) (range)	Improvement rate (fully continent rate)	Complications
Lombardi et al., 2010 [16]	32(32)	39	38	25%, all others improved by at least 50%	
Holzer et al., 2007 [15]	29(29)	36	35 (3-71)	28 patients marked improvements, see text	
Jarrett, 2005 [14]	12(12)	13	12(6-24)	incontinence episodes decreased from 9.33 to 2.39 per week	
Matzel et al., 2003 [2]	34 (0)	37	23.9	83% (37%)	
Ripetti et al., 2002 [3]	4 (0)	21	15(6-24)	100%	
Ramussen et al., 2002 [4]	10	14	4.5	90%	
Kenefick et al., 2002 [5]	14 (0)	ND	24 (3-60)	100% (73%)	
Matzel et al., 2001 [6]	6 (1)	ND	36(5-66)	100%	removal 2 for pain
Rosen et al., 2001 [7]	16 (11)	20	15(3-26)	75%

to permanent implantation. The median follow-up time was 12 (range 6-24) months, the mean number of episodes of incontinence decreased from 9.33 (7.64 per week at baseline 2.39 [3.39] at last follow-up (p = 0.012). The number of days per week with incontinence and staining decreased significantly (p = < 0.001). The ability to defer defecation improved from a median of "not able to defer" (range 0-1 min.) to being able to defer 5-15 min (range 0->15) mean (p = 0.022). The authors conclude that SNS can benefit patients with faecal incontinence following partial SCI. Holzer et al. [2007] [15] reported on 36 patients included in a trial of SNS, of whom 29 subsequently had a permanent implant. After a medium follow-up of 35 (range 3-71) months, 28 patients showed a marked improvement: incontinence to solid or liquid stool decreased from a median of 7 (range 4-15) to 2 (range 0-5) episodes in 21 days (p = 0.002). Saline retention time increased from a median of 2 (range 0-5) to 7 (range 2-15) min. (p = 0.002). The quality of life on all scales among patients who received the permanent implant increased at 12 and 24 months after operation.

Based on a retrospective, non-blinded study without controls comprising 39 patients, Lombardi et al. [16] evaluated the clinical outcome of SNS in incomplete SCI with neurogenic bowel dysfunction: Twenty-three patients were submitted to definitive SNS, maintaining their clinical benefits after permanent implantation with a median follow-up of 38 months. The length of time since neurological diagnosis to SNS therapy represented the only factor significantly related to the success of the implantation. In subjects with constipation [12] the median number of evacuations shifted from 1.65 to 4.98 per week, whereas the Wexner score changed from 19.91 to 6.82 in the final checkup with P<0.05. In subjects with fecal incontinence [11], the median number of episodes per week in the final follow-up was 1.32 compared to 4.55 pre-SNS. General and mental health showed statistically significant improvement. Anorectal manometry showed no important variation compared with baseline. There were no major complications. The authors consider SNS an option for the treatment of neurogenic bowel symptoms for selected patients with *incomplete SCI* when conservative treatments have failed.

The overview of the studies shows that electrical nerve stimulation is effective in partial spinal cord injury. There are no reports for complete spinal cord lesions.

Conclusions

- **SNS is a minimally invasive procedure, and seems to be an option for faecal incontinence and constipation due to functional deficit of the anal sphincter without structural defect in incomplete neurogenic lesions (LoE3/4).**

Recommendations

- **Studies on larges series with long term follow-up are needed to determine the role of SNS in the treatment of faecal incontinence associated with neurological lesions (D) and identify those patients most likely to benefit.**

2. ANTEGRADE CONTINENCE ENEMA (ACE)

The original procedure was developed by Malone et al. [17]. The principles of antegrade colonic washout and the Mitrofanoff non-refluxing catheterisable channel were combined to produce a continent catheterisable colonic stoma. The intention was that antegrade washouts delivered by this route would produce complete colonic emptying and thereby prevent soiling. Malone et al. reported successful results in five children with intractable faecal incontinence. This procedure has been applied mainly to the paediatric population with neuropathic bowel dysfunction and anorectal anomaly, and successful outcome was achieved in 70-100 % [18-38] (**Table 15**). Several modifications have been reported including laparoscopic technique, left colonic continence stoma, etc. This procedure was also applied to adult neurogenic patients with faecal incontinence, and similar success rates (83-100 %) were reported. Overall, stoma stenosis is the most common complication, affecting 10-41 %. In a study of 62 children with median follow-up of 5.4 (3.25 to 8.25) years, 84% were completely continent or had soiling less than once a month [20]. There was a significant correlation between the level of continence and satisfaction with the procedure. Improvement of self-esteem and psychosocial function after the ACE procedure in children with myelomeningocele has been reported [22].

Casale et al. [39] compared total continence reconstruction to staged-reconstruction of neuropathic bowel and bladder. In this retrospective chart review of all patients with myelomeningocele who underwent reconstruction with a cutaneous catheterisable urinary channel or Malone ACE stoma, the authors were unable to find any differences in the continence rate or stoma complications between total continence reconstruction and/ or staged reconstruction. However, because of shared pathology the authors believe that most patients are likely to require intervention for both gastrointestinal and genitourinary problems. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of requiring major surgical procedures on separate occasions for the two organ systems (LOE 3).

Herndon et al. 2004 [40] reported on ACE stoma in 127 patients (76 females and 51 males, average t age at the time of surgery 9.6 years), reflecting a 6-year experience. Diagnoses included myelomeningocele in 116 cases, lipomeningocele in 6, SCI in 2, sacral agenesis in 1 and functional constipation

Table 15: Antegrade continence enema stoma

Table: Summary of reported data on antegrade continent enema for faecal incontinence							
Authors reference no., year	Level of evidence	No. of patients	Mean age (range)	Median follow up (range)	Success rate	Overall complication rate	Stomal stenosis

Squire et al., 1993 [38]	Level 4	25	(3-18)	13 (2-61) mos.	88%	24%	20%

in 1. The mean follow-up was 26.9 months. Faecal continence was reported by 91% of the patients, while 13 stoma revisions were required in 11 patients (for stenosis in 10, prolapse in 2 and leakage in 1). Major complications included a caecal volvulus requiring a right hemicolectomy in one patient, small bowel obstruction in two and a shunt infection and/ or malfunction in two. The authors conclude that the in situ ACE procedure has reliable long-term results for treating faecal incontinence associated with neuropathic bowel.

Bar-Yosef et al. [41] performed a retrospective chart review from 1997 to 2007 in a total of 21 patients with myelomeningocele who underwent total continence reconstruction for urinary and feacal incontinence using the artificial urinary sphincter (AUS) and a Malone ACE stoma (using the appendix in 19 patients and cecal-based flaps in 2). There were 19 patients (90%) who reported fecal continence, with two reporting soiling 1 to 2 times a week. ACE stoma stenosis occurred in 3 patients and 2 required revisions. Sixteen patients (76%) achieved complete continence of stool and urine. Therefore ACE stoma and AUS in conjunction provide urinary and fecal continence in a single total continence reconstruction procedure, for patients.

Conclusion and Recommendation

- **Antegrade continence enema stomas are effective for controlling faecal incontinence and constipation associated with neurogenic bowel dysfunction especially in neuropathic children (LoE 3; Grade B). Patients should be properly selected to determine appropriate motivation.**

3. DYNAMIC GRACILOPLASTY

This procedure consists of transposition of the gracilis muscle around the anal canal and subsequent implantation of a pulse generator to stimulate and entrain the gracilis muscle. Before continuous stimulation is applied, the muscle is trained for 4 to 8 weeks according to a protocol. During a stimulation program the fatiguable type 2 skeletal fibres may be replaced by slow type 1 fibres, which are able to sustain a longer-lasting contraction- though formal documentation of such transition is not evident. Satisfactory continence has been reported in 56% to 81% of patients [42-53] (**Table 16)**. However, all studies presently available include small numbers of neurogenic patients, or there is no subgroup information on the outcome in neurogenic patients.

A prospective study of 200 consecutive patients with a follow-up of at least two years showed a 72% overall success rate. Complication rates are high (42%-92%)- especially infectious complications, which occur in about one quarter of the patients. Impaired rectal emptying occurs in 16% to 29%. A prospective controlled comparative study of a single stage operation with the conventional two-stage procedure showed no significant difference in infection rates, continence rates, morbidity or quality of life between the two groups after a mean 521-day follow up. Chapman et al. [53] reported a systematic review article of this procedure, where they searched articles published until November 1999, and found 40 articles met the inclusion criteria. Mortality rates were around 2% for both graciloplasty and colostomy. However, morbidity rates reported for graciloplasty appear to be higher than those for colostomy. Rongen et al. [42] reported an 80% success rate with this procedure in 16 patients with neurogenic faecal incontinence.

A prospective controlled study comparing dynamic graciloplasty with artificial anal sphincter in 16 patients (8 in each group) showed that both of the two procedures had a high incidence of technical failures and complication requiring re-operation [52], with a median observation time of 44/39 months. In this study, Ortiz et al. [52] came to the following conclusion: the artificial anal sphincter is a more convenient technique than dynamic graciloplasty for institutions treating a small number of patients. However, technical failures and complications during follow-up that require reoperation are very high in both types of treatment.

Conclusions and Recommendations

- **Dynamic graciloplasty seems to be associated with high complication rates, and outcome appears to correlate to surgeon's experience.**
- **Graciloplasty should be carried out in specialist centres with a reasonably large number of patients, and should be reserved for carefully selected patients with intractable faecal incontinence, where other methods have failed (C).**
- **Further studies are needed to determine its role in the neurogenic subpopulation.**

4. ARTIFICIAL ANAL SPHINCTER

Implantation of an artificial anal sphincter (AAS), also referred to as artificial bowel sphincter (ABS) was first reported in 1987 [54]. The sphincter used was originally designed for treatment of urinary incontinence, but subsequently the device was modified. The system consists of an inflatable cuff placed around the upper anal canal, a pressure-regulating balloon to maintain closure of the cuff, placed in the subperitoneal space lateral to the bladder, and a control pump accessible to the patient to empty the cuff for defaecation placed in the scrotum or labium. The system is left deactivated for 4 to 6 weeks after placement. The reported success rates obtaining acceptable continence range from 41 to 90% [55-70] (**Table 17**). A multicentre prospective, non-randomized trial in 112 patients with one year follow-up showed 73 revision operations were required in 51 (46%), and the infection rate necessitating surgical revision was 25%. Forty-one patients (37%) have

Christiansen et al., 1987 [54]	Level 4	1		3	100%				

had their devices completely explanted [55]. Explantation rates in the reported series were 20-40%. Technical complications like rupture of the cuff, which occurred frequently with the earlier versions of the device, are now rare. Emptying problems in the absence of anatomical stenosis, as described for dynamic graciloplasty, have also occurred frequently (13 to 45%) in most series and have necessitated explantation in some patients. Other complications leading to explantation have been erosion of the cuff through the skin, or into the anal canal.

As shown in the Table, most studies have a small number of neurogenic patients or do not indicate the number of neurogenic patients included. In the study reported by Christiansen et al. [63], 10 (59 %) out of 17 patients had neurological disorders, and the overall success rate was 47%, which seems to be lower than the others. The authors mentioned that the result in neurogenic subgroup was clearly poorer than that in non-neurogenic subgroup.

In a prospective, randomized controlled clinical trial of placement of the artificial bowel sphincter for the control of faecal incontinence O'Brien et al. [2000] [61] compared its effects to a program of supportive care and patients were followed for six months from operation or entry into the study. The principal outcome measure was the level of continence, measured with the Cleveland Continence Score, categorising from perfect control through to total incontinence. Secondary outcome measures were peri-operative and late complications in the artificial bowel sphincter group and the changes in quality of life in both groups. In the control group (N = 7) the Cleveland Continence Score was not significantly altered. The artificial bowel sphincter group (N = 7) showed a significant improvement. One patient in the artificial bowel sphincter group had failure of healing and implantation of the device. There were major improvements in the quality of life for all measures in the artificial bowel sphincter group. The authors conclude that the placement of an artificial bowel sphincter is safe and effective when compared with supportive care alone. Perioperative and late problems are likely to continue to occur and between 15% and 30% of patients may require permanent explantation. The authors conclude the device is easy and discrete to use, effective in achieving continence, and able to generate an improvement in quality of life (LoE 3).

In an article on "The artificial bowel sphincter in the treatment of severe fecal incontinence in adults", Lehur and Meurette [68] concentrated on the most recent and significant published data. They state that several centers in Europe, the United States, and Australia have adopted the ABS to treat severe fecal incontinence not amendable to local repair. Reports with larger numbers of cases and longer follow-up have recently appeared, providing a better assessment of the technique and its present place in the treatment strategy of incontinent patients. Contraindications include excessive perineal descent and severe constipation. In cases of neurogenic fecal incontinence it is essential to take into account possible associated bowel emptying problems and excessive perineal descent. The ABS creates an obstacle to rectal evacuation, which can sometimes cause considerable evacuation difficulties. Continence restoration should not be achieved to the detriment of evacuation capacities. However, an objective assessment of the state of pre-operative transit is not always easy.

Michot et al. [69] described an implantation procedure of artificial sphincter for anal incontinence using a transvaginal approach. Between 2003 and 2005, the Acticon Neosphincter was implanted via a transvaginal approach in nine patients (average age 43 (range 25-73) yrs). Successful outcome was achieved in eight of nine patients (89 %), with a mean follow-up of 21.5 (range 8-38) months; incontinence scores decreased from 19 (range 18-20) before the procedure to 8.6 (range 2-14) at the last follow-up. Although it is not stated whether patients with neurogenic faecal incontinence are included, a transvaginal approach could be considered with destroyed or scarred perineum.

Conclusions and Recommendations

- **Implantation of the artificial anal sphincter may be undertaken in neurogenic faecal incontinence, except in patients with previous perianal infections or with a thin and scarred perineum, in whom muscle transposition is preferable.**
- **Due to the relatively high risk of treatment failure and of complications requiring re-operation, patient selection and counselling should be very strict (C).**

5. COLOSTOMY

Several retrospective studies on the effect of colostomy formation in SCI patients showed a significant decrease in the average time spent on bowel care per week and improvement of QoL [70-78]. The early and long-term complication rates reported are 6 to 15%, and 15 to 37.5%, respectively. The commonest long-term complication is mucus discharge per rectum. One of the more frequent, persistent, problematic complications is diversion colitis [81, 82]. Symptoms include hemorrhagic purulent rectal discharge, abdominal pain and tenesmus. This condition is thought to result from a deficiency of luminal short-chain fatty acids [83]. Steroid enemas, 5-aminosalicylic acid enemas or suppositories, or short-chain fatty acid enemas have been reported as helpful [84].

Hocevar and Gray [85] published a systemic review from January 1960 to November 2007 including prospective and retrospective studies that directly compared clinical, functional, QoL outcomes or satisfaction among patients with intestinal diversions with

patients managed by conservative means. Creation of an ostomy in selected patients provides equivocal or superior QoL outcomes when compared to conservative bowel management strategies. Both colostomy and ileostomy surgery significantly reduce the amount of time required for bowel management. Patients who undergo ostomy surgery tend to be satisfied with their surgery, and a significant portion report a desire to be counselled about this option earlier. There are no clear advantages when functional, clinical, or QoL outcomes associated with colostomy are compared to those seen in SCI patients undergoing ileostomy.

Conclusion

- **Elective colostomy may be an option for some SCI patients with severe uncontrolled faecal incontinence (C).**

6. POSTANAL REPAIR

Mackey et al. [86] published the long-term results of postanal repair carried out in patients whose incontinence was thought to be because of neurogenic sphincter weakness. Anorectal physiology studies were carried out in 89% of the cases, and the clinical diagnosis of neurogenic incontinence was confirmed by prolonged unilateral or bilateral pudendal nerve terminal motor latency (PNTML) (>2.2 m/s) or increased threshold of anal mucosal electrosensitivity (or both). Patients were selected for surgery only after failure of medical and conservative therapies, including dietary manipulation, loperamide, or biofeedback where appropriate. A total of 111 patients underwent a postanal repair, 57 remained eligible, for whom full data were available. The mean duration of follow-up was 9.1 years (2.2-18.7 years). Mean CCS (Cleveland Continence Score) was 11.7; 26% scored none or minimal incontinence, 26% moderate and 48% severe incontinence. 97% (n = 45) were satisfied with the outcome. A low CCS significantly correlated with good patient satisfaction and was influenced by high QoL score (P < 0.0001). A favourable CCS was associated with a shorter duration of follow-up. Although a deterioration in continence with passage of time was observed, satisfaction amongst the patients was high. Only a quarter of patients showed a very good continence after a mean time of 9 years. Patients undergoing postanal repair are counselled appropriately and have realistic goals regarding their bowel functions in both the short and long term.

The procedure is inexpensive in comparison with graciloplasty and sacral nerve stimulation, and has low morbidity. Additionally, this procedure be useful in the elderly or those with significant co-morbidities. Although long-term continence has been found to deteriorate, the procedure can result in a satisfactory outcome in the long-term in a proportion of patients.

Conclusions and Recommendations

- **Postanal repair results in satisfactory outcome in the long-term in patients with neurogenic sphincter weakness. However, this is a single centre experience, which needs further confirmation (C).**

E. Specific neurological diseases

I. DEMENTIAS

1. DEMENTIA AND URINARY INCONTINENCE

Methods Using MEDLINE we identified English-language journal articles and reviews published from May 2008 to January 2012, which were added to literature obtained for previous Consultations, looking for the keywords Alzheimer's disease, vascular dementia, dementia with Lewy bodies, frontotemporal dementia, urinary incontinence, bladder dysfunction, management.

The dementias can be categorized according to clinical presentation, neuropathology and/or etiology into four major dementia groupings, (I) the Alzheimer's group (Alzheimer's disease, AD); (II) the vascular group (including large and small vessel disease, particularly white matter disease); (III) the Parkinson's group (including Parkinson's disease dementia complex (PDD, being regarded as identical to DLB), and dementia with Lewy bodies (DLB), both being connoted as Lewy Body diseases); (IV) the frontotemporal group (including Pick's disease and Semantic dementia) [1]. Normal pressure hydrocephalus (NPH) is a less common pathology, but nonetheless important.

2. ALZHEIMER'S DISEASE

a) Epidemiology and prevalence

Alzheimer's disease (AD) is the most common type of dementia in clinical and autopsy surveys. AD affects mostly elderly people. The symptoms include worsening of the memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and ambulatory abilities, incontinence and motor dysfunction. The onset of incontinence usually correlates with the disease progression (LOE 3)[2]. In other words, urinary incontinence inevitably occurs in the advanced stage of disease, while urinary incontinence is not common in the early stage of AD. This is in contrast with early occurrence of urinary urgency and incontinence in vascular dementia and dementia with Lewy bodies. The prevalence of incontinence in AD is reported to be between 23 % and 48 % (LOE 3) [3, 4]. However, most previous studies did not mention the type of dementia concerning 'frequency of

urinary incontinence in dementia'. The prevalence of incontinence in dementia ranges from 10% (of out-patients) to more than 90% (of advanced, institutionalized individuals) (LOE 3) [5].

b) Pathology and disease-specific urinary tract problems

AD at the outset was identified by its unique pathology, the amyloid plaques and neurofibrillary tangles containing phosphorylated tau that Alzheimer referred to as "a clotting of fibrils…. in addition an extraordinary number of peculiar patches disseminated throughout the entire cortex." Amyloid and tau can now be measured in vivo by positron emission tomography and/or examination of the cerebrospinal fluid (CSF). There is a familial occurrence of AD [3]. In such cases, mutations in the genes encoding amyloid precursor protein (APP); presenilin 1 (PSEN1), or presenilin 2 (PSEN2) are reported.

The clinical hallmark of AD is memory impairment. A sense of memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation. AD has a gradual and progressive course, typically 10 years from diagnosis to death. The advent of central cholinesterase inhibitors and glutamate receptor antagonists has had a positive effect on the memory symptoms of AD [6-8].

In early stages of AD the prevalence of urgency incontinence is lower than in dementia with Lewy bodies [9, 10]. During stage III (advanced) AD, urinary and fecal incontinence occur due to loss of sphincter control [10]. In a study by Del Ser et al. (LOE 3) urinary incontinence was associated with severe cognitive decline in pure AD but usually preceded severe mental failure in patients with dementia due to diffuse Lewy body disease [10]. Nobili et al. (LOE 3) performed quantitative EEG in AD patients, finding that incontinence was predicted by alpha power in the right side [11]. In another study by Nobili et al. (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [12]. A brain computer tomography study done by Sugiyama et al. (LOE 3) in AD patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity (DO) than those without it [13]. DO was found in 40-61 % of their patients [13] (LOE 3). The incidence of DO in AD patients is low as compared with vascular dementia and dementia with Lewy bodies [9]. Haddad et al. (LOE 3) described two patients with vesicoureteral reflux, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprostatic and urethrovesicular reflux as a consequence of the neurologic dysfunction [14].

c) Diagnosis and treatment

Franssen et al. (LOE 2) examined the occurrence of the following developmental reflexes: the tactile suck reflex, the palmar and plantar grasp reflexes, and the plantar extensor reflex in healthy elderly, cognitively and functionally mildly impaired patients, and patients with AD [15]. Prevalence of all five reflexes was more than 6 times higher for those categories that comprised permanently doubly incontinent patients as compared to those categories that comprised continent individuals. It is interesting that the frequency of developmental reflexes rose sharply with the onset of progressive incontinence, suggesting its cortical origin. As demonstrated above, the development of incontinence in AD patients is associated with cognitive impairment and brain degeneration, suggesting its CNS origin. Therefore behavioural therapy, toilet training and prompted voiding would be most useful treatment modalities for this type of incontinence.

Hutchinson et al. (LOE 3) suggested that caregivers of patients with AD should study the toileting behaviours. This would permit them to provide physical and cognitive assistance while attempting to avoid accidents and catastrophic events [6]. Tariot (LOE 4) stressed the necessity for taking into account different factors (like mobility, cognitive functions, general medical conditions), when planning treatment (also for incontinence) in AD patients [7]. Lancioni et al. reported three AD patients who could learn to use urine alarms [16] (LOE 4). Again the general guidelines should apply for choosing the best management of incontinence in AD patients. The treatment should be tailored to individual patient needs and disease status.

There is still some controversy that the central acethylcholinesterase (AChE)- inhibitors given by the neurologist might exacerbate urinary incontinence in those patients. Donepezil hydrochloride is a selective central AChE inhibitor, which decreases degradation of acetylcholine in the brain, then increasing the concentration of acetylcholine in the synaptic cleft [17]. This drug is widely used to ameliorate cognitive decline in patients with AD [18, 19] which is thought to be due to a decrease in cholinergic innervation of the cerebral cortex and the basal forebrain [20]. Since the bladder is innervated by the parasympathetic cholinergic nerves, neurogenic lower urinary tract (LUT) dysfunction occurs in a subset of patients with AD [5, 13].

Although donepezil may facilitate cholinergic neurotransmission mostly in the CNS, common adverse effects of donepezil, such as nausea and abdominal discomfort, have been attributed to the peripheral nervous system (PNS) [18]. Therefore, the increased bladder contraction is reasonably attributed to the PNS effects as seen with other cholinergic drugs. However, according to Sakakibara et al. [2005] the patients with AD showed a slight increase in

the bladder capacity, which cannot be explained by the PNS effects alone [21] (LOE 3). Although it is unknown to what extent central cholinergic circuit may participate in the regulation of micturition, recent experimental studies showed that lesions in the nucleus basalis Mynert in the basal forebrain (central cholinergic nucleus projecting fibres to the frontoparietal cortex) give rise to decreased bladder capacity) [22]. In addition, improved cognitive status and alertness may well lead to proper initiative to hold urine. Central AChE inhibitors including donepezil hydrochloride, therefore, may have complex effects on the LUT function. Although the number of the patients was small, it seems possible that donepezil could ameliorate cognitive function without serious adverse effects on the LUT function in patients with AD. This should be true also for other selective central AChE inhibitors.

Many elderly patients and their caregivers seek medical care for dementia and overactive bladder (OAB) together. In order to answer this, recent clinical trials of a combination therapy of central AChE inhibitors and peripheral anti-cholinergics for ameliorating both cognition and incontinence are available. In 26 older individuals who had both cognitive problems and overactive bladder (AD in 8, vascular dementia in 5, a combination of AD and multiple cerebral infarction in 8, and others), Sakakibara et al. reported that addition of 20 mg/day propiverine, an anticholinergic agent, to 5 mg/day donepezil improved OAB without any cognitive change [23] (LOE 3). Sink and colleagues retrospectively studied 3536 nursing home residents who were taking central AChE inhibitors, in whom 10.6% were prescribed anticholinergics together [24]. They found no differences in cognitive function between groups of AChE inhibitors alone and AChE inhibitors with anticholinergics (LOE 3). The combined use of a 'central' AChE inhibitor and a 'peripheral' muscarinic receptor antagonist remains a matter of controversy and needs forther clarification, whereas there is a study indicating that this combination would be pharmacologically sound as a site-directed therapy [25].

d) Guidance for further research

There is still no cure for AD, which is progressive and a type of dementia-associated disease. We are still lacking studies evaluating LUT disorders in AD. No systematic review has been performed regarding the possibilities of medical management (both pharmacological and behavioural) of incontinence. An open issue also remains the question of aggressive surgery for LUT problems in these patients. Whether we should we offer surgical therapy for incontinence in female patients with stress incontinence and progressive AD is so far unanswered.

Conclusions

- **Detrusor overactivity seems to be the most common cause of incontinence in Alzheimer's disease (AD) patients (LOE 3), while the incidence is low as compared with vascular dementia and dementia with Lewy bodies.**
- **The degree of functional incontinence is associated with cognitive impairment and brain degeneration (LOE 3).**
- **EEG studies, occurrence of developmental reflexes and regional blood flow studies can predict the development of incontinence in AD patients (LOE 3).**
- **Selective central AChE inhibitors ameliorate cognitive function without serious adverse effects on LUT functions in patients with AD (LOE 3).**
- **A combination therapy of central AChE inhibitors and peripheral anticholinergics for ameliorating both cognition and incontinence awaits further studies (LOE 3).**

Recommendations

- **The extensive and aggressive therapy of incontinence in AD patients should be reserved for those with good general status and ambulation (C).**
- **In the case of ambulatory patients, prompted voiding, behavioural therapy and oral anticholinergics seem to be the treatment of choice (C).**

3. VASCULAR DEMENTIA

a) Epidemiology and prevalence

Vascular dementia is the second most common form of dementia after Alzheimer's disease (AD) among the elderly. Pooled prevalence from eight European countries was 1.6% for vascular dementia in subjects older than 65, compared to a prevalence of 4.4% for AD (LOE 3) [26]. A meta-analysis of the European studies on the incidence of dementia showed vascular dementia constituted 17.6% of all incident dementia (LOE 3) [27].

In contrast, recent population-based MRI studies suggest that moderate white matter disease (WMD, a major cause of vascular dementia) affects around 10% (7.6–24%) of the general population of persons over 55 years of age [28], comparable to type 2 diabetes. WMD develops into three different geriatric syndromes; 1) vascular dementia (usually mild in the Mini-Mental State Examination and other general cognitive function), 2) vascular parkinsonism, and 3) so-called vascular incontinence, i.e. urinary frequency/ urgency with or without incontinence [29]. Among these three syndromes, urinary and gait disorders are more prominent than dementia, and usually precede dementia. Comorbidity of Alzheimer's disease (a degenerative disease) and WMD (a vascular disease) is not uncommon.

b) Diagnosis

Vascular dementia may be the result of a single strategic infarct, particularly involving the thalamus

and left angular gyrus, or multiple cortical or subcortical infarcts that produce WMD. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2) [30]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer's disease (LOE 3) [31]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [32]. The incidence of WMD significantly increases with gene polymorphism of aldosterone synthase, angiotensin II type 1 receptor, nitric oxide synthase, etc., which are all relevant to atherosclerosis (LOE 3).

c) Pathology and disease-specific urinary tract problems

In patients with WMD, diffuse abnormalities are seen in the small deep perforating vessels of the hemispheric white matter, basal ganglia and brain stem. Pathological changes range from lipohyalinosis to fibrinoid necrosis and disintegration of small vessels. Disruption of the blood brain barrier is likely to precipitate or worsen progression of WMD [33] (LOE 3). Positron emission tomography imaging with 18F-fluoromisonidazole showed higher susceptibility to ischemia of white matter than gray matter in stroke cases [34]. Cortical WMD in MRI looks diffuse. However, within the brain, detailed pathology studies confirmed that the frontal lobe is most severely affected [35]. This is in line with documented frontal lobe atrophy on MRI volumetry, where glucose metabolism was also most severely reduced [36] (LOE 3). Corresponding to this, brain perfusion is most reduced in the frontal lobe of subjects with WMD [37] (LOE 3), a finding that remains to be fully explained.

The frontal cortex is now recognized as an important higher center for micturition: damage to the prefrontal cortex, medial superior/middle frontal gyri, anterior cingulate cortex, supplemental motor area and insula result in marked lower urinary tract dysfunction in humans [38] (LOE 3). These clinical observation have been corroborated by functional neuroimaging in humans [39, 40] (LOE 3). Altered spinobulbospinal micturition reflex micturition control may contribute to DO emergence in brain lesions [41] (LOE 3). Functional neuroimaging studies showed that the prefrontal cortex was deactivated in elderly subjects with urinary frequency/ urgency as compared with controls [42] (LOE 3). Jirovec et al. (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [43]. When the variables were examined together, mobility emerged as the best predictor of the patient's urine control, followed by cognitive impairment.

The prevalence of DO in WMD cases is reported as 70-91% of patients. In Sakakibara's study, urodynamic studies in 33 subjects found DO more commonly in grade 1-4 white-matter lesions (82%) than grade 0 white-matter lesions (9%) ($p<0.05$). Yoshimura et al. (LOE 3) found a 47 % prevalence of DO which correlated with the presence of dementia [44].

d) Disease specific diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence have been described. Since patients with dementia and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow standard principle, bearing in mind that this is a population of frail elderly people. The treatment should start with modification of behaviour, and general rehabilitation targeted at making the patient more ambulatory. No other specific treatment in dementia has been described, however certain issues like prompted voiding, anticholinergic drugs and intermittent catheterization have been studied.

In a review of trials where prompted voiding was implemented, Eustice et al. (LOE 1) found that prompting increased self-initiated voiding and decreased incontinence episodes in the short-term [45]. A single small trial suggested that adding oxybutinin, reduced the number of incontinent episodes in the short-term. In a study by Suzuki et al. (LOE 3) the best results were obtained with ambulatory patients with the use of a portable chamber pot and induced urination, while no improvement was seen in bedridden patients treated with anticholinergics [46]. Sugiyama et al. (LOE 3) studied the effects of anticholinergic therapy in patients aged 65 years or older, with and without dementia. The patients received anticholinergic agents for more than two weeks [47]. Urodynamic studies demonstrated significant increase of maximum bladder capacity in the dementia group and the non-dementia group. There was no significant difference in rate of objective improvement between both groups. On the other hand, rate of subjective improvement was significantly higher in the non-dementia group (40 %) than in the dementia group (15 %). Improvement of functional bladder parameters was not associated however with improvement of subjective symptoms in the dementia patients.

In case of voiding failure, intermittent catheterization (IC) is a treatment of choice. Lieu et al. (LOE 3) found that carer-assisted clean IC is an effective and safe treatment option for persistent urinary retention in elderly female patients with cognitive impairment and other disabilities [26]. With this method of treatment, 54% of the patients were able to void spontaneously and were continent after a median period of 6 weeks with a range of 1 to 40 weeks. 27% had significant improvement in the symptoms of urinary incontinence and the residual urine volumes became progressively smaller. However, 19% failed this treatment modality. The recovery of spontaneous voiding was found to be significantly influenced by the age of the patient, the carer performing the IC and the development of catheter-related UTI. 25% of the study patients developed symptomatic UTI, which was associated with a delay in the recovery of spontaneous

voiding. Its development was also found to be significantly associated with the presence of pre-existing diabetes mellitus, the person doing the catheterization, the presence of dementia and with more predisposing common medical conditions.

Another interesting issue is the surgical treatment in patients with dementia. Two major groups of surgical procedures could be contemplated: prostate surgery and incontinence surgery. Yonou et al. (LOE 3) studied a group of 13 patients with dementia who underwent TURP procedure [48]. Six patients reported good urination, 3 reported some improvement in urination after surgery although requiring IC, and 1 developed incontinence. No specific study addressing the issue of incontinence surgery in woman with dementia has been reported. However, it seems that incontinence surgery in patients with dementia should be reserved only for the cases with good ambulation and without concomitant functional disorders of micturition (overactive bladder, hypocontractile detrusor).

e) Recommendations for further research

Since dementia is not a homogeneous disease, a population study targeted specifically at disorders of micturition is needed. Also, a study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

Conclusions

- **Dementia-associated incontinence occurs in 30-100 % of patients with dementia (LOE 3).**
- **The degree of incontinence is strongly associated with the patient's general status and ambulation (LOE 3).**
- **There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant proportion of incontinence (LOE 3).**

Recommendations

- **Interventional therapy of incontinence in dementia patients should be reserved for patients with good general status and ambulation (C).**
- **In case of ambulatory patients, prompted voiding, rehabilitation and oral anticholinergics can be employed (C).**
- **Where there is a significant post-void residual, intermittent catheterization is the treatment of choice (B).**

4. DEMENTIA WITH LEWY BODIES

a) Epidemiology and prevalence

Dementia with Lewy bodies (DLB) is thought to be the third most common type of dementia in the elderly, accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of DLB was found to be 0.7%, which is consistent with its rate of 10 – 15% of hospital-based cases at autopsy [49]. The epidemiology of DLB is sparse; age and gender distribution, and potential risk factors have yet to be defined.

b) Pathology and disease-specific urinary tract problems

DLB primarily affects both the basal ganglia (as in Parkinson's disease) and the cerebral cortex. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein (SNCA), a ubiquitously-expressed synaptic protein that has been implicated in vesicle production [50]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alpha-synuclein has been shown to be the most sensitive and specific method for detecting Lewy bodies and can be used in a semiquantitative grading of severity of Lewy-related pathology [51]. Alpha-synuclein can now be measured in vivo by positron emission tomography and/or the cerebrospinal fluid.

Many patients with DLB also have Alzheimer's disease pathology, which alters the clinical presentation. DLB patients who also have numerous neurofibrillary tangles display more core clinical features of AD [52]. Conversely, Lewy bodies also occur in more than half of all patients with sporadic and early-onset AD [53]. The essential feature for a diagnosis of possible or probable DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal, from almost normal to markedly confused or hypersomnolent) are a core feature of dementia with Lewy bodies. In DLB, autonomic dysfunctions occur and are included as a supportive feature for clinical diagnosis [54].

Horimoto et al. (LOE 3) found 97 % incidence of urinary incontinence amongst patients with DLB. From the urological point of view, patients with DLB tend to develop urgency and urgency incontinence more often than do patients with Parkinson's disease (PD) or AD. Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in each of these diseases; however, DO, the major cause of urgency and urge incontinence, was more prevalent in DLB than in PD and in AD [9]. Urinary symptoms are seen in one third of patients with DLB. Detrusor overactivity, the major cause of urge and urge incontinence was more prevalent in DLB and AD. No detrusor-sphincter-dyssynergia was observed. DLB patients with detrusor overactivity had significantly higher Hoehn and Yahr scores than did those without detrusor overactivity. Since the prevalence of frequency, urgency, urge

incontinence and detrusor overactivity is markedly lower in AD than in DLB, LUTS may contribute to the differential diagnosis of these two entities.

c) Disease specific diagnosis and treatment

Since patients with Lewy Body disease and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is most often a population of frail elderly people (LOE3).

5. FRONTOTEMPORAL DEMENTIA (FTD)

a) Epidemiology and prevalence

Prevalence studies of FTD are inconsistent (LOE 3), giving ranges of 3.6-15.0 per 100,000 [55]. There is a high familial occurrence of FTD [56]. In such cases, a combination with parkinsonism, and rarely amyotrophic lateral sclerosis, also occurs. The distribution of FTD is equal between men and women. The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years.

b) Pathology and disease-specific urinary tract problems

Frontotemporal dementia (FTD), also known as Pick's disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioral changes, but a language disorder, usually in the form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient's premorbid behaviour. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetric [57]. At autopsy, markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histologic examination the salient features include neuronal loss, micro-vacuolization and astrocytes gliosis centred on cortical layer II. Up to now, molecular pathology of FTD has identified four subtypes. First, classical Pick's disease (Pick body with accumulation of 3-repeat tau); second, mutations in the MAPT (microtubule-associated protein tau) gene; third, accumulation of TDP-43 (TAR DNA binding protein-43) with mutations in the PGRN (progranulin) gene; and fourth, accumulation of FUS (fused in sarcoma) protein.

There a no data on LUTS in patients with FTD, however it is obvious that due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, or they may urinate in inappropriate places and pass urine more often than usual. Moreover, they may be affected by constipation, diarrhoea or faecal incontinence.

c) Diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence were described. There are no studies which show the significance of LUTS in fronto-temporal dementia. Such studies would be of value in future research projects.

Conclusions

- **There are no studies available which show the significance of LUTS in patients with fronto-temporal dementia.**
- **Since the underlying pathology is gross atrophy of frontal and temporal lobes, autonomic dysfunction including LUTS can be anticipated, but further research is needed.**

Recommendations

- **The recommendations do not differ from those for other types of dementia.**

6. CONSTIPATION AND FECAL INCONTINENCE IN DEMENTIA

Only one paper was retrieved related to the influence of dementia on the prevalence of urinary and faecal incontinence in an age group of 85-year-old men and women [58]. This reported the influence of dementia on the prevalence of urinary and faecal incontinence in 85 year-old men and women in a random sample n= 485 of the total population of 85-year-olds from the city of Gothenburg, Sweden. The prevalence of urinary and faecal incontinence and dementia were 38%, 17% and 29% respectively. Demented men (50%) and women (60%) were more often incontinent than non-demented men (18%) and women (36%). Also, faecal incontinence was more prevalent in demented (34,8%) than non-demented subjects (6,7%): both urinary and faecal incontinence were more prevalent in demented women (43% and 20% respectively) than in men (27% and 11% respectively). The prevalence of urinary and faecal incontinence and dementia were higher in residents of a nursing home or hospital (74%, 51% and 92% respectively) than in subjects living at home (32%, 9% and 18% respectively): of the demented residents in an institution 78% were incontinent compared with 37% living at home.

No specific paper was found on the management of faecal incontinence in demented people. Demented patients may benefit from a bowel habit training programme, which also includes management of constipation with non-pharmacologic (such as exercise and fibre) and pharmacologic measures.

Conclusions

- **Although faecal incontinence is prevalent in people with dementia, no paper was found**

dealing with the disease-specific management of faecal incontinence (LOE3).

Recommendations

- **Studies should be undertaken to ascertain management strategies for constipation and faecal incontinence in dementia.**

7. NORMAL PRESSURE HYDROCEPHALUS

a) Epidemiology and prevalence

Normal-pressure hydrocephalus (NPH) is characterized by a clinical presentation of gait disturbance, memory deficit, and urinary incontinence, combined with dilated cerebral ventricles and normal cerebrospinal fluid (CSF) pressure [59] (LOE 3). The clinical triad of this disorder is very much akin to those of vascular dementia or white matter disease (WMD). Therefore, before performing brain imaging, we have to think about NPH as well as WMD. The syndrome was first described by Hakim and Adams in 1965 [60] . After five decades of investigation, the effectiveness of the diversion of CSF flow by shunt operation in treating this syndrome is well documented [59] (LOE 2). Recent population-based MRI studies also suggest that the incidence of NPH, or asymptomatic ventriculomegaly with features of idiopathic normal pressure hydrocephalus on MRI (AVIM), to be around 1% (0.51-2.9%) in the general population of persons over 65 years of age [61], being estimated as one-tenth of WMD (LOE 3).

b) Pathology and disease-specific urinary tract problems

Lower urinary tract symptoms in NPH are basically urinary urgency and frequency (overactive bladder, OAB). Sakakibara et al. found urinary symptoms in 93% of 42 idiopathic NPH patients [62] (LOE 3). These symptoms included storage symptoms in 93% of patients (nocturnal urinary frequency, 64%; urinary urgency, 64%; urgency urinary incontinence, 57%; diurnal urinary frequency, 36%) and voiding/ post micturition symptoms in 71% (hesitancy 50%; prolongation /poor flow, 50%; sensation of post-void residual, 29%; straining, 21%; intermittency, 14%). Particularly, in some patients urinary urgency /frequency preceded urinary incontinence. Among the clinical triad of NPH, urinary incontinence has been regarded a late symptom. However, as in cases of WMD, gait disturbance and OAB can be the early manifestation of NPH.

Urodynamic findings of 42 NPH patients by Sakakibara et al. included low Qmax (<10 cm/s) in 40%; increased post-void residual (>30 ml) in 43% (average PVR volume 42.1 ml); low volume at first sensation (< 100 ml) in 33%; decreased bladder capacity (< 200 ml) in 57%; and DO in 95% of patients [62] (LOE 3). Although the number of cases included in other reports has been small (4-12 cases), DO is also most common (63-100%) [63] [64] (LOE 4). The high prevalence of DO suggests altered brain autonomic control in NPH [65].

c) Diagnosis and treatment

Diagnosis of NPH may comprise:

a) Possible features; gait, cognitive and urinary disorders with typical ventricular dilatation in brain imaging.

b) Probable features; improved clinical symptoms by 30 ml withdrawal of the cerebrospinal fluid by a lumbar tap (the Tap test).

c) Definite; improved clinical symptoms by ventriculoperitoneal shunt surgery etc.

Functional neuroimaging in normal volunteers has shown that the anterior cingulate, prefrontal cortex and insula are activated in response to bladder filling as compared with an empty bladder [41]. Although NPH is a diffuse brain disease with dilated ventricles, hypoperfusion in the frontal lobe has been documented in NPH patients using PET [66], single-photon emission computed tomography (SPECT) [67] , and perfusion-weighted MRI [68] (LOE 3). Therefore, the frontal lobe is thought to be the anatomical substrate for urinary urgency and incontinence in NPH. According to the study by Sakakibara et al, using 97 NPH patients and [123I]-iodoamphetamine (IMP)-SPECT statistical mapping, there was a significant decrease in tracer activity in the right-side-dominant bilateral frontal cortex and the left inferior temporal gyrus in the severe urinary dysfunction group ($p<0.05$) [69]. The findings indicate that there is a link between the right frontal hypoperfusion and urinary dysfunction in NPH. Importantly, bladder dysfunction and frontal lobe hypoperfusion in NPH can be reversed after shunt surgery. Recovery rate of OAB and urinary incontinence in NPH ranges from 20-80% [59] (LOE 4). Among them, cerebral perfusion in the prefrontal cortex and mid-cingulate gyrus tended to return normal particularly in patients with good OAB/ incontinence recovery.

Since there is a surgical shunt therapy for NPH, early diagnosis of NPH in patients with OAB is important. In addition to OAB with/without urinary incontinence, patients with NPH commonly have gait disorder (parkinsonian and wide-based gait) and dementia that is milder than Alzheimer's disease. Differential diagnosis should include vascular dementia or white matter disease. If the shunt surgery failed, or was not applied to individuals with particular reasons such as dementia etc., medical management (pharmacological and behavioural) of incontinence starts. However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH.

Conclusions

- **Clinical manifestations in NPH mimic those of vascular dementia or white matter disease (LOE 3).**
- **Urinary urgency and frequency may precede urinary incontinence in NPH (LOE 3).**
- **Detrusor overactivity seems to be the most common cause of incontinence in NPH patients (LOE 3).**
- **Shunt surgery ameliorates urinary incontinence in NPH but the degree varies significantly (20-80%) (LOE 4).**

Recommendations

- **Typical gait, cognitive and urinary disorders with ventricular dilatation in brain imaging favours the diagnosis of NPH; then a Tap test and a shunt surgery may follow (B).**
- **However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH if the shunt surgery failed or is not applied to individuals (C).**

II. MULTIPLE SYSTEM ATROPHY

1. EPIDEMIOLOGY AND PREVALENCE

Multiple system atrophy (MSA) is a rare, adult-onset degenerative disease of the nervous system of unknown origin. Autonomic failure (postural hypotension and urinary dysfunction) is fundamental to the diagnosis of MSA: it is diagnosed when the criteria of either postural hypotension (systolic blood pressure fall > 30 mmHg or diastolic > 15 mmHg) or urinary dysfunction (persistent, urinary incontinence/ incomplete bladder emptying) or both are fulfilled, along with poorly levodopa-responsive parkinsonism, or cerebellar dysfunction [70]. Based on the major motor deficits, MSA can be classified as MSA-P (Parkinsonism-predominant) or MSA-C (cerebellar-predominant) [70]. The discovery in 1989 of glial cytoplasmic inclusions in the brains of patients with MSA [71] provided a pathological marker for the disorder (akin to Lewy bodies in idiopathic Parkinson's disease), which combined three disorders previously called striatonigral degeneration, sporadic livopontocerebellar atrophy, and Shy-Drager syndrome.

Urinary symptoms of incontinence are caused by neurogenic DO and external sphincter weakness [3] (LOE 2). Sphincter electromyography (EMG) abnormalities were found in 91% of the patients with MSA [72] (LOE 2). Approximately 60% of patients with MSA develop urinary symptoms, either prior to or at the time of presentation with the motor disorder [73] (LOE2). This indicates that many of these patients seek urological advice early in the course of their disease. Although postural hypotension was thought to be a marker for autonomic failure in MSA, Wenning et al. [74] (LOE2) noted urinary incontinence in 71%, urinary retention in 27%; postural faintness in 53%, and syncope in 15% of 100 patients with MSA. Sakakibara et al. [1999] [73] (LOE2) found that urinary symptoms (96%) were more common than orthostatic symptoms (43%) ($p < 0.01$) among 121 patients with MSA. Kirchhof et al [75] (LOE2), found that bladder symptoms preceded symptoms of orthostatic hypotension in 76% of their 71 male patients. Sakakibara et al. [73] (LOE2) also found that among 53 patients with both urinary and orthostatic symptoms, those who had urinary symptoms first (48%) were more common than those who had orthostatic symptoms first (29%), and some patients developed both symptoms simultaneously (23%).

2. PATHOLOGY AND DISEASE-SPECIFIC URINARY TRACT PROBLEMS

Sakakibara et al. [1993] [76] (LOE2) performed an extensive study of the urological symptoms in MSA patients. They found the following prevalence of different symptoms: difficulty of voiding in 79%, nocturia in 74%, sensation of urgency in 63%, urgency incontinence in 63%, diurnal urinary frequency in 45%, enuresis in 19% and urinary retention in 8% of the patients. All of the MSA patients presented with some kind of LUT symptoms; many of them had both storage and voiding urinary symptoms.

In 245 cases of MSA, Ito et al [77] (LOE2), found that average volume of post-void residuals was 71ml at the first year, which increased significantly to 170ml at the 5th year ($p<0.01$) after onset of the disease. Patients were not always aware of their post-void residuals. The frequency of weak detrusor ascertained by a pressure-flow analysis was 20% at the first year, which increased to 53% at the 5th year ($p<0.05$). The frequency of detrusor-external sphincter dyssynergia (DSD) was 12% at the first year, which increased to 39% at the 5th year ($p<0.05$). Therefore, detrusor underactivity seemed to contribute to voiding dysfunction in MSA more than DSD did. The responsible sites of lesion (micturition-facilitating area) for voiding difficulty and retention in MSA seem to be the locus coeruleus (pontine micturition center). The work of Bennaroch demonstrated, that in MSA there is severe depletion of catecholaminergic neurons of the Cl and Al areas in the ventrolateral medulla, and this may contribute to orthostatic hypotension and endocrine disturbances in this disorder, respectively. Loss of corticotrophin-releasing factor (CRF) neurons in the pontine micturition area may contribute to neurologic bladder dysfunction [78] (LOE 2). In addition, the sacral intermediolateral cell columns, where preganglionic neurons innervating the bladder are located, are affected in post-mortem MSA cases.

The prevalence of detrusor overactivity was 61% at the first year, which increased to 75% at the 5th year

(p<0.05) [77] (LOE2). The frequency of neurogenic pattern in the sphincter EMG was 52% at the first year, which increased to 83% at the 5th year (p<0.05) [79] (LOE2). Abnormalities in the videourodynamic study included open bladder neck at the start of filling in 53% of MSA patients [80] (LOE2). Similar results were reported by others [81]. The responsible sites of lesion (storage-facilitating area) for urinary urgency and incontinence in MSA seem to be the basal ganglia, cerebellum [82], lumbar intermediolateral cell columns where preganglionic neurons innervating the bladder neck are located, and sacral Onuf's nucleus innervating the external sphincter, all of which are affected in post-mortem MSA cases, causing urinary stress incontinence.

Repeated urodynamic studies in MSA patients showed that the cystometrogram changed from DO to low-compliance or acontractile detrusor, and from negative to positive bethanechol supersensitivity [83] (LOE2). In fact, as the disease progresses, symptoms may change from urinary urgency and frequency to those due to incomplete bladder emptying. These findings suggest that the responsible sites of the bladder cholinergic disorder may change from the center to the periphery. The cystometrograms of patients with MSA often show neurogenic DO with impaired contractile function (DHIC), mostly accounting for urinary urgency / frequency and large post-void residuals, respectively. This condition presumably reflects lesions in both storage and voiding-facilitating areas in this disorder [84].

Beside bladder disorders, patients with MSA may have nocturnal polyuria, which results in nocturia and morning hypotension. In normal children over 7 years and adults, the circadian release of arginine vasopressin from the posterior pituitary gland into plasma peaks at night. This leads to a nocturnal decrease in urine formation. The ratio of night-time to daytime urine production is usually <1:2, which can be estimated by a bladder diary. A post-mortem study of the brains of patients with MSA revealed the degeneration of arginine vasopressin neurons in the suprachiasmatic nucleus [85] (LOE 2), leading to impairment of the circadian rhythm of the plasma arginine vasopressin concentration in MSA [86] (LOE 2).

3. DIAGNOSIS AND TREATMENT

Since LUT functional disturbances often precede orthostatic hypotension and other autonomic nervous system symptoms in MSA patients, the full assessment of underlying mechanisms of LUT symptoms is of paramount importance.

External sphincter EMG is the most sensitive test. Sphincter motor unit potential analysis showed neurologic motor unit potentials in 93% of those with MSA, suggestive of external sphincter denervation. Palace et al. [87] (LOE 2) demonstrated abnormal sphincter EMG in 93% of MSA patients, which can differentiate this disorder from idiopathic Parkinson's disease. Oertel et al. [88] (LOE2) suggested that reduced genital sensation in females could be pathognomonic for MSA (with equal importance as erectile dysfunction in males). A total of 47% of the MSA patients and 4% of the control group had reduced genital sensation. Moreover, the appearance of reduced genital sensitivity in female MSA patients showed a close temporal relation to the onset of the disease. Hahn and Ebersbach [89] (LOE 2) investigated the value of sonography of the bladder to evaluate post-void residual urine (PVR) for the differential diagnosis between idiopathic Parkinson's disease and Multiple System Atrophy. The positive predictive value of increased residual urine for MSA was 91.6 % in the study, while the negative predictive value was only 67.8 %. They state that bladder sonography is an objective, simple and safe tool that allows one to screen for urinary retention which is highly suggestive, but incompletely sensitive for MSA. Because sonography is easily accessible and rapidly performed, it is feasible for routine assessment of atypical Parkinson syndromes. The overall average volume of PVR was 140 cc in their patients, increasing from 71 cc in the first year, to 129 cc in the second year, and 270 cc in the 5th year.

Aggressive surgical therapy is not recommended in MSA patients. Chandiramani et al. [90] (LOE2) found that all MSA patients who underwent transurethral resection of the prostate (TURP) due to voiding problems were incontinent postoperatively, most probably due to pre-existing sphincter weakness. The same observations were made by Beck et al. [72] (LOE2), who evaluated the results of TURP and stress incontinence surgery in MSA patients. They concluded that the results of surgery were unfavourable. Patients benefited from IC, anticholinergic medication and desmopressin spray [91] (LOE 3), which improved continence in 82%.

As nearly half of the MSA patients suffer from voiding difficulties, its management by means other than IC would be very attractive. Sakakibara et al. [92] (LOE 3) compared different non-selective and alpha-IA selective alpha blocking agents (prazosin and moxisylite) in the treatment of LUT dysfunctions in MSA patients. The respective means for reductions in residual urine volume for the prazosin and moxisylite groups were 38.1% and 35.2%, and there was lessening of urinary symptoms. Side effects due to orthostatic hypotension were seen in 23.8% of the prazosin group and 10.7% of the moxisylite group. A more recent study showed that the effects of alpha blocking agents, as well as those of TUR-bladder neck, for lessening post-void residuals lasted for up to 2 years in MSA, although during that period patients benefited from the therapies [77] (LOE2). On the contrary, administration of amezinium, an adrenergic drug for ameliorating postural hypotension, may increase the risk of retention and post-void residual volume compared to that before treatment [93] (LOE2). Amezinium most probably

stimulates the alpha receptors, both in the vascular wall (alpha1B receptors) and the proximal urethra (alpha1A/D-adrenergic receptors).

Both postural hypotension and bladder dysfunction are common clinical features in MSA. Pyridostigmine, an acetylcholinesterase inhibitor, might be effective in lessening post-void residual volumes, since it stimulates muscarinic acetylcholine receptors on the bladder (M2/3-muscarinic receptors) that are innervated by parasympathetic cholinergic neurons. Pyridostigmine also lessens postural hypotension, presumably by enhancing nicotinic acetylcholine receptor transmission in the sympathetic ganglia [94] (LOE3).

Guidance for further research

MSA is a slowly progressive disease without any cure. More research is needed to evaluate the effects of long term LUT treatment and to evaluate the effects of different drug treatment modalities.

Conclusions

- **LUT symptoms often precede the clinical manifestation of multiple system atrophy (LOE2).**
- **The most common LIJT disturbances are detrusor overactivity, detrusor-external sphincter dyssynergia, sphincter and detrusor weakness (LOE2).**
- **Significant post void residual is observed in about half of the multiple system atrophy patients (LOE2).**

Recommendations

- **The most sensitive test to detect multiple system atrophy associated LUT abnormalities is sphincter EMG (A), and post-voiding residual volume , especially when differentiating from Idiopathic Parkinson's disease.**
- **Due to the complex dysfunction and progressive nature of the disease, aggressive treatment and LUT surgery (e.g. TURP) are not recommended (A).**
- **Treatment of choice in case of increased post void residual are alpha blocking agents and IC (B).**

4. FAECAL INCONTINENCE

Lower gastrointestinal tract (LGIT) dysfunction is also common in patients with MSA. Sakakibara et al [95] (LOE2) performed a bowel questionnaire in 15 patients with MSA and in 10 age-matched healthy control subjects. The MSA group showed decreased bowel frequency (< 3 times a week) in 9, difficulty in expulsion in 11, and faecal incontinence in 3; the control group showed decreased bowel frequency in only 2, mild difficulty in expulsion in 2, fecal incontinence in none. Therefore, constipation is the major bowel dysfunction in this disorder, although in advanced stages faecal incontinence is not uncommon.

Studies on the mechanism of bowel problems in this disorder are scarce. Stocchi et al. [96] (LOE2) performed anorectal manometry in 16 patients with MSA; 13 patients showed paradoxical anal sphincter contraction on fictive straining. Bardoux et al. [29] (LOE3-4) reported a case of a fecally incontinent patient due to MSA, who showed inability of anal squeezing. Sakakibara et al. [97] (LOE2) performed colonic transit time, sphincter electromyography (EMG) and rectoanal videomanometry in 15 patients with MSA and 10 age-matched healthy control subjects. Compared with the control subjects, MSA patients had significantly prolonged colonic transit time in the rectosigmoid segment ($p<0.05$) and total colon ($p<0.05$). Sphincter EMG showed neurogenic motor unit potentials in none of control subjects but in 93% of MSA ($p<0.01$). In the resting state, MSA patients showed a lower anal squeeze pressure (external sphincter weakness) ($p<0.01$) and a smaller increase in abdominal pressure on coughing ($p<0.01$). During rectal filling, MSA patients showed smaller amplitude in phasic rectal contraction ($p<0.01$), which was accompanied by an increase in anal pressure that normally decreased, together with leaking in 3 patients. During defecation, most MSA patients could not defecate completely, with larger post-defecation residuals ($p<0.05$). MSA patients had weak abdominal straining, smaller rectal contraction on defecation and larger anal contraction on defecation (paradoxical sphincter contraction on defecation, or anismus), though these differences were not statistically significant.

Constipation in MSA most probably results from slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, whereas fecal incontinence results from weak anal sphincter due to denervation. The responsible sites for these dysfunctions are still not known. However, as described in idiopathic Parkinson's disease, they most probably reflect lesions of both central and peripheral nervous systems that regulate the LGIT.

LGIT functional disturbance is often preceded by LUT dysfunction in MSA patients. Abnormalities in colonic transit time and rectoanal videomanometry in MSA were mostly similar to those in idiopathic Parkinson's disease, except for the sphincter denervation and resultant fecal incontinence in MSA.

When treatment of the bowel disorder in MSA is planned, use of objective parameters is recommended in order to clarify the action of drugs. A few such studies are available: Eichhorn and Oertel [98] (LOE3) gave polyethylene glycol 3350, an osmotic agent with high water binding capacity, in 2 patients with MSA, and found an improvement in stool frequency and difficult defecation in both

patients. Similarly, Sakakibara et al. [99] (LOE2) measured colonic transit time in 4 patients with MSA. After administration of calcium polycarbophil, an osmotic and highly bulking agent, colonic transit time of total and the right segment shortened significantly. Liu et al. [100] (LOE2) performed colonic transit time and rectoanal videomanometry in 7 patients with MSA. After administration of mosapride citrate, a novel selective 5-HT4 receptor agonist, the patients showed a shortened total and recto-sigmoid segment colonic transit time, lessened first sensation and an augmented amplitude in phasic rectal contraction. During defecation, mosapride augmented the amplitude in rectal contraction and lessened the volume of post-defecation residuals significantly. Similar results were obtained in a study by Sakakibara et al. [101] (LOE2), in which dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action), was prescribed.

MSA is a slowly progressive disease currently without cure. More research is needed to evaluate the pathophysiology of LGIT dysfunction, and to evaluate the effects of different drug treatment modalities.

Conclusions

- **Patients with multiple system atrophy have often abnormal bowel function (LOE2) .**
- **The most common bowel disturbances are slow colonic transit, decreased phasic rectal contraction and weak abdominal straining; faecal incontinence results from weak anal sphincter, due to denervation (LOE2).**
- **Bowel dysfunction, such as constipation, is common and has significant impact on quality of life of patients with multiple system atrophy (LOE3).**

Recommendations

- **More studies on neurologic bowel dysfunction and management in patients with multiple system atrophy are needed before giving any recommendation.**

III. PARKINSON'S DISEASE

1. URINARY INCONTINENCE

Parkinson's disease (PD) is a movement disorder due to degeneration of dopaminergic neurons in the substantia nigra and a loss of dopamine-containing nerve terminals in the basal ganglia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes also have influence on autonomic function; the most common problems are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary systems [102].

LUT dysfunction in PD was estimated to occur in 37-71% in uncontrolled studies. Among these, in a study of Hattori et al. [103] (LOE3) 60% of PD patients had urinary symptoms, which could be divided in the following categories: storage LUTS in 28%, voiding in 11%, and both types in 21%. The prevalence of urinary symptoms correlated with severity of the disease, but not with the duration of illness. Gray et al. [104] (LOE3) reported that LUT functional disturbances in PD are not disease-specific and only correlated with age. In the more recent, control-based studies [106-109] (LOE2) the prevalence of LUT symptoms (LUTS) was found to be 27-64% using validated questionnaires [105-107], or 53% in men and 63% in women using a non-validated questionnaire that includes a urinary incontinence category [7], with all of these values being significantly higher than healthy controls. The majority of patients had onset of the bladder dysfunction after the appearance of motor disorder. In one study, urinary incontinence in PD frequently occurred in conjunction with fecal incontinence, whereas no significant relation was observed between bladder and sexual dysfunction. Bladder dysfunction substantially affects the quality of life in patients with PD [108] (LOE2). Bladder dysfunction in PD correlates with neurological disability [105] (LOE2), and stage of disease [108] (LOE2), both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of PD patients with older age, as in healthy populations. Among LUTS, nocturia (night-time urinary frequency) is the most prevalent symptom (>60%) [105-108] (LOE2). Patients also complain of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 26% of males and 28% of females. These figures are almost the same in untreated, early PD patients [109]. Although less common than storage symptoms, PD patients also report voiding symptoms. In the study by Sakakibara et al. [110] (LOE2), PD patients had significantly higher rates of delay in initiating urination (44% of men), prolongation/poor stream (70% of men), and straining (28% of women) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals.

a) Pathology and disease-specific urinary tract problems

The net effect of the basal ganglia on micturition is thought to be inhibitory [111]; in PD, the bladder becomes overactive. Functional neuroimaging during bladder filling resulted in activation in the globus pallidus of normal volunteers and in the putamen in PD patients with detrusor overactivity [112] (LOE2). In contrast, dopamine transporter imaging (indicating brain dopamine neurons) was decreased in PD patients with urinary dysfunction than in those

without it [13] (LOE2). The micturition reflex is under the influences of nigrostriatal dopamine (both inhibitory in D1 and facilitatory in D2) and GABA (inhibitory). Deep brain stimulation in the subthalamic nucleus results in amelioration of motor disorder as well as increased bladder capacity and decreased post-void residuals [114] (LOE2). Therefore, urinary dysfunction in PD could reflect degeneration of the nigrostriatal dopaminergic cells associated with specific motor disorders. In addition to the nigrostriatal dopaminergic projection, the ventral tegmental area (VTA, the A10 cell group)-limbic cortex and the hypothalamic (the A11 cell group)-spinal cord dopaminergic projections are presumably involved in urinary dysfunction in PD.

In a study of PD and multiple system atrophy (MSA) patients, Sakakibara et al. [116] (LOE2) found urinary symptoms in 72% of PD patients. They were mostly attributed to DO (81%) and external sphincter relaxation problems (33%). Failure of sphincter relaxation may reflect bradykinesia, rather than true DSD. During micturition, PD patients did not demonstrate DSD, but impaired detrusor contractility was observed in 66% of women and 40% of men. In addition, patients with PD had partial bladder outlet obstruction, e.g. mean bladder outlet obstruction index was 43 in men (equivalent parameters gave a value of 40 in women). Nevertheless, average volume of post-void residuals in PD was only 18 ml. Similar observations were reported by Defreitas et al. [117] (LOE2). These urodynamic findings are almost the same in untreated early PD patients [110].

b) Specific diagnosis and treatment

In the differential diagnosis of PD and parkinsonian-type MSA, large post-void residuals, open bladder neck, and neurogenic change in sphincter motor unit potentials are common in MSA [115, 118] (LOE2), whereas they are rarely seen in clinically typical PD [119]. However, recent evidence suggests that PD with dementia, or dementia with Lewy bodies, may have large post-void residuals and neurogenic change in the sphincter motor unit potentials [120], thereby mimicking MSA (LOE3). Bladder dysfunction in PD parallels other autonomic dysfunctions [121], cardiac denervation [122], and falls [123] (LOE3).

Levodopa and other antiparkinson medication may affect bladder function in PD. To date the results are not consistent and the responses are not straightfoward. Some reports have shown storage-facilitating effects of dopaminergic drugs; a questionnaire study reported that voiding symptoms (intermittency and sensation of residual urine) were more common in those taking levodopa and bromocriptine (D2-selective agonist) than in those taking levodopa alone [111a] (LOE2). In contrast, Kuno et al. [124] (LOE3) showed that change of bromocriptine to pergolide (D1<2 agonist) brought lessening of nocturia, and Yamamoto [125] (LOE3) described improvement of DO by pergolide. Others have shown voiding-facilitating effects. In early PD [126] (LOE2) and advanced PD with the on-off phenomenon [127] (LOE2), a single-dose of levodopa exacerbates DO in the filling phase, but also improves bladder emptying through increased detrusor contractility. We still do not know the reasons for the discrepancy between different studies.

There are several factors underlying the complex bladder behaviour in PD. Post-synaptic dopamine D1 (excitatory) and D2 (inhibitory) receptors have a millimolar affinity to dopamine, whereas dendritic D2 (inhibitory) autoreceptors have a picomolar affinity to dopamine. Therefore, when levodopa is administered externally, it may first stimulate dendritic D2 autoreceptors, which might suppress the nigral cells and facilitate the micturition reflex. In cases of PD under long-term treatment with levodopa, dopamine receptors are down-regulated. Bladder overactivity might also involve an activation of D2 receptors in the spinal cord [128] (LOE2). In addition, in experimental animals, single doses of apomorphine showed a biphasic effect [129] (LOE2).

There are no specific studies on systematic anticholinergic drugs to treat neurologic DO in PD patients. A systematic review of anticholinergic use (centrally acting) to treat PD was done by Katzenschlager et al. [130] (LOE I). Cognitive adverse events of anticholinergics are a concern, particularly in elderly PD patients. This was first described in 1997 by Donnellan et al. in PD patients with overactive bladder [131] (LOE 3). They gave oxybutynin in four patients, who subsequently developed dementia, which reversed after discontinuation of oxybutynin. Factors underlying the cognitive effects of these medications include: 1) central muscarinic receptor affinity, e.g. high M1-receptor selectivity; and 2) easy penetration of the blood-brain barrier (BBB), e.g. high lipid solubility (water versus oil partition coefficient [LogP]<3; number of hydrogen bonds<8); a neutral charge or low degree of ionization (polar surface area<90A); and a less bulky (number of rotatable bonds<5) and smaller molecular size (<450Da) [132] (LOE 2). Most anticholinergics are non-selective muscarinic blockers, but darifenacin is an M3-selective antagonist. Regarding BBB penetration, most anticholinergics have a molecular size between 300-400Da. Oxybutynin can readily penetrate the CNS. Trospium, a quaternary amine, has a high polarity that may limit BBB penetration.

Deep brain stimulation (DBS) is a treatment option in advanced PD. The subthalamic nucleus (STN) is regarded as the key area in the indirect pathway, which is dominant in the parkinsonian state. DBS inhibits many cells within the STN, probably due to depolarization block and release of GABA from activation of inhibitory afferent terminals. In the STN, neuronal firings related to the micturition cycle have been observed in cats [133] (LOE2). DBS increased

bladder capacity, facilitated bladder afferent pathways, and augmented activity of the prefrontal cortex in the brain of PD patients [134] (LOE2). DBS can cause urinary retention [135] (LOE3). Intravesical botulinum toxin injection seems to be a promising method to treat intractable DO in patients with PD [136, 137] (LOE3). For voiding failure, the treatment of choice is IC; however, PD patients rarely have post-void residual volume > 100ml.

As in MSA, a very important issue in PD affected patients is the indication for pelvic surgery. Myers et al. [138] (LOE2) found that women with PD and LUT complaints have a lower maximum cystometric capacity and a higher rate of DO at lower bladder volumes in comparison with non-neurologic controls. Therefore surgery for stress incontinence in women with PD should be performed only when no significant DO is present, since this type of surgery can evoke or aggravate DO and subsequent urgency incontinence. A secure diagnosis of BOO is needed before considering transurethral prostate resection in PD, and the neurological diagnosis of PD likewise needs to be secure, since MSA inevitably develops urinary retention in the course of neurologic illness. In true PD, prostate surgery is not contraindicated, whereas it is in MSA.

Conclusions

- **In Parkinson's disease, LUT symptoms are associated with degeneration of dopaminergic neurotransmission (LOE2).**
- **The most common LUT disturbances are detrusor overactivity, and detrusor hypocontractility (LOE2).**
- **The effect of levodopa on LUTS in PD patients remains to be fully elucidated (LOE3).**

Recommendations

- **Detrusor overactivity in PD patients can be treated with antimuscarinic drugs (B).**
- **For voiding failure with significant post void residual, the treatment of choice is intermittent catheterization (B).**
- **LUT surgery for patients with Parkinson's symptoms is an option, but MSA should be excluded. However stress incontinence surgery should not be offered to patients with significant detrusor overactivity (C).**

2. CONSTIPATION AND FAECAL INCONTINENCE

Lower gastrointestinal tract (LGIT) dysfunction is common in Parkinson's disease (PD). In recent, control-based studies, the incidence of decreased stool frequency (< 3 times a week) in PD patients ranges from 20% to 81%, difficulty in stool expulsion 57-67%, and diarrhea 21% [139, 140] (LOE2). All of these values are significantly higher than in the normal population (range, decreased stool frequency, 0-33%; difficulty in stool expulsion, 26-28%; diarrhea, 10%). Fecal incontinence affects 10-24% in PD [139, 141] (LOE2). Therefore, constipation is the most prominent LGIT symptom in patients with PD. Indeed, PD is a risk factor for elderly nursing home residents to have constipation. Bowel dysfunction affects the quality of life in patients with PD. The rate of dissatisfaction for bowel dysfunction (59%) is significantly higher than for urinary (28%) or sexual dysfunction (29%), although the prevalence rate of all three dysfunctions is almost the same (more than 60%). The rate of dissatisfaction for the bowel dysfunction in PD is also significantly higher than in healthy controls (16%) [141] (LOE2).

Difficulty in expulsion, and diarrhea are more common in the higher grade of Hoehn and Yahr staging, suggesting a relationship between dopaminergic degeneration and LGIT symptoms. Fecal incontinence in PD occurs commonly with urinary incontinence, whereas no significant relation has been seen between bowel and sexual dysfunction. Constipation in PD is often associated with a low coefficient of variation in electrocardiographic R to R intervals [142] (LOE3). The findings indicate that parasympathetic dysfunction might underlie these abnormalities.

Intestinal pseudo-obstruction (IPO), also called paralytic ileus, is the most severe presentation of constipation in patients with PD and constitutes a medical emergency. The incidence of IPO/ volvulus is 2.4-7.1% [143, 144] (LOE3). The clinical features are mean age 78.5 years with illness duration 5.3 years, with no gender bias; constipation was seen in all and urinary dysfunction in most. Although rare, emergency IPO needs hospitalization and may lead to a poor outcome. Therefore, preventative treatment of constipation, including consideration of prokinetic drugs is necessary, particularly in elderly PD patients.

There seems to be an association between the frequency of bowel movements and the future risk of developing PD [145] (LOE1). This observation is in line with the pathological staging of PD by Braak et al. [146] (LOE1), in which disease process in the central nervous system starts earlier in the dorsal motor vagal nucleus than in the substantia nigra in PD. From a clinical perspective, it is of particular relevance that patients may see gastroenterologists or physicians first because of their bowel dysfunction, prior to a correct diagnosis of PD being made. Therefore, constipation as the initial presentation of PD is akin to urinary dysfunction as the initial presentation of multiple system atrophy.

a) Pathology and disease-specific problems

The enteric nervous system generates the peristalsis responsible for bowel content transit [147] (LOE2). The components of peristalsis are contraction on the oral side of the bolus, and relaxation on

the caudal side. Cholinergic receptors have a major role in the contraction proximally. The strength of cholinergic transmission is regulated by opposing receptors; serotonin 5-HT4 receptor-mediating excitation and dopamine D2 receptor-mediating inhibition [38]. Post-mortem studies of bowel in PD have shown decrease in dopaminergic myenteric neurons and the appearance of Lewy bodies along the proximal-distal axis, being most frequent in the lower esophagus, but scarce in the rectum [148-150] (LOE2). Thus PD affects not only central, but also peripheral (enteric) nervous system.

LGIT function primarily consists of [1] colonic transport of the bowel content to the anorectum, [2] transient storage in the anorectum, and [3] defecation. In PD, constipation results primarily from decreased transport and/or disturbed anorectal evacuation. Fecal incontinence may result from disturbed anorectal reservoir function, or overflow secondary to constipation. Previous reports have shown that total colonic transit time (CTT) is increased beyond the normal threshold in 80% of PD patients, which translates into an increased average CTT ranging from 44 hours to 130 hours [139, 141, 151] (LOE2), and 89 hours in de novo PD patients [48] (LOE2), all of which are significantly longer than the CTT in controls (range, 20-39 hours). Prolonged CTT has also been documented in PD patients without subjective constipation. Slow colonic transit is the major cause of decreased stool frequency. The slow colonic transit is likely to reflect a decrease in slow waves and spike activities of the colon [147].

In resting anal manometry, the anal pressure of PD patients is low or normal [139, 141, 151] (LOE2). The resting anal pressure may reflect sympathetic innervation in the internal anal sphincter, since lesions or anaesthetic blocks at T12-L3 (where the sympathetic preganglionic neurons are located) substantially lessen the anal pressure. Similarly, most PD patients have normal anal pressure increase on squeezing. This finding corresponds to a lack of neurogenic changes in the external sphincter EMG. Nevertheless, latent anal sphincter dysfunction may explain the fecal incontinence that occurs in most advanced cases. In slow-filling rectoanal videomanometry, PD patients had the same rectal volume at first sensation and a maximum desire to defecate, and the same rectal compliance as control subjects [141, 152] (LOE2). In contrast to the bladder, the normal rectum shows spontaneous phasic contraction. However, the amplitude of the spontaneous phasic rectal contraction in PD patients is significantly less than that in control subjects. The decreased spontaneous phasic rectal contraction may share the same aetiology with the decrease in CTT.

During defecation, healthy subjects utilize the final wave of spontaneous phasic rectal contractions. However, rectal contraction on defecation in PD patients is smaller than that in controls [141] (LOE2). In addition, in PD patients abdominal straining is smaller. In PD patients, paradoxical anal sphincter contraction on defecation (PSCD), or anismus, is observed in studies using sphincter EMG, radiography, and anal pressure measurement. The mechanism of the impaired straining in PD may include rigidity and reduced contractility of the axial muscles, and a failure of coordinated glottis closure. However, neuronal degeneration in the brain of PD patients relevant to straining is yet to be clarified. Mathers et al. [153] consider PSCD a focal dystonia. Dysfunction in the suprasacral descending pathway to the external sphincter may be a contributing factor. Apomorphine was shown to lessen PSCD [153] (LOE2). This effect was not antagonized by domperidone, which does not penetrate the BBB, suggesting that CNS pathology may contribute to PSCD.

b) Disease-specific diagnosis and treatment

Insoluble dietary fibers produced an improvement in stool consistency and an increase in stool frequency in PD, which paralleled an improvement in levodopa absorption [154] (LOE3). Dietary fibers such as psyllium[155] (LOE2) and polyethylene glycol 3350 [156] (LOE2), or bulking and highly hydrophilic agent polycarbophil [157] (LOE2), improve constipation in neurodegenerative disorders, including PD. Although psyllium does not alter CTT or anorectal parameters in PD patients, polycarbophil shortens the total CTT, particularly in the proximal bowel segments.

It is possible that levodopa and other antiparkinson medication may affect bowel function in PD. Endogenous dopamine is thought to inhibit intestinal motility via D2 receptors. Tateno and Sakakibara performed the quantitative lower-gastrointestinal autonomic test (QL-GAT, a combination of colonic transit and manometry) in 19 early, untreated PD patients before and after administration of 200 mg/day of levodopa [158]. Levodopa augmented rectal contraction, lessened paradoxical anal sphincter contraction on defecation (PSCD, anismus), and thereby ameliorated anorectal constipation, without apparent adverse effects. This might be brought about by both peripheral and central dopaminergic stimulation.

Since levodopa is absorbed from the small intestine, bowel dysfunction in PD may interfere with levodopa absorption, worsen the motor disorder, or even lead to malignant syndrome [140, 159] (LOE3/4). Domperidone, a peripheral D2 receptor antagonist that does not cross the blood-brain barrier, causes a mean 12% increase in peak plasma levodopa concentrations that occurs a mean of 10 min earlier than when levodopa is given alone [160] (LOE3).

The selective 5-HT 4 receptor agonist cisapride [161], though no longer licensed, and newer agents such as mosapride [162] (LOE2) and tegaserod [163] significantly reduce CTT and ameliorate constipation in PD. Mosapride shortened total CTT

(particularly the caudal segment), and augmented the amplitude in rectal contraction during defecation in patients with PD [162]. Notably, improvement of parkinsonism is more significant with pergolide-mosapride than with pergolide-domperidone, presumably reflecting better levodopa absorption. Similar results were obtained in PD by dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action) [164] (LOE2). A series has shown a role for Botulinum toxin A injections into the puborectalis muscle [165] (LOE3).

Conclusions

- **Patients with PD often have abnormal anorectal function (LOE2).**
- **The most common bowel disturbances in PD are slow colonic transit, decreased phasic rectal contraction, weak abdominal straining, and paradoxical sphincter contraction on defecation (anismus) (LOE2).**
- **Bowel dysfunction such as constipation is common and has significant impact on quality of life of PD patients (LOE2).**

Recommendations

- **More studies on management of neurologic bowel dysfunction in PD are needed.**

IV. CEREBRAL LESIONS AND CEREBROVASCULAR ACCIDENTS

Listing of terminology used for the searches: cerebrovascular accident, cerebral lesions, bladder dysfunction, urinary incontinence, faecal incontinence.

1. URINARY INCONTINENCE

Cerebro-vascular accident (CVA) is the third most frequent cause of death in industrialised countries, after myocardial infarction and malignancies. Based on age-dependence of CVA and the increasing age of the population, the importance of CVA is increasing: currently one out of 200 people will suffer from a CVA, 80 to 90% of them above the age of 65. The 5-year-survival rate is 56% in men and 64 % in women.

At the time of maximal impairment following a CVA, 41.1% of 4499 patients (46.0% of females and 37.3% of males studied) had urinary incontinence [167]. An analysis of the symptoms of 532 patients seen within 7 days of their stroke found that the presence of urinary incontinence appeared to be a more powerful prognostic indicator for poor survival and eventual functional dependence than a depressed level of consciousness [168, 169]. It was suggested either that incontinence was the result of a severe general rather than specific loss of function or that those who were incontinent were less motivated to recover from both continence and more general function impairment. Outcome was so much better in those who remained or became dry that it seems possible that recovery of continence may promote morale and self-esteem, which might hasten overall recovery. Urinary incontinence with impaired awareness of bladder sensation seem to be associated with poorer outcome than urgency urinary incontinence with preserved bladder perception [170]. 20-30% of patients still suffer from urinary incontinence six months after the CVA if no proper treatment has been instigated [171]. Six months after stroke, 16% of patients experience urine loss, and that urinary loss was perceived as urinary incontinence when it occurred at least monthly [172].

a) Pathology and disease specific LUT problems

Prior to the findings of functional brain imaging studies, all that was known about the cortical control of the bladder was based on clinical studies of patients with brain lesions. The most influential study was that by Andrew and Nathan, 1964 [173]. The typical clinical picture of frontal lobe incontinence they described was of a patient with severe urgency and frequency of micturition and urgency incontinence, without dementia, the patient being socially aware and embarrassed by the incontinence. Micturition was normally co-ordinated, indicating that the disturbance was in the higher control of these processes. The authors made the comment: “this paper was written because people did not believe that there was such a thing as cerebral disturbance of the bladder“.

There have been a number of urodynamic studies of patients who have developed urinary symptoms after CVA, disparate cortical lesions. In general, voiding is normally co-ordinated, as patients do not show DSD, and the commonest cystometric finding is DO [174-176].

At 3 months, 53% of stroke patients have significant urinary complaints [177]. The commonest LUTS were nocturia in 36%, urgency incontinence in 29% and voiding difficulty in 25%. Urinary retention was seen in the acute phase of illness in 6 %. A significant positive correlation was found between the occurrence of a urinary disturbance and hemiparesis. Brain imaging techniques confirmed a more anterior location of brain lesions in these groups. Urodynamic studies on 22 symptomatic patients showed DO in 68% and uninhibited sphincter relaxation in 36%. DSD was reported in 14%, which should not occur in suprapontine lesions; whether DSD was appropriately diagnosed, rather than representing a hold-on manoeuvre to prevent urinary leakage, could not be clarified from the paper. There was some indication that lesion size was related to the occurrence of urinary symptoms. In contrast to the findings of Maurice-Williams [178] and Kuroiwa et al. [176], who found a correlation of urinary incontinence with lesions of the right brain hemisphere, Sakakibara

et al. [177] could not find a preponderance of right sided lesions for incontinence. Their findings suggest that the damage to the antero-medial frontal lobe, its descending pathway and to the basal ganglia is mainly responsible for micturition dysfunction in stroke patients. An epidemiological study showed an association of hemispatial neglect due to right hemisphere and urinary incontinence [180]. In the latter study, no urodynamic tests were done, and urinary incontinence might have been secondary to general neglect syndrome.

Urinary incontinence in stroke patients is usually interpreted as the loss of central inhibition. However, loss of bladder perception as a concomitant factor may also be relevant. Deficit of bladder sensation seems to be associated with poorer general outcome. Such patients have more parietal lobe but less frontal lobe impairment than patients with urge urinary incontinence and preserved bladder sensation [177]. Patients with frontal lobe lesions (tumours) and damage to the right superior bifrontal region have temporary incontinence, whereas permanent incontinence was associated with bilateral damage [180].

Urinary retention has also been described in patients with brain lesions. Three case histories of elderly females with various forms of right frontal lobe pathology were described as urinary retention. In two, one with an abscess and the other with a haematoma, successful treatment brought recovery of bladder function [181, 182]

An experimental model for studying the effect of forebrain lesions and voiding dysfunction was developed in the rat by occluding the middle cerebral artery under pentobarbital or halothane anaesthesia. At thirty minutes after recovery from anaesthesia bladder capacity in animals with cerebral infarct was markedly decreased. The decreasing bladder capacity continued as long as four months after artery occlusion. Based on the effects of two different types of receptor antagonists on OAB induced by left middle cerebral artery occlusion, the authors [183] concluded that the NMDA receptor (N-methyl-D-aspartate) has a role in the development of OAB after CVA. A glutamate receptor antagonist thus might be beneficial for OAB caused by cerebrovascular disease, as the induced potentiation of bladder reflexes seems to depend on NMDA glutamate transmission (LOE 4).

Brainstem lesions give a different profile from hemispheric lesions. In 1926 Holman [184] noted that voiding difficulty could be a sign of tumours in the posterior fossa. In a series of patients with brain tumours, Ueki et al. [185] reported voiding difficulty to occur in 46/152 (30 %) of patients with tumours in the posterior fossa, while urinary incontinence occurred only in 3 (1.9 %). Renier and Gabreels [186] found urinary retention in 12/17 children with pontine glioma. There are a number of case histories published presenting difficulties with micturition in various brain stem pathologies [187-190].

Sakakibara et al. [189] reported the urinary symptoms of 39 patients who had brainstem strokes. Almost half the patients had urinary symptoms, nocturia and voiding difficulty in 28 %, urinary retention in 21 % and urinary incontinence in 8 %. The problems were more common following haemorrhage, probably because the damage was usually bilateral. Urinary symptoms did not occur in those with lesions of the midbrain, but they did in 35 % of those with pontine lesions and in 18 % of those with medullary stroke. Urodynamic studies in 11 symptomatic patients showed DO in 8/11, low compliance in 1/11. Detrusor acontractility occurred in 3 of the 11 at three months, six months and 3 years after the occurrence. A non-relaxing sphincter on voiding was found in 5/11 and uninhibited sphincter relaxation in 3/11 (LOE 3).

b) Disease-specific diagnosis and management

Basic diagnosis comprises a targeted history and clinical investigation, urine analysis, postvoid residual urine and a bladder diary. In patients with significant residual urine of over 100 cc or more than 50 % of bladder capacity, a urodynamic investigation may help to differentiate between detrusor weakness, and functional or morphological outflow obstruction.

Urinary incontinence within seven days of acute stroke has a highly predictive prognostic value for long term outcome [168, 191] (LOE3). Large lesions involving the frontal lobe, which is relevant to bladder control, might also affect the motor function. Immediately after the CVA, an indwelling transurethral or suprapubic catheter allows control of the urinary output in the Stroke Unit. Diuresis should be monitored. Once the stroke situation is stabilised and diuresis is normalised the catheter should be removed and the patient put on intermittent catheterisation if voiding is inefficient. In the early stage after the stroke, urinary incontinence can be managed by a condom catheter or by pads. Further treatment comprises behavioural therapy (initially toileting, later on micturition training) and anticholinergic therapy, if the voided volumes are below 250 cc. The patient's ability to squeeze the anal sphincter voluntarily is a good prognostic sign for subsequent return of continence. In the early phase, especially during catheter drainage, special care must be taken to avoid urinary tract infections with secondary complications. In diabetic patients low dose infection prophylaxis is recommended (LOE 4).

Behavioural intervention has a good outcome for urinary incontinence after stroke [192-194] (LOE 4). When urinary urgency and incontinence persist after stroke, anticholinergics are generally used, but no systematic survey of anticholinergic use in post stroke patients is available. One trial has reported suburothelial injection of botulinum A toxin

for neurogenic DO, including patients post CVA. Results are not as good as for SCI [195].

Regarding further research, there is a need for further epidemiologic studies of the true incidence of LUT symptoms including incontinence after CVA in the longer term. Evidence is lacking concerning efficacy and safety of currently used therapeutic interventions. Controlled studies comparing behavioural therapy and anticholinergic medication alone and in combination would be useful.

Conclusions

- **Incontinence after CVA is a prognostic indicator for survival and eventual functional dependence. (LOE 2).**
- **The commonest urological problems after stroke are nocturia (36 %), urgency incontinence (29 %) and difficulty in voiding (25 %). (LOE 2/3)**
- **There is a positive correlation between the occurrence of urinary dysfunction and hemiparesis. (LOE 2/3)**
- **Urodynamic studies revealed detrusor overactivity in 68%, and sphincter relaxation problems in 36%. (LOE 4)**
- **Damage to the antero-medial frontal lobe and its descending pathways, and the basal ganglia are mainly responsible for voiding dysfunction in stroke patients. (LOE 3)**
- **With brainstem pathology, symptoms of impaired voiding (urinary retention) predominate. (LOE 3)**

Recommendations

- **As the urological symptoms, especially incontinence are very distressing, urological care is mandatory for these patients (B).**
- **Prevention of early urinary tract infection, especially during the acute phase of indwelling catheterisation, is needed. Thereafter, behavioural training and anticholinergic therapy are the mainstays of treatment (C).**
- **Intermittent catheterisation is occasionally necessary, due to inefficient voiding. This may be in men with pre-existing infravesical obstruction, who can consider standard management of bladder outlet obstruction if they achieve satisfactory general recovery (C).**

V. MENINGITIS-RETENTION SYNDROME

Urinary retention in childhood, young adults, and in women is very uncommon, and may reflect a neurologic disorder [196]. Spina bifida occulta/ tethered cord syndrome is one such disorder known to lead to urinary retention without marked neurological abnormalities, except for saddle anesthesia [197]. Fowler's syndrome is another disorder that causes urinary retention, particularly in neurologically-intact young women, and isolated urethral sphincter hypertonicity underlies this condition [198]. Benign inflammatory nervous diseases also cause acute urinary retention, in which patients lack apparent urethral outlet obstruction, but exhibit only minor neurological as well as cerebrospinal fluid (CSF) abnormalities. Based on the mechanism of urinary retention, these disorders can be divided into two subgroups: disorder of the peripheral nervous system (PNS) (e.g. sacral herpes, with unilateral sacral pain, sensory signs and often skin rashes in the same area [199]); and disorder of the central nervous system (CNS) (e.g. meningitis-retention syndrome (MRS), with fever, headache, stiff neck, and minor pyramidal signs). Previously the latter condition has been only occasionally reported, but now it is recognized as a specific category [200, 201], which is considered to be a very mild form of acute disseminated encephalomyelopathy (ADEM) (LOE3). Since it is rare, true prevalence of MRS has not been fully investigated.

In its typical form, ADEM appears after vaccination or after exanthematous infections, and serological and pathological studies have suggested that ADEM is of parainfectious/ autoimmune origin [202]. Antecedent/ comorbid infections are diverse, e.g. human herpes virus 6 [203]. A combination of signs of encephalitis (e.g., disturbance of consciousness, epilepsy, and hemiparesis), signs of myelitis (e.g., sensory disturbance below the level of the lesion, spastic paraplegia, whereby flaccid parapalegia may occur in the initial shock stage), and lower urinary tract (LUT) / bowel dysfunction typically occur in patients with ADEM. Lesions observed in brain MRI are usually confined to the white matter. Lesions in the spinal cord involving the conus are also seen [201]. CSF pleocytosis, increased protein, mildly decreased glucose content, increased myelin basic protein (MBP)/oligoclonal bands, and a lack of increased viral titres, are all features of this disease. Patients with ADEM commonly exhibit LUT dysfunction [204, 205], which varies from urinary retention to urgency incontinence. LUT dysfunction appears to be related to pyramidal tract involvement, and most probably reflects the severity of the spinal cord lesion. Urodynamic findings have included detrusor overactivity in the storage phase, brisk bulbocavernosus reflex, and DSD (reflective of a suprasacral spinal cord lesion); detrusor areflexia in the voiding phase (reflective of either acute spinal shock or conus lesion); and neurogenic sphincter EMG in one of four patients studied (reflective of a conus lesion) [204, 205]. The responsible lesion sites in cases of LUT dysfunction have appeared to be the

cervico-thoracic spinal cord, and, to a lesser extent, the conus [206] (and possibly the spinal nerve roots [207]) in patients with ADEM. In addition, cases of ADEM presented with LUT dysfunction as the only remaining consequence of the disease, thus suggesting that LUT innervation was selectively vulnerable in these cases. Recently, it is also reported that cases of ADEM/ parainfectious myelitis initially presented with urinary retention [208, 209] or leaves urinary retention as the sole sequel [210]. In some cases, abnormal F-waves were recorded, suggesting conus or radicular lesion [201].

Although aseptic meningitis is a common neurological disorder, a combination of aseptic meningitis and acute urinary retention (MRS) has not been previously well recognized. The clinical manifestations of Sakakibara's three cases [200] are mostly the same as those of the six reported cases in the literature (including cases written in Japanese) [211]. The clinical manifestations of MRS cases differ markedly from those of ADEM, because other than presenting with aseptic meningitis, MRS cases lack the following: apparent encephalitic signs such as disturbance of consciousness, epilepsy or aphasia; and myelitic signs such as gait abnormalities, or sensory-level abnormalities. Only one patient reported by Fukagai et al. showed drowsiness without meningeal irritation. Whereas brain and spinal cord lesions typically appear in ADEM, such change is not observed in MRS. However, a reversible splenial lesion was noted in the brain MRI of a patient with MRS [212].

The CSF examination showed a mononuclear pleocytosis of 38-370 /mm3, normal to increased protein content (up to 260 mg/dl), and normal to mildly decreased glucose content (up to 33% of that in the serum). All viral titres studied in the CSF and the serum of such cases were negative. Nevertheless, it appears likely that the urinary retention in such patients is of neurologic aetiology, since none of the patients appear to exhibit urologic abnormalities such as prostatic hyperplasia, and also because a strong chronological association is observed between the onset of urinary retention with, or just after, the occurrence of the aseptic meningitis. As it is observed in ADEM, antecedent/ comorbid infections or conditions with MRS include angiostrongylus cantonensis [213, 214], Epstein Barr virus [215], and herbal medicine use [216], whereas such antecedent infections are not apparent in the remaining cases [217, 218].

Urodynamic study results have shown that all patients examined had detrusor areflexia, which results in an inability to contract the bladder on voiding, and some patients had an unrelaxing sphincter. Detrusor areflexia originates from various lesion sites along the neural axis; most commonly, PNS lesions are observed. However, CNS lesions that affect the spinal cord or the brain can also cause detrusor areflexia, which is particularly seen in the acute shock phase of patients with transverse myelitis (often immune-mediated) or ADEM. A case report described repeated urodynamic studies in one patient, in which an initially areflexic detrusor became overactive after a 4-month period, suggesting an upper motor neuron bladder dysfunction [219]. As described above, encephalitic features are absent in patients with MRS. However, three MRS patients (including Sakakibara's cases 1 and 3) showed the brisk lower extremity reflexes suggestive of mild myelitis. In one of Sakakibara's cases, MBP was increased, which is suggestive of CNS demyelination. Therefore, it appears possible that MRS is a very mild variant of ADEM, which selectively affects LUT innervation.

Arriving at a diagnosis is easy when a combination of aseptic meningitis and acute urinary retention is confirmed, although such a diagnosis should be made both urologically and neurologically, in order to exclude sacral herpes, a benign variant of Guillain-Barre syndrome (inflammatory radiculitis), typical ADEM, myelitis with leg weakness [220], herpetic brainstem encephalitis, chemical meningitis, focal subarachnoid bleeding, and other common causes of neurogenic urinary retention (e.g., diabetic neuropathy, lumbar spondylosis, etc.). For the differential diagnosis, detailed history, brain/spinal MRI and nerve conduction study are necessary.

The term "Elsberg syndrome" has been occasionally used, which is rather vaguely assigned to sacral myeloradiculitis of undetermined etiology, sacral herpes, sacral vasculitic neuropathy, possible MRS, possible ADEM, or conus infarction. However, in contrast to the majority of "Elsberg syndrome" cases, Kennedy, Elsberg, and Lambert [1913] [221] reported five cases of pathology-demonstrated cauda equina radiculitis. Clinical pictures of these cases were characterized by rare CSF abnormalities (only one of the four cases described showed an increased cell count as well as increased protein levels); no clinical meningitis; subacute/chronic course (in one case the course of disease was subacute: 3 months, but in the remaining four cases, the course of disease was chronic: 4.5-36 months); the patients presented with typical cauda equina motor-sensory-autonomic syndrome (in particular, four of the patients had apparent muscle atrophy/ weakness in the lumbosacral segment); Wallerian degeneration of the spinal afferent tracts; and mild upper motor neuron signs. The authors assumed that the etiology of these cases was either inflammatory or toxic. The exact cause of these five cases remains uncertain, although clinical pictures of these cases resemble, at least in part, those of paraneoplastic [222] or autoimmune lumbosacral radiculoplexus neuropathy [223]. Clinical features of sacral herpes or MRS differ markedly from those of Kennedy's cases.

Since MRS has a benign and self-remitting course (i.e., a duration of 2-10 weeks), the effectiveness

of immune treatments (e.g., steroid pulse therapy) remains unclear, although such treatments may shorten the duration of the disease. Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension (LOE4).

Since MRS is rare, true prevalence has not been fully investigated and evaluation of this is warranted in future research. Similarly, in order to shorten the urinary retention period, the effectiveness of immune treatments (e.g. steroid pulse therapy) in MRS remains unclear, and future research is desirable.

Conclusions

- **Meningitis-retention syndrome, with fever, headache, stiff neck, and minor pyramidal signs, is thought to be a very mild form of acute disseminated encephalomyelopathy (ADEM).**
- **Both urologists and neurologists may encounter this disorder.**
- **Initially the bladder is areflexic, but soon becomes normal or overactive during the course of the disorder.**

Recommendations

- **Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension in patients with MRS.**

VI. ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Acute disseminated encephalomyelitis (ADEM), also known as post-infectious encephalomyelitis, is a demyelinating central nervous system (CNS) disorder that usually follows infection, or more rarely vaccination [224]. ADEM can be confused for MS; indeed, the early symptoms of ADEM are similar to an acute relapse of MS. Presence of constitutional symptoms such as fever and headache, and the simultaneous involvement of various parts of the CNS may help differentiate this condition from MS. However, it can be difficult to distinguish the two, and the only sure way is follow up and the observation of any relapses over time.

ADEM is a disease that is characterized by an inflammatory reaction and demyelination in the brain and spinal cord. In contrast to MS, there is a tendency for perivenous localization of pathological changes [225]. Bladder dysfunction is common in ADEM. In a consecutive series of sixty one patients with ADEM, 20 (33%) had evidence of LUTD [205] (LOE 3/ 4). Lesions in the cerebral and spinal cord white matter result in LUTD. Both voiding and storage symptoms are reported in ADEM, however the pattern of bladder dysfunction depends upon the time point at which they are assessed. In the acute stage, Panicker et al. reported that voiding dysfunction is more common; in their series of 20 patients, 16 were in urinary retention [205] (LOE 3/ 4). Urodynamics demonstrated detrusor overactivity in four patients and underactivity in four patients. Incontinence was reported more often in patients with frontoparietal white matter changes in MR imaging [205] (LOE 3/ 4). In the series of Sakakibara et al., patients were followed up for 3 to 38 months, and seven of nine patients with retention were able to pass urine once again, five had difficulty in voiding and four developed urinary frequency or urgency incontinence. Motor unit analysis of the external sphincter revealed polyphasic neurogenic changes in only one of four patients. They also observed that bladder disturbances in ADEM seemed to be as common and severe as in MS [204] (LOE 3/ 4). LUTD is common especially in patients with lower limb pyramidal involvement [205].

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of ADEM. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction often recovers [202, 205]. If suitable, IC could be considered. Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication, once it is confirmed they are not retaining urine.

For future research, there are currently only limited studies evaluating the natural history of LUTD in ADEM and patients should be followed up to assess lower and upper urinary tract changes with time. There is a dearth of information about the role of botulinum toxin or sacral neuromodulation in this condition.

Conclusions

- **In the acute phase of ADEM, LUTS may be seen in a third of patients (LOE3/4).**
- **Both voiding and storage dysfunction are observed in ADEM (LOE3/4).**
- **Recovery of LUT functions occurs, along with the recovery of motor weakness (LOE3/4).**

Recommendations

- **Patients with ADEM and bladder symptoms should be managed according to their symptoms, and the findings on urodynamic tests, particularly post-void residual (C).**
- **LUTS can change as the disease stabilises; re-evaluation during follow-up is therefore recommended (C).**
- **Patients with overactive bladder symptoms are likely to benefit from antimuscarinic pharmacotherapy, once they are shown not to be retaining urine.**

VII. SPINAL CANAL STENOSIS

About half of the patients with intractable leg pain in spinal canal stenosis also have bladder symptoms – urinary difficulty with high post-void residual (PVR) and reduced flow rate and/or incontinence indicating effects on the cauda equina. Such symptoms, including urinary incontinence usually improve after surgical decompression.

Schkrohowsky et al [2007] [226] reported that one third of patients with achondroplasia developed SCS, especially at the lumbar level, and 77% of these had urinary incontinence. According to Johnsson and Sass [2004] [227], in the County of South Jutland, Denmark during a 5-year period [1996-2000], the annual incidence of SCS was 272 per million inhabitants. Of 340 cases diagnosed with SCS during that period, only one patient presented with acute cauda equina syndrome. This was a 74-year-old woman with SCS from L2 to L4, who presented with urinary retention and fecal incontinence (FI) for the preceding 24 hours; after urgent surgery she recovered from her anal sphincter paresis within 5 days and from her bladder paresis within 5 weeks.

Goh et al [2004 [228] carried out a comprehensive retrospective review of the clinical features, radiological changes and outcome of 75 patients with radiologically diagnosed lumbar SCS; imaging of the lumbar spine showed that moderate to severe central spinal stenosis correlated with complaints of weakness and abnormal motor power on clinical examination. The commonest symptom was numbness or tingling of the legs. According to the study of Inui et al [2004] [229], 58.8% of the 34 patients were diagnosed with neuropathic bladder; however there was no difference in the cross-sectional area of dural sac between those with and without neurogenic bladder dysfunction in patients with lumbar SCS. Nonetheless, the anteroposterior diameter of the dura was shorter in those with bladder dysfunction, and a critical size for the dural sac of patients was reported as 8 mm.

Usually signs and symptoms of compressive neuropathy of multiple lumbar and sacral roots is an indication for surgical intervention, but relatively unknown as a post-operative complication [230]. Four years after diagnosis, 65% had undergone surgical decompression; a third of patients felt that their symptoms had improved while a quarter felt that they had worsened. Imran and Halim [2005] [231] reported a 63-year-old man who developed acute cauda equina syndrome due to fat graft compression after decompressive laminectomy, posterior instrumented fusion with pedicle screw fixation for spinal stenosis of L5 and S1 vertebral levels, and free fat grafting to cover the exposed dura; three days postoperatively, gradual neurological deficit started with sensory loss and weakness of the affected dermatomes and myotomes, followed by FI on the 12th postoperative day; and immediate removal of the fat graft resulted in recovery from cauda equina syndrome. Another case was reported by Tubbs et al [2005] [232]; a Caucasian girl who had idiopathic growth hormone deficiency and Klippel-Feil and Duane's syndromes with symptomatic stenosis of the first cervical vertebrae presented with episodes of loss of tone with subsequent falling, facial cyanosis, UI, hand weakness, and difficulties with swallowing; following suboccipital craniectomy and the removal of the posterior arch of the atlas, her symptoms were resolved and UI improved.

To demonstrate narrowing of the lumbar canal with compression of the cauda equina, CT or MRI is often recommended, to reveal either bony or soft tissue compression [233]. Miyata et al [1998] [234] studied the relationship between bladder function and roentgenographic changes in the spinal canals of ossification of posterior longitudinal ligament (OPLL) patients. CO2-filling cystometry, uroflowmetry and PVR were measured and the vertical extent of OPLL and the degree of SCS was estimated by X-ray films and CT. The occurrence of abnormal detrusor activity had no relationship to the degree of canal stenosis, while the occurrence of an areflexic or underactive detrusor correlated with the vertical extent of OPLL [10]. Yamanishi et al [1998] [235] found DO in 14 lumbar canal stenosis patients (29%) and most of them had voiding symptoms and had storage symptoms which seemed to be caused by the irritation of sacral roots. Of 10 patients followed up after surgical decompression, DO disappeared in 5 patients, improved in 1 patient and remained unchanged in 4 patients [235]. Lee et al [1997] [236] did an expansive cervical laminoplasty in patients with non-traumatic cervical spondylosis with myelopathy and found that age greater than 60 years at the time of presentation, duration of symptoms more than 18 months prior to surgery, preoperative bowel or bladder dysfunction, and lower-extremity dysfunction were associated with poorer surgical outcome.

Conclusions

- **Patients with spinal stenosis, especially at lumbar levels, may present with bladder and bowel involvement – urinary retention/ incontinence and faecal incontinence (LOE 3/4).**
- **Lumbar canal stenosis may cause either detrusor underactivity/ acontractility or overactivity (LOE 3).**
- **Imaging helps diagnose spinal stenosis, while urodynamic study categorises neurogenic bladder dysfunction (LOE 3/4).**
- **Acute symptoms of incontinence or urinary retention may recover after decompression of spinal stenosis (LOE 3/4).**

Table 18. Causes for a cauda equina syndrome

Compressive	*Noncompressive*
Central prolapsed intervertebral disc* Trauma- vertebral fracture* Tumour- primary, metastatic Spinal canal stenosis Pott's disease- tuberculosis Abscess	Ischemia- spinal AV malformation causing steal Iatrogenic- spinal surgery* Following spinal anaesthesia- rare* Inflammation

**Can present acutely*

Recommendations:

- **Surgical decompression is recommended in patients with spinal stenosis having acute symptoms of urinary retention/incontinence and faecal incontinence (A).**

1. CAUDA EQUINA SYNDROME

The nerve roots of L2 to S4 that occupy the spinal canal below the termination of the spinal cord, at the lower border of the L1 vertebra, form a tightly-packed bundle giving the appearance of a horse's tail- hence they are referred to as the "cauda equina". Damage to these nerve roots produces a characteristic pattern of symptoms called the cauda equina syndrome where bladder, bowel, sexual dysfunction and sensory loss of the perineum are the predominant complaints. **Table 18** lists the common causes for a cauda equina syndrome.

2. LUMBAR DISC PROLAPSE

Medline/ Pubmed [1966-2012] searched for keywords: Disc prolapse (or disc hernia), bladder dysfunction, neurogenic bladder, sphincter dysfunction, bowel dysfunction, fecal incontinence, and constipation.

Central lumbar disc prolapse compresses sacral nerve fibers to and from the bladder, the large bowel, the anal and urethral sphincters, and the pelvic floor. Cauda equina syndrome due to central lumbar disc prolapse has been reported to be relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [237-244]. Clinical features of the cauda equina syndrome include low-back pain, bilateral sciatica, saddle anesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [240, 243, 245, 246]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes. A retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [247].

The most common urinary symptom associated with lumbar disc prolapse is acute urinary retention [248, 249]. At the onset, acontractile detrusor with impaired bladder sensation is a typical urodynamic finding [240, 246, 248-250]. Severe denervation of pelvic floor [248] and external urethral sphincter [10] is also frequently demonstrated. Detrusor overactivity may occur [250-252]. Urinary disorders usually follow or accompany more obvious neurologic symptoms, such as lumbar pain and perineal sensory disturbances, that prompt the appropriate diagnosis. However, sometimes voiding disturbances may be the only or the first symptom of this condition, which makes it more difficult to diagnose [240, 246]. Nevertheless, urgent MRI assessment is recommended in all patients who present with new onset urinary symptoms concomitantly with lumbar back pain or sciatica because it is impossible in a significant proportion of patients to exclude the diagnosis of prolapsed intervertebral disc in the context of referral with suspected cauda equina syndrome.

Emergency surgical decompression has been reported to increase the chance of satisfactory neurological recovery in patients with cauda equina syndrome due to central lumbar disc prolapse [240, 254, 255]. In a meta-analysis of surgical outcomes, Ahn et al. [2000] [243] reported that a significant improvement in sensory and motor deficits as well as urinary and rectal function occurred in patients who underwent the surgery within 48 hours, compared with those who had the surgery more than 48 hours after the onset of the cauda equina syndrome. Although there is still a controversy [247], most of other reports support the concept that decompression performed within 48 hours of onset of this syndrome resulted in improved functional outcomes [239, 244, 256]. However, acontractile detrusor is usually irreversible, even after immediate decompression [246, 257, 258], although many patients can empty their bladder postoperatively, this may achieved only by straining or changing voiding postures [246, 258]. In contrast to bladder dysfunction, urethral function shows a better recovery after surgery [246, 249].

For future research, good epidemiological studies on the occurrence of lower urinary tract/ bowel dysfunction are needed. This is increasingly relevant with the advent of new, minimally invasive treatment options for disc prolapse.

Conclusions:

- **Cauda equina syndrome is a relatively rare complication of lumbar disc prolapse (LOE 3).**
- **Bladder and bowel manifestations of lumbar disc prolapse include: urinary retention, loss of sensory functions, decreased sexual functions (LOE 3).**

Recommendations

- **Emergency surgical decompression is the treatment of choice, the optimum timing is considered to be within 48 hours (Grade B/C).**
- **Full recovery of lower urinary tract functions, including bladder contractility, is unreliable (Grade C).**

VIII. NEUROPATHIES AND MUSCLE DISORDERS

1. GUILLAIN BARRE SYNDROME

Since the eradication of poliomyelitis, Guillain-Barré syndrome (GBS) has become the most common cause for acute, flaccid paralytic disease in many parts of the world [1]. It presents as a rapidly progressing ascending areflexic motor paralysis, with or without sensory and autonomic dysfunction. Following an initial acute progressive phase, which by definition reaches a nadir within four weeks, there is a plateau phase and finally a recovery phase. Symmetrical limb weakness is the common presentation, however there may be in addition cranial nerve and respiratory muscle weakness. The disorder affects children and adults of all ages and both sexes. GBS is amenable to treatment with intravenous immunoglobulin or plasma exchange. However despite this, 4% to 15% of patients die from this syndrome, most often due to cardiovascular autonomic disturbances, respiratory compromise or aspiration. Nearly 20% have persistent disability [2].

Autonomic dysfunction is a frequently-overlooked complication. Cardiovascular autonomic dysfunction is recognized in up to 60% of GBS patients [3]. However, bladder and bowel dysfunction occurs much less often. Indeed, the presence of bladder or bowel symptoms at the onset of disease, or their persistence, casts doubt on the diagnosis [3A] and other conditions such as spinal cord disease needs to be excluded. During the acute phase, it is often difficult to assess LUTD specifically due to neurological dysfunction. Patients are often catheterized as part of their general nursing care to monitor water balance or maintain hygiene [2]. Furthermore, patients may be on medications such as opiates and tricyclic antidepressants, which in themselves can affect bladder and bowel functions. In the largest study to date, Sakakibara et al. [4] studied 65 patients with definite GBS (meeting clinical and neurophysiological criteria) and LUTD was observed in 27.7% (LOE3/4). This figure is almost is similar to that quoted by Guillain and others in the early papers about this condition [5, 6].

The condition is characteristically a symmetrical radiculo-neuropathy most often predominantly due to demyelination (Acute Inflammatory Demyelinating Polyradiculoneuropathy, AIDP), but also there are subtypes where axonal damage prevails (Acute Motor Axonal Neuropathy, AMAN). There is a dearth of systematic studies evaluating LUTD in GBS. In a few reports [10-12], detrusor areflexia and disturbed bladder sensation were the common findings, and a non-relaxing urethral sphincter was also seen (LOE3/4). In the study by Sakakibara et al. [4], patients most commonly reported voiding symptoms in 24.6%, including urinary retention in 9.2%. Storage symptoms were noted in 7.7%, urinary urgency in 7.7%. None of the patients in this study became incontinent. Urinary dysfunction was more common in AIDP (39%) than AMAN (19%), although the prevalence of urinary retention was almost the same (AIDP, 7%; AMAN, 11%, respectively). Factors that were associated with bladder symptoms included age, severity of motor weakness (Hughes motor grade) and concurrent bowel dysfunction. When patients were followed up, improvment in bladder symptoms paralleled improvement in motor weakness. Interestingly, there was no correlation between the presence of cardiovascular autonomic dysfunction and bladder dysfunction. Urodynamic studies performed within eight weeks of disease (n=9) showed variable results, demonstrating detrusor underactivity (n=2), DO (n=3), both DO and underactivity (n=5) and non relaxing urethral sphincter (n=2). Three patients had an elevated post void residual and one patient had reduced bladder sensations [4] (LOE3/4). Their results were similar to the urodynamic findings from Gabavac et al. [12] (LOE3/4).

a) Urinary dysfunction

Urinary dysfunction in patients with GBS tends to appear after the onset of motor weakness in all cases [4]; however, in two patients with axonal GBS, it was reported that voiding difficulty and motor weakness appeared almost simultaneously [7, 8] (LOE3/4). A close relationship between severity of GBS and bladder dysfunction has been reported [8A] (LOE3/4). Lichtenfeld [9] (LOE3/4) has reported urinary retention in one-third of patients requiring ventilator assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will most often improve along with other neurological signs after supportive patient management, with or without immunomodulation. However bladder dysfunction can persist, and it is reported that urinary retention failed to recover for 10 months, even after a patient (with axonal GBS) regained the ability to walk [8] (LOE3/4).

GBS primarily affects the large myelinated fibers, but pathological studies have demonstrated moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord [1,13]. It has been postulated that LUTD in GBS may be arising from inflammatory or immunologically mediated damage of of the autonomic fibres of the lumbosacral nerves [1,13, 13A] (LOE3/4). Contrast magnetic resonance imaging (MRI) has demonstrated enhancement of the nerve roots of the cauda equina in GBS [14] (LOE3/4). The possible mechanism for DO might be abnormal spontaneous depolarisations in demyelinated nerve fibres, and impairment of inhibitory spinal cord interneurons, both of which can result in lumbosacral autonomic hyperactivity [13A, 15, 16] (LOE3/4).

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of the disease. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction can recover in parallel to recovery of motor weakness, but in some cases this might be delayed. If suitable, IC should be considered. Wosnitzer et al. reported a successful case of sacral neuromodulation for urinary retention that persisted 18 months after GBS [16A] (LOE3/4). Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication once it is shown they are not retaining urine. Of specific consideration to GBS is the side effect of tachycardia, as many patients may have concomitant cardiovascular autonomic dysfunction.

There are only limited studies evaluating the natural history of LUTD in GBS and long-term follow-up studies of patients are required. Studies evaluating the correlation between LUTD and other evidence for autonomic dysfunction (such as cardiovascular autonomic dysfunction) should be specifically evaluated.

Conclusions

- **In the acute phase of GBS, about 25% of patients demonstrate LUT functional problems (LOE3/4).**
- **Both voiding and storage dysfunction are observed in GBS (LOE3/4).**
- **Recovery of LUT function occurs along with the recovery of motor weakness. However, in rare cases it might take months (LOE3/4).**

Recommendations

- **Recovery of LUT functions is expected in GBS; supportive care, including an indwelling catheter or IC, is the treatment of choice for urinary retention (C).**
- **Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic, once they are shown not to be retaining urine.**
- **A systematic evaluation of LUTD during the acute phase and recovery following GBS is required to optimize therapy (C).**

b) Bowel dysfunction

Bowel dysfunction occurs less commonly in GBS, in up to 15% of patients [17, 18]. In a study by Burns et al. [17] (LOE3/4) adynamic ileus was noted in 17 out of 114 GBS patients. However, cardiovascular symptoms coincided with ileus in only 5 patients, suggesting a different pathophysiology for these two manifestations of autonomic dysfunction. Indeed in 4 patients, mechanical ventilation and immobilization was implicated. In 8 patients, pre-existing conditions such as prior abdominal surgery or incremental doses of opiates could also be linked to ileus. However, three case reports by Gazulla Abio et al. (LOE3/4) [19], Sawai et al. (LOE3/4) [20] and Noew et al. (LOE3/4) [21] have also shown that paralytic ileus can be the initial presenting symptom in GBS.

There is a lack of good systematic studies on bowel disorders in GBS during the acute and chronic phase of GBS. However, there are some reports suggesting an involvement of bowel autonomic fibers in GBS. Sawai et al. (LOE3/4) [21] performed a detailed bowel function test in a 47-old man with acute motor axonal neuropathy (AMAN) type of GBS who presented with ileus (also called intestinal pseudo-obstruction) by an abdominal X-ray. Sitzmarks showed prolonged total colonic transit time (86.4 hours; normal 16.0-48.0), suggesting slow transit constipation. Pathological studies of GBS have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord. Therefore, involvement of bowel autonomic fibers might also occur in GBS [21], as shown in an autopsy case of autoimmune gastroparesis [18].

Adynamic ileus or intestinal pseudo-obstruction occurs in up to 15% of patients during a course of GBS, particularly in those with severe motor dysfunction or those under mechanical ventilation [17] (LOE3/4). Recovery of bowel function usually occurs along with the recovery of motor weakness in GBS, after an intensive immune therapy including intravenous immunoglobulin.

There is still a lack of a detailed functional evaluation of the bowel in GBS patients. Such studies are needed in order to optimize the therapy in the future.

Conclusions

- **About 15% of patients demonstrate bowel functional problems particularly in the acute**

phase, but they can also be presenting symptoms (LOE3/4).

- **Constipation and intestinal pseudo-obstruction are observed in GBS (LOE3/4).**
- **Recovery of bowel function usually occurs, along with the recovery of motor weakness.**

Recommendations

- **Supportive care, including laxatives or enemas, is the treatment of choice (C).**

2. FAMILIAL AMYLOID POLYNEUROPATHY

Familial Amyloid Polyneuropathy (FAP) is a rare autosomal dominant neuropathy affecting predominanatly the peripheral autonomic nerves. Neuropathy starts insidiously in the lower limbs and is characterised by lancinating pains, numbness and impaired temperature sensations.

Autonomic manifestations are common and may be the intial manifestation in nearly 25% of patients [22] (LOE3/4). These include erectile dysfunction, orthostatic hypotension, bladder dysfunction, distal anhydrosis and abnormal pupils. LUTS generally appear early on and are present in 50% of patients within the first three years of the disease. Patients most often present with voiding dysfunction and incontinence (LOE3/4). Often, however, bladder dysfunction may be asymptomatic and uncovered only during investigations. Urodynamic studies have demonstrated reduced bladder sensations, underactive detrusor, poor urinary flow and an open bladder neck. There may be failure of relaxation of the smooth and striated sphincters as well. Ultrasound scans of the bladder may show bladder wall thickening, a finding which becomes more prominent as the disease progresses, and may represent either amyloid deposition in the bladder wall or detrusor hypertrophy secondary to functional obstruction (LOE3/4). 10% of patients with FAP type I may proceed to end stage renal disease [23] and bladder diaries may demonstrate global polyuria. Bladder dysfunction is likely to be due to small nerve fibre damage and deposition of amyloid substance in the detrusor muscle.

Patients should be followed up regularly, as overdistention is likely to contribute to bladder dysfunction. In the early stage of disease, post-void residual urine will often be less than 100 ml and bladder scheduling and double voiding is often sufficient. However when bladder emptying deteriorates, intermittent catheterization is required.

Lower gastrointestinal dysfunction results in alternating constipation and diarrhea. This occurs concomitantly with other manifestations such as episodic nausea, vomiting, and malnutrition. Anorectal physiology studies have demonstrated prolonged colonic transit time, low anal pressure at rest and loss of spontaneous phasic rectal contractions during squeeze, suggesting an enteric neuropathy [24] (LOE3/4).

Liver transplantation remains the only potentially curative treatment and gastrointestinal symptoms improve in about half of cases [22]. Studies suggest that bladder dysfunction does not improve following transplantation [25] (LOE3/4). Interestingly, the occurence of urinary incontinence preoperatively has been shown to predict higher postoperative mortality [25].

3. FAMILIAL DYSAUTONOMIA

Familial dysautonomia (FD) or Riley-Day syndrome is the best known of the hereditary sensory and autonomic neuropathies (HSAN). This autosomal recessive condition is characterised by autonomic and small fibre sensory dysfunction. LUTD is known to occur in this condition and patients most often present with incontinence- stress incontinece but also overactive bladder symptoms. The limitation of using antimuscarinics is that it can exacerbate an already dry mouth from the underlying autonomic neuropathy. Less often, patients may have voiding dysfunction manifesting with hesitancy for micturition and high post-void residual volumes, and may be predisposed to recurrent urinary tract infections [26] (LOE3/4).

4. CHARCOT-MARIE-TOOTH DISEASE

Lower urinary tract dysfunction is only occasionally described in Charcot-Marie-Tooth disease. It has been reported in a family with proximal lower limb weakness where it manifested as loss of bladder sensations and urinary retention with detrusor underactivity demonstrated in urodynamics [27].

5. AUTONOMIC NEUROPATHIES

a) Acute Idiopathic Autonomic Neuropathy.

Bladder dysfunction is well recognized in acute idiopathic autonomic neuropathy (acute pandysautonomia). Acute onset autonomic dysfunction is the hallmark, and is thought to be due to lesions of the pre- and postganglionic sympathetic and parasympathetic fibres. Urinary retention and voiding difficulty are common and cystometry demonstrates detrusor areflexia. Bladder dysfunction tends to resolve earlier than other features of autonomic dysfunction, such as orthostatic hypotension. Constipation is common [28] (LOE3/4).

b) Autoimmune Autonomic Ganglionopathy.

Presentation is with rapid onset of severe autonomic failure: orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, bladder dysfunction, erectile dysfunction and sicca symptoms. They have circulating ganglionic acetylcholine receptor (AChR) antibodies. Bladder dysfunction generally manifests with voiding difficulty and incomplete

emptying. Severity and distribution of autonomic dysfunction appear to depend upon the level of antibody titers [29] (LOE3/4).

c) Pure Autonomic Failure.

PAF is a degenerative postganglionic autonomic disorder. Nocturia and voiding dysfunction are common and bladder emptying is often affected. Bladder diaries may demonstrate nocturnal polyuria. Urodynamics may however demonstrate detrusor overactivity in some patients [30]. Bladder dysfunction in PAF appears to be as common as, but less severe than, MSA and this could possibly reflect slower progression of the disease [30] (LOE3/4). Constipation is common.

6. DISORDERS OF THE NEUROMUSCULAR JUNCTION

Widespread autonomic dysfunction is a hallmark of Lambert-Eaton myaesthenic syndrome (LEMS). This is associated with antibodies to voltage-gated calcium channel (VGCC) of the P/Q-type and patients can present with erectile dysfunction, constipation and bladder dysfunction [31].

In the more common disorder of the neuromuscular junction, myasthenia gravis, LUTS is rare. This is presumably because the auto-antibodies are directed against the nicotinic acetylcholine receptors, rather than the muscarinic. However voiding difficulties have been reported and urodynamic studies have revealed detrusor underactivity in these patients. In fact, voiding dysfunction may herald a new diagnosis of myasthenia or an exacerbation of the disease process [32] (LOE3/4). The proposed mechanism is involvement of acetylcholine receptors in the detrusor muscle or pelvic ganglia [33]. Ganglionic acetylcholine receptor antibodies may be present in some patients [34]. Urinary incontinence is a listed side effect of anticholinesterase medications which are used in treating myaesthenia gravis [British National Formulary (online), 2009 March, cited 8 Sept 2009], though in clinical practice this is rarely observed. Intestinal pseudo-obstruction has been reported in patients of myasthenia gravis with subacute autonomic failure.

7. MUSCLE DISORDERS

a) Muscular Dystrophies

Case series in boys with Duchenne Muscular Dystrophy (DMD) have reported the occurence of overactive bladder symptoms, and DO has been demonstrated in urodynamics. Symptoms improve with antimuscarinic medications [35] (LOE3/4). The exact mechanism for DO is uncertain, though it is likely to be due to a disturbance of neural control rather than myopathy of the detrusor or external sphincter. Patients may have severe scoliosis as a consequence of their muscle disorder and this, as well as spinal fusion surgery for correcting scoliosis, can contribute to LUTS because of spinal cord compression [36].

Myotonic dystrophy (MD) is an autosomal dominant disorder caused by unstable trinucleotide repeat expansions. The commonest bowel complaint is constipation, however most disabling is fecal incontinence. EMG has demonstrated myotonia and myopathic changes in the external anal sphincter. Bowel incontinence is often refractory to treatment [37] and procainamide (300 mg twice a day) has been proposed as a treatment option [38]. Constipation is usually treated with prokinetics, laxatives and enemas. Bladder dysfunction is variable and less often reported with detrusor overactivity or atonia being documented in urodynamics [39] (LOE3/4).

b) Mitochondrial cytopathy

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal recessive disorder characterized by gastrointestinal, extraocular, peripheral nerve and cerebral white matter involvement. The gastrointestinal disease manifests with intermittent diarrhea and pseudo-obstruction. Mitochondrial DNA abnormalities and/or thymidine phosphorylase mutations in the proper clinical setting are diagnostic [40]. Bowel dysmotility has also been reported in Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, acronym DIDMOAD) [41]. Lower urinary tract dysfunction has been described in both conditions, and the latter may be associated with urinary retention and dilated upper urinary tracts [41] (LOE3/4).

Conclusions

- **Lower urinary tract and bowel dysfunction can occur in a variety of neuromuscular disorders (LOE3/4).**
- **Both voiding and storage dysfunction are observed in these conditions (LOE3/4).**

Recommendations

- **Patients with neuromuscular disorders with bladder symptoms should be managed according to their symptoms and the findings of urodynamic tests (C).**

LUT and bowel dysfunction can change as these diseases progress and therefore follow-up is recommended (C).

8. PERIPHERAL NEUROPATHY DUE TO IATROGENIC LESIONS (FOCAL NEUROPATHY)

LUT dysfunctions can occur from damage to the nerves innervating the pelvic organs, anywhere in the course of these nerves through the cauda equina, the spinal nerve roots, the sacral plexus, or to the various individual nerves that arise from the plexus. Most injuries to these nerves are iatrogenic. Extensive pelvic surgery, such as abdomino-perineal resection for

rectal cancer, radical hysterectomy, and aorto-iliac surgery are all likely to damage the pelvic parasympathetic nerves to the bladder and genitalia. Of course this listing is not complete and almost any surgery in the pelvis could damage some nerves e.g. adenomectomy, radical prostatectomy, prolapse surgery. Additionally, pelvic irradiation, apart from directly affecting the irradiated tissue, could cause damage to the adjacent nerve fibers, resulting in altered functions. A variety of types of voiding, erectile and fecal dysfunctions can result.

a) Hysterectomy (simple and radical).

It is difficult to attribute certain dysfunctions to neuronal damage alone, since hysterectomy directly affects static and dynamic functions of the pelvic structures. Parys et al. [42] (LOE 3) studied 126 women after simple hysterectomy. The results show that 47.0% had DO, 36.7% had urethral obstruction and 24.8% stress incontinence. Sekido et al. [43] (LOE 3) described 9 women treated with radical hysterectomy more than 10 years before the study. Obstructive voiding symptoms and/or urinary incontinence were observed in 7 patients. Cystometry revealed impaired bladder sensation, detrusor acontractility, straining on voiding, and impaired relaxation of the sphincter in all assessable patients. In addition, decreased bladder compliance was observed in 5 patients. Axelsen [44] (LOE 2) studied 100 women after radical hysterectomy and found that those women who reported incontinence had lower urethral pressure. In a prospective study of over 1000 women Jackson et al. found hysterectomy to be an independent risk factor of incontinence [45] (LOE 2). Plotti et al. analysed literature between 1952 and 2010 and found that in studies with follow up longer than 12 months, 34% of patients demonstrated DO and lowered compliance [46] (LOE 2).

The introduction of nerve sparing hysterectomy appeared to reduce urinary and sexual dysfunctions in comparison with the standard radical hysterectomy. It was found that autonomic nerve preservation significantly improved morbidity 6 months after treatment [3-5] (LOE 3). There is however significant lack of long term observations of patients after radical hysterectomy in terms of lower urinary tract neurogenic dysfunctions.

b) Abdominoperineal resection and total mesorectal excision

Retrospective analysis of 52 patients after abdominoperineal resection was performed by Eickenberg et al. [47] (LOE 3). Neurologic bladder dysfunction of various degrees was found in 50% but represented a long-term problem in only 10%. Baumgarner et al. [48], (LOE 3) studied 86 consecutive cases of abdominoperineal resection and described 11 cases of various functional problems of micturition. These reports lack specific tests of LUT functions and are not prospective. At 1 year follow up, dysuria incidence is higher after abdominoperineal resection than after anterior resection [48] (LOE 3).

Curative total mesorectal excision with autonomic nerve preservation can be done with high rates of preservation of such function. Pocard et al. [49] (LOE 3) investigated 20 patients (13 men, 7 women) following curative total mesorectal excision with autonomic nerve preservation for rectal cancer. There was no difference in preoperative and postoperative LUT function, International Prostate Symptom Score or urodynamic results, nor in the results of the quality of urinary function questionnaire. Sexual function and potency were also unchanged in these men. The authors conclude that autonomic nerve preservation is possible and does not impair urinary and sexual function. Also Kim et al. [50] (LOE 3) showed relative safety in preserving sexual and voiding dysfunction with total mesorectal excision with pelvic autonomic nerve preservation. Evaluation was based on uroflowmetry, voided volumes and residual volume, while symptoms were evaluated with the IPSS. There were significant differences in maximum urinary flow rate and voided volume, but no differences in residual volume before and after surgery. The IPPS increased after surgery from 6.2 +/- 5.8 to 9.8 +/- 5.9 ($p < 0.05$).

Similar results were reported by Turaldo et al. [51] (LOE 3) evaluating incidence and pathogenesis of LUT dysfunction after surgical treatment of rectal cancer in a series of 219 patients with normal urinary function preoperatively. In the immediate follow-up, only 17 patients with dysfunction were observed, 14 stage II, 2 at stage III and 1 at stage IV according to Astler-Koller classification; six months later only 8 patients reported urinary dysfunction and 1 required catheterisation. However no urodynamic studies were performed. There was no correlation of LUT dysfunction with staging, radiotherapy, size of tumour, or surgical technique. However, worse functional results were observed in patients who underwent abdomino-perineal resection.

Lim et al. found that not only surgery but also preoperative irradiation could cause lower urinary tract and anorectal dysfunctions. The maximum resting anal pressures were unchanged after chemoradiation, but the maximum squeeze anal pressures were reduced after chemoradiation. They concluded that preoperative chemoradiation for rectal cancer carries a significant risk of pudendal neuropathy, which might contribute to the incidence of fecal incontinence after restorative proctectomy for rectal cancer [52] (LOE 3). However Lange et al. found that it is mostly the surgery, not the preoperative radiotherapy which is causing urinary dysfunction [53] (LOE 3).

Focal injury to peripheral innervation of the bladder and/or sphincter results in decentralization or denervation of the above mentioned organs. Therefore detrusor hypocontractility (acontractility) and/or sphincteric deficiency will be the result of such

damage. This in turn will result in impaired bladder emptying and/or stress incontinence. No prospective studies referring specifically to the problem of functional disturbances of the LUT in focal iatrogenic neuronal injury in patients after hysterectomy or colorectal surgery have been performed.

Iatrogenic faecal incontinence can be caused by sphincter damage caused during childbirth, and surgery for anorectal problems, trauma, fistulae and abscesses. Vaginal delivery can cause not only sphincteric, but also neuronal damage to the innervation of the anal sphincter [54] (LOE 3). There is a significant paucity of epidemiological data regarding fecal incontinence after pelvic surgery.

Anorectal reflexes and anorectal manometry may predict recovery of function [55, 56] (LOE 3). An interesting test in this specific patient population was described by Nordling et al. [57] (LOE 3). In patients after radical hysterectomy, those who had a completely denervated bladder had a greater rise in maximum urethral pressure during noradrenaline infusion (exceeding 20 cm H2O) than normal subjects (1 to 15 cm H2O). The authors concluded that urethral supersensitivity to noradrenaline may be signify damage of the sympathetic nervous innervation of the LUT.

Detailed knowledge of pelvic neuroanatomy and meticulous preparation of the structures adjacent to nerves potentially at risk is essential [58-61] (LOE 3). Nerve sparing surgery seems to have favourable effect on bladder functions and continence in patients after radical hysterectomy [61-65] (LOE3). Thus it seems that it is the nerve function, rather than the biomechanics of the urethrovesical complex, which are responsible for incontinence. A method of intraoperative identification of the vesical branches of the pelvic nerves during radical hysterectomy was described by Kuwabara et al. [66] (LOE 3). Postoperative compliance of the detrusor in cases where this method was implemented demonstrated less decrement from preoperative values than in cases with conventional approaches. These patients required significantly fewer days to achieve residual urine volumes less than 50 ml after surgery.

Nerve sparing technique and intraoperative identification of parasympathetic nerves seem also to play a role in rectal cancer surgery. Kneist and Junginger studied 62 patients undergoing mesorectal excision. Pelvic autonomic nerve preservation (PANP) was assessed macroscopically and with the aid of intraoperative electrical stimulation of pelvic autonomic nerves. In 46 patients, preservation of parasympathetic nerves was confirmed and these patients remained unchanged in early and long-term urinary function, contrasting with patients in whom preservation of the nerves was not confirmed [67] (LOE 3).

Should injury to the nerves innervating the bladder/urethra complex occur, the treatment should be based on standard principles and on the results of functional examination of the LUT. Zanolla et al. [68] (LOE 2) suggested that early implementation of rehabilitative treatment (prompted voiding) allows satisfactory functional recovery of the bladder activity in 91% of the symptomatic patients after radical hysterectomy. Another interesting issue is the feasibility of the use of the artificial urinary sphincter to treat stress incontinence in patients with outlet denervation after colorectal surgery, hysterectomy and/ or radiotherapy. Only one study on this subject was identified [69] (LOE 3), describing a series of patients after radical prostatectomy and amongst them a patient after abdominoperineal resection with adjuvant radiation. Authors concluded that this method of incontinence therapy should be the method of choice, however there is a significantly greater risk of revision (38% versus 22% in the literature for low risk groups). Bulking agents may be considered after radical hysterectomy, if no other treatment options are possible [10]. If not resulting from sphincter damage, fecal incontinence after colorectal surgery might be considered for sacral neuromodulation [70] (LOE 3).

Future research priorities include good epidemiological research, particularly prospective studies of the true incidence of peripheral injury related functional disorders of micturition. Descriptive studies of diagnostic testing and therapy are needed. A registry database of urinary and fecal incontinence after different types of pelvic surgery would be a considerable benefit for insight into prevalence and preparation of guidelines on treatment/prophylaxis

Conclusions:

- **Injury to the bladder/sphincter innervation occurs in 30-50% of patients after extensive pelvic surgery (LOE 3).**
- **Pelvic irradiation could cause nerve damage affecting bladder/bowel functions (LOE 2).**
- **Fecal incontinence due to iatrogenic innervation damage could occur after complicated labor, anorectal surgery and pelvic irradiation (LOE 3).**
- **Focal injury results in impaired detrusor contractions and/or external urethral sphincter deficiency or detrusor/sphincter dyssynergia (LOE 3-4)**
- **The key means to avoid these complications are nerve sparing techniques and intraoperative nerve identification (LOE 3).**

Recommendations:

- **.Patients after extensive pelvic surgery demonstrating functional disorders of micturition should be properly evaluated due to the varied potential underlying mechanisms (C)**

- **Early rehabilitation of the LUT and of the anal sphincter might improve voiding in a majority of patients (C).**
- **Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B).**
- **Autonomic nerve preservation should be considered when performing surgery for rectal cancer. Targeted voiding history before and after surgery and post-operative post-void residual urine measurements are mandatory to minimise risk of secondary detrusor damage through chronic urinary retention (B).**

IX. MULTIPLE SCLEROSIS

1. EPIDEMIOLOGY

Even though there are few studies today to confirm it, the impact on the quality of life for patients with vesicosphincteric disorders (VST) due to multiple sclerosis (MS) is probably significant. Moreover, in a recent cross-sectional study (LOE4), Notvedt et al [1] demonstrated that those patients with VST had distinctly lower quality of life scores on the SF36 scale in comparison with the population of MS patients that is asymptomatic. The tools for evaluating quality of life that take into account VST in MS have been validated so that variations in it over the course of the illness can be measured [2-5].

VST is extremely polymorphic, and it appears in the great majority of cases within the first 6 to 10 years of the progression of the illness [6-11]. Once VST has started (2 to 10% of cases as primary symptom [7, 12-14]), they will present a more elevated risk of developing severe follow-on urological problems (LOE4) [15]).

The prevalence of VST in the global population of patients who are suffering from MS is in the order of 30 to 96% [6-8, 10, 11, 13, 14, 16-32] (LOE 2b-4). The size of this interval manifests the differences linked to the type of MS, to the duration of the illness, and to the degree of handicap, as well as to a probable under-evaluation by certain practitioners of the urological problems that develop progressively and slowly.

2. URINARY DYSFUNCTION IN MS

Urinary symptomatology in MS is polymorphic and, like its incidence, probably subject to change over time. The most frequent urinary symptoms are indisputably overactive bladder (OAB) symptoms: urinary frequency (32 to 99%), urgency (32 to 85%), and urge incontinence (19 to 80 %) (LOE2b-4) [7-11, 13-15, 18-22, 24-34].

Obstructive urinary symptoms also exist to a lesser degree: difficulty of voiding and chronic or acute urinary retention. Dysuria was found in 6 to 79% of the patients, and acute episodes of urine retention were reported in 8 to 73% of the patients (LOE2b-4) [8-11, 13, 14, 18-22, 24-35].

All of these studies were carried out most frequently in a retrospective fashion or on a population of patients coming for a consultation for another reason, which can upwardly bias the estimated frequency of the disorders. There was a cross-sectional study from Marrie et al [5] (LOE4) of 16,858 patients. Of those patients, 9688 (57.5%) had responded to the two questionnaires that were posted (Bowel Control Scale (BWCS) and Urogenital Distress Inventory-6 (UDI-6)). The figures confirm the frequency of urinary disorders in the MS population: urinary frequency (28%), urgency (17%), urge incontinence (14%), and difficulty with bladder emptying (12.5%). Independent of the non-response rate, there are several elements that cause us to think that these figures are in actuality higher. Indeed, 65% of the patients complain of having at least 1 episode of urinary tract infection, and the majority of patients have not been treated or had a specific checkup. One can think of this very elevated rate of episodes, labeled “UTI”, as manifesting the underlying vesicosphincteric disequilibrium in numerous patients. Problems with emptying the bladder are particularly poorly evaluated by patients, with a large number of patients having a significant post-void residual amount without an evident clinical manifestation. In a cross-sectional study (LOE4) carried out in 2004, Kragt et al had also found a proportion of 16% of patients who had a post-void residual (PVR) greater than 100 ml but without any symptoms that were detected by the questionnaires that are normally used in evaluations of MS (EDSS, Guys Neurological disability Scale (GNDS)).

The estimation of the global incidence of these disorders in the body of patients with MS underlines the frequency of VST in this population. In practice, it is therefore important that the tools that are used to evaluate these problems are the most appropriate ones possible, because, all of the authors agree that the fact that VST is often ignored by the doctors who take care of these patients is due to the fact that the patients under-report their symptoms (LOE5). What is more, a certain number of the patients will suffer from uronephrological complications secondary to VST. It is therefore important to be able to isolate the groups of patients that are at risk so that complex examinations that are seen as risky are not imposed upon the entire population of patients who are suffering from MS [8, 29, 35].

In a systematic review of the literature, De Sèze et al [17] found that the duration of the progression of MS was one of the principal factors that influenced the frequency of VST (LOE 2b-4). Thus, the majority of the studies that were carried out in patients who had a duration of the progression of MS of more than

13 years found a more homogenous frequency for the different symptoms that was in the high range in comparison with the other figures cited up until the present: urinary frequency (38.5 to 99%), urgency (44 to 85%), and urge incontinence (63 to 72%) (LOE2b-4). The frequency of obstructive disorders is likewise markedly more elevated [36-79.5%) [7-10, 14, 18, 20, 25, 28]. A second important factor that is associated with the frequency of VST is the degree of the patient's physical handicap as estimated by the EDSS (LOE2b-4)(Expanded Disability Status Scale) [1, 8, 20, 29, 36-40]. It is difficult to confirm from these studies whether this factor has a role in itself, however, on the other hand, clinical practice indicates this common sense observation. A person who can compensate for the urgency by going to the toilet beforehand will see the appearance of urge incontinence following the appearance of a new motor or visual handicap (LOE5). The appropriate management of this problem can allow the improvement of urinary disorders without any specific action on the bladder or the sphincter. As in those patients who have medullar injuries, the clinical examination does not always allow the discovery of the specific neurological insults that are associated with VST. Certain authors have found an association between the pyramidal syndrome and irritable VST [8, 14, 20, 29]. No neurological presentation has been found that is associated in a manifest fashion with bladder voiding disorders [10, 41, 42]. No correlation between radiological insults on the central nervous system (localization and intensity) and clinical VST has actually been found [36, 43-45]. The analysis of a series of autopsies that were done on patients who had a sacral and lumbar insult (autopsy series) did not find any correlation with clinical VST [46] (LOE5).

Other associations have been indicated, but they have all been controversial. The type of progression for the MS (progressive or by crisis), the age at which MS started, and the sex, the age, the geographical location where the patient lives, and the like do not thus appear to be associated with a more elevated frequency of VST [14, 20, 29, 36, 38-40, 47]. The age of the patient does not have impact anymore. On the other hand, older patients will have the same problems as the general population (benign prostate hyperplasia in men and stress urinary incontinence in women), and those problems will of course often be more difficult to treat than they are in the general population.

It is difficult to precisely establish mortality from uronephrological complications. In a recent study of the causes of death in MS patients in the U.S. that was carried out using death certificates (LOE4), a symptomatic urinary tract infection was considered as a contributing cause to the death in 8.4% of the cases, which made it one of the principal causes that were associated with mortality [48]. In that study, terminal renal insufficiency was not found to be a notable cause of mortality.

a) Infectious complications

The reported frequency of lower urinary tract infections is elevated in the literature, ranging from 13 to 80% [17] [7, 9, 10, 18, 21, 25, 29, 30, 38, 49-52] after at least 10 years of progression of the illness. In the study by Marrie et al, 64.6% of the patients indicated at least one annual episode of urinary tract infection. The diagnoses of symptomatic urinary tract infection is therefore very difficult in those patients who have a neurogenic bladder. Indeed, in close to half of these cases the symptoms that are related to neurogenic detrusor overactivity will be complicated by a lower urinary tract infection, as has been well demonstrated by Lisenmeyer et al (LOE 3c) in spinal cord injury patients (SCI) [53]. There is also an incompressible rate of asymptomatic bacteriuria in many neurological patients [54] (LOE4). The occurrence of febrile urinary tract infection (pyelonephritis, orchitis, or prostatitis) is estimated to be between 2 and 23% (9% on average). In addition to the risk of mortality from certain of these infections that has already been underlined, several retrospective studies (LOE5) report an aggravation of MS following an episode of this type [1, 55, 56]. Neurogenic detrusor overactivity is probably a significant factor in the occurrence of upper urinary tract infections. Game et al [57] have also reported a prospective open study in which the injection of botulinum toxin in the detrusor in patients with MS had allowed a significant reduction of symptomatic urinary tract infections to be observed (LOE3c).

b) Alterations of the bladder

Morphological alterations of the trabeculation, thickening of the bladder wall, and diverticula were found in 4 to 75% of cases according to the series (30% on average) [9, 10, 14, 19, 21, 25, 27-31, 34, 38, 49, 50, 52, 58, 59]. These alterations did not have pathological consequences that were different from those that are found in the general population (primarily increased risk of symptomatic urinary tract infections). The exact proportion of vesical calculus is difficult to estimate, because the majority of studies do not indicate the precise site of calculi events. It can be estimated to be in the neighborhood of 5%. Several factors are associated with the discovery of morphological alterations of the lower tract: post void residual greater than 100 ml and a progression of MS of more than 10 years in duration [19, 60]. There is no correlation between VST and the morphological anomalies that were found [14].

c) Bladder cancer

The data on the more elevated risk of a vesical tumor in patients with MS are controversial. Indeed, it known that those patients who have a neurogenic bladder have had a more elevated risk of developing a particular bladder tumor: epidermoid carcinoma (LOE2b-4) [61-64]. There are other factors that increase this risk in theory, such as tobacco use, indwelling urinary catheters, untreated vesical calculi,

and chronic urinary tract infection. In patients with MS, the use of treatment by cyclophosphamide can be an additional risk. The risk is even further elevated in those patients who have an indwelling urinary catheter or who have been exposed to tobacco. The risk of bladder cancer appears to be slightly increased in those patients who suffer from MS, as a result of risk factors related to their neurogenic bladder as well as from medullar trauma: indwelling urinary catheter, vesicular calculi, and chronic infections. There are other factors that increase this risk in theory, such as tobacco use and treatment with cyclophosphamide. The several studies that have specifically analyzed the risk of vesical tumor in patients with MS (LOE4-5) allow its incidence to be estimated at around 0.29%, which is two to three times higher than the incidence in the general population [23, 65-67]. The diagnoses of these cancers is particularly difficult in neurological patients, especially if they have been catheterized, because the usual diagnostic tools (cystoscopy, cytology, and BTA test) may not be as accurate as usual because of the inflammatory change of the bladder [63].

d) Complications of the upper urinary tract

Renal calculi were found in 2-10% of the cases, hydronephrosis was found in 1 to 16% of the cases, and vesicoureteral reflux was found in 2 to 15% of the cases (LOE 2b-4) [9, 10, 14, 18, 21, 25, 27-31, 34, 38, 49, 50, 52, 59]. Contrary to the case in medullar traumatization and in spina bifida, the incidence of terminal renal insufficiency is rare in patients with MS, and does not appear to be greater than what it is in the general population [68]. On the other hand, a certain degree of renal insufficiency is indicated in certain articles, and may be as high as 2 to 3% in those patients whose illness has progressed for more than 10 years [19, 25, 27].

e) Risk factors in urological complications

As we have specified previously, the great heterogeneity of the clinical signs of VST in MS leads to delayed diagnosis of urological complications. Simple clinical surveillance therefore exposes one to the risk of overlooking a complication that could significantly increase the risk of urinary tract infection, such as post micturition residue (LOE4) [42]. De Sèze et al [17] looked at data based on the literature in an attempt to discern the principal risk factors for urological complications. Those results must be considered with prudence, because the majority of the studies that were used in that analysis were retrospective (LOE4). The duration of the progress of MS is the principal risk factor, with an increase in the frequency of disorders appearing after 6 to 8 years of progression of the illness. These data are consistent with two cross-sectional studies (LOE4) that report a duration of the progress of MS that is significantly more elevated in those patients who have alterations of the upper urinary tract [9, 49].

The second significant risk factor (especially infectious) is the method of urinary drainage. The indwelling catheter (LOE2b-4) [9, 25] has been associated with a number of known infectious complications [69]. The utilization of suprapubic catheters was associated with a reduced risk (LOE3c) [70, 71], however, the series that was published was mid-term [5 to 6 years) and not long term follow up. If one relies on the data that is available for the treatment of patients with SCI, then the best urinary drainage methods are intermittent catheterizations and voluntary voiding (when it can be done without residue) (LOE2) [72].

The third classic risk factor, independent of diagnosis with MS, is the occurrence of post void residual, which is associated with a more elevated risk of urinary tract infection, of vesicular calculus, and, over time, of the distention of the upper urinary tract.

The other risk factors, suggested by many authors, are more rarely reported and do not allow for a group analysis. The urodynamic risk factors will be addressed in the following chapter. The progression of MS and the patient's sex are not associated with particular alterations of the upper urinary tract. Men were more disposed to have febrile urinary tract infections (LOE4) [8, 9, 25, 35]. Older patients were more susceptible to presentation with urological complications, due on the one hand to the occurrence of urological pathologies at their age, but also probably due to the longer progression since the start of MS [17]. The same factor could explain the data of certain authors who report more frequent urological complications in those patients who have a more severe handicap (LOE4) [9, 14, 15, 51].

f) The role of urodynamics in multiple sclerosis

The clinical manifestation of vesicosphincteric disorder in MS is heterogeneous, and urodynamic examination is indicated in two situations. The first is in cases in which the patient requests treatment for urinary symptoms that bother him or her. The purpose of the examination is to understand the vesicosphincteric disorder that is causing the clinical symptom and to propose an appropriate treatment. The second situation is one in which the patient is considered at risk and for whom a search for additional urodynamic risk factors is to be carried out.

With urodynamic examination before the treatment of urinary symptoms, the most frequently found anomaly is detrusor overactivity, which is found in 34 to 99% of cases. It is defined by the presence of detrusor contractions outside of the bladder filling phase. The second anomaly was detrusor underactivity, which was found in 5 to 37% of the cases [6, 9-11, 18, 20, 22, 24-26, 28-30, 32-36, 38, 50, 52, 59, 73, 74]. In those patients who have urinary symptoms, a normal cystomanometry was found in at the most 30% of the cases [21, 25, 33].

Regarding the sphincter, vesicosphincteric dyssynergia (VSD) was found in 6 to 82% of the cases (35% on average). It is defined by the absence of relaxation or by the reinforcement of the electrical activity of the external sphincter during vesicular contraction for micturition, and is the object of needle electromyography of the anal sphincter [58, 75]. VSD is associated indifferently with detrusor overactivity or detrusor underactivity, although the association of detrusor overactivity with VSD (43 to 80% of cases [7, 18, 34, 50, 51]) is more frequent than that of detrusor underactivity with VSD (less than 10% [9, 73]). OAB syndrome seems to more often be the result of DO, especially urgency incontinence [20, 52] (one of the incontinence risk factors that was found was the female sex and the existence of low closure pressure [25]). Obstructive VST was as often associated with DO as it was with detrusor underactivity, and there is also often an associated VSD [10, 20]. VSD does not appear to correlate to the type of urinary symptom [20].

The urodynamic presentations progress through time in a manner that cannot be predicted, especially from the detrusor component. However, VSD, when it is demonstrated in a patient, most often persists without change [26, 59, 73, 76].

The role of the urodynamic examination (UDE) in a patient who is considered at risk for urological complications is much more debated. Certainly, UDE is indicated because of the association of certain UDE anomalies with the possible occurrence of urological complications. The purpose of UDE is therefore the exclusion of an area of risk for the occurrence of complications. Even though this approach is today the most agreed upon, it is useful here to remember that, at least in the case of MS, it has never been evaluated in a strict fashion as part of a prospective protocol. This is explained in part by the fact that sometimes many years will pass before the urological complications occur, which makes the task of evaluation very difficult. The adversaries of proceeding in this fashion propose a more pragmatic approach, with regular surveillance of simple criteria (post micturition residue, renal echography) and they propose a therapeutic approach only in those patients who present with a complication. This approach has the advantage of simplicity for the patient and for the doctor. The theoretical risk is that of the late diagnoses of a future complication (indeed, close to 50% of asymptomatic patients have urodynamic anomalies (LOE4)) [21] and of having to therefore propose a therapy to the patient that is more intensive than what could have been proposed had an earlier diagnosis been made.

The three elements of UDE that were strongly associated with urological complications were detrusor overactivity, bladder compliance failure, and VSD [9, 77]. The relationship between DO, bladder compliance failure, and the alteration of the upper urinary tract are classic in neurogenic bladders. The advent of the use of intradetrusor botulinum toxin reinforced the notion of causality between an elevated intravesical pressure regime and the risk of alteration of the upper urinary tract, because certain authors indicated a disappearance of vesicorenal reflux after injection of botulinum toxin, at which time the intravesical pressure regime normalized [57]. The relationship between urological complications and VSD is more debated [15, 29, 35]. The practical difficulties of researching this anomaly, the invasive nature of the electromyogram that is necessary for confirmation, and the absence of targeted therapeutic efficacy for VSD restrict this systematic search.

3. COLORECTAL DYSFUNCTION IN MS

a) Epidemiology

Digestive disorders are very frequent in patients who have MS, and, like the urinary disorders that are to blame, when they are significant they have a significant impact on patients' quality of life (LOE4) [1, 5, 78]. What is more, the patients seem to tend to be ashamed of these problems and seldom report them. Clinicians have few tools at their disposal for evaluating this impairment. Consequently, digestive disorders are often undetected (LOE3-4) [27, 34].

Taking into account the great diversity of definitions in the several studies that are concerned with this problem, one is obliged to regroup the digestive symptoms into two large groups: those symptoms that can be defined as "retentive", including abdominal pain, flatulence, and constipation on the one hand, and those symptoms that can be defined as "irritant", including false urges to defecate, diarrhea, and/or incontinence of stool and/or gas on the other hand. Digestive disorders of both types were found in 45 to 68% of the cases (LOE 4) [27, 78-82]. The frequency of the "retentive" symptoms was clearly the more elevated, ranging from 31% to 54% [27, 78-82]. The frequency of the irritant symptoms ranged from 6 to 20% [27, 78-82]. The authors who had sought to flush out the more exceptional episodes of incontinence found a frequency of at least one episode of that type in the months that preceded the interview in 29 to 30% of the cases [27, 79]. Finally, a proportion of about 20% of the symptomatic patients had a combination of irritant and retentive disorders [27, 78-82]. The figures were clearly more significant than in the general population, where the "retentive" disorders have a frequency that is estimated to be around 2 to 20% and the "irritant" disorders have a frequency of 2% [83].

Risk factors for digestive disorders in MS have not been identified, to enable [27, 78-82]. Similarly, the duration of the progress of MS does not appear to be a factor that influences the frequency of digestive disorders. The factor that seems to be the most important is the estimated degree of disability (LOE3c-4) [82, 84]. Thus, Munteis et al. [84] found in

a case control study (LOE 3c) a frequency of digestive disorders that exceeded 21.2% if the patients had an EDSS between 0 and 1. This frequency exceeded 78% in those patients who had an EDSS that was greater than 4.5. Other risk factors were suggested (LOE4), but they seemed to have an influence that was less clear, such as female gender, the existence of related urinary disorders, age, and taking anticholinergic treatments [27, 78-82, 84].

b) Pathophysiology of MS-related digestive disorders

Few studies have been carried out specifically in patients who have multiple sclerosis. One of the difficulties is the frequent existence of related treatments that can themselves bring about the specific symptoms. The colic transit times can be extended or shortened in those patients who present with digestive disorders [85-87]. Several anorectal manometry anomalies were in evidence: reduced tone and compliance, a reduced sensation of filling and incoordination of the external anal sphincter during expulsion, with an onset of the phenomenon known as paradoxical anal sphincter contraction. In patients with faecal incontinence, a decrease in anal canal pressures and hyper-reactivity of the rectal wall have been shown manometrically. In the most recent of these studies, Munteis et al [84] has found that the anomalies that are found the most often are those of maximal sphincter pressure, of anal inhibitory reflex (which occurred later than in the control population), and the presence of paradoxical contraction of the puborectal musculature during straining. These anomalies might be able to allow the proposal of biofeedback re-education in affected patients. However, at present the benefit of this approach has not yet been proven.

X. SPINAL CORD LESIONS

1. URINARY INCONTINENCE

a) Epidemiology and prevalence

Spinal cord injury (SCI) including cauda equina injury usually causes impairments of urinary functions such as urinary incontinence (UI) and/or difficulty in urination. Studies on prevalence of bladder management in chronic SCI persons [1-3] (see **Table 19**) and one study in patients with chronic cauda equina lesions [4]. About 8%-11% of chronic SCI persons had normal voiding [1,2], not different from the time after initial rehabilitation [2]; and more normal voiding in tetraplegics then paraplegics [2].

According to the study from Denmark [2], at discharge from the initial rehabilitation period of 233 traumatic SCI patients, bladder-emptying methods were as follows: 12% normal voiding, 57% suprapubic tapping, 19% abdominal pressure, 5% Crédé manoeuvre, 11% CIC, 2% SIC, 8% urethral indwelling catheter (IDC), 0.4% suprapubic catheter (SPC), 0.4% sacral-anterior-root-stimulation (SARS), and 5% use of condom-catheter or diaper. When dividing the patients by years of injury (before 1981 and after 1980), there was a decreasing trend of using suprapubic tapping (drop from over 60% to 45%), abdominal pressure (from over 20% to 15%) and Crédé manoeuvre (drop from over 12% to 1%) but there was an increasing trend of using CIC (rise from 0% to 26%). Over times, 37.5% to 46% of SCI persons changed their bladder-emptying management [2,3]; 28% found their bladder-emptying methods to be a problem; of these 58% were tetraplegic [2]; and the biggest bother bladder management to the subjects was in the compression or straining group (over 50% of the subjects) [1].

There was a statistically significant difference in the frequency of urinary tract infection (UTI) between the bladder management (P< 0.001) [1]; the frequency of UTI was high (about 70%) in the mixed group (65% used CIC with other methods) and the CIC group and less (less than 50%) in the groups with catheter free [1]. According to the study financed by Medicon Valley Academy and Coloplast A/S and done in Denmark, of those using CIC, 92% reported using hydrophilic-coated catheters [2] but there was no report about frequency of UTI. However there was a report of reused silicone catheter for CIC in 28 SCI men done in Thailand [5] with the average time of usage of each catheter of 3 years, 36% reported fever with cloudy urine and 64% of foul smell urine; however, where the frequency of CIC is higher, the abnormality of the urethra was lower (P, 0.05) [5].

In a large prospective cohort study, Drake et al. [4] reported the changes in bladder management method with advancing time after SCI, finding that 29% of patients with SCI for at least 20 years changed method over the 6 year period. Podnar et al [5] studied 55 patients with chronic cauda equina or conus medullaris injury: 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (UI) (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear regression analysis, perianal sensory loss (P=0.0001) and female gender (P<0.02) had a significant positive effect on urinary incontinence score [5].

b) Pathology and disease-specific LUT problems

Pontari et al. [6] analyzed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC) and compared them with bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction alters, and found that whereas normal detrusor contrac-

Table 19: Studies reporting prevalence of specific bladder management methods in chronic SCI

Study (year)	Subjects	Methods of bladder management
Dahlberg et al (2004)[1]	129 traumatic SCI in Finland; mean time since injury 18 years (SD 13)	Normal voiding: 11% Controlled voiding (assisted voiding or incontinence: 12% CIC: 12%; mixed (CIC with other methods):23% Suprapubic tapping 24% Compression or straining (usually with condom catheter): 12% Catheter or conduit: 5%
Hansen et al (2004)[2]	233 SCI in Denmark (82% males, 47% tetraplegics, mean age at the time of follow-up of 50.5 years and mean time since injury of 24.1 years)	46% changed bladder emptying method Normal voiding: from 12% to 8% CIC: from 11% to 36% SPC: from 0.4% to 6% Suprapubic tapping: from 57 to 31% Crede manoeuvre: from 5 to 19%
Patki et al (2006)[3]	64 traumatic pediatric onset, ambulate SCI; mean follow-up 7 years; mean age 46 years	Spontaneous voiding: initial 62.5%; 47.5% of them deteriorated CSIC: initial 31.2%; 25% of them improved SPC: initial 6.3% 37.5% required a change in urological management 68.7% had abnormal urodynamics at the last follow-up

tions are mediated by the M3 receptor subtype, in patients with NBD, contractions can be mediated by the M2 muscarinic receptor subtype [6]. Haferkamp et al [2006] [7] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients. Oner-Iyidoğan et al [2004] [8] found that urine 8-iso PGF2alpha concentrations were significantly increased in SCI with hyperreflexic group (median value 0.89 pg/mg creatinine) compared to both normal control (0.52 pg/mg creatinine) and SCI with areflexic groups ($P < 0.001$); and the lowest concentrations of urinary 8-iso PGF2alpha were observed in the areflexic group (0.22 pg/mg creatinine) [8].

According to the study of viscerosensory pathway of the lower urinary tract (LUT) by Schmid et al [2004][9], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2 ms, 2 to 3-fold sensory threshold, 60 mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients [9].

Schmid et al [10] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with incomplete SCL, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses were normal; and the ratio (5.5) was increased. Those with a complete SCL showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a SCL. Ten patients with incomplete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots. In patients with complete cauda equina injury neither central nor peripheral responses could be evoked [10].

According to Dai and Xiao [2005] [11], the thresholds of stimulation on ventral root were 0.02 ms duration, 0.2-0.4 mA, (mean 0.3 mA+/-0.07 mA), compared with 0.2-0.4 ms duration, 1.5-3 mA (mean 2.3 mA+/-0.5 mA) for dorsal root ($P<0.01$) to cause evoked potentials and EMG. The continuous stimulation for about 3-5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz, and 0.4 mA) could resulted in bladder detrusor contraction, but the strongest bladder contraction

over 50 cm H2O was usually caused by stimulation on S3 ventral root in 7 of the 10 patients [11].

1. Urodynamic Studies

Ockrim et al [2005] [12] found that in men with SCI, cystometric variables and detrusor overactivity (DO) remained consistent over sequential studies while in those with LUT symptom of urge, a significant decrease in the number and pressure of involuntary detrusor contractions (IDCs) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. Chou et al [2006] [13] did a retrospective study on urodynamic studies to provide reference ranges for "normal" variability in urodynamic parameters that can be considered as "no real change" from one study to the next. Fifty consecutive individuals with SCI had 2 trials (trial 1 and trial 2) of urodynamic studies done 5 minutes apart, and the following data were collected: maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and postvoid residual (see **Table 20**).

Generao et al [2004] [14] did a retrospective review of SCI cases with 1-year minimum follow up to determine the effect of SCI on the developing bladder and kidneys using video-urodynamics, sonograms. In 42 children (average age at injury of 5.3 years and mean follow up of 5.5 years), 40 used CIC and 37 took antispasmodics. No patient had reflux, hydronephrosis or renal scarring. Safe bladder capacity, the pressure specific volume at 40 cm water or less, was less than the expected capacity in 80%, 58% and 50% of cervical, thoracic and lumbar injured patients but 100%, 76% and 67% of the respectively groups undergoing multiple urodynamics had increasing capacity with time.

Ersoz and Akyuz [2004] [15] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to determine to examine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying in this patient group. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were statistically significant differences between three groups with respect to bladder sensation category (P<0.001). About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before Pves reached 25 cmH2O and simultaneous bladder capacity of more than 150 ml was present in 61.2, 41.2 and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had second cystometric examination.

To quantitatively measure bladder mucosal sensory function, Ukimura et al [2004] [16] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete supra-sacral SCI, the bladder CPT value (4.0+/-1.9) at 5Hz was significantly lower (p<0.01) than that in the controls (26.2+/-17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infra-sacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz (p<0.05), 250Hz (p=0.07), and 2000Hz (p<0.05) compared to the controls. As described in the section diagnosis of neurogenic urinary incontinence, no fibre specificity has so far been found depending on frequency of current used or current type.

Table 20: Variability in urodynamic parameters for 50 SCI individuals (adapted from Chou et al. [13])

Urodynamic parameters		Maximum 5th to 95th percentile		Maximum 10th to 90th percentile		Maximum 25th to 75th percentile	
	Mean	Increase	Decrease	Increase	Decrease	Increase	Decrease
Cystometric capacity (mL)	234.63	+213.50	-158.05	+126.40	-74.60	+72.00	-27.00
Opening pressure (cmH2O)	54.56	+30	18.00	+13.70	-12.00	+4.00	-9.50
Maximum detrusor pressure (cmH2O)	60.82	+17.35	-27.80	+10.00	-20.00	+4.00	-10.00
Volume voided (mL)	122.20	+177.25	-176.00	+105.60	-82.00	+50.00	-30.00
Postvoid residual (mL)	176.06	+197.25	-118.00	+131.00	-86.00	+50.00	-30.00

2. Detrusor (external) Sphincter Dyssynergy

Schurch et al [2005] [17] assessed types of DSD in 105 chronic SCI males and evaluated the change in the DSD pattern over time. Results showed that those with an incomplete sensory and motor SCL presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. A correlation was also found between the AIS and the DSD type but not between the DSD type and the level of lesion; and at medium to long-term follow-up, a significant change was found in the DSD type [17]. Generally, presence of DSD was determined by increased wire needle EMG activity and/or by dilated bladder neck and proximal urethra during detrusor contraction, in the absence of valsalva or attempt to inhibit voiding. De et al [2005] [18] did a comparative study to explore the diagnostic congruence for DSD between needle EMG and voiding cystourethrogram (VCUG) in the neurogenic population. They found 60% agreement and 40% disagreement between EMG and VCUG for diagnosis of DSD. Binomial testing demonstrated significant disagreement ($P < 0.000$) in observed proportions [18]. By retrospectively analyzing clinical data consisting bladder and EAS EMG from 41 SCI individuals with NDO, Wenzel et al [2006] [19] found that the onset of bladder contractions was detected within 1 sec of the start of the EAS contraction for both synergic and dyssynergic human subjects; and they concluded that this detection could be used as a control signal to deliver inhibitory ES to arrest nascent bladder contractions and maintain continence [19].

3. Complications Related to Urethral Indwelling Catheterization (IDC)

During 2004-2006, at least three papers reporting urinary complications related to prolonged urethral IDC such as follows: the catheter balloon of a Foley catheter inserted only half-way was inflated in the urethra distal to the stricture and a long-term IDC caused urethral erosion and a severe degree of hypospadias (Vaidyanathan et al, 2004) [20]; contracted bladder followed by autonomic dysreflexia (AD), gross hematuria and extravasation of contrast media due to improper technique of voiding cystourethrography (Kovindha et al, 2005) [21]; and continuously incontinent despite a catheter and low bladder compliance leading to a urinary diversion to achieve continence (Stoffel and McGuire, 2006) [22]. In chronic SCI, IDC was associated with higher mean levels of C-reactive protein (CRP) while intermittent catheterization was associated with lower levels of CRP when compared with other methods of bladder management [Frost et al, 2005] [23].

4. Vesicoureteral Reflux (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer et al [2004[[24], there was an association of posterior position of ureteral orifices and reflux ($p = 0.004$) but no differences were found with regard to bladder capacity, bladder wall compliance, or voiding pressures between the reflux group and nonreflux group.

5. Stone Formation

Linsenmeyer and Linsenmeyer [2004] [25] found that the majority of bladder stones were calcium phosphate (46.8%) or struvite (26.7%). According to the retrospective study in 32 patients with NBD, Matlaga et al [2006] [26] found renal stones were infectious in etiology in 37.5% (12 struvite/carbonate apatite) and metabolic in 62.5%. All with struvite calculi were infected with urea-splitting bacteria.

Stone formation is usually related to IDC. In 2006, there were five papers reporting on such. Ke et al. [27] found bladder calculi with a nidus of hair that could have been introduced into the bladder accidentally during the cystostomy catheter replacement. According to the retrospective study of Ku et al [28], over the 17 years 28% and 15% of 140 men were diagnosed with bladder and renal stones for a total of 59 and 25 episodes, respectively; bladder stone was more common in patients injured when aged > or = 24 years than in those injured when aged <24 years (OR 2.5; 95% CI 1.1-5.7; $P = 0.03$); patients with complete injury had a greater risk of renal stone formation than those with incomplete injury (OR 4.1, 95% CI 1.3-12.9; $P = 0.016$); renal stone was more common for patients with urethral catheterization than for those voiding spontaneously (OR 5.7, 95% CI 1.3-24.6, $P = 0.021$) and for patients with bladder stone than for those without (OR 4.7, 1.5-15.1; $P = 0.01$). According to the review by Ost and Lee [29], recurrent UTI, IDC, VUR, and immobilization hypercalcuria were major risk factors for the development of urolithiasis.

According to the retrospective study of Ozawa et al [2005] [30], the incidence of bladder stone in urethral IDC was 1.11 times/100 months, cystostomy was 1.05, contemporary urethral IDC at night time only was 0.96, CIC-wet was 0.61, and CIC-dry was 0.21; and the urethral IDC group had significantly higher incidence of bladder stone than CIC-dry ($p<0.05$).

Linsenmeyer and Linsenmeyer [2006] [31] did a prospective cohort study by examination of IDC for encrustation at the time of removal for cystoscopy and found that 35% of 49 SCI individuals had bladder stones. Catheter encrustation was noted in 13 patients and 11 of them also had bladder stones i.e., a positive result for catheter encrustation had a positive result for bladder stones 85% of the time. Thirty-six individuals had no catheter encrustation; of these, 16% were found to have bladder stones.

6. Bacteriuria

In a retrospective study, Jayawardena and Midha [2004] [32] suggested that healthy asymptomatic

SCI patients who came for annual evaluations should not have routine urine cultures if they are at low risk for UTIs; that is, <6 WBC/HPF in the urine and/or nitrite negative [32]. Svensson et al [2004] [33] studied the occurrence of bacteriuria in SCI patients with NBD who used CIC. Of 344 cultured samples, there were 285 isolates: coagulase-negative Staphylococci (27%), Enterococci (25%), Klebsiella spp (19%), and Escherichia coli (12%); and bacteria grew at concentrations of 105-108 cfu/L, but only a few at 104 cfu/L. Levendoglu et al [2004] [34] prospectively studied in 27 SCI patients who applied CIC during the initial rehabilitation and 40 controls. E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli (P=0.82); and Pseudomonas was colonized more in male patients [34]. Waites et al [2004] [35] found that among 77.1% of men with bacteriuria, uropathogens were shown in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria.

7. Epididymo-Orchitis and Other Complications

Over the 17-year follow-up study of Ku et al [2006] [36], of 140 male patients (24.3% complete, the average age at onset of 24.8 years old, the average time since SCI of 16.9 years), 27.9% were diagnosed with epididymo-orchitis; and in multivariate analysis, patients on CIC had a 7.0-fold higher risk (OR, 6.96; 95%CI, 1.26-38.53; P=0.026); however, a history of urethral stricture lost statistical significance (P=0.074). Nambiar et al [2005] [37] reported a C4 tetraplegia man presenting with a necrotic ulceration on the ventral aspect of the penis and scrotum of 2 days duration and diagnosed with fulminant Fournier gangrene. Vaidyanathan et al [2004] [38] reported cases of a perirenal haematoma due to warfarin and a tumour like of necrotic slough and debris in the bladder.

8. Quality of Life (QoL)

Oh et al [2005] [39] conducted a prospective trial involving 132 SCI patients and 150 controls matched to age and sex to determine the psychological and social status of patients using CIC. According to health-related quality of life (HRQOL), the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36) scores did not reveal any significant differences between the men and women in the patient group. When patients and controls were divided into two groups according to sex and age, the SF-36 scores of the patients were significantly lower than the controls across both sex and all age groups, other than the energy and vitality scale, the differences for which were not statistically significant in women and those younger than 50 years. Later Oh et al [2006] [40] used the Beck Depression Inventory (BDI) with SCI patients on CIC and control group and found that, the average total BDI scores were 20.3+/-1.0 in the patient group and 11.4+/-0.5 in the control group, respectively (P<0.001); 69.6% of 102 the patients reported severe depression; female patients had a 3.8-fold higher risk (OR 13.83; 95%CI 1.42-10.31; P=0.008) of depression than male patients; and those who were unable to perform catheterization independently had a 4.6-fold higher risk (OR 4.62; 95% CI 1.67-12.81, P=0.003) of depression than those who were able to perform self-catheterization.

c) Disease specific management

1. Urological Follow-up Practice

According to cohort studies [4, 5, 41], there was evolution of bladder management by time, outcomes and complications in both pediatric onset and adult onset SCI; treatment was modified in a substantial proportion of patients over the observation periods. Regular urodynamic follow-up is warranted for protection of the upper urinary tract (UUT) and maintenance of continence, however, urological follow-up practice varied: in Bochum, Germany, follow-up included urodynamic evaluation, sonography of the UUT and LUT, urine examination, and evaluation of renal function and treatment modifications were based on the urodynamic findings [42]; in the Spinal Injuries Units of U.K., all units performed routine upper tract screening, ranging from annually to every 3 years [43].

According to the retrospective chart review of Sepahpanah et al. [44], the 24-hour creatinine clearance (CCr) was highly variable from one evaluation to the next and the within-subject standard deviation (SD) for CCr was 25.9mL/min; for all comparisons of repeatability, variability, and reliability, serum creatinine was superior to CCr; and renal ultrasound results and post-void residuals were the major factors in changing medical management with regard to renal function preservation. To determine the accuracy of bladder stone detection by abdominal x-rays of individuals with SCI, 13/62 (20.97%) of stones found during cystoscopy were detected by the x-ray; the detection by x-ray was 33% for stones 1.0 cm to 1.49 cm, 33% for stones 1.5 cm to 1.9 cm, and 54% for stones > or = 2.0 cm; and 57% for volumes > or = 1.0 cm3 [25]. In addition, long-term SCI individual with aged 50 to 60 or more should be screened for prostate and bladder cancer [45, 46]; however, PSA cannot be used in patients with IDC and diagnosis should be based on prostatic biopsies [45].

2. Intermittent Catheterization (IC)

IC is recommended as the safest method of bladder emptying for SCI persons with NBD [47], especially for those who have sufficient hand skills or a willing caregiver to perform the catheterization [48]. Mizuno et al [2004] [49] reported a paraplegic

woman using CSIC for 27 years who had no complications and absence of UI due to underactive and normal capacity bladder. However SCI men on CIC, according to the retrospective comparative study of patients on CIC had a 7.0-fold higher risk of epididymo-orchitis [28].

3. Techniques

Previously, recommended bladder training with CIC was time-dependent, however, some experienced bladder over-distention, especially in those with polyuria that made an IC programme unmanageable [50]. Polliack et al [2005] [51] compared volume-dependent IC (VDIC) following bladder volume measurement by a portable ultrasound device in SCL patients with time-dependent IC (TDIC). After 12-30 days follow-up, the number of IC per patient per day, the time required to perform volume measurements and IC, and their total cost, were approximately 44, 49, and 46% lower in the VDIC group than in the TDIC group. UTI was found in three patients in the TDIC group and in none in the VDIC group.

4. Type of Catheter

In developed countries, there is a variety of urethral catheters available for SCI individuals.

However, in reviewing all controlled trials comparing methods of using catheters in people with neurogenic bladder dysfunction, Jamison et al [2004] [52] could not draw any conclusions regarding the use of different types of catheter. According to the multicentre RCT of De Ridder et al [2005] [53], 57 SCI male patients completed the 12-month study; 64% of those using the SpeediCath hydrophilic-coated catheter experienced 1 or more UTIs compared to 82% of those using the uncoated polyvinyl chloride (PVC) catheter ($p = 0.02$); and twice as many patients in the SpeediCath group were free of UTI. According to another multi-centre study of Bjerklund Johansen et al [2007] [54], of 378 SCL (the mean duration of IC was 4.6 yr) who completed a 12-d trial of the novel hydrophilic catheter: LoFric Primo, 55.2% of the patients were happy to continue with the novel device, which was 74% of patients using standard PVC catheters and 36% of those using prelubricated PVC ($p=0.04$).

In a developing country, such as Thailand, Japanese reusable silicone catheters were reused and median duration of usage for each catheter was 2 years. Electron microscopic findings of the reused catheters for 2 years revealed encrustation but no obstruction in the lumens and 20% increase in stiffness. Demographic data, urinary management and complications did not have significant relation to the abnormality of the urethrogram or UTI [21].

Ozawa et al [2005] [30] applied a contemporary (reusable) balloon catheter at night time only. After a mean follow up of 41 months, the incidence of febrile episode was as follows: CIC-wet 3.36 times/100 months, IDC 2.96, cystostomy 1.26, the contemporary catheter 0.57, and CIC-dry 0.42. The incidence of febrile episode in CIC-wet and IDC were significantly higher than in CIC-dry ($p<0.05$). The incidence of bladder stone was as follows: IDC 1.11 times/100 months, cystostomy 1.05, the contemporary catheter 0.96, CIC-wet 0.61, and CIC-dry 0.21.

5. Bladder Relaxants

Many SCI individuals with NDO experienced high detrusor pressure with incontinence and post-voiding residual, bladder relaxants – antimuscarinic drugs, usually are prescribed for those applying CIC as well as IDC. Tolterodine, 2 mg twice daily [55], controlled release oxybutynin (OXY-XL) [56], doubled dosage of tolterodine ER or Trospium [57] and self-selected dosages (SSD) of tolterodine and oxybutynin [55] showed reduction in degree of UI and increase in IC volumes, and cystometric capacity; but the side effect of dry mouth was differed significantly when comparing tolterodine SSD with oxybutynin SSD ($P < 0.05$) [55].

6. Intravesical Vanilloid Instillation

According to a review article [58], intravesical treatment options may either act on the afferent arc of the reflex such as local anaesthetics or vanilloids or on the efferent cholinergic transmission to the detrusor muscle such as intravesical oxybutynin or botulinum toxin. Clinical trials and case series done in SCI with NDO proved the efficacy of intravesical instillations of various concentrations of resiniferatoxin (RTX) by cystometric/ urodynamic parameters and degree of UI [59-64]; intravesical capsaicin (CAP) also improved in symptoms and urodynamic parameters [57,61], without a significant difference between the CAP and the RTX groups [61]. When compared RTX with injection of 300 units botulinum A-toxin diluted in 30 ml normal saline, both treatments provided significant reduction in mean catheterization and episodes of incontinence, and a significant increase in mean first involuntary detrusor contraction and in mean maximum bladder capacity at 6, 12 and 24 months after therapy; while botulinum-A toxin significantly reduced also the maximum pressure of uninhibited detrusor contractions more than RTX at all follow-up time points [59].

7. Treatment of DSD

In those using reflex voiding to empty bladder, it is recommended to attempt use of non-surgical methods – for example alpha-blocker and botulinum toxin injection into the urethral sphincter [48]. According to the study of Reitz et al [2004] [65], 12 male SCI patients with NDO and DSD received 10 mg of isosorbide dinitrate sublingually and found that nitric oxide significantly reduced external urethral sphincter pressures at rest ($p < 0.05$) and during dyssynergic contraction ($p < 0.05$); and the mean post triggering residual volume was significantly reduced ($p < 0.05$).

8. Prevention of UTI

According to 2 double-blinded, placebo-controlled RCTs [66, 67] studying the effectiveness of cranberry supplement (400-mg cranberry 3 times a day for 4 weeks [66] and 2 g per day for 6 months [67]), at preventing UTIs in SCI individuals with NBD, bacterial count, white blood cell (WBC) count, bacterial counts in urine, urinary pH or episodes of symptomatic UTI did not differ between the placebo and cranberry groups. According to another RCT to determine the effectiveness of methenamine hippurate (MH) (1 g twice-daily) and of cranberry (800 mg twice-daily), MH as well as cranberry did not have a significantly longer UTI-free period compared to placebo Lee et al [2007] [68]. In addition, when taking phosphorus supplementation, there was no significant change in urine pH during the 2-week period compared to when the patient was off supplementation Schlager et al [2005] [69].

9. Antibiotic Prophylaxis

Some advocated antibiotic prophylaxis for recurrent UTI [43]. To determine the safety and efficacy of a weekly oral cyclic antibiotic (WOCA) regimen consisting of the alternate administration of an antibiotic once per week over a period of at least 2 years to prevent UTI in SCI adult patients, symptomatic UTI dropped from 9.4 to 1.8 per patient-year; and no severe adverse events and no new cases of colonization with multiple drug resistant bacteria were reported [Salomon et al, 2006] [70].

10. Bladder Irrigation

Waites et al [2006] [71] conducted a randomized, double-blind comparison of twice daily bladder irrigation using 1 of 3 different solutions for 8 weeks with 30 mL of (a) sterile saline, (b) acetic acid, or (c) neomycin-polymyxin solution in community-residing persons with NBD who used IDC. Results showed that the 3 irrigants had no detectable effect on the degree of bacteriuria or pyuria; no significant development of resistance to oral antimicrobials beyond what was observed at baseline; but all groups had a significant increase in urinary pH.

11. Treatment of UTI

Bycroft et al [2004] [43] found few routinely treating asymptomatic UTI in SCI individuals using catheters; and the range of recommended duration of treatment for symptomatic UTI was 3-14 days (mean 6.3).

12. Electrical Stimulation

Lavano et al [2004] [72] reported improvement in bladder emptying and continence in 6 neuropathic patients treated with sacral nerve stimulation (SNS) and results were unchanged during the follow-up (maximum 26 months) in all except 1 patient. Kutzenberger et al [2005] [73] reported a 17-year experience with sacral deafferentation (SDAF) and implantation of sacral anterior root stimulator (SARS). Of 464 paraplegics receiving a SDAF-SARS, complete deafferentation was successful in 94.1% and continence was achieved in 83%. With a mean follow-up of 6.6 years, 420 out of 440 paraplegics used the SARS for voiding (frequency 4.7 per day) and 401 used it for defecation (frequency 4.9 per week); UTI declined from 6.3 per year preoperatively to 1.2 per year postoperatively and kidney function presented stable. Hansen et al [2005] [74] applied automatic event driven ES of the dorsal penile/clitoral nerve triggered by Pdet exceed 10 cmH2O and reported during stimulated filling Pdet never exceeded 55 cm H2O and an average bladder capacity increase of 53% was achieved in suprasacral SCI patients.

d) Guidance for further research:

Most of the papers relating to epidemiology and pathology of urinary incontinence in spinal cord lesion patients were case series; and few papers were clinical trials or RCTs relating to pharmacological treatments. As UTI is a common complication among SCI individuals, further RCT to prove whether a weekly oral cyclic antibiotic for UTI prophylaxis as well as optimal dosage, effectiveness and safety of bladder relaxants including drugs for blocking nerves innervating bladder is beneficial in SCI with NBD should be done. Regarding types of catheter, RCT should be conducted to prove whether to reuse catheters is safe. In addition, to make an automatic, event driven electrical stimulation for the treatment of NDO suitable in a clinical setting further investigations are needed.

Conclusions:

- **The profile of muscarinic receptors in the bladder may be altered in patients with neurological disease (LOE 3).**
- **Skin sympathetic responses and motor evoked potentials may help assess autonomic and somatomotor pathways of the lower urinary tract. (LOE 3).**
- **In patients with neurological disease, individuals often change their method of bladder management, influenced by a range of factors including renal function. (LOE 2)**
- **Long-term urethral indwelling catheterization leads to bladder and urethral complications (LOE 3).**
- **Encrustation of a catheter is predictive of bladder stones; abdominal x-ray is not an adequate method to detect bladder stones (LOE 3).**
- **Volume-dependent intermittent catheterization may offer advantages compared with time-dependent intermittent catheterization. (LOE 3)**
- **Combined clean intermittent catheterization during the day time with indwelling contemporary balloon catheter at night time showed less**

urinary infection than clean intermittent catheterization with incontinence and permanent urethral indwelling catheterization. (LOE 3)

- **Increased dosage of Tolterodine or Trospium gave a better effect to control neurogenic detrusor overactivity with incontinence. (LOE 2)**
- **Urethral flora may be a bacterial source for the development of urinary infection. (LOE 3)**
- **Low bacterial concentrations in the urine (<105cfu/L) of patients on intermittent catheterization might be due to contamination. (LOE 3)**
- **Cranberry extract, methenamine hippurate or phosphorus supplements were not found to be effective in acidifying urine or preventing urinary tract infection. (LOE 2)**
- **A weekly oral cyclic antibiotic seemed efficacious in preventing UTI. (LOE 3)**
- **Bladder irrigation was not effective in reducing bacteriuria in persons with neurogenic bladder using indwelling catheterization. (LOE 2)**

Recommendations:

- **Regular urological monitoring, at least annually, is appropriate to early detect complications and to adjust bladder management in patients with neurogenic bladder dysfunction. (A/B)**
- **Recommend urine culture only there is high risk of urinary tract infection. (C)**
- **Routinely inspect catheters for encrustation, as an early indicator of risk of bladder stone formation. (C)**
- **Cystoscopy is necessary if bladder stones are suspected. (C)**
- **Adjust urinary tract management according to results of urological evaluation and emergence of complications. (B)**
- **Clear diagnosis of DSD requires VCUG facilitated by EMG. (C)**
- **Clear instructions on catheter management can help to reduce risk of complications. (B)**
- **Dosages of bladder relaxant drugs in excess of the licensed doses have been used in attempting to control neurogenic detrusor overactivity and incontinence; if side-effects cannot be tolerated, intravesical botulinum toxin injection are effective. (B)**

2. FAECAL INCONTINENCE

a) Epidemiology and prevalence

[According to Dvorak et al, 2006] [75], in patients with central cord syndrome, bowel and bladder continence was reported by 81% in those with American Spinal Injury Association (ASIA) motor score improvement from a mean of 58.7 at injury to a mean of 92.3 at follow-up. However, neurogenic bowel dysfunction (NBoD) is common among spinal cord injury (SCI) patients (**Table 21**). From 2004 to 2007, there were 6 studies reporting epidemiology of NBoD in chronic spinal cord injured (SCI), from various countries [76-80] (more details see section D1 in this chapter). Apart from SCI [2-6], there were other spinal cord lesions (SCL) that causes NBoD such tumors (e.g. a conus medullaris ependymoma and filum terminale lipoma [81]; a clear cell meningioma along the thoracic and lumbar levels [82], neuroblastoma [83]); venous congestive myelopathy, mostly at thoracolumbar and/or conus medullaris levels [84]; transverse myelitis [85]; and iatrogenic [86, 87]. Tanaka et al [2006] [85] 77% of 22 transverse myelitis (average age at onset 8.8 years, mean follow-up 7.1 years) had NBoD.

Table 21. Prevalence of neurogenic bowel dysfunctions reported in spinal cord injury patients

Study (year)	Countries	Subjects	Prevalence		
			Faecal incontinence	Constipation	Others
Liem et al (2004) [76]	Canada	352 SCI (> 20 years)	41.8% (including diarrhea)	47.9%	
Ng et al (2005) [77]	Australia	110 SCI (duration from injury, median 17 years)	41%	46% (including laxative use)	Abdominal pain 33% Abdominal bloating 22%;
Tongprasert & Kovindha (2006) [78]	Thailand	100 SCI (duration from onset, mean 6 years)	35% (normal subjects: 1.8%, p = 0.0013)	86% (including uses of laxative, enema, etc)	Haemorrhoid 16% (normal subjects, 20%, p =0.338)
Vallès et al (2006) [79]	Spain	54 motor complete SCI (mean duration from onset 6 years)	85%	67%	
Vallès et al (2006) [79]	Spain	109 patients 83% had spinal sacral reflexes (SSR)	31%	27% more in tetra A,B,C	
Pagliacci et al (2007) [80]	Italy	403 SCI (duration from discharge to follow-up, mean 3 years)	2.7% (20.1% partial)		

b) Pathology and disease specific lower gastrointestinal (LGIT) problems

According to electromyography (EMG) of external anal sphincter (EAS), 18 and 22 of 64 patients with cauda equina or conus medullaris lesions had bilateral and unilateral EMG abnormalities [88]. Using anorectal manometry, the maximum anal resting pressure of a 26-lumbosacral SCI patients group with mixed symptoms of constipation and/or FI was slightly lower than that of a 13-normal volunteers control group [89]. During defecation , 88.5% of the patients but 7.7% of the control group significantly showed pelvic floor dysfunction (PFD). Rectoanal inhibitory reflex (RAIR) was identified in both groups. The rectal volume for sustained relaxation of the anal sphincter tone in lumbosacral SCI patients group was significantly higher than the control group. The mean rectal volume to generate the first sensation was significantly higher in SCI patients than in the control group. Regarding constipation, its association with level of injury was supported by many studies, i.e. upper motor neuron vs lower motor neuron NBoD. Decreased colonic pressure activity was found during sleep in SCI individuals and may contribute to delayed colon transit time after SCI [90].

Furlan and Fehlings [2006] [91] examined the characteristics of the top 100 most frequently cited articles (so-called “citation classics”) on traumatic SCI that were published between 1986 and 2003, and compared this selected professional literature with the consumers’ perspective on the key issues in SCI research. From a SCI consumers’ perspective, the areas of greatest interest included motor function, bowel and bladder control, sexual function, and pain. Motor function was the leading topic in the matching list between professional literature and consumers’ perspective. According to Anderson’s quality of life (QOL) survey of the SCI population [2004] [92], regaining arm and hand function was most important to quadriplegics, whereas regaining sexual function was the highest priority for paraplegics; and improving bladder and bowel function was of shared importance to both injury groups. Later, according to a web-based survey of 286 SCI population aged 18 years or older completed the survey, results showed that bladder and bowel concerns during sexual activity were not strong enough to deter the majority of the population from engaging in sexual activity [93]; however, bladder and/or bowel incontinence during sexual activity was a highly significant concern in women with SCI. In addition, the occurrence of autonomic dysreflexia (AD) during typical bladder or bowel care was a significant variable predicting the occurrence and distress of AD during sexual activity [94].

FI had 10 times more impact on QOL than those with no FI and NBoD had significant impact on their QOL [95]. They had significantly lower Gastrointestinal QOL score as compared with the normal persons [96]. There were no statistically significant differences in satisfaction or QOL between those with colostomies and those with traditional bowel care programs; however, 55.7% of those with colostomies and 41.7% of those without colostomies were very unsatisfied with their bowel care program [97].

c) Conservative bowel management

According to the “Neurogenic Bowel Management in Adults with Spinal Cord Injury” Clinical Practice Guideline published by the Consortium for Spinal Cord Medicine [98], rectal stimulations help assist elimination of the stool: mechanical stimulations – digital rectal stimulation (DRS) and manual evacuation; and chemical stimulations – suppository and mini-enema (liquid suppository). Korsten et al. [99] used a manometric catheter to assess colonic motility at baseline, during DRS, and after DRS and evacuation of barium oatmeal paste in six subjects with SCI; and results showed that manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. In patients with cervical SCI, a significant increase in systolic blood pressure (BP) was induced by insertion of rectal medications and persisted during additional DRS, and the manual removal of stool induced AD were reported; however, systolic BP recovered to pre-program values within 5 min after defecation[100].

Uchikawa et al. [101] reported a successful bowel movement in 75% of 20 SCI patients by using a modified washing toilet seat equipped with a camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement for a maximum of 30 minutes. Regarding transanal irrigation, it showed improvement in constipation, FI and symptom-related QOL in SCI individuals [102].

Push up, abdominal massage and a forward-leaning position may aid evacuation by increasing abdominal pressure [98]. Ayaş et al. [103] studied in patients with SCI and showed that abdominal message gave positive effects – increase in frequency of defecation per week, decrease in total colonic transit time and lesser FI. As contraction of the abdominal wall musculature plays a role in normal defecation, Korsten et al. [104] assessed whether an abdominal belt with implanted electrodes would improve difficulty with evacuation in SCI individuals and demonstrated that neuromuscular stimulation of the abdominal wall improved defecation function, including time to first stool and total bowel care time.

Oral medications to enhance bowel movement have been used, but evidence of efficacy is lacking. Cisapride does not seem to have clinically useful effects in people with SCI [104]. Korsten et al. [105] did a randomized, blinded design, to test the efficacy of neostigmine in SCI persons with defecation difficulty by infusing one of three intravenous infusates (normal saline, 2 mg neostigmine, or 2 mg

neostigmine + 0.4 mg glycopyrrolate – to prevent neostigmine's muscarinic effects) on separate days and determining on bowel evacuation of the barium paste, heart rate and airway resistance; and results indicated that both neostigmine and neostigmine + glycopyrrolate resulted in prompt bowel evacuation. Studies have shown that neostigmine + glycopyrrolate intravenous administration is safe and well tolerated in persons with chronic SCI [105, 106] and studies have been under way to assess the efficacy of neostigmine by other routes [106].

d) Guidance for further research

Most of the studies reported were case series and used different definitions of faecal incontinence and constipation. Therefore further researches should base on internationally acceptable definitions so that they can be compared. In addition, RCTs on rectal or anal stimulations both mechanical and chemical as well as medications promoting bowel movement are needed.

Conclusions:

- **Constipation is more common than faecal incontinence among people with established SCI (LOE 3).**
- **Constipation is more common in those with preserved sacral reflexes, whereas faecal incontinence is more common in those without sacral reflexes. (LOE 3)**
- **Faecal incontinence has impact on the QOL of SCI individual and is a substantial concern for women with SCI during sexual activity. (LOE 3)**
- **Digital rectal stimulations aid bowel evacuation in individuals with SCI, in part by increasing left-side colonic motility. (LOE 3)**
- **Transanal irrigation with water improves constipation and quality of life in individuals with SCI. (LOE 2)**
- **Abdominal massage may be effective in enhancing bowel movement and defecation. (LOE 3)**
- **Anal stimulation by water stream may be effective in stimulating bowel movement and shortening bowel care time. (LOE)**

Recommendations:

- **Encourage adherence to the clinical practice guidelines on neurogenic bowel management in adults with spinal cord injury (A).**
- **Apply mechanical stimulation e.g. digital rectal stimulation, to aid bowel evacuation- especially in those with preserved sacral reflexes (B).**
- **Use chemical stimulants when mechanical stimulation fails (C).**
- **Beware of autonomic dysreflexia during bowel care, especially in those with a high SCI lesion (C).**
- **Consider transanal irrigation with water for those with severe chronic constipation and faecal impaction (B).**

XI. MYELOMENINGOCOELE

The following text describes the literature relating to adult patients.

1. URINARY INCONTINENCE

Myelomeningocele (spina bifida) is one of the most common birth defects of the spine and brain. It occurs in 1-2 births per 1000, potentially involving all levels of the spinal column (lumbar 26%, lumbosacral 47%, sacral 20%, thoracic 5% and cervical spine 2%). Associated Arnold- Chiari malformation is seen in 85% of children, often requiring ventriculoperitoneal shunting of cerebrospinal fluid. Ingestion of folic acid prior to conception and during the first trimester of pregnancy has significantly reduced the incidence of this problem and other associated neural tube defects. The neurologic defect produced is quite variable and cannot be totally predicted by the vertebral level of the lesion. Additionally the fibrosis associated with myomeningocele closure, may tether the cord. Subsequent growth of the infant or child will produce further neurologic problems, manifesting as changes in bladder, bowel and lower extremity function.

The incidence of urethrovesical dysfunction in myelomeningocele is not absolutely known, but most studies suggest it is very high (>90%). Similarly, anorectal dysfuction is very common, but its exact incidence has not been reported. Congenital neurologic bladder dysfunction with spina bifida and sacral dysgenesis that manifested itself only at middle age in a 48-year-old male is reported by Kaneoya et al. (LOE4) [1]. Yamamura et al. reviewed the literature of tethered cord of adult onset and found 56 cases published.(LOE 3) [2].

The two major consequences of the vesicourethral dysfunction are urinary incontinence and hydroureteronephrosis which can occur early or later in life. There are many studies documenting the urodynamic characteristics of the vesicourethral unit in myelomeningocele patients but almost all in children. Almodhen and colleagues examined myelomenigocele patients in postpubertal age and correlated these findings with upper urinary tract changes [3] (LOE 3). Of the 26 patients with urinary incontinence before puberty, 12 achieved continence following puberty. Hydronephrosis remained stable in 4 patients, improved in 3 and was new onset in 3 , whilst vesicoureteral reflux persisted in 1 patient, resolved in 4 and was new onset in 1. Regarding the urodynamic findings in patients

achieving urinary continence following puberty, total cystometric bladder capacity increased significantly and maximum detrusor pressure and detrusor leak point pressure showed insignificant changes. Conservative treatment is thus a viable option for some myelomeningocoele patients, and with current treatment modalities including IC, significant upper tract deterioration is rare after puberty.

In the past, much attention has been directed at the significance of dyssynergia between the external sphincter and the bladder, and the associated deterioration of the upper renal tracts in these patients. With the increasing use of IC, more emphasis has been placed on the pressure the bladder is able to generate prior to leaking as a prognostic factor in predicting upper tract deterioration.

Urodynamics is the cornerstone in the diagnosis of vesicourethral dysfunction in myelomeningocele. Urodynamic findings may predict the patients at risk of upper tract deterioration. Controversy continues as when to initiate these studies, either as soon as possible after back closure, at the first sign of upper tract changes, or before considering management of incontinence. Studies supporting each position have been reported, although the preponderence of evidence suggests earlier diagnosis of potentially unfavourable factors is advisable.Taskinen et al. [4] examined 30 patients with anorectal anomalies. All patients underwent spinal magnetic resonance imaging and urodynamic investigation. Major lumbosacral abnormalities were detected in 57% of patients, including 13, 4 and 3 with a tethered cord, syringomyelia and caudal regression, respectively. Significant dysfunction of the LUT in 57% of the cases involved DO in 11, DSD in 4, distended bladder in 4 and lazy bladder in 1. When the spinal cord was normal, 54% of the patients had abnormal urodynamic findings but when the spinal cord was abnormal, 59% had abnormal urodynamics. When the bony spine was normal, 33% of the patients had an abnormal spinal cord but when the bony spine was abnormal, 69% had an abnormal spinal cord (LOE3).

As hydronephrosis and vesico-ureteric reflux are a consequence of detrusor dysfunction, synchronous fluoroscopic evaluation of the urinary tract is advisable at the time of urodynamics. Similarly, renal ultrasound has become an invaluable routine serial evaluation in these patients, assessing renal growth, development of scarring and, most importantly, hydroureteronephrosis. Repeat urodynamics and ultrasound may have a role in this patient population, however recommendations for timing and frequency of these studies still need to be elucidated. Although renal scans are routinely used, especially in the myelomeningocele patient with hydronephrosis, the exact role of this study in these patients is not clear.

Urologic treatment depends on the age of the patient and the nature of the vesico urethral dysfunction as characterized by urodynamics. In a retrospective study, urinary sepsis accounted for the majority of admissions (62%), while 38 of 62 patients required 60 surgical procedures [5]. Targeting the primary urological abnormality (the dysfunctional and usually poorly compliant bladder) allowed implementation of effective treatments, including regular IC (52%) in order to preserve upper renal tract function. Associated postural abnormalities complicated both conservative and interventional therapies.

The mainstay of treatment is IC and antimuscarinic medication. As continence is not at issue in the neonate and infant, treatment may be postponed, unless upper tract changes are present. Some evidence exists pointing to the fact that early initiation of treatment may prevent subsequent deleterious bladder changes. Recently botulinum toxin was suggested as a possibility to avoid invasive surgery in these patients [6].

In adult patients who in childhood underwent bladder augmentation surgery, it is thought that there is an increased risk of a developement of bladder malignacies. This assumption is made on case reports only. However a detailed analysis comparing control group with patients after ileal/colonic cystoplasty revealed that there was no difference ($p=0.54$) in the incidence of bladder cancer in patients with augmentation cystoplasty vs controls [1] (LOE 2). Screening for bladder malignacies in a myelomeningocele group of patients with augmented bladder was not shown to be cost effective [2] (LOE2). Bruschini et al. evaluated 104 patients who were not managed and followed-up adequately during their childhood [7] (LOE 3). Reflux and urinary tract damage were found in 30 patients, and 6 patients presented signs of upper tract damage without reflux. The cystometry showed DO in 48% of patients, poor compliance in 49% of patients, increased bladder capacity in 2% and normal cystometry in 1%. Detrusor leak point pressure over 40 cm H_2O was associated with upper urinary tract damage. Patients with a decrease of functional bladder capacity over 33% had more renal scars than their counterparts. Overall, 26 % of urological untreated myelomeningocele patients had kidney damage.

On the other hand, work by Olsson and colleagues, evaluated 175 Swedish myelomeningocele patients in adult age [8] (LOE 3). IC for bladder emptying was used by 85%, and 59% used enemas on a regular basis because of the neurogenic bowel dysfunction. Renal dysfunction was than seen only in 1.7% of the adolescents.

Lumbar to sacral nerve re-routing was suggested to be a viable alternative to restore voiding and bowel movement in spina bifida patients. Recently a study from North America demonstrated a 78 % sucess rate of this novel treatment modality [3] (LOE3). Another interesting treatment option is fetal surgery. However recent data from an observational study of

28 patients who underwent in utero surgical myelomeningocele clossure between 1997 and 2002 demonstrated that at a mean age of 9.6 years 23 used IC to manage the bladder, 24 required a bowel regimen to manage constipation and 6 underwent lower urinary tract reconstruction with enterocystoplasty and a catheterizable bladder channel. Videourodynamics performed in 14 patients at a mean age of 7.4 years revealed decreased bladder capacity in 71%, DO in 35% and increased detrusor pressure in 25% [4]. Management of incontinence and/or upper tract deterioration mirrors the treatment of neurologic bladder dysfunction. Variations in this algorithm include the use of vesicostomy in the younger child who has failed conservative measures and has evidence of deteriorating upper tracts. External sphincterotomy has no routine place in the management of these patients and the use of the appendico vesicostomy in continent LUT reconstruction (Mitrofanoff) has become very popular. Most studies on surgical management of the myelomeningocele bladder are descriptive (LOE 4) at best.

Data from adult and paediatric surveys show renal damage to be the single most prevalent cause of morbidity and mortality; even in children, 30-40% exhibit evidence of renal damage. Additional factors such as chronic infection and stone formation will then render the kidney more vulnerable to progressive loss of renal mass and subsequent chronic renal failure. Renal transplantation is now considered the optimal treatment for end-stage renal disease in all age groups. Although more prone to complications, recent data on patients with meningomyelocele or severely abnormal LUTs demonstrate good patient and graft outcomes [9](LOE 3).

Guidance for further research

Further clarification of the role of fetal surgery to repair the neural tube defect is required, especially in term of prevention of damage to the lower urinary tract. Similarly the role of early intervention, conservative or surgical, is required. The timing of surgical intervention needs further study as well as better quality of life assessments and risk/ benefit analyses of LUT reconstructive procedures. The development of a tissue-engineered substitute for cystoplasy and nerve re-routing is being studied. Finally, the fate of the adult myelomeningocele patient, especially those who have undergone reconstruction needs to be documented.

Conclusions:

- **Myelomenigocele is one of the commonest birth defects (LOE 1).**
- **Incidence is decreased by appropriately-timed folate ingestion during pregnancy (LOE 2).**
- **Most patients have bladder dysfunction which can lead to incontinence and / or upper tract deterioration (LOE 3).**
- **The majority will derive significant benefit from conservative measures (LOE 3).**

Recommendations

- **Regular surveillance with urodynamics and renal ultrasound is mandatory from infancy. However the exact timing is not defined. One must observe the general rules for neurogenic bladder (B).**
- **Early initiation of conservative measures (clean intermittent catheterization, antimuscarinic medication) generally provides protection of the upper urinary tract (B).**
- **The role of new treatment options, for example biotechnology and nerve surgery, needs to be evaluated (C).**
- **Extensive surgery is reserved for failed conservative treatment (B).**

2. BOWEL PROBLEMS

Using MEDLINE we identified English-language journal articles and reviews published from 2000 to April 2012, looking for the keywords myelomeningocele, fecal incontinence, management.

Voluntary control of defecation requires rectal sensation, peristalsis and adequate anorectal sphincter function. Neurological defects in patients with spinal lesions may affect one or more of these components resulting in different types of defecation disorders: fecal incontinence, chronic constipation or both. Incontinence is one of the major stigmas affecting patients born with myelomeningocele [10]. Bowel dysfunction occurs in most children with spinal cord impairment from disease or injury.

Although many different regimens have been used to manage this problem, none has had universal success. Behavioural modification and laxatives failed to achieve an acceptable result because of the persistence of soiling. A small dose of laxatives alone accomplished nothing while administering a large dose to an incontinent patient only resulted in profound embarrassment [11]. Biofeedback was introduced for use in children with intact rectal sensation, but recent trials have reported less encouraging results. “Digital disimpaction” is unpleasant to perform and only succeeds in emptying the distal rectal ampulla.

Bearing in mind that none of these patients can resist the push of peristalsis, the most effective therapy is complete emptying of the colon, since it takes at least 24–48 h to refill again. This can be achieved nowadays by two ways, (A) retrograde colonic enema (RCE) using a special ballon catheter or (B) an operative procedure which allows an antegrade continence enema (ACE). In neurological fecal incontinence, standard enemas are difficult if not impossible to administer, because there is inability to retain

the enema- which flows out involuntarily through the weak anus during its instillation. Therefore a catheter-based RCE system has been developed by industry, the application of which can easily be applied either by the parents or even by children over the age of 7–8 years. Not all children tolerate this procedure, as colonic peristalsis creates pains in some of them. However the reported results are good according to Eire et al. [12]. Shandling et al. [13] reported 100% success in using the enema continence catheter in the management of his patients with spina bifida. These authors regard the RCE as one of the best conservative methods of treatment for relieving fecal incontinence originating from myelomeningocele and other neurological problems.

The impact of ACE surgery in the management of patients with myelomeningocele was analysed by Lemelle et al. [10]. 47 patients were treated with ACE, of whom 41 still used the method at a mean time of 4.1± 1.9 years after the ACE operation. With ACE, faecal incontinence was significantly improved compared with conventional management and neither retrograde rectal enema nor digital extraction were required. In most cases, ACE was performed using the appendix or the caecum. Six patients (12.8%) stopped using the ACE for various reasons, from conduit problems due to stomal stenosis or catheterization difficulties, lack of motivation or "too long time to empty the enema". ACE stoma surgery was applied before, concomitantly or after urinary incontinence surgery in 5, 27 and 10 cases respectively. Enemas were performed at most three times a week, and tap water was used in the majority of patients. Mean volume for ACE was 1.2 L (range 0,25–3,0 L). Mean enema time for colonic washout with ACE was 50 ± 19 min (range 15–90 min), however mean washout duration for ACE tended to be shorter with implantation of the conduit on the left-segment of the colon.

Casale et al. [18] were unable to find any differences in the continence rate or stomal complications between total reconstruction (ACE and continent urine stoma) or staged reconstruction. However, because of shared pathology the authors believe that most patients benefit from intervention in the gastrointestal and the genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3). Nevertheless, conventional treatment should be tested first, and the efficacy of RCE may be a predictor of the efficacy of ACE on bowel management. Moreover, percutaneous endoscopic insertion is fully reversible and does not present drawbacks potentially encountered with the catheterizable conduit [10]. Nevertheless, experience with the Malone procedure has proved that a suitable continent and catheterizable conduit can be obtained with an appropriate technique. In selected and motivated patients, and with the help of a specialist nurse providing close support in the postoperative period, surgical ACE procedure might be preferred according to the surgeon´s experience.

As no absolute indication has been defined for ACE, other criteria should be used to evaluate clinical outcome of bowel management, including health – related quality of life (HRQoL). The development of a disease-specific HRQoL measure for use with myelomeningocele has been proposed by Parkin et al. [20]. HRQoL assessment should be performed prospectively when ACE produce is planned and performed during pre and post-operative periods. According to Eire et al. [1998] ACE procedure and RCE can be the best options for achieving the best social integration. For wheelchair users and other selected patients, the ACE (being faster and easier) is better than the RCE, which needs some help in its use [12, 15].

Sacral neuromodulation has been described also in the therapy of these patients, but the persistence of continence control and tolerance of the patient need to be evaluated for a prolonged period of time. Sacral neuromodulation may only be successful in a small selected number of patients, in whom preserved anatomy of the sacral nerves permits placement of the electrodes on the sacral nerves [19].

Conclusions (LOE 3)

- **Neurologic bowel dysfunction and bowel problems, including fecal incontinence and constipation, are prevalent among myelomeningocele patients.**
- **Fecal incontinence and methods of bowel care affect the QoL and social activities of myelomeningocele patients.**
- **The main goal is to empty the colon as much as possible, to achieve continence during the subsequent 24–48 hours. This can be achieved by retrograde colonic enema using a special ballon catheter, or by an operative procedure which allows an antegrade continence enema (ACE).**

Recommendations B/C:

- **colorectal problems deserve more attention in the treatment of myelomeningocele patients**
- **Appropriate bowel programme / management should be properly designed for each person, after adequate counselling.**

XII. SYSTEMIC AND OTHER CONDITIONS

1. SYSTEMIC LUPUS ERYTHEMATOSIS

a) Urinary incontinence

Nervous system involvement occurs in about half of patients with systemic lupus erythematosis (SLE).

Neurological manifestations of systemic lupus erythematosis are subacute encephalo-myelopathy, subacute myelopathy (rarely) and chronic encephalomyelopathy. Seizures and psychiatric disorders are the most common manifestations; spinal cord lesions are uncommon. Symptoms of LUT dysfunction can occur, however data on prevalence are not available.

Sakakibara et al. (LOE 4) [1] published the findings of 6 women and 2 men, mean age 23 years, suffering from SLE for 2-25 years under immunosuppressant therapy. All 8 patients had urodynamic abnormalities: 5 had decreased urinary flow, 3 increased post-void residual urine, 2 increased maximum urethral closure pressure, 5 detrusor overactivity, and 5 impaired detrusor contractility. Detrusor-sphincter dyssynergia was found in 4 patients and abnormal motor behaviour of the external sphincter during EMG. They found DO more common in patients with brisk deep tendon reflexes (80%) than in those without (33%). Repeated studies during a follow-up period of between 2 months and 8 years showed deterioration in 3 patients including loss of bladder sensation, development of a low compliance bladder and decreased bladder capacity (LOE 4). A study by Duran-Barragan et al. demonstrated similar findings in their series of ten patients and they postulated that LUTD was predisposing the patients to recurrent UTIs [3] (LOE 4).

Yu et al. studied 152 women with SLE and found a significant relationship between central nervous system involvement and the adapted AUA index score. The most common urodynamic finding was a small cystometric bladder capacity (<150 ml; n = 7 patients), followed by a weak urinary flow rate (<12 ml/second; n = 6 patients). In 3 of 7 patients with small cystometric bladder capacities, imaging studies documented a contracted bladder with marked hydroureteronephrosis [2] (LOE 3)

Conclusions

- **Half of the patients with systemic lupus erythematosis show nervous system involvement. In 30%, subacute and chronic encephalomyelopathy may cause LUT dysfunction with variable patterns, including; reduced bladder capacity, detrusor overactivity, impaired detrusor contractility, pathologic voiding pattern and increased post-void residual urine (LOE 4).**

Recommendations

- **The dysfunction pattern may change over time, therefore urological follow-up is recommended (C).**
- **Urodynamic tests are necessary to define the underlying pathophysiology of the urinary symptoms (C).**
- **Patients with SLE and voiding dysfunctions should be managed expectantly, according to the urodynamic results (C).**

2. HERPES ZOSTER

Herpes zoster (shingles) results from reactivation of the dormant varicella-zoster virus (VZV) resulting in vesicular eruptions of the skin or mucous membranes. Two distinct syndromes due to genital varicella zoster infection, cystitis and urinary retention, have been described. Cystitis classically presents with dysuria, frequency and hematuria and cystoscopic verification of local inflammatory changes on the bladder mucosa should be performed for the diagnosis of herpetic cystitis [4] (LOE 3).

The overall incidence of LUT dysfunction is 4% [5], however involvement is reported as high as 28 % if cases of lumbosacral involvement are considered. According to Chen et al., voiding dysfunction following herpes zoster can be; 1. Cystitis-associated, whereby direct involvement of the bladder wall results in herpetic cystitis, 2. Neuritis-associated, due to retrograde spread of infection by the VZV from the dorsal root ganglia of the sacral segments, or 3. Myelitis-associated, caused by herpetic myelitis. Occasionally, patients with skin rash in the lumbar or even lower thoracic dermatomes may develop bladder dysfunction and this is thought to be due to spread of VZV to the sacral segments (LOE 3).

Two case reports describe urodynamics findings in herpes-zoster patients. Usually patients develop complete urinary retention, with or without overflow incontinence due to detrusor acontractility and lack of bladder sensation. Repeat urodynamic studies at week 10 after the onset of the disease demonstrated a return of the detrusor contraction, normalising after 14 weeks [6, 7] (LOE 4).

Herpes zoster-associated voiding dysfunction is a transient phenomenon and is not uncommon in patients with lumbosacral dermatome involvement. Treatment with IC or indwelling catheter placement is recommended in order to avoid secondary damage to the LUT due to chronic urinary retention or UTIs. The disease usually is of a benign clinical course, with recovery of bladder functions.

Conclusions

- **28 % of patients with Herpes zoster in the lumbosacral dermatomes show LUT dysfunction, with impaired voiding as the most common symptom (LOE 4).**
- **The most common symptom is overflow incontinence due to detrusor acontractility and lack of bladder sensation (LOE 4).**
- **Voiding dysfunction has a transient course and almost every patient will regain normal voiding within 3-4 months, or at the least achieve balanced bladder function (LOE 3).**

Recommendations

- **Till functional recovery takes place, urinary tract management with intermittent catheterisation or indwelling catheter is recommended ©.**

3. HIV

a) Urinary incontinence

HIV virus belongs to the family of retroviruses. This family of viruses is known for latency, persistent viremia, infection of the nervous system, and weak host immune responses. HIV has high affinity for CD4 T-lymphocytes and monocytes. HIV binds to CD4 cells and becomes internalized. The virus replicates itself by generating a DNA copy by reverse transcriptase. Viral DNA becomes incorporated into the host DNA, enabling further replication. HIV enters the nervous system early, at the time of initial infection, and may immediately cause symptoms, or it may cause delayed-onset symptoms, potentially at any time during the person's lifetime. All parts of the nervous system may be involved. Neurological disorders could be HIV-related, or due to secondary infections, malignancies, metabolic or nutritional problems and to therapy.

It is estimated that up to 80% of patients are symptomatic in terms of nervous system and for 30%, neurological symptoms are the initial clinical problem, in the absence of anti-retroviral treatment. Neurological syndromes may be the sole clinical problem or cause of death. The following brain symptoms have been described: meningitis, dementia, stroke, seizures, and degenerative disorders. For the spinal cord, transverse myelitis and progressive myelopathy have been observed.

Due to nervous system involvement in HIV infection, consequent effects on LUT function can be anticipated [8]. Shin et al. (LOE3) described a higher prevalence of incontinence in HIV-positive patients as compared to HIV-negative in nursing homes [9]. Whether this represents a true trend, or or an observation related to the terminal stage of the disease and associated comorbidities, remains to be elucidated. Gyrtrup et al. (LOE 3) found voiding problems in 12% of HIV-infected patients, mostly in advanced stages of the disease [10].

Virtually all parts of the body could by involved in AIDS patients, either as the primary location of HIV infection or secondary to HIV-related complications. Among the different manifestations, particular attention should be paid to the primary locations as they develop early in the stage of the disease. HIV can affect all areas of the central and peripheral nervous system- for example, HIV-associated dementia, vacuolar myelopathy, distal sensory peripheral neuropathy and myopathy. Pelvic organ dysfunction has, however, been little studied. Patients may develop voiding dysfunction and chronic retention due to lumbosacral polyradiculopathy. Prior to the introduction of the newer anti retroviral therapies in the 1990s, infection with cytomegalovirus was the most common cause [11] and other causes include lymphomatous infiltration, syphilis or a herpetic radiculopathy due to herpes varicella zoster or simplex. Mahieux et al. (LOE 3) described a case of acute myeloradiculitis due to cytomegalovirus as the initial manifestation of terminal stage HIV [12]. Matsumoto et al. (LOE 3) [13] reported a case of lumbosacral polyradiculopathy where voiding difficulties and lower limb paresis were the primary manifestation of HIV infection. Another pattern of LUT dysfunction is urgency incontinence and DSD [14] in the context of vacuolar myelopathy.

Begara et al. (LOE 3) performed urodynamic studies in 10 patients with AIDS and voiding disorders and found that the most common symptom was urgency incontinence and the most common urodynamic finding was DSD [15]. In 3 patients they found demonstrable functional disorders of the LUT (2 patients had DO: one of them had a history of encephalopathy from HIV and the other patient had polyneuritis; the third patient had myelitis and a urodynamically-diagnosed sympathetic decentralization. Detrusor areflexia was described in 2 HIV-positive patients by Menendez et al. [16] (LOE 3). One of them had an ascending myelitis of probable herpetic origin, the other had a cerebral abscess caused by Toxoplasma gondii.

Since during the course of the disease all parts of the nervous system can be involved, either as the primary location or secondary to AIDS-related complications, no disease specific diagnosis or treatment can be proposed. It is important to observe that sometimes functional disorders of the LUT can be the first manifestation of the HIV infection. When managing the patient with HIV infection one must bear in mind that both storage and voiding problems can occur and that both should be treated according to the results of urodynamic studies.

Future research needs to be supported by a stronger evidence base. All reports of HIV and voiding problems are rather anecdotal and no good prospective studies exist. The need for such studies is particularly important, when realizing that it takes up to 20-30 years from HIV infection to AIDS full manifestation, and that new antiviral treatment modalities could prolong the life of a patient with HIV significantly. Particular attention should be paid to primary nervous system involvement by HIV and the voiding dysfunctions that could be the side effects of HIV drug therapy.

b) Faecal incontinence

As diarrhoea is common in HIV infected patients, faecal incontinence can also occur, mostly due to anal sphincter weakness. The true incidence of HIV neuropathy-related faecal incontinence is not known and further studies are needed [17] (LOE 4). Many of the limitations of knowledge seen with urinary incontinence apply to faecal incontinence.

Conclusions:

- **HIV can influence the nervous system and LUT function in two ways: as a result of primary**

infection, or secondary to AIDS-related complications (LOE2/3).

- **Nervous system manifestation of HIV infection can by the only sign of infection, and it is therefore important to take the possibility of HIV infection into consideration when facing unusual signs and symptoms from the LUT without any other obvious cause (LOE 3).**
- **HIV/AIDS is a progressive disease and dynamic changes to the LUT functions can occur during the evolution of the disease (LOE 2).**
- **Faecal incontinence in HIV/AIDS patients is usually associated with diarrhoea, however the true incidence is not known (LOE 4).**

Recommendations:

- **Patients with HIV and nervous system pathological signs and symptoms should be evaluated for functional LUT problems (B).**
- **Due to the variety of LUT functional damage in HIV patients, dynamic evaluation of LUT function is essential for tailoring of therapy (C).**
- **No HIV-specific therapy of LUT problems and faecal incontinence is currently available. Due to the variety of functional damage, therapy should be individually tailored, according to the results of functional/ imaging studies (C).**

4. NEUROSYPHILIS

Neurosyphilis results from longstanding infection with Treponema pallidum. Bladder dysfunction is common, though most classically in tabes dorsalis. The predominant neurological manifestations are sensory ataxia and spontaneous lancinating pains. Voiding dysfunction occurs due to involvement of sacral posterior roots and the dorsal column of the spinal cord, resulting in loss of bladder sensation and significantly elevated post-void residual urine. The bladder is atonic, though there may be some myogenic damage from chronic over distention. Some patients may demonstrate detrusor overactivity and DSD [18, 19]. The condition is rare and there is no contemporaneous epidemiological data.

5. DIABETES MELLITUS

a) Urinary incontinence

Diabetes is one of the commonest causes of polyneuropathy. Amongst different types of polyneuropathies in diabetic patients “diabetic cystopathy” occurs in 43% to 87% of insulin-dependent diabetics, with no sex or age differences. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment. A Scandinavian study showed that in patients who have had diabetes for 10 years, the prevalence of diabetic cystopathy in those who were insulin-dependent was 2 to 4 per 1000 and in those on oral hypoglycemic agents was 1 to 3 per 1000. The correlation between diabetic cystopathy and peripheral neuropathy ranged from 75% to 100%. Nephropathy was seen in 30% to 40% of cases [20] (LOE 3)

Diabetes duration, treatment type, peripheral neuropathy, and retinopathy were significantly associated with severe incontinence in multiple regression models adjusted for age, education, and history of UTI [21] (LOE 3). Lewis et al. in a cross-sectional studies of 50-90 year old women found that insulin dependent diabetes was strongly associated with urinary incontinence, while non insulin dependent diabetes was not [22] (LOE 2).

Van Poppel et al. [23] reported neuropathological examination of bladder biopsies from 14 patients with severe insulin-dependent adult-onset diabetes, compared with acetylcholinesterase and S100 staining of 38 control specimens. A decrease in acetylcholinesterase activity, due to axonal degeneration was found in all cases. An increase in S100 positivity was found in the majority and is due to Schwann cell proliferation as a regeneration attempt after demyelination or axonal degeneration. When acetylcholinesterase activity decreases and an S100 density increase is found in a patient with diabetes, this combination is highly suggestive of diabetic cystopathy amenable to early symptomatic treatment (LOE 2). Because of the uncontrolled hyperglycemia, patients with DM develop altered NGF activity, which may be a mechanistic factor in the development of diabetic bladder dysfunction [24, 25].

Since the peripheral nerves are involved, the clinical manifestations of diabetic cystopathy might be very different. Usually there is reduced sensation of bladder fullness, and decreased frequency of voiding. This is followed by slowing of the urinary stream and difficulty in voiding due to impaired detrusor contraction. Post-voiding dribbling may also occur. The impaired bladder emptying and urinary retention predispose to urinary tract infections. No prospective studies referring specifically to the problem of functional disturbances of the LUT in diabetic patients have been reported. It has been shown that urine output does not contribute significantly to diabetic cystopathy [26].

Yamaguchi et al. studied 84 diabetic cystopathy patients [27]. In addition to large post-void residual and decreased sensation, urinary urgency, DO, and increased bladder sensation were seen in 55%, 42% and 14%, respectively. The prevalence of DO in patients with increased bladder sensation was 58%. DO increased with age, but not with the duration of diabetes. A brain MRI was performed in 32 cases. The prevalence of multiple cerebral infarction in patients with DO was 76.5%. The authors concluded that urinary urgency is not uncommon in diabetic cystopathy. Both central and peripheral mechanisms are involved [28] (LOE 3).

Ishigooka et al. [29] (LOE 3) described the results of the ice-water test in diabetic patients with and without

cystopathy. 12.5% of patients without cystopathy and 25% of patients with cystopathy did not feel the ice water sensation. Ueda et al. [30] (LOE 2) performed studies evaluating sympathetic skin response in correlation with cystometry. They found that patients without sympathetic skin responses had increased residual urine and decreased detrusor contraction pressure, while patients with a lower amplitude of sympathetic skin response and more prolonged latency than controls had a significant decrease in detrusor contraction pressure. The changes within the bladder function were observed as early as within one year from the diagnosis of diabetes.

Beylot et al. [31], (LOE 2) found that the presence of residual urine in diabetic patients, after exclusion of co morbidities, was strongly associated with peripheral neuropathy. Ho et al. showed increased bladder sensation, followed by DO in 94 female diabetic patients undergoing urodynamic studies [32]. Those patients with OAB are more likely to have impaired voiding function.

No specific treatment has been described in regards to the population of patients with diabetic cystopathy. Therefore general rules as for the other bladder conditions with impaired (absent) detrusor contractions should be followed. Sacral Neuromodulation has been used to treat LUTD in DM, with similar long term results as in non DM patients [33].

Future research should endeavour to give epidemiological information on the incidence of diabetes-related functional disorders of micturition, and specific results of therapeutic interventions.

Conclusions:

- **Diabetic cystopathy occurs in up to 80% of insulin dependent diabetes mellitus (LOE3).**
- **Urinary incontinence is strongly associated with insulin dependent diabetes, but not with insulin independent diabetes (LOE 2).**
- **Overactive bladder is not uncommon in diabetes, presumably reflecting both central and peripheral mechanisms (LOE 3).**
- **Patients with diabetic cystopathy generally can have OAB and/ or impaired detrusor contractions with increased post-void residual (LOE 3,4).**
- **Recurrent urinary tract infections might be a long term problem (LOE 3,4).**
- **There is a lack of specific treatment for diabetic cystopathy.**

Recommendations:

- **Post void residual measurement and urine dipstick (optional culture) for patients with insulin dependent diabetes mellitus should be performed yearly (C).**
- **In case of increased post-void residual, prompted voiding might be useful (C/D).**
- **Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B/C).**

b) Faecal Incontinence

Caruana et al. [34] (LOE 3) found that diabetic patients with faecal incontinence showed increased thresholds of phasic external sphincter contraction ($P<0.05$) and had reduced resting/ maximal voluntary anal sphincter pressures compared with controls ($P< 0.05$). Increased thresholds of conscious rectal sensation in some incontinent patients with diabetes may contribute to faecal incontinence by impairing the recognition of impending defecation. Nakayama et al. [35] (LOE 3) found that age and diabetes have an independent negative influence on faecal incontinence after stroke. Abnormal internal-anal-sphincter function could be contributory in diabetic patients with faecal incontinence [36] (LOE 3). Russo found that acute hyperglycaemia inhibits external anal sphincter function and decreases rectal compliance, which could explain the aetiopathogenesis of faecal incontinence [37] (LOE 3).

Talley [38] (LOE 3) studied gastro-intestinal symptoms, frequent abdominal pain, bowel-related abdominal pain, reflux, dyspepsia, constipation, diarrhea and fecal incontinence in diabetic patients. There was a clinically significant decrease in QoL scores in diabetics compared with population norms across all subscales. The impact on QoL in diabetes was predominantly observed in type 2 diabetics. For all the Short Form-36 subscales, GI symptom groups were significantly (all $p < 0.0001$) associated with poorer QoL in diabetes, independent of age, gender, smoking, alcohol use, and type of diabetes.

Conclusions

- **Faecal incontinence in diabetes patients may be due to impaired anorectal sensation and/or decreased anal closing pressure after hyperglycemic episodes (LOE 3).**
- **Gastro-intestinal symptoms impact negatively on health-related QoL in diabetes mellitus (LOE 3).**

Recommendations:

- **Patients with diabetes and fecal incontinence should have anorectal manometry performed before introducing therapy for fecal incontinence (C/D).**
- **More studies on neurologic bowel dysfunction and management in diabetes are needed before giving further recommendation (B).**

LIST OF ABBREVIATIONS

Most abbreviations used in the text are given here. Others may be given within the front of the section in which they are used

ACh	acetylcholine
AChE	acethylcholinesterase
AD	autonomic dysreflexia
ADL	activities of daily living
ALD	Alzheimer's disease
AS	anal sphincter
AUS	artificial urethral sphincter
BBB	Blood-brain barrier
BCR	bulbocavernosus reflex
BST:	bethanechol supersensitivity test
CC	cystometric capacity
CIC	clean intermittent catheterization
CMG	cystometrogram
CPG	clinical practice guideline
CPT	current perception threshold
CT	computer tomography
CTT	colonic transit time
CUM	continuous urodynamic monitoring
CVA	cerebro-vascular accident
CVC	conventional cystometry
DI	double incontinence
DLB	dementia with Lewy bodies
DOA	detrusor overactivity
DRS	digital rectal stimulation
DSD	detrusor sphincter dyssynergia
ES	electrical stimulation
EAS	external anal sphincter
EMG	electromyography
EPT	electric perception threshold
FI	faecal incontinence
FTD	fronto-temporal dementia
GBS	Guillain-Barre Syndrome
ID	indwelling catheter
IC	intermittent catheterization
IVES	intravesical electrical stimulation
IWT	ice water test
LGIT	lower gastrointestinal tract
LMNL	lower motor neuron lesion
LOE	level of evidence
LS	lumbosacral
LUT	lower urinary tract
LUTD	lower urinary tract dysfunction
LUTS	lower urinary tract symptoms
Pdet max	maximum detrusor pressure
MMC	meningomyelocoele
MUP	motor unit potential
MRI	magnetic resonance imaging
MS	multiple sclerosis
MSA	multiple system atrophy
NBo	neurogenic bowel
NBoD	neurogenic bowel dysfunction
NDO	neurogenic detrusor overactivity
NLUTD	neurological lower urinary tract dysfunction
NUI	neurogenic urinary incontinence
NFC	natural fill cystometry
OR	odds ratio
PD	Parkinson's disease
PF	pelvic floor
PFD	pelvic floor dysfunction
PSP	progressive supranuclear palsy
Psym	parasympathetic
PVR	post void residual
QoL	quality of life
RCT	randomised controlled trial
SARS	sacral anterior root stimulation
SCI	spinal cord injury
SCL	spinal cord lesion
SDAF	sacral deafferentation
SIC	sterile intermittent catheterization
SLE	systemic lupus erythematosis
SNS	sacral nerve stimulation
SOM	somatic
SPC	suprapubic catheter
SSEP	somatosensory evoked potentials
SSR	sympathetic skin response
SUI	stress urinary incontinence
Sym	sympathetic
TBI	traumatic brain injury
TRI	transrectal irrigation
TURS	transurethral sphincterotomy
UFM	uroflowmetry
UI	urinary incontinence
UMN	upper motor neuron
US	urethral sphincter
U/S	ultrasound
UTI	urinary tract infection
UUT	upper urinary tract
VCUG	voiding cystourethrogram
VSD	vesicosphincteric disorders
VUR	vesicoureteric reflux
WBC	white blood cells

A. General considerations

I. INTRODUCTION

Older people have the highest known prevalence of urinary incontinence (UI) of any group, other than those with specific neurological disease (e.g., spinal cord injury). As the proportion of older people in the populations of the developed world increases, so will the absolute numbers of those with either urinary (UI) or faecal incontinence (FI) or lower urinary tract symptoms.[1] Even if improvement in physical functioning among older people continues, and research in the field is able to demonstrate continuing benefit whilst containing costs, the impact on future health care and long-term care costs will still be profound.[2] Early signals suggest however that the decrease in disability for older people observed in the last two decades of the twentieth century has not been seen in those aged 40 – 64 years[3].

No matter how one defines "older" or "elderly," this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally- and cognitively-impaired persons in their late 60's. Because the healthier group is closer in phenotype and physiology to middle aged than to frailer older people, information relating to the management of urinary and faecal incontinence in this group is integrated into the other ICI chapters. This chapter focuses on frailer older people, emphasizing not only the different aetiologies and treatment of UI and FI, but the additional issues of disease burden, disability, altered responses to drug therapy, the role of caregivers, and goals and organisation of care. This chapter is aimed at all those who work with the frail elderly, and is also intended to be relevant to specialists who may find standard approaches ineffective in this population.

The committee took the view that where there is a paucity of data reflecting the efficacy or utility of approaches to the treatment of UI or FI in frail older adults, interventions aimed at community dwelling, fitter older adults should be employed with due regard to the likely benefits, harms, feasibility, expectations and outcomes of treatment, rather than be denied any intervention. The pathophysiology of UI in the frail elderly requires a broader conception of "disease," centreing on patient-level factors rather than just the bladder or bowel and its neurological control. UI and FI in frail older people is normally a result of multiple interacting risk factors, including age-related physiological changes, comorbidity, polypharmacy and common pathways between them. Furthermore, the impact of urinary or faecal incontinence in the frail elderly includes functional impairment, and extends beyond the affected individual to their caregivers, leading to caregiver stress and an increased likelihood of institutionalisation. Therefore, assessment in frail persons requires a broader scope. Failure to address the multifactorial nature of disease and treatment limits not only clinical care and research, but also important opportunities to improve function and quality of life[4]. Treatment is usually multicomponent, and must address the many associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining lower extremity exercise with prompted voiding)[5]. Drug therapy must be placed in the context of altered pharmacology, polypharmacy, and an increased susceptibility to adverse effects. Effective management may also require system-level approaches, with different models of care (e.g., for institutionalised persons).

The challenge in providing a review of UI in frail older people is the relative dearth of Level 1 evidence for interventions; the frail present multiple challenges for research (not the least of which is substantial trial drop-out due to intervening illness and death) and there is still a systematic problem in including older people in clinical trials[6]. Over and above this problem is the ***continuing paucity of new clinical trials,*** despite the clear epidemiological imperative that the oldest-old are the fastest growing group of affected individuals. Intervention studies and outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique to this population[7].

II. SEARCH STRATEGIES

Overview

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS , frail, FRAIL ELDERLY, FRAILTY, function, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL; and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URETHRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGYNECOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION , nocturia OR nocturia OR "night-time voiding" OR "nighttime voiding" OR "nocturnal voiding" OR "nighttime voids" OR "night-time voids" OR "nocturnal voids" OR "night-time frequency" OR "night-time frequency" OR "nocturnal frequency" OR "nighttime urination" OR "night-time urination" OR "nocturnal urination" OR "night-time micturition" OR "night-time micturition" OR "nocturnal micturition" OR "night-time polyuria" OR "night-time polyuria" OR "nocturnal polyuria" OR nocturia) OR ((noctur* OR night*) AND (void* OR urination OR micturition OR polyuria OR pollakiuria OR "LUTS" OR "lower urinary tract symptoms" OR "BPH" OR "benign prostatic hyperplasia")) AND ("aged, 80 or over" OR aging OR elderly OR older OR "very old" OR senior OR "all aged" OR geriatric OR frail OR aged) AND ("double blind method" OR "double blind" OR placebos OR placebo OR "controlled clinical trial" OR "randomized controlled trial" OR "random allocation" OR "single blind method" OR "research design" OR "exp clinical trials" OR "clinical trial" OR "single blind" OR "double blind" or "triple blind" OR "single mask*" OR "double mask*" or "triple mask*") (longitudinal OR "natural history" OR cohort OR incidence OR remission OR progression OR prospective OR "community-based" OR "population-based" OR epidemiol* OR "follow-up"); TOLTERODINE; OXYBUTYNIN; SOLIFENACIN; PROPIVERINE; TROSPIUM, IMIDAFENACIN; DARIFENACIN; FESOTERODINE; Ovid Expert Search Filter; Publication years 2004-11. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations.

III. DEFINING THE FRAIL OLDER POPULATION

1. FRAILTY

Who, then, are the frail elderly? Consistent with increasing consensus in the geriatric literature, we define "frail older persons" as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion) [8-10] . Frailty is not, however, synonymous with disability and comorbidity. In one study, among persons meeting strict phenotypic criteria for fragility, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability without comorbidity, and 27% had neither comorbidity nor disability [9]. Frail people usually have multiple chronic medical conditions, take multiple medications, require care from others and assistance to perform some or all of the personal activities of daily living (PADLs) (e.g., bathing, dressing, toileting, and mobility), are often homebound or institutionalised They have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1,8]. For example, in the US, 10% of all persons over 65 require help or supervision with at least one ADL,[11] and the total prevalence of frail elders has been estimated at 6.1%.[12] From the United Kingdom Hertfordshire cohort study of men and women aged between 65-74, the prevalence of frailty was 8.5% among women and 4.1% among men [13].

Several studies suggest that the relationship between UI and frailty is not unidirectional. Incident UI in those over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [12]. In a population-based study of older Mexican Americans, incident but not prevalent UI was independently associated with functional decline in ADLs, IADLs, and physical performance [14]. Another population-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [2]. The authors suggest that the relationship between UI and adverse outcomes may be mediated by baseline illness severity and functional impairment [2]. A recent Portuguese study showed that older people who presented with either "slowness" or "exhaustion" had a risk of UI almost five times greater than those without [15].

2. IMPACT OF UI ON MORBIDITY AND INSTITUTIONALISATION

UI in frail persons can have much more severe consequences than in healthy older persons. Although one early study suggested that older persons with UI had a higher mortality risk, [16] subsequent studies that more fully adjusted for comorbidity and functional status have not found any association. [2,12, 17,18] Several multivariate studies suggest that patients with new onset UI at the time of stroke have higher rates of death or disability at 2 years (OR 4.43; 95% CI 1.76 to 11.2)[19] to 5years (OR 3.21 [95% CI 1.04−9.91]), [20] especially if UI persists (OR 7.47 [95% CI 2.29−24.42]).[20]

Given its association with frailty, it is not surprising that UI remains a risk factor for nursing home admission, despite global variation in services and temporal changes in elder care. Studies showing a significant association between UI and institutionalisation have been done in: Finland (men [not women] with urgency UI);[21] Germany;[22] New Zealand (persons > age 65);[23] US (men more than women,[24] after hip fracture,[25] among Hispanic elderly,[14] and patients attending a dementia clinic[26]); Japan (men only)[27], and Hong Kong[28]. Two studies failed to find a significant association after controlling for comorbidity, using US[2] and Canadian databases.[29] It is estimated that the fraction of US NH admissions attributable to UI in men is 0.10 (95% CI 0.08–0.13) and in women 0.06 (95% CI 0.05–0.09).[30] The prevalence of UI at NH admission in the U.S. shows small area variation of almost 50% and differs by race,[31] suggesting that patient and caregiver factors and local resources affect the role UI plays in institutionalisation. An important methodological issue for such studies is the erroneously low prevalence of UI found in administrative long-term care databases when UI is defined by physician diagnosis in the medical record.[32, 33] Another issue, particularly in studies of institutionalisation in persons with dementia, is the failure to include UI as a risk factor [34] or defining it only by a composite function score [35]. The significant association of faecal incontinence and institutionalisation (odds ratio 1.79, 95% CI: 1.00-3.20), in one Canadian study was lost when adjusted for cognition, ADL dependence, and self-reported health[36], although a survey of US geriatricians found that the presence of faecal incontinence was more likely to result in a referral to a nursing home than not [37].

B. Urinary Incontinence in frail older people

I. AETIOLOGY AND ASSESSMENT

1. BACKGROUND

The aetiology of UI in frail older adults is grounded in the concept of a classic geriatric syndrome, involving multiple interacting risk factors, including age-related changes, comorbidity, and potentially common pathways between them. This section addresses all of these components.

2. QUALITY OF THE DATA

The data on the aetiology of UI in the frail elderly population is limited, and observational studies of varying quality constitute much of this literature. Additionally, longitudinal studies of large numbers of frail individuals are difficult to carry out because of paucity in recruitment and the high rate of natural attrition. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

3. UI AS A GERIATRIC SYNDROME

In older adults, especially those who are frail, UI is considered to be a geriatric syndrome, because many of its risk factors are not directly related to the genitourinary tract.[38, 39] Geriatric syndromes have been defined as ‘‘multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges”.[38] Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges (**Figure 1**). This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes.[38]

Nevertheless, because common risk factors (e.g. lower and upper extremity weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence) [40], they may represent particularly attractive sites for intervention development.[38] For example, as proposed by Kuo and Lipsitz,[41] the presence of brain white matter hyperdensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI. In fact, recent functional magnetic resonance imaging (fMRI) studies have begun to identify central nervous system areas that are particularly relevant to urgency [42-44]. Therefore, failure of activation within orbitofrontal regions may contribute to an older individuals’ decreased ability to suppress urgency [44]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role in maintaining continence,[43, 44] supporting the concept that declines in connectivity[45] and

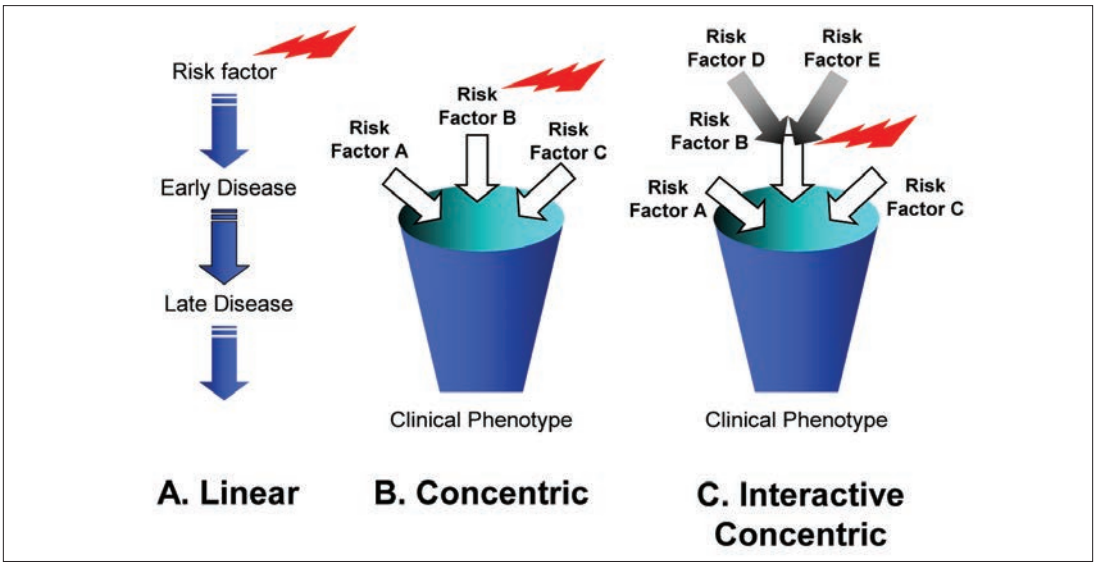

Figure 1. Mechanistic of Geriatric Syndromes

coordination[46] between different brain regions represent early critical events in aging. These findings suggest the possibility that interventions to prevent the development of white matter hyperintensities, such as control of vascular risk factors, could also prevent UI.

4. AGE-RELATED CHANGES RELEVANT TO UI IN THE FRAIL ELDERLY

Age-related changes in the LUT can function as risk factors for the development, continuation, and worsening of UI in frail elderly persons (**Table 1**). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on "normal" LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate "normal LUT ageing" from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe "age-related" associations, as opposed to normal ageing. Other limitations include: derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; "age-effects" derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as "normal" controls. Even the definition of "normal" can be difficult: is it continence, absence of LUTS, lack of comorbid disease, or normal physiological testing [47]? The following sections focus on findings from more robust and, where possible, confirmatory studies.

a) Bladder. Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of "normal," and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral nervous system innervation, and reflex patterns as determinants of bladder function in older persons. The research focus has been urodynamic function, neurohumoural responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciated (See Committee 2, Cell Biology; Committee 3, Neural Control; and Committee 4, Pathophysiology), there are only limited human data on urothelial changes with age. Urodynamic changes associated with age have typically included smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity (DO)). Correlations with age are often small, suggesting that other factors are at least as important [48]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy persons over age 55, DO was found in 42% of continent women, one-third of whom were totally free of LUTS [47]. In another study, charts of 53 consecutive females over age 80 undergoing multichannel urodynamics according to ICS standards were retrospectively analyzed. All of these elderly patients presented with LUT symptoms, yet in 11% urodynamic studies were reported as being normal, with considerable other discordance between symptoms and urodynamic findings [49].

Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [50]. The ability of the bladder to empty efficiently also declines in healthy older men and women who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [47, 51]. A variety of different risk factors associated both with ageing and common comorbid conditions may contribute to age-related declines in detrusor contractile function, which may ultimately lead to detrusor underactivity [52, 53]. Decreased contractile function during voiding in older persons is associated with lower urine flow rates and a small increase in post voiding residual volume (PVR) (generally to < 50 ml) [54]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractility rather than obstructed voiding [55]. While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Neural Control). More recently, Smith highlighted the potential contribution of age- and disease-related declines in bladder afferent sensory activity in contributing to impaired voiding performance seen with detrusor underactivity [56]. Incomplete bladder emptying from all such causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [52]. The recent development of a model allowing continuous uroflow in mice has led to studies evaluating the impact of normal aging on overall LUT performance [57, 58]. While aging did not influence measures of detrusor expulsive strength, pre-contraction pressures, intervoid intervals, per-void volumes and voiding flow rates all increased with aging [57]. Moreover, aged animals demonstrated

Table 1. Age-related changes that can contribute to UI in frail elderly persons

Age-Related Change	Potential Effects on Continence
Bladder ultrastructure on electron microscopy	
Dysjunction pattern	Bladder overactivity and urgency UI
Muscle and axon degeneration	Impaired bladder contractility, increased residual urine, and decreased functional bladder capacity
Bladder function	
Decreased capacity	Increased likelihood of urinary symptoms and UI
Decrease sensation of filling	
Increased detrusor overactivity	
Decreased bladder contractile function	
Increased residual urine	
Urethra	
Decreased closure pressure in women	Increased likelihood of stress and urgency UI
Prostate	
Increased incidence of benign prostatic obstruction	Increased likelihood of urinary symptoms and UI
Increased incidence of prostate cancer	
Decreased oestrogen (women)	Increased incidence of urogenital atrophy and related symptoms
	Increased incidence of recurrent urinary tract infections
Increased night-time urine production	Increased likelihood of nocturia and night-time UI
Altered central and peripheral neurotransmitter concentrations and actions	Increased likelihood of lower urinary tract dysfunction
Altered immune function	Increased likelihood of recurrent urinary tract infections
Increased prevalence of white matter hyperintensities in brain	Increased prevalence of severe urge / urgency, link to cognitive impairment and impaired mobility

a decreased homeostatic capacity to respond to the challenge of continuous bladder filling, with indirect measures suggesting a role for decreased bladder volume sensitivity [57, 59].

In human studies, the observation that bladder volume at the initial desire to void declines with age may be confounded by comorbid conditions and concurrent medications [60]. Furthermore, unlike the positive association between detrusor contraction strength and DO found in younger subjects, older adults fail to demonstrate this DO-associated increase in detrusor contractility [61]. Moreover, many frail older persons with UI present with a combination of DO on filling and poor contractility during voiding, an association termed detrusor hyperactivity with impaired contractility (DHIC) [52, 62, 63]. In such cases, the bladder contraction does not empty the bladder fully, leaving a large PVR otherwise not explained by BOO. Because DHIC symptoms can include urgency UI, stress and mixed UI, dribbling, frequency, and nocturia, they may be mistaken for other conditions. At the same time, DHIC may be mistaken for DO with normal contractility because significant detrusor underactivity may be present in the absence of any relevant symptoms.

Ultrastructural studies demonstrate cellular changes associated with age-related changes in detrusor function. One series of such studies involved symptomatic and asymptomatic persons aged 65 to 96, using urodynamic testing and electron microscopy of bladder biopsy specimens, which were read in a blinded fashion using explicit protocols [54, 64-68] A consistent, one-to-one correlation between specific urodynamic findings and bladder ultrastructure was observed, although there has been considerable debate about the veracity of these findings and they have not been reproduced and have been disputed by the findings of a later study which found the ultrastructural changes described evenly distributed between normal women (n = 15) and women with detrusor overactivity (n = 22) .[69] The small number of asymptomatic patients with no DO, normal contractility, and no obstruction, detrusor muscle fascicles were largely intact, with two distinctive ultrastructural findings that may be related to ageing alone: muscle cell membranes characterized by numerous “dense bands” and markedly depleted caveolae, and slightly widened spaces between muscle cells with limited content of collagen and elastin. Depletion of caveolae may be related to de-differentiation of muscle cells, which could eventually result in the reversion of actively contractile cells to inactive, synthetically immature cells. A similar phenomenon has been reported in atherosclerotic blood vessels and postmenopausal myometrium, and may be related to reports of increased collagen in bladders from older women [54, 70]. Moreover, lack of oestrogen contributes to, and oestrogen replacement reverses, both caveolar depletion and detrusor fibrosis [71, 72]. Thus, both ageing and post-menopausal decline in oestrogen levels may contribute to bladder muscle cell differentiation and contractile function [52].

The natural history of these ultrastructural changes remains largely unknown. From the ultrastructural studies described above, a subset of 23 patients was followed longitudinally [67]. The previously observed one-to-one correlation between ultrastructure and function was maintained, but it was unclear whether urodynamic or ultrastructural changes occurred first in subjects who developed or had a change in LUTS. The pattern of dense-bands and nondisruptive muscle cell degeneration varied over time: the DO with dysjunction pattern developed in some subjects, and impaired detrusor contractility and the corresponding degeneration pattern was observed to progress in severity or develop. Other investigators have found similar results but without the one-to-one correlation (e.g., see Brierly et al [73]). Clearly, further work is needed understand the associations between changes in ultrastructure,urodynamic features and clinical syndromes.

In addition to such alterations in ultrastructure, a variety of changes involving relevant nerve fibres, receptors and signalling pathways have also been described in bladder tissues from aged animals, and to lesser extent human biopsies. For example, with aging overall, sympathetic nerve fibre density may decrease [74, 75]. Bladder biopsies from older subjects with normal urodynamic profiles typically show little or no evidence of axonal degeneration and the density of some CGRP-positive sensory nerves is maintained in old age, yet the impact of aging on other categories of sensory fibres or on motor fibres remains unknown [54, 74]. Examples of other changes include decreased contractility and calcium fluxes in response to cholinergic agonists or depolarization [76]; increased responsiveness to adrenergic agonists with increased expression of the alpha 1D-adrenergic receptor [75]; declines in phosphodiesterase 5 (PDE5) levels and possibly signaling [77]; as well as decreased P2X1 purinergic receptor expression [78]. Unfortunately, the interpretation and generalisability of these findings is often limited by a failure to include intermediate age-points which would allow investigators to distinguish changes attributable to aging as opposed to maturational processes [79, 80].

b) Urethra. Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes similar to the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls.

Urethral closure pressure decreases with age [81, 82]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH2O per decade [83]. A number of anatomical and physiologic changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [84]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [85]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen.[86] Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [87-89]. However, age explained only 9% of the variability in vascular density in one study [90], and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [91, 92].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral wall of the proximal urethra [93, 94]. These authors estimated that striated fibres decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [95]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra. Moreover, a recent study raised the possibility that TNF-alphamay contribute to age-related rhabdosphincter satellite cell death and muscle loss with aging [96]. Urethral sensation, measured as current perception thresholds, was significantly higher in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI [85], and another in asymptomatic women [97]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity [85], and the “asymptomatic” older women may have had urodynamic DO [97].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles -benign violaceous soft swellings-often appear at the meatus, and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [98]. Diverticula should be considered in women who have repeatedly failed “conventional” UI treatment. Diagnosis requires imaging by voiding cystourethrography, ultrasound, or magnetic resonance scans. Urethral obstruction is relatively uncommon in older women, and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or is iatrogenic (from LUT/pelvic surgery or radiation. In men, age-related decrease in striated sphincter muscle cell density occurs as well, [99, 100] and has been associated with increased muscle cell apoptosis [99] . While some investigations describe an increase in resting prostatic urethral pressure with age, [101] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [102]. These discrepancies may reflect differences in prostate volume and morphology.

c) Pelvic floor. Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity [103]. A number of studies are cross sectional rather than longitudinal, and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI, after adjustment for obesity, birth history, menopause, and hormone use [104]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [105]. In contrast, a recent study combining an interview, physical exam and transperineal ultrasound identified age as a weak ($r = -0.25$) but statistically significant predictor of pelvic muscle weakness and levator ani morphometry even after controlling for obvious confounders [106]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2, Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [85]. A his-

tomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (</> age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [107]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [108] but this association does not imply a direct causative effect of "ageing." Constipation may independently contribute to pelvic floor dysfunction in older women [109, 110].

d) Vagina. The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [111]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamentum rotundum [112]. Yet, as the Women's Health Initiative trial has shown, one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms [113, 114]. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [86].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail elderly women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4. [¬68] These changes can lead to loss of normal adherent flora (lactobacillus), colonisation with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [115].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age. Whether this is oestrogen-related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases, and may be accompanied by invasion by lymphocytes and plasma cells [115]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [112]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [116]. Vaginal shape also may be altered by POP. Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symptoms/LUTS should not be automatically assumed. Very few randomised trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [117]. There are insufficient data to provide an evidence-based approach to symptomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring). The validation of vaginal self-swab collection specimen collection offers new opportunities for extending relevant questions to epidemiological studies of older women living in the community [118].

e) Prostate. Histological benign prostate hyperplasia (BPH) is strongly age-related [119], and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5-α reduction of testosterone. Dihydrotesterone levels decrease with age, while oestradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the oestradiol/dihydrotesterone ratio and promoting stromal proliferation [120, 121]. Epithelial hyperplasia in turn is mediated by an array of stromal factors [122].

Histological BPH occurs in nearly 80% of men by age eighty [119]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate specific antigen level of >1.4-2 ng/mL [123]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [124]. Natural history studies and randomized intervention trials, however, consistently demonstrate that symptomatic progression of benign prostate disease is not inevitable. LUTS remit in about one-third of symptomatic men without treatment [125]. Approximately one-third to one-half of affected men develops DO. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate-related LUTS in older men a diagnosis of exclusion. Nevertheless, age-stratified normative values for prostate

volume, PSA level, as well as indicators of clinical symptoms, quality of life measures and urodynamic parameters may help in such decisions [126].

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail elderly men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence is contradictory as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [127]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infarction and AUR [128]. Nevertheless, a recent study demonstrated phenotypic changes and an increased differential expression of a variety of genes involved in inflammation and oxidative stress within glandular adjacent stroma microdissected from young and aged mouse prostates [129]. Such changes may play a role in promoting the development of BPH, BPE and cancer in aged prostates [130].

f) Other changes. The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee, Cell Biology). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older persons.

The prevalence of both asymptomatic bacteriuria and UTIs increase with age [115], and the two are often found together in the frail elderly. Age-related changes in immune function, vaginal epithelium, faecal incontinence, and insufficient hygiene related to disability, cognitive impairment, and/or lack of caregivers may predispose the frail elderly to bacteriuria and recurrent UTIs. However, the role of otherwise asymptomatic bacteriuria (often found in association with pyuria) [131], in the aetiology of UI in frail elderly people remains unclear [132]. Treating otherwise asymptomatic bacteriuria in frail elderly patients with chronic, stable UI does not, in general, reduce UI severity [133]. UTI symptoms may be subtle and non-specific in this population, and include worsening of UI, altered mental status in patients with dementia, decreased oral intake, or a minor but important decline in functional ability [133]. At the same time, current consensus criteria for UTI are poorly sensitive and only fairly specific for UTI in frail elderly. In a prospective cohort of 340 nursing home residents, in which UTI was defined as pyuria (>10 white cells) with >100,000 colony forming units on culture, the McGeer, Loeb, and revised Loeb UTI criteria had sensitivities of only 19-30% and specificities of 79-89% [134].

5. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO UI

Of 8,688 participants in the English longitudinal study of ageing, of whom 4,417 had one or more diagnoses, there were shortfalls in receipt of basic recommended care, most noticeable in areas associated with disability and frailty [135], A hallmark of UI in the frail elderly population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to leakage (**table 2**).

a) Medications. Older people consume a high proportion of prescribed medications. Those over 65 years of age comprise between 12 – 16% of the population in the US, UK and Canada but consume 32%, 50% and 45% of prescribed medications respectively and are therefore at greater risk of experiencing adverse events associated with their use [136-141]. The risk of difficulty in controlling urination in community dwelling older women taking medications with LUT effects was about 30% higher compared to those who did not take such medications (OR 1.31 [95% CI 1.05–1.21]) Overall, 20.5% of these women reported incident incontinence at Year 4 (3 years from baseline). We found one additional study since the 4th ICI which examined 959 elderly community dwelling women from the Health, Aging and Body Composition Study, multivariate logistic regression analyses revealed that current users of alpha blockers (adjusted odds ratio (AOR) =4.98, 95% confidence interval (CI) =1.96-12.64) and oestrogen (AOR=1.60, 95% CI=1.08-2.36) had a greater risk of urinary incontinence than nonusers. There was no greater risk of UI associated with current use of anticholinergics, central nervous system medications, or diuretics [142]. Many classes of medications commonly prescribed for the frail elderly can cause or contribute to the development of UI (**Table 3**). The possibility that UI could be caused by a medication should be taken into account before prescribing drug treatment for UI in older persons.

b) Co-morbid conditions and functional impairment: The prevalence of urinary incontinence (UI) is increased in the presence of frailty. The elderly are prone to frailty and commonly have co-morbid medical illnesses. In a large population-based observation study UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29% and three or more in 13% [143].

In a sample of 572 older Latinos participating in a programme to increase walking, medical comorbidity was independently associated with higher rates of UI (OR 1.66). A higher degree of physical activity was independently associated with lower rates of UI (OR

Table 2. Comorbid conditions that can cause or contribute to UI in frail elderly persons

Conditions	Comments	Implications for Management
Comorbid medical illnesses		
Diabetes mellitus	Poor control can cause polyuria and precipitate or exacerbate incontinence; also associated with increased likelihood of urgency incontinence and diabetic neuropathic bladder	Better control of diabetes can reduce osmotic diuresis and associated polyuria, and improve incontinence
Degenerative joint disease	Can impair mobility and precipitate urgency UI	Optimal pharmacologic and non-pharmacologic pain management can improve mobility and toileting ability
Chronic pulmonary disease	Associated cough can worsen stress UI	Cough suppression can reduce stress incontinence and cough-induced urgency UI
Congestive heart failure Lower extremity venous insufficiency	Increased night-time urine production at night can contribute to nocturia and UI	Optimizing pharmacologic management of congestive heart failure, sodium restriction, support stockings, leg elevation, and a late afternoon dose of a rapid acting diuretic may reduce nocturnal polyuria and associated nocturia and night-time UI
Sleep apnoea	May increase night-time urine production by increasing production of atrial natriuretic peptide	Diagnosis and treatment of sleep apnoea, usually with continuous positive airway pressure devices, may improve the condition and reduce nocturnal polyuria and associated nocturia and UI
Severe constipation and faecal impaction	Associated with "double" incontinence (urine and faecal)	Appropriate use of stool softeners Adequate fluid intake and exercise Disimpaction if necessary
Neurological and psychiatric conditions		
Stroke	Can precipitate urgency UI and less often urinary retention; also impairs mobility	UI after an acute stroke often resolves with rehabilitation; persistent UI should be further evaluated Regular toileting assistance essential for those with persistent mobility impairment Optimizing management may improve mobility and improve UI
Parkinson's disease	Associated with urgency UI; also causes impaired mobility and cognition in late stages	Regular toileting assistance essential for those with mobility and cognitive impairment in late stages Patients presenting with all three symptoms should be considered for brain imaging to rule out this condition, as it may improve a ventricular-peritoneal shunt
Normal pressure hydrocephalus	Presents with UI, along with gait and cognitive impairments	Regular toileting assistance essential for those with mobility and cognitive impairment in late stages
Dementia (Alzheimer's, multi-infarct, others)	Associated with urgency UI; impaired cognition and apraxia interferes with toileting and hygiene	Optimizing pharmacologic and non-pharmacologic management of depression may improve UI
Depression	May impair motivation to be continent; may also be a consequence of incontinence	
Medications	See Table 3	Discontinuation or modification of drug regimen
Functional impairments		
Impaired mobility Impaired cognition	Impaired cognition and/or mobility due to a variety of conditions listed above and others can interfere with the ability to toilet independently and precipitate UI	Regular toileting assistance essential for those with severe mobility and/or cognitive impairment
Environmental factors		
Inaccessible toilets Unsafe toilet facilities Unavailable caregivers for toileting assistance	Frail, functionally impaired persons require accessible, safe toilet facilities, and in many cases human assistance in order to be continent	Environmental alterations may be helpful; supportive measures such as pads may be necessary if caregiver assistance is not regularly available

UI = urinary incontinence

0.77). Hypertension, congestive heart failure, arthritis, depression and anxiety were associated with a higher prevalence of UI. A linear correlation was found between prevalence of UI and the number of comorbid conditions. (correlation coefficient =0.81) [144].

A decline in physical health has been associated with an increase in the incidence of incontinence. [145] In an observational study of 6,361 community-dwelling women, aged 65 and older, participating in the study of Osteoporotic Fractures, after adjusting for confounders, women with recent physical function decline (a worsening of 1 standard deviation from baseline) were more likely to report weekly incontinence (OR 1.3) for decline in walking speed over 6 metres and (OR 1.4) to stand from sitting. [146]. The Nurses' Health Study found that moderate-intensity physical activity including walking resulted in a 20-25% reduction in the risk of developing UI in older women [147].

Likewise, impaired cognition is associated with an increased likelihood of UI. For example in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (Mini Mental State Exam score <= 23, prevalence 18%) were significantly more likely to have UI (adjusted odd ratio [OR] 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7) have had at least two falls in the previous six months (OR 1.4), and report poorer health (OR 1.9) [148].

Comorbid conditions can affect incontinence through multiple mechanisms e.g. diabetes mellitus, present in approximately 15-20% of frail elderly,

Table 3. Medications that can cause or contribute to UI in frail elderly persons

Medications	**Effects on Continence**
Alpha adrenergic agonists	Increase smooth muscle tone in urethra and prostatic capsule and may precipitate obstruction, urinary retention, and related symptoms
Alpha adrenergic antagonists	Decrease smooth muscle tone in the urethra and may precipitate stress urinary incontinence in women
Angiotensin converting enzyme inhibitors	Cause cough that can exacerbate UI
Anticholinergics	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause cognitive impairment and reduce effective toileting ability.
Calcium channel blockers	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause dependent ooedema which can contribute to nocturnal polyuria
Cholinesterase inhibitors	Increase bladder contractility and may precipitate urgency UI
Diuretics	Cause diuresis and precipitate UI
Lithium	Polyuria due to diabetes insipidus
Opioid analgesics	May cause urinary retention, constipation, confusion, and immobility, all of which can contribute to UI
Psychotropic drugs Sedatives Hypnotics Antipsychotics Histamine$_1$ receptor antagonists	 May cause confusion and impaired mobility and precipitate UI Anticholinergic effects Confusion
Selective serotonin re-uptake inhibitors	Increase cholinergic transmission and may lead to urinary UI
Others Gabapentin Glitazones Non-steroidal anti-inflammatory agents	 Can cause ooedema, which can lead to nocturnal polyuria and cause nocturia and night-time UI

UI = urinary incontinence

may cause UI by diabetes associated LUT dysfunction (DO , OAB, cystopathy and incomplete bladder emptying) or by poor diabetic control (hyperglycaemia causing osmotic diuresis and polyuria). The Nurses Health Studies, NHS and NHS II [149] showed an increase in weekly urgency incontinence (OR 1.4) in women with type 2 diabetes compared to those without. Findings from the NHANES 2001-2002 Survey showed that prevalence of UI was significantly higher in women with impaired fasting glucose and diabetes mellitus compared to those with normal fasting glucose. Two microvascular complications caused by diabetes - peripheral neuropathic pain and macroalbuminuria (approaching significance) were associated with weekly UI.[150]

See **Table 2** as to how comorbid medical conditions can contribute to UI

***c) Neurological and psychiatric disorders*:** A more detailed summary of neurological disorders and their impact on UI is covered in Chapter X. Neurological and psychiatric disorders are highly prevalent in the frail elderly. Neurological conditions in the elderly commonly associated with urinary incontinence include stroke, dementia of the Alzheimer's type (AD), multi-infarct dementia or a combination of the two, Diffuse Lewy body (DLB) disease and Parkinson's disease. Less common conditions include Normal Pressure Hydrocephalus and Multiple System Atrophy (MSA). Each of these conditions is associated with the development of brain lesions that can interfere with the normal ability to inhibit voiding as well as affecting cognition. These conditions are associated with impaired mobility and also affect the ability to toilet independently.

In Alzheimer's disease UI is often associated with severe cognitive decline whereas in DLB it usually precedes severe cognitive impairment [4]. Occurrence of UI was significantly earlier 3.2 yrs in DLB compared with 5.9 yrs in Alzheimer's dementia [151].

Normal pressure hydrocephalus should be considered as a diagnosis in any frail elderly person who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefit from surgical implantation of a cerebrospinal fluid shunt [152].

LUTS, UI and urodynamic DO are common in older persons with Parkinson's disease. A logistic regression analysis of 3,414 Parkinson's disease patients found a significant correlation of orthostatic hypotension and urinary incontinence with age and duration of the disease. The presence of UI in people with Parkinson's may in turn increase their risk for disability: in one series of patients with Parkinson's, UI increased the risk of falling by nearly six-fold. Urinary symptoms are often non-responsive to L Dopa therapy and there is an increased risk of cognitive decline in people with Parkinson's disease when given anticholinergic agents [153, 154].

Multiple system Atrophy presents with a combination of impaired autonomic function, Parkinsonism (MSA-P) or cerebellar ataxia (MSA-C) or both [155]. It frequently begins with bladder dysfunction and erectile dysfunction in males. It is associated with bladder symptoms of DO and often progressing to incomplete emptying. The early appearance of LUTS and high post void residuals may help in pointing to a diagnosis of MSA-P rather than Parkinson's disease [156].

With the introduction of magnetic resonance brain imaging into routine clinical practice, reports in older patients have increasingly emphasized the presence of structural abnormalities involving the white matter[157]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (Binswanger's disease, a specific and relatively rare form of dementia), towards leukoaraiosis [158] and, most recently, to the concept of white matter signal abnormalities (WMSA).[157, 159]. A dichotomous diagnosis of "cerebral white matter lesions" on CT scans provided by a radiologist demonstrated no relationship to the presence or absence of UI. A semi-quantitative measure of global WMSA appears to be associated with increased urgency UI and nocturnal frequency [160]. In 699 non-disabled elderly subjects with WMSA on MRI there was a significant difference in prevalence of urgency but not incontinence between mild and severe groups [161]. WMH have been linked to severity rather than to the presence of incontinence [162].

d) Depression. As in younger people, the frail elderly with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and under-treated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [163]. UI may add to the burden of depression by decreasing life satisfaction and self-rated health and by its association in frail elders with comorbidity. [164-167]

Studies of the association of depression and UI in older persons are consistent across several depression measures. The validated Centre for Epidemiologic Studies-Depression scale was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based people found an adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55]) [168]. A large community-based study of older Mexican Americans reported an adjusted OR for depression of 1.94 [95% CI 1.46-2.59]) [169] . The emotional disturbances and social isolation subscales of the Nottingham Health Profile Questionnaire was associated with urgency but not stress urinary incontinence and have included studies in Asia [145, 170]. Although no association between UI and depression was found in a Korean study of

135 community living elderly aged greater than 85 years, it used a higher cut-off (>7) on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility[171]. Self-report of depression or sadness has and has not been associated with UI. [172-174]

Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR 5.60 [95% CI 1.88–16.67]), but not in whites, in a cross-sectional study of community based older persons with mean age 67 years[175]. However, a longitudinal analysis of the same population over 13 years found that people with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR 6.55 [95% CI 1.94-22.12]). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR 3.66 [95% CI 1.61–8.33]) [176].

EpiLUTs, a large cross-sectional internet study, showed significant impairments in mental health and HRQOL when different urinary symptoms were combined [177, 178].The US sample of the EpiLUTS study, involving 2,485 men and 2,877 women aged 65 and older, found OAB was associated with significant impairment in HRQOL. Rates of Anxiety of >7 on the HADS-A were 16.4% for men and 23.6% for women with OAB compared to 3.3% and 8.6% with minimal or no symptoms. Similarly rates for depression on the HADS-D were 17.3% and 15.7% for OAB compared to 4% and 6.4% in those with no or minimal symptoms. [179]

A case controlled study of 100 elderly men attending a Urology outpatients, matched with 100 age matched controls from the community and Geriatric outpatient clinics, found those with moderate to severe LUTS had worse HRQOL. This was evident in a number of ageing male symptoms including depression, decline in feelings of general well-being, decreased sexual performance and decreased muscle strength [180].

The direction of the causal relationship between UI and depression in frail persons is unclear, as nearly all of these studies were cross-sectional. The results of the one available longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most closely associated with psychological distress, even after controlling for important covariates [163].

e) Falls: Overactive bladder (OAB), present in up to 20% of older adults, and its component symptoms of urinary urgency and urinary incontinence, urinary frequency, and nocturia have been identified repeatedly as risk factors for falls among community-dwelling older adults [181-186]. Mixed incontinence (a combination of urgency and stress incontinence) has also been associated with falls risk in women 70 years and older [187].

In hospital, the need to use the toilet has been reported to increase falls, especially among older patients [188]. Urinary incontinence is also associated with falls in institutionalized older persons [189, 190].

f) Stroke: Conservative interventions (e.g. bladder training, pelvic floor muscle training and prompted voiding) have been shown to have some effect in Cochrane systematic reviews, but have not had their effectiveness demonstrated with stroke patients. UI may have particular prognostic implications after stroke, being associated with greater mortality, a poorer functional recovery and an increased likelihood of institutionalization than those following strokes who regain continence. Of 1,187 patients aged 60–96 with stroke, those with low bladder maintenance scores (more dysfunction) fared worse with rehabilitation than those with higher scores [191]. A survey of stroke unit practice in Australia showed that less than half had a formal plan for continence care and in the UK, as part of the national sentinel audits of stroke, there was little advance in continence care [192, 193]. A comparative study of stroke nursing found a dearth of evidence and treatment focused on containment and social continence, highlighting the need for systematic assessment and management [194].

g) Recommendations for research

Further research is required to:

1. Examine the effect of treatment for UI in older people with Parkinson's disease
2. Examine the temporal association and mechanism underlying falls and UI in frail older persons
3. Examine the effect of structured treatment for UI in older people following stroke.

h) Recommendations for practice

1. Clinicians need to assess and manage co-existing co morbid conditions which are known to have an impact on continence status or the ability to successfully toilet.

6. ENVIRONMENTAL FACTORS

This section addresses those factors unrelated to underlying pathophysiology which affect continence status in frail older persons.

- The physical environment
- Processes of and/or quality of care
    - o assessment
    - o practices that reduce mobility
    - o toileting assistance
    - o staffing levels and skill mix
    - o use and misuse of continence products

In this section we defined processes of care as the instrumental procedures involved in the assessment and management of incontinence relating to frail older persons.

a) The physical environment

Although the physical environment is considered a risk factor for incontinence in frail older adults, there is limited research on this topic. We located seven publications with evaluative data on this topic: two of these studies were conducted over 40 years ago [195, 196] prior to the establishment of internationally agreed standards for reporting trial data. Three were published from a series of projects conducted in the USA to examine the impact of the physical environment on specific problems of people with Alzheimer's disease and related disorders [197-199]. One qualitative study was identified that employed an ethnographic design [200]. Each of these studies involved individuals in long-term care institutions. One study evaluated the prevalence and risk factors for incontinence in a sample of 5,418 community-dwelling frail older adults who were receiving home care services [201]. Environmental barriers as well as the use of physical restraints, along with UTIs were the most common reversible risk factors for urinary incontinence: increasing the risk of urinary incontinence by over 50% [201]. In this study, environmental hazards included a lack of access to the toilet, unavailability of grab rails, inappropriate toilet seat height, inadequate lighting, and inadequate toileting substitutes such as commodes or urinals.

Attempts to evaluate the effects of enhancing the physical environment of long-term care on rates of incontinence were first reported by Chanfreau-Rona [195, 196]. In both studies, the intervention involved enhancing visual access to the toilet by painting toilet doors in bright colours and strategically locating pictorial signs and other visual cues. In addition, staff were asked to accompany residents to the toilet at predetermined 'peak times' and to employ operant conditioning techniques to reinforce residents' appropriate toileting behaviour. In the first of these trials, 24 elderly female residents, most of whom had cognitive impairment, were purposively assigned to either the intervention, or to usual care for seven weeks [195]. The same procedures were repeated in a subsequent trial (1986), [196]. Although reductions in incontinence were noted for residents in the experimental groups compared to the control groups, the extent to which these reductions were related to the intervention is difficult to determine as both studies lacked power and did not control for confounding factors. Nonetheless, these studies represent an early, multifaceted intervention that involved evaluating the effect of changes to the physical environment to reduce incontinence in among frail older adults in long-term care.

According to the findings of a series of projects conducted by Namazi and colleagues, the overall physical environment has a considerable impact on the well being and quality of life of individuals with Alzheimer's' Disease (AD), affecting their ability to function in the face of incontinence, distraction and disorientation [197]. One of the projects focused on the clinical utility of using environmental cues (i.e. signage, colour differentiation and images) in a dementia-specific unit to assist compensate for resident' visuo-perceptual deficits [198]. The most effective environmental cue in terms of orienting individuals with AD to the toilet was a combination of using a sign with the word 'toilet', together with 'wayfinding' arrows on the floor. No single strategy was suitable for all individuals with AD due to the variability in the ability of individuals with AD to perform all of the tasks associated with successful toileting. The researchers therefore recommended "to maximize the remaining strengths of those who are afflicted with AD, each component of the morphology which creates difficulties for AD patients must be identified and treated individually". In essence, individuals with AD may need individually targeted cues that address identified specific areas deficit.

In a second project, Namazi and colleagues [199] systematically examined toilet use in a dementia-specific unit under two conditions: with the toilet highly visible to residents, and with the toilet concealed. The frequency of toilet use increased when toilets were visually accessible during the 45 hours of observation. Visibility and accessibility of toilets may be an important factor in supporting individuals to maintain continence.

Toilet accessibility also featured highly in a qualitative study conducted by Sacco-Peterson and Borell [200]. Using ethnographic methods, the researchers collected over 200 hours of field observational data and conducted in-depth interviews with nine residents. They reported that different aspects of the facility's physical and socio-cultural environment influenced residents' abilities to maintain autonomy in self-care. For example, there was an inadequate number of toilets, inadequate privacy for toileting, inappropriate toilet heights, excessive distances to the toilet, and a lack of call light, toilet paper, soap, paper towels, lighting and commodes. Despite the challenges of negotiating this 'defeating ward geography', many residents attempted to participate autonomously in toileting, whilst others were deterred because of a fear of falling.

b) Processes and quality of care

In a systematic review of the prevalence and risk factors for urinary incontinence in nursing homes Offerman and colleagues [202] identified 46 risk factors for urinary incontinence in nursing homes. These factors were grouped into 1) locomotion, 2) cognitive function and 3) drugs. However, in addition to these risk factors, the reviewers stated "differences in the care process and quality of care can also influence urinary incontinence prevalence;

reasons for a less-than-optimal approach in nursing homes may include, for example, inadequate knowledge of and skills for urinary incontinence in general, inability to use guidelines for urinary incontinence care, insufficient staffing and poor communication among healthcare professionals" (p. 291). They recommended that risk factors related to care processes be further investigated.

Two studies offer qualitative data on how processes of care in nursing homes may represent a risk factor for incontinence. For example, descriptive information derived from semi-structured interviews with six elderly women from two nursing homes in Canada, suggests that some residents experience an environment characterised by rituals and routines, pad rationing, limited assistance with pad changing, restrictions on the type of products available, set times for toileting and pad changes, ageism, and a lack of recognition of attempts to maintain continence [203] Sacco-Peterson and Borell [200] also found that 'toileting assistance was provided at set times, and 'if residents required more assistance other than at set times, pads were used'. Pad use also correlated with residents' mobility level, rather than their cognitive or continence status. Additionally, night-time use of pads often started following a fall at night. Residents did not divulge their difficulties to staff, and were reluctant to ask for help and thus staff members were unaware of residents 'difficulties and efforts. Residents valued the capacity to exercise some power and autonomy with regard to self care, and didn't want to be 'a bother to the nurse'. Thus, their attempts to maintain continence may be undermined by care processes that unintentionally diminish an individual's independent toileting.

c) Assessment

A comprehensive assessment to determine type and causes of incontinence is an essential precursor to appropriate management. However, many people with incontinence do not have access to this assessment, and are therefore at risk of remaining incontinent (**Table 4**). This finding is consistent for older adults across different countries and settings.

d) Knowledge

A lack of knowledge about incontinence and its management may operate as an antecedent to care processes that inadvertently promote incontinence. A number of studies reveal gaps in nurses' and nursing aides' knowledge about and attitudes toward older people with incontinence in long-term [204-224], as well as acute care [221, 225-229]. Other research highlights gaps in medical practitioners' knowledge about incontinence [230-234]. For example, a survey of general practitioners (GPs) knowledge of investigation modalities and treatment options for individuals with faecal incontinence in the UK, found that only 32% were aware of at least one investigation, and 32% were aware of at least one form of surgical treatment [230]. In a cross-sectional national survey to determine knowledge, attitudes, and management of urinary incontinence among family physicians in Canada, less than half (46.0%, 284/617) indicated that they had a clear understanding of incontinence and just 37.9% (232/612) had an organized plan for incontinence problems [234]. Szonyi and Millard [232] reported a significant improvement in GPs knowledge about incontinence following receipt of an education package.

Knowledge about incontinence and its management in the general community is also lacking, especially amongst men, those aged 85 and older, and those with lower levels of education [235]. For instance, a nation-wide consumer survey conducted in the USA in 2000, found four in ten people (41%) thought that loss of bladder control was a disease and a similar percentage (38%) believed it was a natural part of ageing [236].

e) Processes of care that reduce functional status

Impaired functional ability can cause or contribute to incontinence in frail older persons. Care processes that restrict or minimise mobility and the ability to function constitute a critical risk factor. The use of physical restraints is one such practice. Although restraint-free care has been recommended as standard, restraints remain widely used in long-term care – ranging from 12-47% internationally [237]. In a multivariate analysis of data from 2,014 residents from 270 USA Medicaid-certified nursing homes, Brandeis and colleagues (1997) identified that urinary incontinence was independently associated with impairment in ADLs (OR = 4.2; CI = 3.2,5.6), dementia (OR = 2.3;CI = 1.8,3.0), the use of anti-anxiety/hypnotic medications (OR = .7;CI = .5,1.0) (all $P < .04$) and the use of restraints of the trunk (OR = 1.7; CI = 1.5,2.0), restrained to a chair (OR = 1.4; CI = 1.2,1.6), and bedrails (OR = 1.3; CI = 1.1,1.5). Similarly, in a community–based sample of frail older adults, the use of physical restraints was a key reversible risk factor for urinary incontinence [201].

f) Lack of toileting assistance

An obvious, yet often overlooked risk factor for incontinence is a lack of toileting opportunities and assistance for individuals who are care-dependent. Research from USA shows that the frequency of toileting assistance actually provided in nursing homes is too low to maintain continence [238].

In recent years, the UK media has drawn attention to the fact that many people in hospital do not receive timely assistance to use the toilet: a situation that contributed to the establishment of the "Dignity in Care Campaign" – launched in 2006. In response to concerns about neglect in aspects of personal and healthcare, the British Geriatrics Society proposed that the ability to use the toilet in private was in fact, a marker of human rights, and developed a

Table 4. Evaluative studies on assessment of incontinence in frail older adults

Study	Objective	Sample	Method	Findings
[943] Du Moulin et al., 2009	To assess the prevalence of UI and gain insights into care issues	2866 patients (mean age 80 ± 7.2yrs) living at home receiving home care in Holland	Survey + audit of medical records	Type of UI was diagnosed in 49% of patients. Management did not differ for patients with and without a diagnosis of UI type
[614] Georgiou et al., 2001	To evaluate the recommended outcome measures in clinical practice	1125 residents in 17 residential homes, 14 nursing homes and 5 long-stay wards in UK.	Analysis of data on the UI section of the Royal College of Physicians Continuous Assessment Review and Evaluation Scheme audit tool	Rates of full clinical assessment were • 48% for people in residential homes • 24% for people in nursing homes • 36% for people in long-stay wards
[254] Rodriguez et al., 2007	To explore continence prevalence, knowledge and care	66 care homes in Birmingham, UK	Survey completed by managers or other senior staff	Only two respondents gave information indicative of a full assessment. Most respondents had difficulty identifying the process of assessment.
[257] Pringle-Specht et al., 2002	To determine patterns and treatment of urinary incontinence	145 residents with dementia (mean age 83.3yrs) from 13 special care units in long-term care facilities in USA	Retrospective audit of residents' medical histories using 'Incontinence Patterns Tool' (IPT)	55% of residents with UI and dementia had a documented care plan for treatment of UI 2.1% (n=3) had a current medical diagnosis of bladder incontinence
[245] Wagg et al., 2008	To assess the quality of continence care for older people	Patients from 138 primary care trusts, 195 secondary care trusts, and 27 care homes in UK	Audit of patients' clinical records	Poorly documented aspects of a clinical assessment across all settings: rectal examinations and post-void residual urine volumes. In secondary care trusts, 919/3509 (25%) of histories had documentation of an assessment to determine UI type or cause
[944] Watson et al., 2003	To assess the use of the Agency for Healthcare Policy and Research Guideline for managing UI in nursing homes	200 residents with new UI or newly admitted with UI from 52 nursing homes in upstate New York, USA	Retrospective chart review and Nursing Assistance screening interviews	4 new cases of UI per 100 beds over 12 weeks UI Guideline standards met 20% of cases (0-45%). Aspects of assessment rarely performed • rectal examination (15%) • digital examination of prostate (15%) • pelvic examination (2%)

"Behind Closed Doors Campaign". The aim of the campaign was to empower, educate and influence providers and policy makers to adopt a more proactive stance to demand better continence care. A more recent campaign, again led by the British Geriatrics Society, titled "Do not forget the person" was launched in March, 2010. The extent to which such awareness raising activities affect day-to-day care processes in the absence of structural change and resources requires evaluation.

Structured toileting programmes require a staff to patient ratio of 1:5. A lack of staffing or institutional understaffing represents a key risk factor for incontinence among individuals who are dependent on another person to use the toilet. Factors which have been identified in the success (or otherwise) of such programmes are covered in Section 7.

g) Staffing levels and skill mix

Estimating and achieving the optimal level and skill mix of any workforce is a challenge. In long-term care where residents' have chronic health problems and complex health needs, this problem is exacerbated by a high staff turnover. Nurses consistently cite inadequate staffing levels as a major barrier to continence care [239-243]. The extent to which patients and residents' continence care needs are considered in formulas designed to establish the right staffing level and skill mix is unclear. The time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management and manage incontinent episodes require consideration in service planning.

h) Use and misuse of continence aids

For many people, continence aids represent a means by which they can achieve effective and discrete containment of incontinence, minimise physical discomfort and optimise psychological and social function [244]. At the same time, overuse and misuse of continence aids, may represent a risk factor for incontinence and, for pads, urinary tract infection. Although continence aids have an important place in the control of incontinence, their use in the general community, in hospital settings, and in long-term care institutions is widespread (**Table 5**). For example, in the largest and widest audit of continence care conducted in the UK and involving over 6,000 patients across primary and secondary care trusts, and care homes, containment strategies (i.e. the use of continence aids) far exceeded all other forms of documented continence management [245].

- ***Community / home care / primary care***

Extrapolating data from users of absorbent pads in one area in Sweden, Samuelsson and colleagues [246] found 6.4% of all women and 2.4% of all men in the country, used continence aids: equating to 3.7% of the total population. Most of these users were aged over 75 years of age and 21% lived in special accommodation. Other studies have examined use of continence aids in targeted populations. For example, among individuals receiving home care services in European countries, rates of continence aid use vary from 29-52% (mean 39%) [247] to 57% [248]. And across primary care trusts in the UK, containment strategies are used by 48% of patients [245].

- ***Acute care / hospital / secondary care***

Rates of continence aid use in elderly patients in acute care across a number of countries are similar and range from 55.1% in Italy [249], 56% in the UK [245] to 60% in Singapore [250] and Australia [251]. Not only are they widely used but they are often used indiscriminately. One of the earliest studies to draw attention to an overreliance on pad use was conducted by Starer and Libow [252]who found more residents using pads than those with incontinence. More recently, Ostaszkiewicz and colleagues found that in the inpatient care setting, pads were inappropriately used for some patients, and were underused for others [251]. Of 121 patients who were using pads at the times of the survey, 50(41%) reported no UI or FI in the preceding 24-hours. However, 18% of patients who had no pad did report such an episode. This mismatch between incontinence and pad use has been noted in other research. [253] [249]

- ***Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes***

We located six studies that provided data on the use of continence aids in long term care facilities. These were conducted in the UK [245, 254], the USA [255-257], and in Norway [258]. Wagg and colleagues reported that of 488 residents from 27 care homes included in the national audit of continence care in the UK, 307 (63%) used a containment strategy to manage their incontinence [245]. Roderiguez and colleagues reported similar rates based on interview data from managers of 66 care homes in Birmingham [254].

In the USA, Brandeis and colleagues reported a higher rate of pad use (84%) in their sample of 2,014 residents from 270 Medicaid-certified nursing homes[255]. Eighty-four percent were managed with pads/briefs, and more than one third of incontinent patients were managed with two modalities. A recent evaluation of the use of urinary collection devices by 57,302residents from five skilled nursing facilities found that pad use remained relatively stable over a 12 month period [256]. Pad use among a sample of 11,549 newly admitted 75-84 year old residents was 58.7% at admission and 61.1% twelve months later. This rate was higher for residents aged 85 years of age and older (i.e. 60.3% at admission and 62.6% one year later). In a survey of patterns and treatments of urinary incontinence in 13 special care units in the USA, Pringle-Specht and colleagues (2002) re-

Table 5. Evaluative studies on the use of continence aids (pads and briefs)

Community / home care / primary care				
Study	Objective	Sample	Method	Results
[943] Du Moulin et al., 2009	To assess the prevalence of UI and gain insights into care issues	2866 patients (mean age 80 ± 7.2yrs) living at home and receiving home care in Holland	Survey + audit of medical records	Pads were used by 59.2% of patients with diagnosis of UI type and by 55.8% of patients with no diagnosis of UI type
[945] Samuelsson et al., 2001	To study age- and sex specific use and costs of freely available incontinence aids in Sweden	2542 women & 1292 men living in their homes (including special accommodation) in a county of Sweden who were using incontinence aids	Audit of incontinence aid prescriptions – data extrapolated to general population	Incontinence aid use 367000 (3.7%) of all people in Sweden 6.4%-women /2.4%-men in the county 765000 (66%) in special accommodation Costs 925 million SK 50% of cost attributable to those aged 80 yrs or >
[247] Sorbye et al., 2008	To determine prevalence and characteristics associated with UI	4010 randomly selected older persons (mean age 82.3 ± 7.3 yrs) living at home in one of 11 European countries and using home care agencies	Cross sectional survey using the International Resident Assessment Instrument for Home Care (RAI-HC)	39% used pads (highest usage in France -52% / lowest usage in Norway and Czech Republic – 29%) Pad use correlated with need for toileting assistance (p<0.001)
[245] Wagg et al., 2008	To assess the quality of continence care for older people	2717 patients from 138 primary care trusts in UK	Audit of patients' clinical records	Containment strategies were used by 1294/2717 (48%) of patients
Acute care / hospital / secondary care				
Study	Objective	Sample	Method	Results
[250] Kadir, 2004	To determine the incidence and appropriateness of incontinence aid use	333 elderly patients in an acute hospital (Singapore)	Survey – patient self report	200/333 (60%) - using some form of aid 101 (50.1%) could have been managed with alternatives
[249] Palese et al., 2007	To evaluate the incidence of pad use and explore appropriateness and reasons for use	396 patients (mean age 76.8 ± 11.8yrs) admitted to medical units in 2 acute care units in Italy	Survey – interview + clinical assessment 3 x day each day during hospitalization	Inpatient use of pads – 218/396 (55.1%). Of this cohort, 120/396 (30.3%) had incontinence prior to admission Rationale for pad use: urinary incontinence associated with acute confusion or dementia
[251] Ostaszkiewicz, et al., 2008	To determine the prevalence of UI & FI + pad use + documentation of incontinence	447 inpatients (mean age 70 ± 18.7yrs) admitted to 3 acute and 1 subacute care hospitals in Australia	Point prevalence survey + an audit of medical records	266/446 (60%)- using a continence product/ device 50/121 (41%) of patients using pads had no UI or FI in the preceding 24 hrs. 18/113 (16%) patient with UI or FI in preceding 24 hrs had no continence product/device
[245] Wagg et al., 2008	To assess the quality of continence care for older people	3683 patients from 195 secondary care trusts (hospitals) in UK	Audit of patients' clinical records	2070/3683 (56%) patients used containment strategies
[253] Zisberg 2011	To determine incidence of incontinence brief [pad] use	465 older patients (mean age 78.6 ± 5.8 yrs) who were not using incontinence briefs prior to admission to medical acute care units in a 900 bed teaching hospital in Israel	Admission interview and then every day after first 48 hrs	65/465(14%) used incontinence briefs during most of their hospitalization. Brief use was associated with low mobility
Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes				
Study	Objective	Sample	Method	Results
[255] Brandeis et al., 1997	To describe the frequency and correlates of potentially treatable causes of urinary incontinence	2014 residents (mean age 84.3 ± 8.7) from 270 Medicaide-certified nursing homes in USA	Review of MDS data / Interview with the nursing home staff, and interaction and observation of residents	990/2014 (49%) of residents were incontinent. Of these, 84.0% were managed by pads/briefs. More than one-third (n = 350) of the incontinent residents were managed with two modalities
[258] Omi et al., 2010	To determine daily pad usage & association with UTI, and fluid intake	153 residents (mean age 83 ± 8.2 yrs) from 6 nursing homes in Norway	Number and weight of pads per/resident calculated over 2 days	118/153 (77%) used pads 36/48(75%) men 82/105(78%) women Average number of pad changes p/day-2.7 UTI correlated with pad use but not fluid intake or number of pad changes
[254] Roderiguez et al., 2007	To explore incontinence prevalence, knowledge and care	66 care homes in Birmingham, UK	Questionnaire to care home managers	Several methods to manage incontinence were cited however briefs and pads accounted for over 50% of responses

ported that 72% (n=105) of residents used a continence aid: the most common type of aid being a continence brief or pad (n=93) [257].

According to Omli and colleagues who estimated the daily pad usage of 153 elderly residents from six nursing homes in Norway, 77% of residents use pads [258]. Omli and colleagues also found that residents' pads were changed infrequently (i.e. an average of 2.3 times a day (range 0.5-8.0) for female residents and 3.1 times a day for male residents (range 1.0-9.0). Moreover, urinary tract infections were associated with pad use (41 vs. 11%; P = 0.001): but not with fluid intake or number of pads changes. Residents pad usage did not correlate well with the volume of their incontinence:

As inappropriate use of continence aids may contribute to onset, or continuation of, incontinence, it is important that clinicians who advocate or authorise their use, are familiar with evidence-based guidelines that advocate an active approach to diagnosing and treating incontinence.

i) Recommendations for research

Further research is required to:

1. explore the physical environment as a risk factor for UI in frail older adults, and to evaluate the effect of modifying the environment.
2. explore the extent to which socio-cultural factors and care processes in particular, influence frail older adults' abilities to maintain autonomy and continence.
3. identify the association between fear of falling, reduced mobility, and UI in frail older persons.
4. evaluate the effect of awareness raising activities that aim to enhance day-to-day continence care processes in healthcare settings.

j) Recommendations for practice

1. Environmental cues such as toilet visibility, signage, colour differentiation and images should be used to compensate for visuo-perceptual deficits in frail older adults with cognitive impairment.
2. As remaining physical strength and exterity varies in individuals with cognitive impairment, each component of the toileting process which creates difficulties for such patients should be identified and treated individually.
3. Awareness raising activities should be conducted to enhance day-to-day continence care processes in healthcare settings.
4. Ensure that the time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management and manage UI episodes are considered in service planning.
5. Continue to address gaps in healthcare practitioners' knowledge about preventing and managing incontinence in frail older persons.
6. As inappropriate use of continence aids may contribute to onset or continuation of UI, clinicians who advocate or authorise their use, should be familiar with evidence-based guidelines that advocate an active approach to prevention, diagnosis and treatment.

II. ASSESSMENT OF THE FRAIL OLDER PERSON WITH UI

Recommendations for the basic assessment of the frail elderly persons with UI are summarised in the algorithm (see Summary Document). Because UI in the frail elderly is multifactorial, it is essential to conduct a comprehensive assessment with the goal of identifying all potential contributing factors. Collaboration among primary care physicians, geriatricians, surgical specialists, nurses, other health professionals, and caregivers, both formal and informal is usually necessary for optimal assessment and management.

Since the last Consultation, the European Association of Urology published guidelines on UI which include those for frail older men and women. These are largely based on the findings of the 4th ICI [259].The UK NICE guidelines for the management of lower urinary tract symptoms in men contain no specific recommendations for older men but are perhaps more age applicable than those which exist for UI in women.[260, 261] The US government sets minimum quality standards for UI assessment and management in long term care, but these standards, along with basic fundamental principles of UI, are poorly understood by long term staff [262]. Two groups, the US Assessing Care of Vulnerable Elders (ACOVE) project and the UK Clinical Effectiveness and Evaluation Unit, have developed quality performance measures for UI care in frailer older persons, using structured literature review and expert panel review.[263-267] These measures are not guidelines *per se*, and in some instances lack sufficient detail. Although both groups have demonstrated using their measures that UI assessment and care by practitioners in the US and the UK is poor, and of a lower standard than that afforded to younger adults, there is evidence that integrated services are more likely to provide a higher standard of UI care [268] Thus, there is an urgent need to re-establish the fundamentals of UI assessment and management for all personnel who care for frail older persons with UI and ensure that there is adequate service provision.

1. COMPONENTS

a) Identification of frail older persons. Health care providers can screen older patients with UI for

frailty using the Vulnerable Elders Survey, which can be administered in person or by phone [269]. Persons with a score of 3 or greater have four-fold increase in the risk of death and functional decline compared with persons with lower scores. A patient self reported scale in which those people classified as either frail or pre-frail had higher frequency of hospitalization, a higher probability of co-morbidity and higher mortality than those classified as non-frail has recently been reported [270]. However, caution still needs to be exercised when classifying an older individual as frail as there is considerable heterogeneity within this group [271].

b) Primary care assessment. Physician education using a modified version of the ACOVE model to reach a large group of primary care physicians resulted in between 80% and 92% of them planning to make a change in their practice behaviour [272], although no formal assessment of carry through was undertaken. Geriatricians' and primary care physicians' (PCPs) UI assessments were compared in a randomized multicentre study involving 364 subjects, 42% of whom self-reported UI to the investigators. Geriatricians were significantly more likely to detect UI (59% of cases vs. 16%), regardless of the severity of UI, and were more likely to refer to Continence Programmes (25%); all referrals by PCPs were to urologists.[273] An assessment strategy based on clinical evaluation, simple cystometry, and several criteria for referral was compared with urodynamic diagnosis. Approximately 25% of patients met criteria for referral, half of patients accepted urodynamic evaluation, yet urodynamics changed the treatment plan in only 12% of the patients who did not met the *a priori* criteria for referral [274].

Practice patterns and adherence to US UI guidelines were evaluated by retrospective chart review of 300 consecutive patients aged >65y, seen by either an internist or geriatrician for UI at a tertiary care centre. Geriatricians ordered more testing, such as urodynamics, before referring patients to a surgical specialist. [275] Overall, primary care practitioners rarely follow the US Agency for Healthcare Research and Quality UI guidelines (now obsolete), [276] and nursing home practitioners rarely follow the Federal guidance for UI care regarding recommended physical examination, PVR testing, urinalysis, and identification of potentially reversible causes [277]. Okamura and colleagues investigated the diagnosis and treatment of lower urinary tract symptoms (LUTS) by general practitioners (GPs) according to the "Practical manual for LUTS evaluation and treatment in the elderly For GPs (Japanese)" and found adherence to the manual, reinforced by educational and promotional activities resulted better treatment outcomes [278, 279].

A systematic review of articles identified only 5 studies meeting eligibility criteria, and all were in women. None of studies found sufficient diagnostic evidence (defined as positive > 5 and negative likelihood ratios < 0.02) for different types of UI. The best was a general population study reporting the utility of history and exam for the diagnosis of SUI (positive and negative likelihood ratios 3.23 and 0.40, respectively) [280]. Adding a nurse practitioner to general practitioner care for adult patients with UI can reduce the impact of UI [281].

c) Cough stress test. We found no additional evidence on the utility of the cough stress test since the last consultation. Utility of the cough stress test was studied in 97 incontinent female long-term care residents using blinded comparison with single channel cystometry. Of the 77% in whom single channel cystometry diagnosis was congruent with the stress test (i.e., urodynamic DO with negative cough test, no DO and positive cough test), all were correctly classified; no woman with SUI was missed nor were any with DO misclassified.[282] An analysis, 200 older women with UI found that provocative full-bladder cough test was as effective as radiographic or urodynamic pressure measurement in detecting SUI. Clinical diagnosis incorporating the cough test with leakage symptoms was 78% accurate, with only 6% false negatives for SUI, but was only 44% accurate with 45% false negatives for urgency UI [283].

d) Postvoid residual measurement. We identified no studies evaluating the impact of PVR measurement on clinical diagnosis and treatment outcomes. One study of 100 patients consecutively admitted to a geriatric ward found that 34% had PVR > 50 mL; these patients tended to have more UI (57% vs. 38%, p >.05), greater functional dependency, and a higher mortality rate (36% vs. 9%).[284] A study of the residual urine in a randomly selected community dwelling sample of men and women aged 75 years of age found more than 10 ml of residual urine in 91 of the 92 men (median 90 ml; range 10-1502 ml), and in 44 of the 48 women (median 45 ml; range 0-180 ml). The significance of this single measurement could not be estimated [285].

e) Urodynamic testing. Urodynamic testing is feasible and safe, even in frail nursing home residents. [63] There is no evidence, however, that urodynamic diagnosis changes the outcome of treatment. Expert guidelines have recommended urodynamic testing before surgical or minimally invasive UI treatment in frail elders [286].

f) Ultrasound estimation of bladder weight. A single study of men attending the uroflow clinic of mean age 65 (range 23 – 90) detected no statistically significant differences in ultrasound estimated bladder weight between men with Qmax <10mL/min versus those with >15mL/min [287].

2. SUMMARY OF EVIDENCE

1. Active case finding and screening for UI should be done in all frail older persons because many do not spontaneously report their symptoms. (Level 1).
2. Screening for frailty is possible with short screening instruments (Level 1).
3. Current quality of primary care assessment of UI in frail elders is poor (Level 2).
4. Cough stress test has moderate accuracy in frail institutionalized women (Level 2).
5. No recommendation is possible on the utility of PVR testing in the assessment of UI in frail elderly (Level 4).
6. Urodynamic testing is feasible in frail older people (Level 1) but it is unlikely to change management or outcomes except, perhaps, in those considered for surgical treatment of UI (Level 4).

3. RECOMMENDATIONS FOR EVALUATION (SEE ALGORITHM)

The essential first step is to actively case find in the frail elderly, as the condition is generally underreported. The second is to identify treatable, potentially reversible conditions and other factors (medications, environment) that can cause or contribute to UI. Although UI associated with such factors has been commonly called "transient UI," for most frail elderly it is a chronic and often progressive condition. It is important to evaluate for such contributing factors because their amelioration may improve UI directly, make UI more amenable to other interventions, and overall improve the patient's (and carer's) quality of life.[288]

The common, treatable, potentially reversible conditions that can contribute to UI in frail older people can be defined by the mnemonic DIPPERS ((Delirium, Infection [urinary tract), Pharmaceuticals, Psychological, Excess fluid (in/out), Restricted mobility, and Stool impaction [and constipation]). This is a useful aid to teach and remember these conditions [289]. Cognisance must be made of the potential to overtreat asymptomatic bacteriuria as apparent infection because of the risk of adverse outcome [290].

III. FACTORS IN MANAGEMENT

1. BACKGROUND

This section highlights the issues that distinguish management of incontinence in frail older people from that of healthier older adults. These include preferences for care, goals of care, determination of costs and benefits, special issues in drug treatment, and issues unique to frail elderly men. They incorporate knowledge of physiological, psychological, sociological, and economic changes associated with frailty and advanced age, and reflect the importance of patient-centred goals and the role of caregivers in this population. These factors provide the context of continence care and should be incorporated into the management of all incontinent frail persons, regardless of the choice of specific treatment.

2. ROLE OF COMORBIDITY IN MANAGEMENT DECISIONS

Many frail older people will have co-existing disability and comorbidity, both of which can influence the clinical presentation and assessment of UI, as well as responsiveness to interventions. Frail older people are not only at higher risk for unintended adverse effects from treatment (e.g., fulminate *Clostridium difficile* colitis from antibiotics used to treat otherwise asymptomatic bacteriuria), but also may realise additive benefits in domains other than UI [291] from UI treatment that is aimed at underlying comorbidity and impairment (e.g., topical oestrogen for irritating urogenital atrophy reduces recurrent UTIs); and a nursing home exercise programme done in the course of toileting improves both physical function and UI [5]). Likewise, management of chronic cough from obstructive pulmonary disease may benefit stress urinary incontinence.

3. DEFINING OUTCOMES FOR TREATMENT

Outcome measures must be fundamentally different from those used in healthy older persons, because of the heterogeneity of this frail population regarding comorbidity, remaining life expectancy (RLE), patient perceptions, personal values, and the involvement of caretakers and proxy decision makers. Unfortunately, intervention studies in the frail elderly remain focused on objective disease related variables and seldom, if at all, take account of these factors. Additionally, comorbidity is frequently used as an exclusion criterion in therapeutic trials. A review of care home residents' views on continence showed that they valued having independent bowel and bladder function, but believed incontinence to be inevitable and intractable. Residents often had low expectations, and declined further evaluation and treatment [292]. There are no data on frail older peoples' expectations from specific treatments.

Although quality of life (QoL) is a key concern for UI in all persons (see Committee 5, Initial Assessment Including Quality of Life), and has special relevance in frail elderly with limited RLE, there are few validated QoL outcome measures applicable to this population. Only one validated UI-related QoL measure is derived specifically from patient-based data among persons older than 65, and these subjects were community-dwelling and relatively healthy [293]. None of the ICI-endorsed UI-related QoL measures have been validated in oldest-old or cognitively and/or functionally impaired persons. Traditional UI QoL domains—e.g.,

impact on IADLs, travel, sexual relations—are often not relevant to frail elderly, and there could be significant "floor effects" for social and role function domains. One alternative QoL domain for frail elderly is social interaction, especially for nursing home residents;[294] an analysis of cross sectional and longitudinal data from over 100,000 US nursing home residents found that prevalent and especially incident UI had negative impact on social interactions, particularly among persons with moderate ADL impairment [294]. An analysis of older Medicare beneficiaries over 65 years of age, and including those over 85, found significant impairment of QoL, in accordance with that found in younger people [295].

The profound question when considering UI outcomes in frail older persons is, "Is complete cure ever possible?" In short, this depends on patient factors, specific treatment(s), and the target outcome. While no geriatrician endorses "ageism" and therapeutic nihilism, research evidence suggests that complete dryness is unlikely for certain frail patients, particularly frail institutionalised persons with severe cognitive and functional impairment. Even "intractable" UI is amenable to interventions that may improve the patient's urinary and bowel function and quality of life [4]. The Frail Elderly Committee of the Third ICI introduced an alternative continence paradigm for frail elderly (**Figure 2**), which subsequently was generalised for all persons with UI [296]. In this paradigm, people with "dependent continence" are dry as a result of ongoing assistance, behavioural treatment, and/or medications. UI would return if the interventions ceased, a situation analogous to chronic disease models [297] such as "controlled hypertension" or "controlled diabetes." Persons with "independent continence" are cured without need for ongoing treatment (e.g., dry after successful anti-incontinence surgery). For patients who are unable to achieve independent or dependent continence, "contained incontinence" should be possible by use of appropriate products such pads, catheters, and appliances (See Committee 20, Management Using Continence Products), thus providing "social continence" or "accepted incontinence."[298, 299] The balance between the degrees of continence achieved may vary as UI severity changes, and are dependent upon patient and caregiver preferences. All of these continence outcomes encompass a common need: to be both realistic and hopeful about UI in frail elders while avoiding nihilism and neglect; maintaining comfort and dignity and preventing avoidable complications of UI.

Although the ICS standardisation document on outcomes in older patients is now over 10 years old, little progress has been made and many of the identified needs still pertain (see Recommendations for Research) [7].

4. ROLE OF REMAINING LIFE EXPECTANCY IN TREATMENT DECISIONS

Remaining life expectancy (RLE) is a key yet often misunderstood concept in treatment decisions for frail older people. RLE is *not* uniformly short in this population; moreover, there is a demographic trend of increasing RLE, with a smaller proportion of persons spending their remaining years living with disability [300]. Evidence shows that many health care professionals will underestimate life expectancy[301]. Reference to actuarial tables produced for insurance purposes is often enlightening. Incorporation of RLE into treatment decisions in urology and gynaecology has been studied only in relation to cancer treatment. Only two studies, both in prostate cancer, examined specialists' ability to estimate RLE. Canadian urologists were more accurate in estimating longer RLE: using scenarios based on actual patient data, 31% were accurate within 1 year, 67% within 3 years, and 82% in estimating greater than or less than 10 years in 82% of responses [302]. Comprehensive Geriatric Assessment can help estimate remaining life expectancy and can help predict treatment-related morbidity and mortality in older men with prostate cancer [303].

Walter and Covinsky [304] developed a graphical tool for estimating quintiles of RLE by age. Medical conditions most closely associated with shorter RLE are class III/IV congestive heart failure, end-stage renal disease, and oxygen-dependent chronic obstructive pulmonary disease. Estimates of RLE are significantly affected by frailty and cognitive impairment [305]. Functional status has a dramatic impact on life expectancy. For example, 75-year-old men and women without limitations have life expectancies 5 years longer than those with ADL limitation and more than 1 year longer than those limited in mobility [306]. Alzheimer's dementia decreases RLE profoundly (by nearly 75%) among older persons who otherwise would be in the top quintile of RLE [307]. Compared to older persons with at most one IADL deficit, persons with more deficits have significantly higher 5-year mortality (with two deficit, adjusted RR 1.46 [95% CI 1.20 – 1.78] ; with three or more deficits, adjusted RR 1.64 [1.26 – 2.14]) [305].

5. PREFERENCES FOR CARE

Because there are multiple treatment options available for frail older adults with UI, and individualised care should be emphasised, obtaining patients' and carers' opinions regarding preferences and goals for care is essential for quality care planning. It should not be assumed that persons with cognitive impairment are unable to make their care preferences known or participate in treatment decisions and all reasonable efforts to help them to do so should be made.

Preferences for toileting and changing were studied in 111 nursing home residents with UI; residents

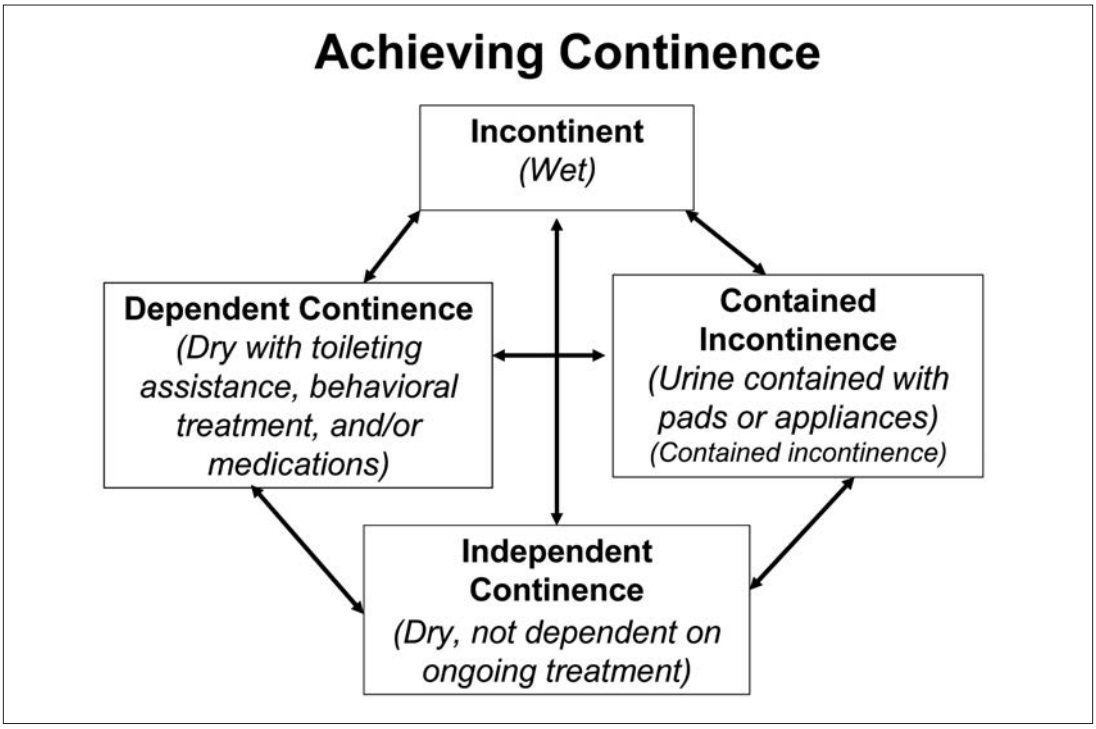

Figure 2. A Paradigm for Continence

preferred an average of 2 pad changes, 1.5 toilet assists, and 2 walking assists more than they actually received, yet even these levels were lower than guidelines recommend, suggesting that residents may have reduced expectations based on their experience [308]. In a second, residents of board-and-care facilities and two nursing homes, their family members, and facility nursing staff were given definitions of and information about five UI treatment options (indwelling catheter, prompted voiding, adult diapers, electrical stimulation, and medications) [309]. Respondents were asked their preferences between pairs of treatment options (e.g., "diapers" versus prompted voiding). Most of the board-and-care respondents were continent, although some were undergoing UI treatment at an outpatient clinic. Patients and family members were evenly divided between "definitely" and "probably" preferring prompted voiding versus diapers. Almost 80% of nursing staff, however, preferred prompted voiding to diapers. Families perceived staff members as unwilling to perform prompted voiding, and some thought prompted voiding was degrading to the resident and that it was bothersome to be asked to go to the toilet frequently. Using a similar method, a German study with 117 geriatric hospital patients (mean age 85; 43% with UI), 72 staff members, and 71 family members, found that most patients preferred diapers (79%), medications (78%), and scheduled toileting (79%) over urinary catheters, and 64% preferred scheduled toileting [310]. When choosing between diapers and medication, equal proportions preferred each option. Patients with greater functional dependence were more likely to prefer catheters, and those with experience with diapers were more likely to prefer medications and toileting. Notably, spouses showed moderate to almost perfect agreement with patient preferences, but those of other family proxies had only slight to fair agreement. In a qualitative study of 25 women with pelvic floor dysfunction living in residential facilities, residents expressed a desire to live with their problem rather than undergo assessment and management, emphasizing the need to include the patient in management decisions at the outset [311].

6. COSTS AND BENEFITS OF UI TREATMENT IN FRAIL ELDERLY

An overall discussion regarding UI-related costs is covered by Committee 22, Economics of Incontinence. The following discusses UI cost issues specific to the frail elderly.

a) Estimating Costs. For the majority of developed countries, the greatest increase in population is occurring in the oldest old, those > age 85. This group has the highest prevalence of UI, and accordingly the increased prevalence of lower urinary tract symptoms will result in higher UI care costs. Such an increase has already been observed between 1992 and 1998 amongst US women aged > 65 [312]. The costs of care for older persons has

been estimated at double that for people under 65, but care for those older persons living in institutions was less than for community dwelling individuals [313]. Likewise, the cost of OAB in five European countries is estimated to rise by one billion Euros between 2000 and 2020,[314] and in the US it has been estimated that by 2030 the greatest increase in demand for UI care (81%) will be in older women aged 60-89 with OAB symptoms [315]. In one US study using of a community managed care population, the presence of OAB and comorbidity doubled the associated costs of UI care [316]. In South Korea, the estimated cost of treating overactive bladder was 117 billion Korean Won (KRW) in 2006 and 145 billion in 2007. The estimated total cost in treating stress urinary incontinence was 122 billion KRW in 2006 and 59 billion in 2007 [317].

Costs can be expressed as direct costs, indirect costs, and intangible costs [318]. Previous estimates have focused on diagnostic costs, treatment (including routine care and pads), and consequence costs (skin irritation, urinary tract infection, falls, fractures, additional nursing home and hospital admissions, longer hospital length of stay). Direct healthcare costs are most often estimated but there is a lack of meaningful research into indirect costs and those related to comorbidity in the frail elderly. Intangible costs have not been considered in these estimates because of their subjective nature and the methodological difficulty of collection and estimation. Much of the evidence for the cost of UI in older persons has been gathered from either epidemiological surveys or analyses of claims from insurance databases; these have often involved many assumptions or complicated formulae to calculate final costs. There is a consistent theme that the cost of caring for older adults with UI will increase, but the estimated magnitude of this increase is variable.

For the frail elderly, especially those in long term care, cost calculation is especially complex. The greatest costs for UI care in nursing homes are by far nursing labour costs [319]. Extrapolated costs for nursing home admission due to UI was $6 billion (2000 US dollars),[30] with institutional costs of UI management and consequences of $5 billion (2000 U.S. dollars). [320] In one small 6-month study, the mean daily cost of UI care, including direct nursing care, indirect nursing overhead, and supplies, was $9.09 (+ $ 10.52) per resident (2003 U.S. dollars) [321]. The costs for UI pads alone in Dutch long-term care have been estimated at 160 million Euros [322]. In an Australian subacute care setting, the costs of daily UI care was $49 AU, with most spent on staff wages [323]. In Canada, researchers found that 1% increase in UI prevalence was associated with an 11-12% increase in costs [324]. The extra nursing time needed to maintain toileting programmes contributes to high costs [325]. Routine garment and laundry costs may be lower than estimated because in practice residents are not changed as often as needed. In addition, for prompted voiding to remain effective, such things as regular refresher education programmes for staff or wet sensors may be necessary, and thus are rarely considered in cost estimates. Moreover, the time period over which the costs and benefit are calculated needs to be explicit because both benefit and costs will change, and patient morbidity and mortality need to be considered. The costs of correcting functional and medical causes of UI are rarely considered. Also, the potential differential in costs across the span of cognitive and functional impairment has seldom been assessed,[326] despite evidence that UI care costs are closely related to the degree of functional impairment [327]. Some surveys suggest that the costs of care for younger community dwelling adults outweighs that associated with the elderly, but there are wide variations of estimates depending upon the population studies [328].

Costs related to caregivers of frail persons with UI living in the community include lost wages, decreased productivity (both within and outside of the home), the additional number of caretaking hours when a frail person develops UI,[329] and the cumulative effect of increased strain and burden, along with any resultant illness. Overall, there is still limited data on costs of UI treatment in other residential (such as assisted living or rest homes) and acute care settings [330 (2004)],costs may vary by access to care. Because so many frail elderly are homebound or live in institutions, they often do not have the same access to the UI therapies as other populations. Their health care providers may be limited to primary care physicians, community nurses, and care assistants or aides with little to no expertise in UI management. Specialist consultation may be minimally available in home or long term care settings, leading to a focus solely on behavioural management and/or containment products. An assessment of a multi-component intervention based upon absorbent products, a structured skin care regimen, and nursing advice on incontinence associated dermatitis revealed that incontinent residents used an average of 5.19 absorbent products, at a mean cost of € 1.79 per day. Following introduction of the intervention, the mean number of absorbent products consumed per day was 2.02 per incontinent patient, at a mean cost of € 0.97 per day [331].

Cost relates strongly to reimbursement, which varies considerably from country to country, depending not only on structure of the health system but special programmes for the aged and persons with UI (see Models of Care below). Within particular countries, there may be further variation based on insurance, co-insurance, drug versus procedure coverage and incentives, access to care, programmes for vulnerable populations, and urban/rural differences.

b) Benefit and effectiveness of treatment. The ability to define the benefit of UI treatment in frail older people is highly dependent on the individual, their caregivers, and the health care system. Out-

comes research indicates that patients value quality of life, which encompasses many domains besides reduction in UI (See Committee 6, Symptom and Quality of Life Assessment). Even cognitively impaired people can still express treatment preferences [310, 332], so it is also possible to evaluate domains of quality of life (e.g., social interaction) [294] and assess treatment satisfaction directly or behaviourally. At the same time, we found no data on the value or utilities frail elderly or their caregivers assign to varying degrees of UI (with or without treatment intervention) versus "dryness." Standard outcomes such as quality adjusted life years (QALYs) may overestimate effectiveness in older people,[333] not just because of potentially different utilities, but because of the altered importance of "years of life saved" in a population with variable and sometimes limited remaining life expectancy.

The need for novel and specific outcomes for use in both trials of UI interventions and clinical care of incontinent frail elderly people continues. Outcomes measured by single item tools of perceived benefit or satisfaction with treatment are unlikely to be generalisable across the heterogeneous older population. It should not be assumed that perceived benefit of treatment can be measured with the same tools across cultures and health systems, unless such tools are sensitive to differences in such things as reimbursement and provision of continence services and supplies. The association between expectations, preferences, and outcomes needs to be prospectively studied in relevant ad representative populations. New approaches and tools to assess UI-specific quality of life in cognitively-impaired frail elderly are needed, as well as better understanding of the interaction between functional impairment and the impact of UI [294]. When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analysed by age and also possibly health status.

7. ISSUES IN DRUG TREATMENT

a) Age-related changes in pharmacology. Specific age-related changes in pharmacokinetics, alteration in drug absorption, distribution, metabolism and clearance, and their potential effect on UI drugs, are shown in **Table 6**. Age-related pharmacokinetic changes are rarely considered in planning the duration of time off previous UI medications, placebo-run in periods, and wash-out periods in UI drug trials in older persons. The numerous factors potentially affecting drug clearance in such patients, as well as previous and/or cross-over compounds, may confound observed drug effects. Age-related changes in pharmacodynamics have been described for benzodiazepines, beta-adrenergic agents, and opiates [334, 335] but there are few available data concerning change, even in these, other than for limited numbers of community dwelling older people.

b) Availability of low dose agents. One effect of the under-representation (if not exclusion) of frail older persons in UI drug studies is a lack of knowledge regarding minimal effective drug doses for this population. The age-related changes in pharmacology noted above suggest that some UI drugs may be effective at lower than standard doses in frail elderly with concomitant decreased adverse effects [336]. This issue is especially relevant for extended-release preparations, which cannot be divided into smaller doses. There are some data supporting the effective use of low dose oxybutynin in older persons, but such studies are exceptional [337, 338].

c) Inappropriate polypharmacy. Approximately 60% of people over age 65 take at least one prescribed medication, and about one-third take more than five prescribed drugs. In addition, many take over-the-counter and naturopathic or herbal agents, with the rate of use varying across countries and cultures. The likelihood of adverse drug reactions (ADEs) and drug interactions rises exponentially as the number of medications increases. This has led to the recommendation in geriatric prescribing to "subtract before adding," to consider whether target symptoms might be due to medications before adding another drug targeting those symptoms. This approach is relevant in geriatric UI, as UI may have been precipitated and/or worsened by medications (see **Table 3**). Changes to existing drug regimens should be considered in the management of UI in all frail older people. The national audit of continence care in the United Kingdom reported that of older adults, mean age 80 years, only 27.5% (2082/7572) had documented evidence of a medication review [339].

d) Adverse drug effects. ADEs are extremely common in older persons,[340] with rates up to 35% among community-dwelling persons aged > 65 in the US [341], and up to two-thirds of long term care residents [342]. In a recent UK study, 59% of ADEs requiring hospital admission involved patients aged > 60 [343]. Factors associated with higher ADEs in the elderly are higher drug doses, age-related pharmacological changes, polypharmacy, comorbid conditions, and the interactions between them and female sex [344, 345]. Older people are at higher risk of ADEs from antimuscarinics because of age, and comorbidity-related changes in muscarinic receptor number and distribution, blood-brain barrier transport, and drug metabolism [346]. Whereas antimuscarinic ADEs in younger persons are bothersome, in the frail elderly they can result in serious morbidity such as sedation, heat intolerance, delirium, and falls.[4]

A major antimuscarinic ADE of concern in frail adults is cognitive decline, yet there is little data about its actual incidence or prevalence. Cognitive effects may be under-detected because they are clinically subtle, neither asked about nor reported by the patient, or mistaken for age-related diseases

Table 6. Pharmacokinetic changes in older persons

Parameter	Age-associated Changes	UI Drugs Potentially affected
Absorption	Minimal quantitative change despite ↓ gastric motility, yet little known regarding effect on slow-release agents	Extended release preparations
	↓ Skin thickness	Transdermal preparations
Distribution	Decrease in lean body mass leads to ↓ Vd /↓T½ for hydrophilic drugs and ↑Vd/↑T½ for lipophilic agents	Lipophilic agents, tricyclic antidepressants
	Decreased protein binding in frail patients with low albumin, leading to higher concentration of free drug	Tolterodine
Hepatic metabolism	↓ Phase I reactions (oxidation/ reduction)	Tricyclic antidepressants
	No change in Phase II reactions (glycosylation)	
	↓ Hepatic blood flow and ↓ hepatic mass, leading to reduced clearance for agents with first-pass metabolism	Oxybutynin Tolterodine Solifenacin Darifenacin
	Stereoselective selectivity in metabolism (hypothetical)	Enantiomers
	Cytochrome P450	Oxybutynin Tolterodine Solifenacin Darifenacin
Clearance	Decrease in renal clearance	Tolterodine

Vd = volume of distribution, T½ = half life

and ageing [347, 348]. Persons with pre-existing cognitive impairment (especially from conditions known to affect central cholinergic pathways) may be at greater risk for this ADE although there are some data to suggest that those with established dementia may not experience cognitive decline following therapy with anticholinergic agents [349]. Actual incidence rates of cognitive impairment with antimuscarinic agents for UI are difficult to estimate because of probable under-reporting [64], the different measures used across studies, failure to specify the measure in published trials, the use of proxy measures (such as quantitative EEG), and differences in psychometrics and clinical relevance of self-report, physiologic, and performance measures of cognition.

Xerostomia is common in older people [350]. A study of 175 acutely hospitalized community dwelling older people (mean (SD) 82 (5.7) years) and 252 outpatients (mean (SD) 77 (5.7) years) found that 63% of the hospitalized elderly and 57% of outpatients complained of dry mouth. Dry mouth was more common amongst those on multiple medications [351]. In general, older people, women and those taking multiple medications are more likely to report the symptom . Antimuscarinics clearly may exacerbate this condition, leading to concerns about deteriorating dental health and a 2011 warning to the Food and Drug Administration from the American Dental Association [352]. Meta-analyses of bladder antimuscarinics show minor variations in the incidence of dry mouth from clinical trials, with oxybutynin associated with the highest prevalence [353]. A recent subcut analysis of a randomized controlled trial of solifenacin, 5mg/day, versus oxybutynin 5mg tid, examined the tolerability of both drugs in subjects under and over the age of 65 years, the study found that dry mouth was no more common amongst those over the age of 65 but was more common and more severe with oxybutynin [354]. In those over 75 years of age treated with 8mg versus 4mg of fesoterodine from a pooled analysis of data from registration trials, dry mouth was more common in the older aged sample [355].

Another antimuscarinic ADE to which the frail elderly may be predisposed is decreased visual accommodation, yet this has been specifically evaluated only in young healthy volunteers,[356] and

drug trials typically report only "blurred vision," without further characterization.

The incidence of increased PVR as an ADE is seldom reported in clinical trials of antimuscarinics for UI or OAB. When it has been reported, the magnitude of increase is seldom of clinical significance. The incidence of acute urinary retention with antimuscarinics in general is low, but it has not been systematically evaluated in the frail elderly. There is no consensus as to what constitutes a sufficiently high PVR to preclude antimuscarinic treatment or to require dose adjustment of an already prescribed agent. If urinary frequency or UI worsens after an antimuscarinic is started or increased, then PVR should be checked because an increased PVR will lower functional bladder capacity and worsen UI. PVR should be monitored in frail older men treated with antimuscarinics who may not reliably report change in LUTS or voiding difficulty. The majority of men with clinically relevant outlet obstruction are excluded from treatment trials and the results of these should be viewed in that light.

***e) Drug interactions*.** Because frail older people take higher numbers of drugs and usually have several comorbid conditions, drug interactions are more common [357]. All antimuscarinic agents for UI will have additive side effects when combined with other anticholinergic agents. Antimuscarinics could potentially alter the absorption of other drugs by slowing gastrointestinal motility.

Drug-drug interactions for oxybutynin, solifenacin, darifenacin, and tolterodine include potent CYP3A4 inhibitors (azole antifungals, macrolide antibiotics, cyclosporin, and vinblastine). Fesoterodine, a prodrug that is converted to tolterodine by non specific esterases, is also dependent upon CY3A4 for its excretion. There is one case report of interaction between tolterodine and warfarin in 2 older patients, [358] which has not been seen in healthy volunteers. Naturopathic/ herbal preparations should also be considered for potential interactions, especially in areas where these agents are used frequently.

There is still uncertainty regarding interactions between antimuscarinic agents for UI and cholinesterase inhibitors (CEIs) used for dementia. There is evidence CEIs can cause or worsen UI from a case report [359] and also a case series of 216 consecutive patients with probable Alzheimer's disease attending a memory treatment centre [360]. In the latter, CEI treatment was overall associated with 7% risk of new UI: the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Further evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [361]. Residents with dementia, newly treated with cholinesterase inhibitors, were more likely to then be prescribed a bladder antimuscarinic than those residents with dementia not given a cholinesterase inhibitor, an example of a geriatric "prescribing cascade."[362] Concomitant use of antimuscarinics (extended release oxybutynin and tolterodine) and cholinesterase inhibitors in nursing home residents was associated with a decline in ADL function in the most functionally able residents but there was no worsening of cognition, probably because the cognitive measure (MDS-COG) was inadequately sensitive. More importantly, there was no case of delirium observed [363]. A recent study in which the primary objective was to assess the cognitive impact of trospium chloride in older people with dementia treated with galantamine over a six month period. The study hypothesised that galantamine in combination would not result in any adverse outcome such as that reported by Sink [363]. 46 subjects with UI and dementia were enrolled, 10 withdrew from the study. No effect on cognition or activities of daily living was detected over the duration of the study. A within group analysis demonstrated an improvement in nocturia and reduction in pad use in this combination group [364]. A small study reported some positive effect of the treatment of UI with propiverine in subjects with probable AD taking cholinesterase inhibitors [365]. Although intuitively illogical, given the opposing pharmacological actions, there seems to be no reason not to use bladder antimuscarinics for older people with dementia. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living.

Drugs also may interact with comorbid conditions (drug-disease interactions), such as diseases that affect hepatic or renal metabolism and clearance, slow gastric motility (e.g., advanced diabetes), predispose to delirium, or are associated with impaired central cholinergic transmission (Alzheimer's and Parkinson's diseases).

f) Potentially inappropriate drugs for older persons. Efforts at quality improvement for older populations have led to the development in several countries of expert consensus guidelines regarding inappropriate drugs for older persons,[366, 367] although the continuing relevance of these guidelines has been questioned and alternative systems suggested [368, 369]. A revised Beers criteria was introduced in 2012 [370]. These guidelines focus on drugs with lower risk-benefit ratios and higher potential for drug-drug and drug-disease interactions, and are used for nursing home regulation and quality performance measurement. The concerns regarding oxybutynin and tolterodine in causing urinary retention have been removed. All bladder antimuscarinics are included because of their risk of causing constipation and darifenacin, fesoterodine, flavoxate, oxybutynin, solifenacin, tolterodine and

trospium are noted with respect to their anticholinergic properties.

8. SPECIAL ISSUES UNIQUE TO FRAIL OLDER MEN.

Although their ranks thin into the ninth decade, men still comprise a significant portion of frail older persons. The prevalence of UI increases in men after age 80, going from about one-third of the rate in women to the same. Over the past ten years, the prevalence of UI in US male nursing home residents aged 65-74 has increased to a greater extent than in female residents (from 39% to 60%, compared with 45% to 59%) [371]. At the same time, frail men are under-represented in UI treatment trials, whether behavioural, pharmacological, or surgical (see also Committee 15: Surgery for Urinary Incontinence in Men). Since the time of the last ICI, the European Association of Urology has summarized their recommendations (2012) for Urinary incontinence in frail/older men and women [372]

This under representation is unfortunate, because results from treatment trials in frail women cannot be directly extrapolated to men for several reasons:

- **Differences in comorbidity:** frail older women have higher rates of functional impairment and chronic disease and geriatric syndromes which may mean that frail men may be more likely to respond to behavioural intervention [373, 374]. For older adults who become incontinent, a composite measure of physical performance (rising from a chair, walking, balance) is a better predictor of UI incidence in men than in women [375].

- **Differences in the relationship between UI and cognition:** one systematic urodynamic study of nursing home residents with UI found a significant association between DO and more severe cognitive impairment in women, but not in men (although power was likely low, as the number of men was only 17) [63].

- **Differences in caregivers:** more older men have living spouses who can provide care, with a potential impact on the risk and type of caregiver burden associated with UI management.

- **Prostate cancer:** nearly all men in their ninth decade have histological evidence of prostate cancer. However, it is not clear that frail elderly men have an increased risk of prostate cancer-specific mortality, especially given that their RLE is primarily affected by comorbid conditions. The need to screen for and treat prostate cancer diminishes with functional status, comorbidity, and RLE [376]. At the same time, more men are living with the sequelae of prostate cancer treatment, particularly stress UI after radical surgery.

- **Benign prostate disease:** the prevalence of histological BPH, BPE, and BOO increase with age, and is associated with LUTS, UI, and DO. In the urodynamic study cited above, 29% of men had BOO and 59% had DO as the predominant cause of UI, versus 4% BOO and 61% DO in women [63].

- **Risk of urinary retention:** because of age-related decrease in detrusor contractile function and increased likelihood of BPE and BOO, it is often assumed that frail elderly men have a higher prevalence and risk of urinary retention. However, this has never been demonstrated. Among NH residents with UI, the prevalence of underactive detrusor was similar in women and men (38% and 41%, respectively), despite the higher prevalence of BOO in men [63].

- **Differences in device usage:** A nationally-representative survey of adults in the US showed that older men were nearly three times less likely than older women to use pads to contain leakage (15% vs. 45%) [377]. Newer data from Scandinavia, where some countries provide absorptive pads as part of the health care benefit, showed that this gap might be narrowing (22% vs. 48%), and that increased functional impairment was associated with greater pad usage [378]. In a survey of patients recruited from family practice clinics in the Netherlands, the gender difference for pad usage by older adults with UI was even higher, with 4 out of 5 women using pads versus 1 of 9 men using pads [379]. Men are also more likely to be users of indwelling catheters, both in the long-term care setting [256] and in the community [378].

- **Differences in medical treatments:** there are medications that might be used by only one gender, or might have distinct side effect profiles. Alpha-blockers in particular should be cautiously considered in men with suspected outlet obstruction from prostate disease, due to their potential side effects of causing orthostatic hypotension. (Grade C) [372]. The interactions of UI and other conditions with regards to orthostatic hypotension and risk of falls merits attention. In a German registry of 3,414 patients with Parkinson's disease, for those with urinary incontinence (716; 21%), orthostatic hypotension was reported for 14% of the men, yet only 9% of the women [380]. On the other hand, for women and men who had strokes and urinary incontinence, both were equally more likely to sustain a fall after stroke, though women were more likely to sustain an injury (OR 1.5) than were men [381].

- **Differences in surgical treatments:** there are gender-specific devices and surgical approaches that do require active management on the part of the patient. In particular, certain frail older men might not be appropriate for placement of an artificial urinary sphincter due to co-morbidity, medications and cognitive and/or functional impairment would not allow for the individual to manage the device on his own (Grade C) [372].

Despite the issues noted above, evaluation and management of UI in most frail older men follows the same roadmap as for frail women (see Algorithm).

9. SUMMARY OF THE EVIDENCE

1. Patients and caregivers have clear preferences for the type of UI management, and they are often discordant between the two groups **(Level 2)**
2. Age-related changes in pharmacokinetics affect antimuscarinic drugs for UI and should be incorporated into treatment planning. **(Level 1-2)**
3. Drugs may be effective at lower doses in frailer compared with healthier older persons **(Level 3)**
4. Polypharmacy increases the chance of adverse reactions to drug therapy. **(Level 1)**
5. Adverse drug events are more common in the frail elderly. **(Level 2)**
6. Drug-drug and drug-disease interactions are common in frail older persons **(Level 1-3).**
7. The economic burden of UI in frail elderly, as well as the cost-benefit, cost-effectiveness, and cost-utility of its treatment, has been incompletely characterised **(Level 4)**
8. The majority of drugs for treatment of overactive bladder remain flagged as potentially inappropriate medications for older people **(Level 3-4)**.

IV. TREATMENT OF URINARY INCONTINENCE IN THE FRAIL ELDERLY

1. LIFESTYLE INTERVENTIONS

As treatable and potentially treatable correlates of and risk factors for UI are determined, interventions that ameliorate their effects have been devised. Several lifestyle interventions have been evaluated in healthier older and younger women, including dieting and medication to help with weight loss, dietary modification, fluid selection and management, and constipation management (See Committee 12, Adult Conservative Management). Although many health care professionals advocate lifestyle interventions to treat UI,[382-385] we did not locate any studies investigating these interventions for the frail elderly. Some of these interventions may be inappropriate for or impractical to use in frail older people, for example weight loss, yet advanced age alone should not preclude use of lifestyle interventions if assessment warrants this. Inadequate fluid intake and dehydration are common in long-term care residents [386] . Dehydration may actually increase the risk of UI in frail elders, because of its significant association with constipation and delirium, both known risk factors for UI [387-389].

a) Quality of data and results.

We located articles addressing lifestyle interventions for UI in older women, but the number of oldest-old subjects was very small, few to none appeared to be frail, and no studies stratified results by age. Two very small older trials and one recent small RCT [390] raise the possibility that increased hydration for incontinent frail elderly may actually decrease UI [391, 392].

b) Summary of the evidence (see **Table 7***)*

1. No recommendations are possible regarding lifestyle interventions for UI in the frail elderly (Level 4)

2. BEHAVIOURAL INTERVENTIONS

Behavioural interventions have been especially designed for frail older people with cognitive and physical impairments that may affect their ability to learn new behaviours or to actively participate in self-care activities. These interventions evolved from classical behavioural change theory, using antecedent and/or consequent conditioning to shape the desired behaviour. Because behavioural interventions have no side effects, they have been the mainstay of UI treatment in the frail elderly [393]. Behavioural

Table 7. Lifestyle Interventions.

Intervention	Authors	Study Design	Sample	Methods	Results
Fluid management	Kincade et al, 2007[383]	Two arm, randomized trial	224 community-dwelling women aged 18 years and older with UI	Self monitoring was individualized and women were counselled on fluid consumption, quick pelvic floor muscle contraction, management of constipation and voiding frequency.	After adjusting for age, hormone status, and race women in the self-monitoring group had statistically significant less urine loss (average 13.3g less urine loss) than women in the wait list group.
Caffeine reduction	Bryant et al, 2002 [946]	Prospective randomized controlled trial	95 consecutive adults with UI coming to two continence nurse advisors	Treatment group received education regarding caffeine reduction; control received no information.	Caffeine intake was significantly reduced in treatment group and frequency and urgency was significantly improved compared to control group one month post intervention.
Multifactorial intervention: food and fluid intake, exercice, prompted voiding	Schnelle, Leung, Rao, Beuscher, Keeler, Clift & Simmons, 2010[390]	Randomized controlled trial	112 residents (average age 86 years) in 12 nursing homes	Prompted voiding, physical activity. mobility endurance, food and fluid ake (i.e., offering fluids and snacks of choice between meals)	Significant improvement in UI frequency and percent of appropriate toiletings. Individuals with lower Mini Mental Status Examination (MMSE) scores responded well to treatment.

interventions, also called voiding programmes, used predominantly in frail adults, ***all of which require active caregiver participation***, include:

- ***Prompted voiding***, involving prompts to toilet with contingent social approval, is designed to increase patient requests for toileting and self-initiated toileting, and decrease the number of UI episodes. It was first used in the 1980s for incontinent nursing home residents [394].

- ***Habit retraining***, which requires the identification of the incontinent person's individual toileting pattern, including UI episodes, usually by means of a bladder diary. A toileting schedule is then devised to pre-empt UI episodes. There is no attempt in habit retraining to alter an individual's voiding pattern [395, 396] ***Timed voiding*** involves toileting an individual at fixed intervals, such as every 3 hours. This is considered a passive toileting programme; no attempts are made at patient education or reinforcement of behaviours, or to re-establish voiding patterns [397]. Other terms used to describe timed voiding are scheduled toileting, routine toileting, and fixed toileting [393, 397]. ***Combined toileting and exercise therapy.*** Functional Intervention Training incorporates strengthening exercises into toileting routines by nursing home care aides (nursing assistants) [398]. Another combination intervention, administered by occupational or physical therapist, involves toileting and mobility skills [399].

Cognitive and functional impairments common in frail elderly persons may preclude the use of some of these interventions. In addition, the context in which care is provided has been implicated in the provision of continence care [400-402]. Staff buy-in for the intervention is considered an important component to behavioural interventions [403]. Consideration of organisational and social factors and interplay among older adults, by the healthcare team, is considered important to implementation of evidence-based practices [404].

Although pelvic floor muscle rehabilitation has not been studied extensively in frail older persons, age and frailty alone should not preclude their use in appropriate patients with sufficient cognition to participate [405, 406]. Similarly, a combined behavioural modification programme involving pelvic floor muscle exercises, bladder training, and information about lifestyle modifications that prevented UI in community-dwelling older women aged between 55 and 80 years[407], could be effective in some frail older women, but we located no studies that reported on promotion or maintenance of urinary continence in frail older adults.

a) Quality of data

Since the last ICI, we identified a metastudy of systematic reviews for bladder training, prompted voiding, habit retraining, and timed voiding using a metastudy framework [396]. This metastudy confirmed our earlier findings. The majority of trials included in the systematic reviews did not determine the type of UI, or sufficiently describe whether comorbidity that possibly contributed to UI was evaluated or treated. Randomised trials in long term care have overwhelmingly depended on research personnel to supervise or conduct the interventions. Studies repeatedly show that, once a trial ends, the long-term care staff rarely maintains the intervention at the same level, if at all. Outcome evaluation is usually limited to "wet checks" (percentage of times the patient is found to be wet on a set schedule) and not UI, and no studies report cure or patient-based outcomes, such as satisfaction with treatment and quality of life. No studies reported impact on caregivers. One trial investigated the effects of prompted voiding, exercise, fluid and food intake on faecal and urinary incontinence. Trained research staff provided the intervention 5-days a week between 7am to 3:30pm for 12 consecutive weeks [390]. Few intervention studies have been conducted with incontinent hospitalised and homebound frail elders. One study with hospitalised older patients found that the main intervention used for urinary incontinence was absorbent products [408]. Incident urinary incontinence at hospital discharge was associated with absorbent product use during hospitalisation [409].

Limitations in many studies include: small samples with low power to detect significant differences; variable terminology and operational definitions making comparisons across studies difficult. Additionally, there is little ethnic or cultural diversity; much data are limited to women, especially in nursing home trials. There is little focus on night-time UI; little consideration as to the psychological impact of toileting programmes on patients and caregivers, and no long-term follow up [393, 410]. Many studies excluded frail older adults with terminal illness, inability to respond to a one-step command, or poor language ability [411-414]. Ethical concerns for human subjects prohibits withholding treatment, thus true "control" groups were nearly impossible to create. Two studies used delayed treatment as controls [413, 414] The frequency of the intervention varied across studies as well, with toileting conducted every two hours over 12-hour, 14-hour, and 24-hour schedules [394].

b) Efficacy (**Table 8**)

Prompted voiding is more effective, in the short-term, than no intervention for improving daytime dryness in nursing home residents and some home care clients (Level 1) [415]. A three-day trial of prompted voiding should be initiated, and the intervention should be continued, but only in those that achieve appropriate toileting rates (the number of times the resident voided into the toilet divid-

Table 8. Behavioural interventions

Intervention	Authors	Study Design	Sample	Methods	Results
Prompted Voiding					
	Palmer, 2005[394]	Systematic literature review	1 quasi-experimental, 1 repeated measures, 1 prospective case series, and 1 systematic (Cochrane) review	Sample, methods, and results were examined to address: is prompted voiding effective in reducing wetness episodes and increasing requests for toileting?	Different prompted voiding protocols were used limiting comparison across studies. Sample sizes were small and mainly white elderly female long-term care residents participated. Staff adherence to the protocol was important to its success. Little evidence exists that self-initiated requests for toileting is increased. Wetness episodes decreased in the short-term.
	Eustice, Roe, & Paterson, 2000 [415]	Cochrane Review update	Nine trials included, N = 674 older adults.	Literature searched according to protocol (all randomized or quasi-experimental studies). Two reviewers evaluated studies for methodological quality; third reviewer proof read the review.	Insufficient evidence to reach firm conclusions for practice. Suggestive evidence exists for short-term benefit from prompted voiding, longer effects are not known.
	Schnelle, Leung, Rao, Beuscher, Keeler, Clift & Simmons, 2010[390])	RCT	112 nursing home residents in 12 nursing homes in USA	Prompted voiding, exercise and mobility endurance, food and fluid intake administered by trained research staff for 5 days a week from 7am to 3:30pm over 12-week period. Frequency of urinary and fecal incontinence and constipation were outcome variables.	Urinary incontinence frequency and number of appropriate toiletings improved.
Habit Retraining					
	Ostaszkiewicz, Chestney & Roe, 2004 [947]938]	Cochrane Review	Four trials included, N = 378.	Literature searched and evaluated per protocol. Trials too heterogeneous to for meta-analysis.	Adherence to habit retraining protocols is difficult for staff. Evidence is too limited to judge if improvements in continence make habit re-training protocols worth investment.
	Nikoletti, Young & King, 2004 [948]	Randomized controlled trial	41 elderly incontinent patients on acute care rehabilitation units in Australian hospitals	Patients in the treatment group were monitored for 72-hours with an electronic device. Patients in the control group received standard habit training. Prescribed voiding times for both groups (control and monitoring group) were developed and continence outcomes were measured.	No statistically significant improvements in self-reported or carer reported UI frequency. Significant reduction in self-reported and carer reported severity of UI in one-month follow up of treatment group. Missing data and problems with using the electronic monitoring device were noted.

Table 8: Behavioural interventions (continued)

Intervention	Authors	Study Design	Sample	Methods	Results
Timed Voiding					
	Ostaszkiewicz, Johnston & Roe, 2004 [420]	Cochrane Review	Two trials met inclusion criteria, N= 298 female subjects with reduced mobility and cognitive impairments.	Literature searched and evaluated per protocol.	Nighttime incontinence was significantly lower in intervention group. Data were considered too few to make a recommendation for or against timed voiding.
Mobility and Toileting Interventions					
	Ouslander, Griffiths, McConnell, Riolo, Kutner & Schnelle, 2005 [5]	Randomized controlled trial cross-over design.	102 residents in four Veterans Affairs nursing home	Research staff implemented the Functional Incidental Training (FIT) intervention four times daily, five days a week for eight weeks.	FIT improved endurance, strength and UI; 64 residents completed the intervention.
	Van Houten, Achterberg & Ribbe, 2007 [399]	Randomized single blinded trial.	57 dependent women with no cognitive impairment with longstanding UI living in 24 long-term care institutions.	Physiotherapists or occupational therapist administered the intervention to the treatment group for an individualized eight-week long programme of mobility and toileting skills.	Intervention group experienced 37.7% reduction in the daily amount of urine loss, but results were not statistically significant.
Prevention Interventions					
	Diokno et al, 2004 [407]	Randomized controlled trial comparing behavioural modification programme (BMP) to no treatment group.	Ambulatory postmenopausal continent volunteer women, N = 359.	Women in BMP intervention group received educational sessions and individualized evaluations of knowledge, adherence and skills.	At 12 months follow up, women in BMP group had significantly better continence status, pelvic muscle strength and displacement score.

ed by the total number of voids) of > 66%, or a wet check rate (number of times the resident was wet when physically checked) of <20% [416]. All others should be managed by check and change. This approach allows prompted voiding to be targeted just to the approximately one-third of residents who are eligible for and respond to prompted voiding, and could help decrease the considerable time and labour costs now used for inappropriate, unsuccessful toileting [417]. The 2005 revised US guidelines for continence care in nursing homes approved this approach as quality care [418]. Prompted voiding with food and fluid management and exercise was effective in reducing UI frequency and increasing the number of appropriate toileting episodes. Those nursing home residents with less cognitive impairment (higher Mini Mental Status Examination scores) showed lower improvement than those with more cognitive impairment [390].

The large majority of prompted voiding trials were conducted in the United States. No data are available about the long-term effects of prompted voiding and there is no evidence relating to the adoption of such programmes in other jurisdictions.

There is insufficient evidence to determine if ***timed voiding*** improves continence (Level 4) [419]. No additional intervention studies on timed voiding were located since the previous International Consultation. Several of the studies included in a systematic review had only female subjects with cognitive impairment, and included use of additional interventions such as antimuscarinic drugs (propantheline or flavoxate), staff education, bedside commodes, and absorbent products.

There is insufficient evidence to determine if ***habit retraining*** improves continence (Level 4) [420, 421].

Functional Incidental Training (FIT) incorporates endurance and strengthening exercises (e.g., sit-to-stand, bicep curls) while an aide conducts prompted voiding with a resident. FIT significantly improves physical endurance and UI (measured by wet check). Across several different long-term populations, FIT led to a 38% reduction in daily urine loss [5, 398, 399]. However, all FIT efficacy trials relied on trained research nursing staff, FIT costs more than usual care, and it may be difficult to implement in nursing homes without changes in existing staffing levels, limiting its generalisability [5, 422, 423].

Operant behavioural strategies have shown some effectiveness in improving UI in long-term care residents (Level B) [394, 395]. The underlying principle is that behaviour is modified by its consequences, even in frail adults [424]. A balance must be struck, however, between encouraging self-care activities and patient preferences for care and functional ability, on-going evaluation of the frail older person's status, and treatment effectiveness.

c) Summary of evidence

1. Prompted voiding is effective in the short-term treatment of daytime UI in nursing home residents and home-care clients when caregivers comply with the protocol **(Level 1)**.
2. Prompted voiding is ineffective and should not be used for people who need the assistance of more than one person to transfer; these people should be managed with "check and change." **(Level 1)**.
3. Prompted voiding should not be continued in eligible persons who have less than a 20% reduction in wet checks **(Level 1)** or toilet successfully less than two-thirds of the time after a three day trial; these people should be managed with "check and change." **(Level 1)**.
4. Interventions combining toileting and exercise, decrease wet checks and improve endurance in nursing home residents, including those with psychiatric disease **(Level 1)**.
5. Interventions combining prompted voiding, exercise, fluid and food intake interventions improve UI frequency and appropriate toileting **(Level 1)**.
6. It is uncertain whether habit retraining reduces UI in frail older persons **(Level 4)**.
7. It is uncertain whether timed voiding reduces UI in frail older persons **(Level 4)**.
8. There are no proven interventions to reduce night-time UI in frail older persons **(Level 4)**.
9. There are no proven interventions to reduce the incidentce ofUI in hospitalized frail older persons **(Level 4)**.

d) Interventions with caregivers and long term care staff

Acute care patients have preferences for urinary incontinence treatment that is significantly discordant to hospital staff. For example, nurses and physicians preferred scheduled toileting over diapers more than did the patients [310]. The authors suggested that communication about treatment preferences should occur.

3. INTERVENTIONS WITH LONG TERM CARE STAFF AND CAREGIVERS

Many frail elderly people rely on family, caregivers, or residential and/or nursing staff for toileting assistance and personal care. These carers may not be available as frequently as necessary for the frail elder to maintain continence, and even if available they may not be able or willing to provide the needed assistance. Research has shown that the frequency of toileting assistance actually provided in US nursing homes is too low to maintain continence [425, 426]. There is dissonance between

nursing home surveyors, nursing staff, and nursing home administrators' knowledge and beliefs about UI and its management, which may be an important barrier to effective UI care [427]. A number of studies suggest that nurses in acute and long-term care settings continue to provide urine containment interventions rather than promoting continence [249, 250, 253, 255-258, 428-432]. For example, 99% of residents with UI in one study facility wore absorbent products and only 3% had received UI treatment [433]. Moreover, nursing staff preferences for UI management (toileting) often conflict with those of residents and their families' patient treatment preferences (medications and garments) [309, 310, 434]. Acute care patients' preferences for urinary incontinence treatment also differ from hospital staff preferences [310]. For example, nurses and physicians preferred scheduled toileting over diapers more than did the patients [310]. The authors suggested that communication about treatment preferences should occur.

In long term care, a two-pronged behavioural intervention to UI care, one geared towards the resident and the other geared towards staff members, appears necessary [435-437]. Nursing assistants play a key role in the success of behavioural programmes, and organisational schemes need to be devised to create incentives for them to keep residents continent [438]. Direct care providers will be unlikely to implement programmes unless residents and their families advocate for them [439]. This advocacy, however, appears unlikely if, based on their experiences, nursing home residents have reduced expectations and do not anticipate receiving sufficiently frequent and prompt toileting, and therefore express no desire for more frequent toileting [426]. One documented barrier to toileting programmes in long term care is their labour intensity. Bladder training programmes are considered one of the three most time consuming activities for long-term care staff [321].

A number of approaches have been trialled in an attempt to promote continence and to improve the management of incontinence care in long term care facilities. One involves a specialty practice exemplar model to improve continence care in long-term care, with a nursing faculty member with expertise in the assessment and treatment of UI having a clinical practice in a facility. Graduate nursing students, working with this individual, focus on the Minimum Data Set Resident Assessment Protocol for UI. Assessment and treatment skills ultimately are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [440]. Quality assurance programmes using incontinence quality indicators have also been proposed [441]. A clinical leadership model in the sub-acute setting in Australia used a staff empowerment and mentorship model to make evidence based changes related to continence care during the patient's stay and on discharge [442]. The effectiveness of clinical leaders may depend on a number of factors including, but not limited to their educational preparation for the role; the extent to which they feel supported; and; maintenance of the role (i.e. succession planning).

a) Quality of data.

Several authors point to the difficulty of conducting research in long-term care settings [435, 436, 443]. Factors such as staffing ratios, changes in administrative and regulatory policies, and fiscal issues are beyond researchers' control. Several investigators report that staff compliance was less than total, and some experienced problems with staff training. For instance, in one study several staff members did not attend group-training sessions and needed one-on-one training, and other staff members did not perform the protocol or document its use, especially when staffing levels were low [436]. Little staff intervention research to improve continence in older persons has been conducted in the acute-care setting.

b) Results

1. Interventions With Long-Term Care Staff

A recent systematic review of the management of incontinence and promotion of continence in older people in care homes concluded that use of incontinence pads and toileting programmes comprised the most common management strategies, and assessment processes were inconsistently used [444]. Assessment protocols are a key first step in the process of identifying residents' individual continence care needs. A number of assessment tools have been developed for this purpose. They include, but are not limited to:

- the Resident Assessment Instrument/Minimum Data Set (RAI/MDS) used in US nursing homes;
- the 'Continence, History, Assessment, Medications, Mobility, Plan' (CHAMMP) tool, developed to support the use of the RAI/MDS [445],
- the 'Capital Health Authority (CHA) Screening Tool' for use within community and clinical settings in Canada, [446], and
- the Continence Assessment Tools for Residential Aged Care' for use within Australian long-term care settings [447].

Toileting assistance programmes also play a central role in optimising continence for frail older adults in long term care settings. One group of researchers investigated the effect of a scheduled toileting programme on the incidence of nursing home staff injury, using a quasi-experimental design using a 75 bed unit and a similar comparison unit [448]. Fifty residents in the intervention unit were selected to participate based on an assessment indicating their eligibility for a toileting pro-

gramme. Mechanical lifts were purchased for the intervention unit in anticipation of an increase in toilet transfers. Regular toileting increased from 12% pre-intervention to 67% in the intervention and 26% in the comparison unit. Staff injuries related to toileting did not increase in the intervention group, and the staff also noted less resident agitation. A pre-post test trial of toileting assistance programmes involving 153 elderly residents in Japan also reported improvements in residents' continence status following a multifaceted intervention. Managerial support was key to the success of the intervention, as was the involvement of a clinical leader on each unit to oversee the protocol [449].

Although toileting assistance programmes are effective in reducing incontinence rates when implemented, and in-service classes on UI may change staff knowledge and attitudes about UI, in-service-classes alone do not improve resident toileting. In one study, only 70% of toileting assists were completed [435]. The authors noted that staff members believed that toileting was "not worthwhile" for some residents. In a randomised study using advanced practice nurses (with post-graduate training) to work with staff to implement evidence-based protocols, residents in the intervention arm experienced significantly greater improvement in UI compared with those receiving usual care [450].

In response to knowledge deficits, some researchers have developed and trialled education and awareness-raising strategies, designed to enhance knowledge, that would subsequently lead to improvements in practice that would, in turn, enhance the quality of continence care in long-term care [205, 208, 220, 403, 451-455]. For example, a number of countries have established post-graduate and continuing education courses that prepare nurses and physiotherapists to address the broad spectrum of continence issues.

However, the association between improved knowledge and improved practice is not straightforward. Some researchers reported improvements in knowledge that did not translate into improvements in practice [205, 220, 453]. Cognisant of this dilemma, Henderson and Kashka [212] examined the association between knowledge, beliefs, attitudes and practice about incontinence in a sample of 126 nurses from hospital, home health and long-term care settings in Texas, USA, using a tool titled 'the Urinary Incontinence Scales'. Using a multiple regression analysis, they found that although participants' knowledge and belief were positively associated with their self-reported practice, attitude alone had a direct effect on self-rated practice [212], thus highlighting the need for educational strategies that address the effective behaviours associated with caring for incontinent persons. In response to this finding, and to greater calls for UI content in nursing curricula, as part of a larger educational programme on rehabilitation, one researcher designed a novel six hour experiential learning activity for nursing students to experience wearing an absorbent incontinence product [452].Twenty-one senior nursing students volunteered to participate in the pilot trial. Using the Urinary Incontinence Scales to measure participants' attitudes, beliefs, knowledge and practice, the researchers reported a post-test median increase of < 1% in attitude scores; 3.6% in belief scores; 4.4% in knowledge scores, and 47.6% in practice scores.

Given the longstanding challenges surrounding the uptake of evidence into practice, in 2005, Stolee and colleagues conducted a qualitative study to explore the factors within the work environment that impacted the effectiveness of continuing education. Data were derived from a series of focus groups with a sample of 35 staff and managers of long term care facilities, in Ontario, to collect information about facts affecting transfer of learning. This information was collated and a Delphi approach was used with 34 experts in long term care to validate and refine the list of factors. The need for managerial support was ranked as the most important factor. This was followed by: sufficient resources to implement new learning; the learner's belief in the practicality of training; integration of the learning into ongoing practice; staff feeling valued; on-the-job reinforcement of learning; knowing change of practice is supported; seeing benefits of new approaches; and attitudes toward elderly people [456]. Whilst all of the above mentioned resource factors are important to optimise evidence-based continence care practice, a number of researchers draw attention to the need for theory to inform improvements in the quality of care [395, 457-462]. However, many translation of research into practice models for LTC rely on the belief that usual care staff are able to implement better care if they know what to do and are properly motivated [463]. One of the key steps in the process of translating evidence-based knowledge into practice is to identify potential barriers to change [464].

Research literature on UI in long-term care identifies extensive barriers to UI care [433, 463, 465]. A staff survey revealed that nursing assistants believed prompted voiding was very helpful to residents in reducing the frequency and volume of incontinent voids, but that inadequate staffing, staff work load, turnover, and absenteeism were significant barriers to prompted voiding. They believed that increased numbers of staff, improved communication, ongoing education, and alternative modes of care delivery were necessary to facilitate prompted voiding. Overall, staff believed toileting programmes improved resident quality of life but the realities of long-term care made them difficult to implement [466]. Nursing assistants believed that UI was a normal part of ageing and that nothing could be done for it, 99% of residents with UI in the study facility wore absorbent products and only 3% had received UI treatment [433].

A further challenge to continence care in long term care is the fact that differences may exist between documented care, reported care, and actual care. For example, when staff perceptions regarding completed toileting assistance were compared to research staff observations, staff over-inflated the percent of toilet assists they completed (stating 80-90% when the observed was 70%) [467]. Staff members also believed that residents were happier with a prompted voiding programme, yet only 52% thought the programme improved residents' continence. In another study, long-term care facility residents reported a mean of 1.8 daily assists to the toilet, regardless of whether they were on a toileting programme or not [439].

Another approach to translating evidence based protocols into practice, to enhance continence care for individuals living in long term care, involves the use of quality management programmes. Schnelle and colleagues tested a computerised quality management programme for prompted voiding in a convenience sample of 85 residents in eight US nursing homes [468]. Each facility was asked to identify staff members for the following roles: main contact person; quality control specialist; two licensed personnel who would conduct UI assessments; and two nursing/health care assistants who would implement the prompted voiding intervention. Information on the computer system included UI assessment and residents wetness rates. Research staff monitored the database and provided the nursing staff feedback by telephone consultation. The programme was effective in improving dryness for six months while research staff monitored the database, but only one facility continued the programme after the research ended [465]. The researchers noted that current incentives for nursing homes to maintain UI management systems are insufficient.

One disincentive that needs to be addressed, at a resource and policy level, is the fact that toileting assistance programmes require statistically significantly more staff time than the practice of checking and changing residents' pads. Engst and colleagues reported that the latter practice was four minutes duration for residents who were soiled and in bed, compared to six minutes to provide residents with toileting assistance [448]. Schnelle and colleagues have also reported a cost disincentive for maintaining residents' functional ability to walk to the toilet [469]. In an analysis of the cost and time involved in changing residents' pads, compared with implementing prompted voiding, or a functional improvement program (FIT), these researchers found that changing residents pads involved an average of 5.5 minutes, compared with 7.7 for prompted voiding and 13.7 for FIT [398]. Although FIT resulted in significantly better outcomes for residents in terms of their strength, mobility and continence, it relied on a staff to resident ratio of one aide to five residents [470]. These resource costs may however be offset over time by improvements in residents' functional abilities. Another cost minimisation strategy is to identify and target residents who are most likely to benefit.

As reduced mobility is a major risk factor for incontinence, further attention should be directed toward developing, implementing and evaluating interventions that increase residents' functional skills, or at the very least, minimise their functional decline, and prevent falls. van Houten and colleagues [399] report reductions in the daily loss of urine for elderly dependent women randomized to an 8-week individualised training programme of mobility and toileting skills. Two systematic reviews affirm the value of rehabilitation and falls minimisation strategies for frail older adults in long-term care [189, 471]. Given the association between the use of restraint and incontinence in long-term care settings, interventions designed to prevent and reduce restraint use should also be adopted.

Interventions for continence care in frail older adults should also aim to minimise the incidence of incontinence-associated dermatitis (IAD). Palese and Carniel [472] describe a three-phased multi-intervention incontinence care programme in a long-term care facility in Northern Italy that reduced the incidence of IAD, and the number, and cost of absorbent products. The intervention consisted of an assessment process, the introduction of new absorbent continence aids, a structured skin care regimen and advice and education from a Continence Nurse Advisor. To this end, it is important to use tools that help staff differentiate between IAD and pressure ulcers such as the Pressure Ulcer Classification (PUCLAS) education tool [473].

2. Interventions To Manage Night-Time Incontinence In Long-Term Care

Night-time sleep in long-term care residents is often fragmented and disrupted [474-479] and much of this fragmentation and disruption is caused by noise, light and incontinence care routines [476-478]. There is some evidence to suggest residents may spend long periods of time in bed overnight (returning to bed after dinner about 6.30pm and waking between 0600-0700hrs), and staff conduct pre-scheduled rounds to reposition residents and change their pads [478]. In this study, although senior staff stated that such rounds were conducted every two hours during the night; the number of observed rounds was 0.3 - 4.5 per resident [478].

Interventions that have been trialled in an attempt to enhance the quality and duration of sleep for residents' with incontinence include:

- a daytime physical activity programme [480]
- a daytime physical activity programme combined with a night staff behaviour programme aimed at reducing noise, light and sleep-disruptive care practices [481].

- a two or four hourly incontinence care schedule based on an individualised assessment of each resident's skin health [482].
- an individualised incontinence care routine combined with feedback to usual care staff about methods to reduce noise levels [483].
- a two or four hourly prompted voiding schedule based on an individualised assessment of each resident's skin health [484].
- a four or eight hourly pad changing regime based on an individualised assessment of each resident's skin health [485].

The combined findings of these trials suggest that continence care at night in long-term care settings can, and should be individualized based on an assessment of residents' skin health; their ability to spontaneously move in bed; and on their sleep/wake status. It should also be based on an assessment of residents' preferences. Whilst toileting assistance should be available to residents' during the night as well as day, one study suggests that prompted voiding is not effective or well tolerated at night. The researchers concluded that 'in general, incontinent nursing home residents are not responsive to prompted voiding at night, even when the prompts are carried out so as to be minimally disruptive to sleep [486]. Clearly, further research is needed about residents' preferences for nighttime continence care.

One of the main reasons for residents' sleep disruption is due to the time-honoured practice of waking residents with incontinence to check their continence status and to reposition them in order to minimise the risk of pressure ulcers. The Agency for HealthCare Policy and Research Agency, (now the Agency for Healthcare Research and Quality) identified incontinence as a risk factor for pressure ulcers in its now archived Clinical Practice Guideline for Pressure Ulcers in Adults (1992). The guideline also recommends that 'any individual in bed who is assessed to be at risk for developing pressure ulcers should be repositioned at least every two hours if consistent with overall patient goals'. However, advances in the design and absorbency of pads and of pressure relieving devices, may mitigate the number of times residents' need such care. Fader and colleagues randomly assigned 81 residents of residential homes in the UK to either a four or an eight hourly nighttime pad changing regime [485]. They found no evidence that the less frequent pad changing regime had an effect on skin erythema or on skin pH. However, residents on the less frequent pad changing regime had wetter skin (P=0.01; 95% CI: 2.89-21.39) and five residents developed grade 2 ulcers. Further research on this issue is warranted to guide practice.

3. Interventions With Caregivers

Family caregivers of frail elders with UI report a high level of physical fatigue (70%) [487]. This is particularly so for family caregivers of individuals with UI and dementia [488]. Upton and Reed conducted a qualitative study on caring in the context of incontinence and dementia and reported that the relentless nature of incontinence was psychologically draining and demanding on caregivers. This was particularly the case if the care-recipient had challenging behaviours; in which case, incontinence typically presented as a behavioural problem [488]. Similar findings were reported by Hutchinson and colleagues [489] who used an ethnographic design, to examine the range and variation of toileting problems and management strategies used by family and employed caregivers of individuals with Alzheimer's' Disease (AD). The researchers reported that toileting emerged as a complex event with many stages and as a task that was unaesthetic and unpleasant for caregivers and clients. It also occasionally triggered a severe emotional response from the person with AD. Caregiver's responses were variable, however, some read cues and interpreted toileting behaviours. These findings from qualitative research draw attention to the complexities of managing incontinence in the context of dementia.

Family caregivers report embarrassment and social isolation as their most frequent emotional responses to UI, and a need for information about resources.[487] In a small pilot study, caregivers at home felt that the requirements of a behavioural protocol were more than they could manage [490]. However, in contrast to long term care staff, family caregivers were adherent with prompted voiding 89% of the time, and 93% were somewhat or completely satisfied with the decrease in UI [491]. Using data from a cross-sectional survey of the Dutch national prevalence measurement of Health Care Problems, Du Moulin and colleagues found that more than half incontinent older adults (mean age 80) living at home and receiving home care services, had no diagnosis of the type of incontinence. The most common management strategy, regardless of diagnosis, was the use of pads [492].

c) Recommendations for practice

- Family, caregivers, or residential and/or nursing staff dealing with different levels of UI (mild, moderate, catheter managed) have different educational needs and require different levels of support.
- Interventions to support family caregivers of individuals with UI may need to be adapted to suit formal carers or staff in long-term care so that they accommodate the organisational context.
- a one-size fits all approach will not accommodate the diverse needs of older people in long term residential care.

- Interventions or approaches to caring for an individual with UI and cognitive impairment need to be tailored to the person's unique abilities and disabilities.
- Interventions for UI should be theory-based, multi-component, interdisciplinary and person-centred.

4. PHARMACOLOGICAL TREATMENT

a) Background

This section deals with the management of the frail elderly. The pharmacological management of UI in healthy older persons is discussed in Chapter 10, Drug Treatment. Specific treatments for bladder outlet obstruction and associated LUTS in frail elderly men are outside the scope of this chapter; special issues in the care of frail older men with UI are discussed above.

Frail persons with UI should be considered for drug treatment only following a comprehensive evaluation of remediable causative factors, and if they are appropriate for and have had a trial of behavioural and lifestyle interventions. Drug treatment should not generally be used for persons who make no attempt to toilet when aided, become agitated with toileting, or are so functionally and cognitively impaired that there is no prospect of meaningful benefit. Even so, a recent study of US nursing home residents suggested that only a small proportion of incontinent residents potentially suitable for drug therapy ever received it [493].

b) Quality of data

Since the last ICI we located a further 13 randomised placebo controlled trials (RCTs) of antimuscarinic medication, involving subjects over the age of 80. As before, the majority of studies addressing frail older people are of only modest quality, reflecting their vintage. The available RCTS were predominantly done in the US, with a small number in Europe, the UK, Germany, Taiwan and Japan. . All focus on antimuscarinic treatment of presumed urgency UI. UI diagnosis was overwhelmingly symptom-based; only three studies included urodynamic evaluation. There have been two large studies of older people, one in Europe and one in the US; the latter targeted at frail older people identified by the VES-13 [494] For most studies however, it was impossible to identify whether subjects were frail, even though the spread of co-morbid condition and co-existing medication suggests a representative sample of community dwelling older people except where the study was performed in an institutional environment, in which it is reasonable to assume a high prevalence of functional and cognitive dependence.

The methods of blinding and randomisation in RCTs were seldom specified. Other than those conducted by the pharmaceutical industry, most studies were generally small and potentially under-powered, and others lost power because of high dropout rates due to illness and death (inevitable in trials with frail elderly persons). Because of these issues, many RCTs provide only Level 2 evidence. Some larger studies in older persons without clear frailty are included here, to recognise an increasing emphasis on including older persons in drug trials.

Precise descriptions of the target population - including the definition of "frail persons" and a comprehensive description of the degree of cognitive and functional impairment - were usually absent. Although some investigators included information on patients' functional and cognitive status, as well as comorbid conditions, the descriptions were often only qualitative, and none addressed these issues adequately in the analyses. Explicit, concurrent behavioural therapy was used in most nursing home studies, yet may have occurred in many others although these are usually specifically prohibited in trials managed by the pharmaceutical industry. Combination therapy and high comorbidity could have attenuated differences between drug and placebo, and make it difficult to compare results directly with studies in healthy older and younger persons. Outcomes in care home studies were universally assessed by UI frequency (pad-weighing, bladder diaries, and wet-checks), and none reported quality of life outcomes.

In at least six studies, investigators treated subjects with "urinary tract infection" (usually defined as pyuria and bacteriuria in the presence of UI) before initiating antimuscarinic therapy, and one study excluded such subjects. In another, investigators treated urogenital atrophy with oestrogen prior to antimuscarinic therapy, possibly leading to an additional amelioration of symptoms. However, no other reversible causes were addressed prior to entry or randomisation in most studies.

The generally low quality of these trials reflects not just study design, but the larger issue of the difficulty of doing large, prospective intervention trials in frail populations. Moreover, UI in frail elderly is universally a multifactorial problem involving a large number of factors beyond the bladder. Thus, the expectation that drug therapy targeted solely at urodynamic DO or SUI would markedly improve/cure UI in this population is unlikely to be realised. Additionally, the reporting of adverse events relevant to managing older people appears to be deficient. A meta-analysis examining the measurement and reporting of CNS outcomes showed that, 77% (242/314) of eligible trials identified, neither measured nor reported CNS outcomes. Of the remaining 23%, it was difficult to ascertain whether CNS adverse events were systematically measured or spontaneously reported. Only one of 72 trials objectively measured changes in cognitive performance. Age-stratified analyses of CNS outcomes from trials

in adults aged 65 and older with overactive bladder were found in only eight publications [495].

c) Results

Results from randomised trials are summarised in **Table 9**; the following sections discuss specific drugs in detail.

1. Oxybutynin

The majority of older studies in frail older persons used immediate-release oxybutynin (oxybutynin-IR). There are two studies of extended release oxybutynin (oxybutynin-ER), one examining cognitive effects in nursing home residents with dementia and urgency UI,[496] and the other involving community-dwelling women over age 65 [497] Published trials of the efficacy of transdermal oxybutynin included subjects up to age 100 and in institutional care settings, but did not stratify results by age or comorbidity [498].

The pharmacokinetics of oxybutynin-IR and its active metabolite, N-desethyloxybutynin, in one study tended to show greater plasma levels and bioavailability with increasing frailty and age.[499] Another found peak levels in 21 octogenarians similar to those reported in young normal males (12.5 ng/mL vs. 8.9 ng/mL) [500]. A study of the pharmacokinetics of transdermal oxybutynin showed no significant difference in plasma levels between young and old (up to 77 years) subjects [501].

- **Efficacy.** An early, small (n=15) trial of **oxybutynin-IR** and habit training in long-term care residents showed no effect on UI episodes.[502] However, in a subsequent and larger study in long-term care residents study who had failed prompted voiding alone, the addition of titrated oxybutynin-IR resulted in a significant but modest reduction versus placebo.[503] Wet-checks decreased from 27% at baseline to 20% on drug and 24% on placebo, leading the authors to conclude that the improvement was not clinically significant, especially given the continuing requirement for nursing intervention. However, their *a priori* definition of "clinically significant improvement" (one or fewer episodes of daytime UI) was achieved by 40% on drug but only 18% on placebo ($p<0.05$). The dose generally associated with improvement was 2.5 mg three times daily. In another controlled study of UI in long-term care residents (n=24), there was little effect of oxybutynin-IR 5 mg twice daily given for 8 days, but all residents were toileted 10 times daily, and the dose may have been too high and given too infrequently.[504] In a randomised two month trial in frail community-dwelling elderly, oxybutynin-IR plus bladder training was subjectively and objectively superior to bladder training alone in improving urinary frequency (95% CI 6-27 fewer voids per 2 weeks) but not UI.[505] Insufficient information was available regarding a Japanese study in 75 "elderly" patients to assess the population and outcomes.[506] A study in 416 community dwelling older persons, including the fitter elderly, found 68% reported a partial or complete symptomatic cure with 2.5 mg three times daily; 30% of subjects experienced ADEs, but only 10% withdrew because of them.[337]

Only one of the two identified RCTs in frailer older people examined the efficacy of **oxybutynin-ER**. [497] The other examined the effect on cognition [496] and is discussed below. No published RCTs of **transdermal oxybutynin** in the frail elderly were found, and *post hoc* sub-analysis of efficacy in subjects over the age of 65 has been published only in abstract form. In a small Japanese case series (n=13, mean age 75) in persons with urgency UI and cystometric DO, **intravesical oxybutynin** caused no significant increase in mean bladder capacity one hour after installation of 5 mg oxybutynin at pH 5.85. [507] In four patients who continued twice daily installation, two had UI "disappear" and one "markedly decrease" (duration until effect not noted). No patient developed an "increased PVR" (not defined).

- ***Predictors of efficacy.*** Predictors of efficacy were studied in one study in persons with urgency UI and urodynamic DO (n=41, mean age 79) treated with 2-4 weeks of oxybutynin-IR (5-15 mg/day).[508] Factors associated with baseline urine loss (by pad weighing) were impaired cognitive orientation (on the Cambridge Mental Disorders of the Elderly Examination), number of daily voids, and fluid intake. Persistent urine loss after treatment was associated with impaired orientation, reduced sensation of bladder filling during cystometry, and most significantly global cortical under-perfusion on single photon emission computed tomography scan, suggesting that cortical factors are the main determinant of the severity of urgency UI before and after oxybutynin. In a study of 80 older patients (mean age 74), patients with dementia (by Hasegawa dementia scale) were less likely than cognitively intact patients to report subjective improvement in UI with antimuscarinic agents, despite similar objective outcomes.[509] However, these results could reflect treatment-associated cognitive effects.

- ***Adverse reactions.*** A comparative sub-analysis of oxybutynin IR versus solifenacin in subjects below or above 65 years of age (mean 71 years in >65 year age group) showed subjects receiving oxybutynin IR at a fixed dose of 15mg/day were over eight times more likely to have dry mouth than were those receiving solifenacin 5mg /day, irrespective of age (OR 8.88; 95% CI 3.91–20.17) [354] (Note that the median dose of oxybutynin used in clinical practice is 5mg bid). A comparative study against once daily trospium chloride conducted in subjects up to the age of 91, but with mean age 61 (SD 12.4) years showed oxybutynin to be non- inferior to trospium in terms of resolution of UI episodes, but was associated with twice the incidence of dry mouth (7.7% versus 4.1%) [510].

Table 9. Evaluable drug trials in frail older people (see text for explanation)

Drug	Study	Design	Setting and pts	Results	Comments
Oxybutynin	Minassian 2007 [497]	prospective randomized 12-week, open-label study to investigate the effectiveness of extended release versus immediate release oxybutynin	community-dwelling female population over the age of 65	72 women (23%) were enrolled over 34 months (33 in the immediate release group, and 39 in the extended release group). The study was stopped prematurely	
	Sand 2007 [949]	randomized, open-label, assessing health-related quality-of-life (HRQoL) and safety with oxybutynin transdermal system (OXY-TDS)	community-based study of 2878 participants aged >/=18 years who had been given a diagnosis of OAB.	There were clinically meaningful and statistically significant improvements in nine of 10 domains in KHQ at the study end; the greatest improvements were in Incontinence Impact (-13.5), Symptom Severity (-12.4), and Role Limitations (-13.3).	No age stratification, not obviously a frail element to the study sample
	Lackner 2011[950]	efficacy of oral extended-release oxybutynin for urge urinary incontinence	4 week trial in 50 older female nursing home residents with mild to severe cognitive impairment.	both groups achieved a significant median decrease in mean urinary incontinence episodes and urinary frequency at 4 weeks (P = .01-.05).	No between group differences in any outcome
Solifenacin	Herschorn 2011[354]	randomized, multicentre, prospective, double-blind, double-dummy study to compare the incidence and severity of dry mouth and other adverse events in patients ≤ 65 years and >65	132 subjects with ≥ 1 urgency episode per 24 h, with or without urgency incontinence, and ≥ 8 micturitions per 24 h for ≥ 3 months.	incidence and severity of dry mouth and other adverse events with solifenacin were similar between younger and older patients. solifenacin 5 mg/day was associated with fewer episodes and lower severity of dry mouth, and a lower discontinuation rate	adverse events were evaluated in subgroups of patients ≤ 65 years and >65 years. No stratification otherwise

Table 9. Evaluable drug trials in frail older people (see text for explanation) (continued)

Drug	Study	Design	Setting and pts	Results	Comments
Darifenacin	Chapple 2007 [951]	RCT assessing efficacy, tolerability, safety and quality of life in 400 subjects mean age 72 years	randomized (2:1) to 12 weeks of double-blind treatment with darifenacin 7.5 mg once daily for 2 weeks, then optional titration to 15 mg daily or placebo with sham titration	Mean urgency urinary incontinence episodes decreased significantly with both darifenacin (-88.6%) and placebo (-77.9%; p > 0.05), QoL assessments revealed significant improvements with darifenacin versus placebo	Unsure re “frailty” of sample
Fesoterodine	Wagg 2010 [527]	RCT, efficacy and PRO comparing fesoterodine to placebo	794 community dwelling men and women >65 (1/3 >75)	improvement in urgency episodes (-1.92 v -3.47, p<0.001), micturitions (-0.93 v -1.91, p<0.001), nocturnal micturition (-0.27 v -0.51, p=0.003), severe urgency episodes (-1.55, -2.40, p<0.001), and incontinence pad use The response on the treatment benefit scale, OAB-S, PPBC, and UPS significantly greater in fesoterodine group	Community dwelling sample, including very elderly, no assessment of frailty, largely cognitively intact
	DuBeau 2012 [528]	12 week double blind, placebo controlled study	562 people of mean age 75 years fulfilling definition of vulnerable elderly	mean reductions in UUI episodes at week 12 versus placebo -0.65 (0.21), p<0.0018) and 24h micturition frequency -0.84 (0.23), p<0.0003)	

Cognitive side effects from oxybutynin have been reported in older persons. In one case series, four older men with Parkinson's disease and mild-severe cognitive impairment developed confusion, psychosis, hallucinations, behavioural disturbance, and/or paranoia after receiving oxybutynin-IR (5-15mg/day), which resolved when oxybutynin was stopped.[511] Of note, each patient was also on L-dopa (co-beneldopa) and selegiline, and the observed effects could reflect drug-drug interactions. However, these results are belied by a large RCT in which oxybutynin-ER 5 mg daily did not cause more delirium than placebo in NH residents with UI and dementia [496].

There are case reports of reversible peripheral neuropathy confirmed by re-exposure in a 70 year old woman taking oxybutynin-IR 5-7.5 mg/day[512] and recurrent heat stroke associated with oxybutynin in one elderly patient.[513] Few studies have addressed cardiac effects. A small study of older persons in the community with UI (n=20, mean age 75) found no change in resting heart rate or electrocardiograph evidence of either prolonged PR interval or QTc, or QTc dispersion after 4 weeks of oxybutynin-IR (mean daily dose 7.6 mg [range 2.5-10 mg]).[514] Using a large administrative utilisation database, no association was found between antimuscarinics (oxybutynin, flavoxate, hyoscyamine) and ventricular arrhythmia and sudden death.[515] Post-marketing adverse events with extended release oxybutynin include tachycardia and hallucinations.

2. Tolterodine

Since the last ICI, we identified no further studies of tolterodine for OAB/ DO. Analysis of the studies of tolterodine in "older patients " does not allow any conclusion to be drawn about the frail elderly. For example, "older" patients in one RCT of **tolterodine-ER** were all community-dwelling, able to complete a 7-day bladder diary, had a high prevalence of previous antimuscarinic treatment (53-57%), and a low prevalence of arthritis (15-18%), unlike most frail older persons.[516] Although several trials include elderly persons in their ninth and tenth decades,[516-518] mean age (~64 years) was much lower, persons with "[unspecified] disease which the investigator thought made the patient unsuitable" and/or "renal disease" were excluded, and results were not stratified by age. In a secondary analysis of a large, open label German trial of **tolterodine-IR** 2 mg twice daily, higher age was significantly associated with "less favourable efficacy."[519] However, the absolute difference in odds was only 0.019, there was no association of tolerability with age, only mean age is described, and UI frequency was based on patient report, not bladder diaries, all of which fail to add up to a clinically meaningful difference. In a non-randomised study, tolterodine was given to 48 nursing home residents who did not respond to toileting alone; 31 of these patients had a 29% increase in dryness (versus 16% in residents on toileting alone) [484]. We did locate a trial of 1 year duration of the addition of tolterodine ER 4mg to alpha blocker or 5 ARA therapy in older men (mean age 74.9 years) which resulted in a between group, statistically significant decrease in the storage symptom score on the IPSS [520].

- ***Adverse reactions.*** There are no prospective systematic data on tolerability in frail patients. There have been case reports of hallucinations (73 year old woman with dementia [521]) and worsening memory,[522] including a 65 year old cognitively intact woman.[523] There is a case reports of delirium when tolterodine was given with a cholinesterase inhibitor [524]. Analysis of prescription-event monitoring in the UK (mean patient age 63) found a significant association between age (>74 years) and psychiatric events and tachycardia (odds ratios not given) [525]. In a similar database study, the age- and sex-adjusted risk of hallucinations with tolterodine was 4.85 (95% CI 2.72-8.66) compared with 10 other drugs (acarbose, alendronate, famotidine, 3 proton pump inhibitors, finasteride, meloxicam, misoprostol, and nizatidine) chosen for presumed lack of antimuscarinic, cardiovascular, and CNS activity, and available in the database. Important confounders such as other drugs and comorbidity were not evaluated. Similar to oxybutynin-ER, post-marketing information on tachycardia and hallucinations was added to the tolterodine-ER package insert in 2003.

3. Fesoterodine

Since the 4th ICI we located four studies of age related pharmacokinetics in younger versus older subjects (although not frail), a pooled analysis demonstrating efficacy of fesoterodine in subjects over the age of 65, stratified into >65 and >75year age groups, a large prospective study which reported the efficacy of fesoterodine in subjects stratified by age (>65 and >75) years of age and a prospective study in the frail elderly [355, 526]The pharmacokinetic study found no clinically meaningful effect on 5-HMT, the active metabolite of fesoterodine pharmacokinetics or pharmacodynamics after single-dose administration of fesoterodine 8 mg. The efficacy of fesoterodine has also been studied in a European trial in 794 elderly men and women with OAB [527], 47% were men. Forty-six percent of subjects reported urgency incontinence episodes at baseline, and 64% had prior treatment with antimuscarinics. At week 12, the improvement from baseline in urgency episodes (-1.92 v -3.47, $p<0.001$), micturitions (-0.93 v -1.91, $p<0.001$), nocturnal micturition (-0.27 v -0.51, $p=0.003$), severe urgency episodes (-1.55, -2.40, $p<0.001$), and incontinence pad use were statistically significantly greater with fesoterodine than with placebo. The responses on the treatment benefit scales, OAB-S, PPBC, and UPS were also significantly greater in those in the fesoterodine group versus placebo. The effect of fesoterodine has

also been assessed in vulnerable older people as assessed by the Vulnerable Elders Survey Survey [269], which identifies those at risk of death in the following two years. This 12 week double blind, placebo controlled study including 562 people of mean age 75 years resulted in mean reductions in UUI episodes at week 12 versus placebo (-0.65 (0.21), p<0.0018) and 24h micturition frequency (-0.84 (0.23), p<0.0003) [528].

- ***Adverse effects:*** The cognitive safety of fesoterodine has been assessed in a single small study of cognitively intact older subjects, using alprazolam as an active control and placebo. There were no statistically significant changes in performance on a computer assisted battery of cognitive tests versus placebo [529].

4. Solifenacin

We located a sub-cut analysis from a Canadian study which reported tolerability of solifenacin versus oxybutynin in older subjects, reported above [354]. Otherwise, there were no further relevant studies. Pharmacokinetics of solifenacin have been evaluated in 23 older subjects (mean age 68); t_{max} was longer and there was a higher maximum plasma concentration, but the differences from results in younger patients were small and deemed by the authors to be clinically irrelevant.[530]. A secondary analysis of pooled Phase III data in patients aged 65 and older (all community dwelling and fit, mean age 72) found similar efficacy to that reported for younger and middle aged persons [531]. However, direct comparison with subjects < 65 yrs from the same pooled trials was not done. Adverse effects in older frailer patients have not been specifically reported. However, data from an open-label, 12-week trial in patients treated by community urologists found that overall treatment-emergent adverse events were more likely in patients aged >80 years (OR 3.9 [95% CI 1.3-11.5]) and taking concomitant medications (OR 1.8 [95% CI 1.2-2.6]) [532]. Patients with concurrent medications were more likely to be male and on average about 12-14 years older, have comorbid disease, and be administered higher doses of solifenacin, yet had no observed increase in heart rate or blood pressure with solifenacin.

- ***Adverse effects:*** The cognitive safety of a single dose of 10mg solifenacin was tested versus placebo and 10mg oxybutynin IR in an exploratory study in 12 cognitively intact older subjects. Solifenacin showed no evidence of impaired cognition or self-ratings of mood and alertness versus placebo [533]. In a 3-way crossover design, chronic dosing of 5mg solifenacin, placebo and 5mg bid of oxybutynin were compared using a similar battery of tests in 23 older subjects with mild cognitive impairment. There was no statistically significant effect on cognition of solifenacin versus placebo. Oxybutynin 5mg bid was associated with impairment in power and speed of attention in a *post hoc* analysis of pooled time points at 1+2h post dose [534].

5. Darifenacin

We located one RCT of darifenacin for OAB in persons aged ≥65 (mean 72), in which there was no statistically significant difference between drug and placebo for the primary end point, UI frequency. [535] There were statistically significant improvements with drug for urinary frequency (-25.3% vs. -18.5% with placebo; p < 0.01) and quality of life, as measured by OAB-q and patient perception of bladder condition. A 2 year extension study in subjects >65 was reported, showing maintenance of OAB symptom improvement over the 2-year period with 44.4% patients achieving > or = 90% reduction in incontinence episodes at 2 years for the 64% (137/214) subjects remaining in the study [536].

- ***Adverse effects.*** Cognitive adverse effects of darifenacin have been prospectively studied in a series of trials. The first was a 3-period crossover RCT in 129 older subjects (mean age 71, 54% of those screened), 88% of whom had comorbid medical conditions and 93% were on other medications.[537] Cognition was assessed using a standardized computerised test battery. Darifenacin at variable doses did not adversely affect cognition compared to placebo, but results were aggregated so that patients did not serve as their own controls. A subsequent study in cognitively intact older persons (n = 49, mean age 66) using a similar computer cognitive test battery compared titrated darifenacin and oxybutynin-ER with placebo over 3 weeks.[538] Oxybutynin-ER but not darifenacin or placebo adversely affected the primary endpoint, delayed recall on the Name-Face Association test. However, oxybutynin was titrated one week earlier than darifenacin, and to a final dose (20 mg daily) much higher than is commonly used in clinical practice. Also, there were no differences between the two drugs and placebo for many other domains of the cognitive battery.

6. Trospium Chloride

Although often promoted for use in the elderly because of the reduced likelihood that the drug crosses the blood-brain barrier, we found no studies that evaluated the agent specifically in frail older persons. All studies have included “younger elderly,” but even the most recent has not stratified results by age [539].

- ***Adverse effects:*** The effect of 60mg trospium chloride once daily over 10 days on either learning or memory was assessed in 12 cognitively intact older people (>65 – 75 years). There was no change in standardised testing. Additionally, no trospium was detectable in the CSF of the subjects at day 10 [540, 541]. As part of a larger study of trospuim chloride 20mg bid, 36 (26 completed). Subjects with UUI and dementia, treated with galantamine and trospium) were examined. Subjects with severe dementia were excluded in this

non-randomised, open label study. There was no observable decrement in either cognition, but only measured by MMSE, or ability in terms of activities of daily living in the dually treated group [364].

7. Propiverine

In 46 patients with dementia (mean age 81), there was a 40% decrease in urgency UI with propiverine 20 mg/day for 2 weeks,[542] similar to two small Japanese trials [543, 544]and a German trial in 98 patients.[545] The agent's high protein binding, extensive first pass metabolism, 15-hour half life (in normal younger persons), and renal clearance [542] need to be considered if used in frail older people. There have been no new trials reporting on either efficacy or tolerability in older people.

8. Imidafenacin

There have been no pharmacokinetic studies of imidafenacin in older people [546]. However, a population pharmacokinetic analysis demonstrated that oral clearance was decreased with advancing age, increasing hepatic function parameters (AST and ALP), food intake, and itraconazole co-administration. The absorption rate constant was decreased with food intake [547]. The drug is metabolised by the CYP3A4 system, and it is affected by drugs which inhibit this system [546] . There appears to be no affect on digoxin pharmacokinetics in healthy volunteers [548]. There are no trial data on older patients using this agent.

9. Duloxetine

There was a statistically significantly reduced rate of clearance of duloxetine in patients over age 65, based on a study in 12 fit women aged 65-77.[549] The authors felt the differences were not clinically significant given the "similar safety profile" of the drug in older and younger women. In three large RCTs in women with SUI, aged 24-83 years, n = 494 [none frail];[550] with OAB, aged 21-84 years [none frail], n = 306 [551];and with mixed UI, up to age 85[552]), duloxetine decreased UI and urinary frequency, but none stratified outcomes or adverse effects by age. In a newer randomised controlled study of 265 community dwelling older women, 134 treated with duloxetine, of whom 20% had mild cognitive impairment as classified by the modified mini-mental state exam [553], duloxetine treatment led to a statistically significant decrease in incontinence episode frequency (median percent change 51.6%) versus placebo (32.1%) for stress predominant mixed symptoms, but did not reach significance for stress urinary incontinence (53% v 42%) [554]. Duloxetine is neither approved by the US FDA nor recommended by the UK National Institute of Healthcare and Clinical Excellence.

10. Mirabegron

There are no trials of mirabegron in the frail elderly. There are data on the comparative pharmacokinetics in older people, but not specifically the frail elderly. In available studies, there were no statistically significant differences in mirabegron exposure between older volunteers aged 55 years and above and younger volunteers (18-45 years). Similar results were obtained for those aged 65 years and above. AUC was predicted to be 11% higher in a subject aged 90 years of age [555]

11. Oestrogen

Oral oestriol 3 mg/day was compared to placebo for 12 weeks in 34 women aged 75 [84]. The group was highly self-selected; complete results were available for 11 with SUI, 12 with urgency UI, and 8 with mixed. Two-thirds of urgency UI and 75% of mixed UI patients reported improvement; there was no effect on SUI. Four patients reported metrorrhagia and mastodynia. A 10 week crossover trial comparing quinestradol 0.25 mg four times a day with placebo in 18 women in long-term care (type of UI not reported) found a mean 12% decrease in UI episodes vs 22% increase with placebo.[556] The combination of conjugated oestrogen 0.625 mg/day and progesterone 2.5 mg/day was evaluated in a 6 month, placebo-controlled trial in 32 female NH residents with predominantly urgency UI, who also received prompted voiding [557]. In the 21 women who finished the trial, there was no difference in wet checks between drug and placebo despite increased serum oestrogen levels and partial oestrogen effect on vaginal cytology and pH in the women on drug. Two women on the drug developed vaginal spotting, and 10% developed breast tenderness. Similar lack of efficacy despite vaginal changes were found in a case series of 9 frail women (mean age 83) with urgency or mixed UI using an oestrogen-implanted vaginal ring (Estring ®) [558].

12. Miscellaneous Medications

Readers interested in agents which are seldom used in clinical practice should refer to the 4th International Consultation on Incontinence for data relevant to frail older people for information on:

Emepronium bromide, Flavoxate, Propantheline, Imipramine, Flurbiprofen, Procaine haematoporphyrin.

13. Comparative Trials

We found no studies that compared antimuscarinic agents in frail older persons. Other comparative studies in community dwelling elderly, where relevant, are mentioned above.

d) Summary of the evidence

1. Short-term treatment with oxybutynin-IR has small to moderate efficacy in reducing urinary frequency and urgency UI when added to behavioural therapy in long term care residents. **(Level 2)**

2. Low dose oxybutynin-ER does not cause delirium in cognitively impaired nursing home residents **(Level 1**)

3. Oxybutynin-IR has been associated with cognitive adverse effects in persons with dementia and/or Parkinson's disease **(Level 3)**, although the incidence and prevalence are unknown **(Level 4)**

4. Oxybutynin has been associated with tachycardia **(Level 3)**, but not associated with QTc prolongation **(Level 3)** or ventricular arrhythmia **(Level 2)**

5. Oxybutynin is less effective in persons with impaired orientation, cerebral cortical under-perfusion, and reduced bladder sensation **(Level 2)**

6. Oxybutynin is less well tolerated, versus solifenacin, in older people **(level 2)**

7. Fesoterodine is effective in ameliorating the symptoms of OAB in frail older people, identified by VES-13 **(level 1).** There is insufficient evidence to determine the efficacy, tolerability, and safety of the following agents in the frail elderly **(Level 4)**:

    a. Intravesical oxybutynin

    b. Transdermal oxybutynin

    c. Trospium

    d. Tolterodine

    e. Darifenacin

    f. Solifenacin

    g. Mirabegron

    h. Duloxetine

    i. Oral and topical oestrogen

8. Tolterodine is associated with cognitive impairment and tachycardia **(Level 3)**, although the incidence and prevalence are unknown. **(Level 4)**

9. Solifenacin (5mg/day) is associated with no impairment of cognition in older persons with mild cognitive impairment versus placebo **(level 2)**

e) Recommendations for practice

• A global assessment of the cognitive and "at risk" status of the patient should be undertaken. Unfortunately, the MMSE and ADAS-Cog seem to be insensitive to change in cognitive impairment due to bladder antimuscarinics [527, 559]. Patients that might be at risk of impaired cognition have been well described [348] and consist of those with mild cognitive impairment, long-standing type II diabetes, alcohol misuse, dementia and Parkinson's disease. Those with Parkinson's disease may be exquisitely sensitive [560]. These individuals will need to be carefully assessed, both prior to, and shortly after, initiation of treatment with bladder antimuscarinics. Treatment may necessarily depend upon a global assessment of cognition during the clinical assessment and, if possible, a carer's impression of change. In addition to the of likely benefit from drug treatment, considering the life expectancy and wishes of the patient, account should be taken of total anticholinergic load, as this clearly increases the likelihood of cognitive impairment. There is evidence of cognitive safety of these drugs, for the most part in cognitively intact older adults, and therefore, prescribing bladder antimuscarinics as single agents is, on the whole, probably safe.

• Those studies using high doses (20mg) of oxybutynin are associated with an increased likelihood of causing cognitive impairment, which may not be apparent to either the patient or the clinician. This drug should probably be avoided in the elderly at high dose, and in those at cognitive risk, in any case. The other antimuscarinics should be initiated carefully, at the lowest dose for tolerability, with dose increases where indicated for efficacy, and reviewed early.

• The length of exposure to anticholinergics seems to be important, studies suggest a lack of decline in those with established dementia [349, 561] , but with exposures of at least two years, there is a reported increase in mortality [562-564]. To what extent this is explained by case mix, comorbidity or other factors is not known and will be the subject of further research. Consideration should be given to limiting the overall exposure of antimuscarinics, particularly if in combination with other drugs with anticholinergic properties.

5. SURGICAL TREATMENT IN THE FRAIL ELDERLY

a) Background

Despite ongoing reports concerning the aetiology and pathophysiology of UI in older people, information on surgical management of the frail elderly is scarce [565, 566]. Nevertheless, currently, surgical management of stress incontinence (SUI) in elderly women is the same as in younger stress-incontinent patients [567, 568]. However, the outcomes of anti-incontinence surgery in frail elderly patients may be affected by inherent co-morbidities, as well as impaired bladder and pelvic floor function. There are still very few studies of gynaecological surgery in older frail women, surgical treatment for post-prostatectomy UI in frail men, and minimally invasive procedures, or peri-operative care (including prevention of common postoperative complications) in urological and gynaecological patients. We reviewed the available data and general issues regarding peri-operative care which could improve surgical outcomes in this group. Aspects of surgical treatment of UI in healthy older persons are also covered in 13: Surgery for Urinary Incontinence in Men, Chapter 14: Surgery for Urinary Incontinence in Women, and Chapter 15: Surgery for Pelvic Organ Prolapse.

In providing an evidence-based summary on this topic, we have taken advantage of the recent literature review and research recommendations from

the American Geriatrics Society, New Frontiers in Geriatrics Research: An Agenda for Surgical and Related Medical Specialties. [569]. This project involved systematic literature reviews that were used to generate summary statements and recommendations for research. Their findings and recommendations pertinent to the frail elderly regarding surgical treatment of geriatric UI, geriatric gynaecological surgery, and general care of the geriatric surgical patient are included in the summary statements below. Data supporting these conclusions are available in the monograph [570].

b) Incontinence surgery in frail elderly women

Surgical intervention is considered to be the most efficient and durable approach for the treatment of SUI. A wide variety of surgical techniques have been described, among which the mid-urethral sling procedures have gained worldwide popularity. Since the last ICI report on UI surgical treatment in frail elderly appeared, there are few new data on which to base appropriate recommendations for this group. Several studies have used U.S. national hospital discharge databases to examine surgical rates, but unfortunately they either age-adjusted results [571] or used relatively young cut-off points (e.g., </> 50 years) [572]. Even in series that do specifically look at elderly women (mean age 78, range 68-90), most patients are cognitively intact (95%) [573]. Cognitive impairment appears to bias against having surgery: in one study, only 0.11% of operations for UI were done in women with dementia, cerebrovascular disease, or hemiplegia combined. Despite the fact that absolute numbers of ambulatory UI surgery cases in women increased from 1994-1996, the percent done in those aged > 80 years remained the same (4-5%) [574], with the same proportions for pelvic organ prolapse surgery (5%) [575]. In the US, surgery rates in elderly women vary by region and race [576].

One single-centre, community-based series of 54 patients aged 70 years and above provides a picture of this surgical population. Twenty-eight percent of patients were aged > 80, four resided in a nursing home or assisted living facility, 82% had significant comorbidities, and 32% were classified as American Society of Anaesthesiology class III risk. Intra-operative complications occurred in 11% of patients; postoperatively, 11% required intensive care monitoring, 6% had serious complications, 7% became delirious, and 9% experienced a slow return of bowel function. The authors concluded that discharge planning was especially important for these patients, and recommended presurgical planning with regard to discharge destination and likely need for assistance [577].

Although higher complication rates generally reflect the comorbidity common in frail elders (10.4% complication rate with comorbidity vs. 5.8% without it, p<.001) [572], some studies have found age protective (in one, age >73 years is associated with lower risk of vaginal cuff infection and recurrent prolapse following vaginal sacrospinous fixation [578]). The morbidity and mortality for geriatric patients undergoing anti-UI procedures appear to be similar to those of other major non-cardiac surgical procedures [569]. Mortality is inconsistently associated with increased age, and most strongly related to cardiac or cancer complications [579]. Many studies do not uniformly control for the impact of comorbidity on mortality [579]. Pre-operative administration of oestrogen appears ineffective in promoting wound healing [580]. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time administered medications in cognitively intact geriatric patients [580]. Choice of anaesthetic agent may affect postoperative cognition and urinary retention. The use of methyl naltrexone to treat opioid-related urinary retention or constipation may become an important adjunct to surgical care in frailer patients [581]. There are few age-specific data on outcomes available, and no studies systematically examine quality of life, functional outcome, or discharge destination.

With the advent of newer “minimally invasive” procedures, there has come some modicum of use in older, albeit, not frail patients. Injection of bulking agents in women appears to be as little effective in younger women as in elderly patients and age does not appear to relate to outcomes [569]. There are several published reports examining outcomes of tension-free vaginal tape (TVT) in the elderly population. However, most of these studies are limited by short term follow-up, small patient groups and confounding variables [582-584]. Hellberg *et al.* showed that at three months, women ≥ 75 years old had a cure rate of 81.6% compared with a rate of 92.8% in women <75 years old. At later follow-up, regardless of duration since the TVT procedure, the proportion of women with cure for ‘any’ incontinence decreased with increasing age. Women ≥ 75 years old had a cure rate of 55.7%, compared with 79.9% in women < 60 years old (p= 0.0001) [585]. In one single institutional study, authors showed no significant difference in cure rate (85% vs. 91.3%, respectively). However, follow-up was only 10.4 months [586]. In a randomized controlled trial of tension-free vaginal tape (TVT) versus 6-month wait-list control, the intervention group at 6 months had a statistically significantly greater improvement in mean I-QOL score, patient satisfaction score, and urinary problem score [587]. There was no objective measure of cure. Peri-operative complications were common, with bladder perforation by needle in one-in-five (22.6%) which required 24 hours of indwelling catheterisation; urinary retention (12.9%), and less than 5% with either a urinary tract infection or new urinary urgency (3.2%). In an uncontrolled case series examining the use of the suprapubic arch (SPARC) sling procedure, the outcomes in 43

older women (ages 65-91) were separately examined. Objective cure rate was evaluated by clinical and urodynamic examination and subjective cure rate by using a visual analogue score.At a mean follow-up of 36 months (range, 12 - 54 months), objective and subjective cure rates in 997 women were 91% and 95%, respectively [588]. There was statistically significant improvement in pad weight and pad numbers (from a mean of 5 to 0) and the visual analogue score. No severe intra- or post-operative complications were observed, and no patient developed *de novo* urgency UI. In a case series, long-term clinical outcomes following placement of a retropubic mid-urethral sling (SPARC) in patients aged 70 and over were compared with outcomes of a younger cohort. Overall success rate after a follow-up of 4 years was 83.2% in the younger group and 53.1% in the group of older patients (p= 0.0003) [589]. In a comparative prospective single-centre study examining safety and efficacy of TVT-O in elderly versus younger stress-incontinent women, after mean follow-up of 30±17 months early and late postoperative morbidity was similar in both groups, except for significantly more cases of postoperative recurrent UTIs among the elderly women (13.7% vs. 6.2%). Incidence of persistent urodynamically confirmed overt SUI was similar in both age groups (5%). However, asymptomatic urodynamic SUI was significantly more common among elderly patients (19% vs. 3.7%, P<0.05). The incidence of persistent OAB was similar in both groups (68% and 62%, respectively), while *de novo* OAB was significantly more common in elderly patients (11.9% vs. 4.7%, P<0.05) [590].

c) Incontinence surgery in frail elderly men

No specific conclusions can be drawn regarding surgical treatment of UI in frail men. Typical studies of anti-UI surgery in elderly men are very small or fail to stratify results by age and/or comorbidity [591, 592]. One small study (n=46) found that advanced age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI [593], while another (n=12, mean age 80 years) of trans-urethral resection prostatectomy (TURP) for obstruction-associated urgency UI concluded that cognitively impaired men demonstrated the greatest UI improvement [594]. In a single-institution case series of men aged > 80 years old undergoing TURP (68% of whom had urinary retention), 80% were satisfied with their outcome. Of the men with retention, 80% were able to void with a small PVR by six weeks. Complication rates were 41% (early) and 22% (late) [595]. Urodynamic evaluation of post-prostatectomy UI was recommended prior to surgical treatment, such as implantation of an artificial sphincter [592].

d) General issues in surgical care of the frail elderly

Important factors in the surgical care of frail patients include: preoperative risk stratification (e.g., American Society of Anaesthesiology class, Charlson index, Modified Cardiac Risk Index , Burden of Illness Score [596]; ensuring adequate nutrition, especially when patients cannot take oral feeding or become delirious; proactive management of comorbid heart disease, diabetes, and pulmonary disease; prevention [597, 598],recognition [599], and treatment of postoperative delirium [600]; adequate pain assessment and treatment, especially in cognitively impaired persons [601]; recognition of the hazards of prolonged bed rest [602] and the prevention [603] and treatment of functional impairment; use of specialised care units for the elderly [604]; and discharge planning regarding rehabilitation, need for assistance, and site of discharge. All need to be actively considered and dealt with in any plan of surgical care of frail elderly patients.

e) Summary of evidence

1. No studies were identified regarding gynaecological surgery in institutionalised elderly women. **(Level 4)**

2. Exogenous administration of oestrogen is ineffective in promoting wound healing after gynaecological surgery in older women. **(Level 3)**

3. Injection of bulking agents for SUI appears to give minor benefit in women, however the technique is minimally invasive and age does not appear to correlate with outcomes.**(Level 3)**

4. No studies were identified that evaluate functional or quality of life outcomes after UI surgery in frail older persons **(Level 4)**

5. Risks of morbidity and mortality for frail patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures. **(Level 2)**

6. Surgical mortality risks are still low in elderly persons, and when deaths do occur, they are often due to cardiac or cancer complications. **(Level 2-3)**

7. Operative mortality is inconsistently associated with increased age, and many studies do not uniformly control for comorbid conditions. **(Level 2-3)**

8. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed-dose and time-administered medications in cognitively intact geriatric patients. **(Level 2)**

9. Choice of agent for patient-controlled analgesia may affect postoperative cognition. **(Level 3)**

10. Some case series and waitlist-controlled trials suggest that minimally invasive surgical approaches may be useful in older adults, yet these trials may have little to do with whether surgical treatments are appropriate in the frail elderly **(Level 3)**

f) Recommendations for management

a. Age alone is not a contraindication to surgical treatment of UI **(Grade C)**.

b. Urodynamic evaluation should be done before considering surgical treatment of UI in frail older persons **(Grade B)**.

c. Preoperative risk should be stratified using established indices **(Grade A)**.

d. Ensure adequate post-operative nutrition, especially in patients who cannot take oral feeding or who become delirious **(Grade C)**.

e. Programmes to prevent post-operative delirium should be utilised **(Grade A)** along with proactive use of established measures to diagnose delirium **(Grade A)**.

f. Pain assessment in cognitively impaired persons should use measures specially-designed for this population **(Grade B)**.

g. Proactive preventative approaches to hospitalisation-related functional impairment should be used **(Grade A)**.

h. Specialised care units may improve selective outcomes for frail older patients **(Grade A)**.

i. Discharge planning should begin before surgery takes place **(Grade C)**.

j. Patient controlled analgesia can be used in cognitively-intact frail older persons **(Grade B)**.

k. Analgesic agents associated with delirium (e.g., meperidine) should be avoided **(Grade B)**.

l. Long-term outcomes before the operation should be discussed with the patient **(Grade C)**.

g) Recommendations for research

- Inclusion of older-old and frailer patients in surgical studies, with stratification of outcomes by age, comorbidity, oestrogen status (women), and urodynamic findings
- Prospective studies to determine the magnitude and severity of common geriatric complications following anti-incontinence surgery
- Develop and validate guidelines for identifying frail elders who would benefit from gynaecological/ urological anti-incontinence surgery

6. CATHETERS

a) Background

The use of indwelling urethral catheters (IDC) is clinically indicated in a limited set of circumstances (see Box 1) and should not be considered as a substitute for nursing care of the frail older person with incontinence [605]. Despite this recommendation, a number of studies report potentially inappropriate IDC use in frail older adults. The information in this section reviews research on rates of IDC use in the frail elderly; the appropriateness of IDC use in this population; complications (morbidity and mortality); management recommendations and recommendations for research. Detailed discussion of key issues related to catheters more broadly, including intermittent catheterisation, is provided in Chapter 20.

Box 1. Appropriate Indications for Indwelling Urethral Catheter Use

- Patient has acute urinary retention or bladder outlet obstruction
- Need for accurate measurements of urinary output in critically ill patients
- Perioperative use for selected surgical procedures:
- Patients undergoing urological surgery or other surgery on contiguous structures of the genitourinary tract
- Anticipated prolonged duration of surgery (catheters inserted for this reason should be removed in PACU)
- Patients anticipated to receive large-volume infusions or diuretics during surgery
- Need for intraoperative monitoring of urinary output
- To assist in healing of open sacral or perineal wounds in incontinent patients
- Patient requires prolonged immobilisation (e.g., potentially unstable thoracic or lumbar spine, multiple traumatic injuries such as pelvic fractures)
- To improve comfort for end of life care if needed

Healthcare Infection Control Practices Advisory Committee [2009]

b) Quality of the data

Some of the difficulties in conducting research on use of IDCs are discussed in Chapter20… We located a number of articles on the use of catheters in frail older persons. These largely described the prevalence of catheters in this population. Few studies addressed the specific complications associated with IDC in frail older adults. It is therefore difficult to determine the relative effect of frailty and ageing on the incidence and prevalence of IDC complications. There is a lack of research on the use of catheters for individuals with terminal illness (i.e. end of life care), and for different cultural groups of frail older persons. Although intermittent catheterisation is associated with fewer risks compared to IDC use, there is limited research on its use in this older group. Guidelines and recommendations that apply

to the IDC use in other populations equally apply to IDC use in frail older adults. Catheter use should be avoided wherever possible and only adopted for those in whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [606].

c) Rates of IDC use in frail older adults

Despite the presence of guidelines cautioning their use, IDCs are used to manage urinary incontinence and other conditions in a substantial number of frail older persons in long-term care facilities, in the community, and in acute care. The lowest rate reported in the reviewed literature was 3% of women in Swedish nursing homes [607] and the highest was 38.1% in frail older community-dwelling women in Italy who were listed on a Home Health Agency database [608]. In a one-day point prevalence survey conducted in 2009 involving 2625 residents from 78 nursing homes in Sweden, 50 (3%) of women and 135 (16%) of men had an IDC. Just over half (58%) had had their IDC at the time of admission to the facility. For many of those who had their IDC inserted since their admission, the catheter was inserted during a temporary stay at hospital [607].

Data from the US Department of Health & Human Services, Centres for Medicare and Medicaid Services (third quarter of 2010) [609] indicates that, in the USA, 7% of residents in long-term care facilities have an IDC, however rates vary between states (4.5% to 12.3%). This finding compares with 7-10% of residents in 1987 [610] and research reported in 2003, from the USA National Nursing Home Survey for 1995 to 1999, on the prevalence of urinary incontinence among female nursing home residents, when 9.5% to 11.7%% had an IDC or ostomy [611]. A web-based point prevalence survey of nursing home-associated infections (NHAI) conducted in 2005 in 133 USA Veteran Affairs homes, [612] found 1233 (10.7%) of 11475 residents had an IDC and was reproduced in a follow-up survey conducted by the same researchers in 2007 [613]. Rogers and colleagues [256] analysed data from 57,302 residents admitted to skilled nursing facilities in USA in 2003, and reported that 0.5 million nursing home residents have some form of catheter, and rates vary from 12.6% at admission to 4.5% ($P<0.001$) at annual assessment. IDC use was associated with male sex, and with conditions such as paraplegia, quadriplegia, multiple sclerosis, diabetes mellitus, renal failure, skin conditions, deep vein thrombosis, aphasia, or end-stage disease, obesity, taking more medications, as well as those who are comatose.

Rates of IDC use in nursing homes in the UK appear relatively stable over time. Based on 2001 survey data from 1125 residents in different healthcare settings for the elderly, 5% (0-20%) of individuals living in residential homes in the UK had an IDC, 10% (0-44%) in nursing homes, and 6% (0-20%) in long-stay wards [614]. Similar rates were reported by McNulty and colleagues in 2003 based on a sample of 4900 residents from registered nursing homes [615]. and from a more recent survey involving 3190 residents from 92 homes, where 8% of resident had an IDC, although rates varied considerably with one facility having up to 47% of residents with an IDC [616]. In 57% of care homes, residents received their IDC as a hospital inpatient [616]. A more recent audit of continence care in UK conducted across England, Wales, and Northern Ireland estimated that 13% (62/488) of individuals living in care homes had an IDC [245]. These rates are consistent with IDC rates in individuals living in long-term care facilities in Canada, which range from 5% to 10% [617].

Estimating the prevalence of IDC use in frail older adults living in the community is more difficult as community samples differ, as do methods to define and measure IDC use. With the exception of one study, prevalence data do not differentiate between IDC use among frail and non-frail older community-dwelling individuals. One of the earliest reports on rates of IDC use in the community was based on a sample of individuals receiving district nursing home care in the UK. During the four weeks of data collection (Feb 1987) a total of 1709 patients were being attended by the district nursing services, with 61 (4%) known to have an IDC. In a larger context, the population for the health authority was 178,300 of whom 61 (0.03%) were patients aged from 22-95 years living in the community and had an indwelling urethral catheter (mean age 67.6 years, SD 19.56)." (p44) [618]. A more recent prospective, population-based survey of 4 010 older people >65 years of age (mean age 82.3) receiving home care in 11 European countries, found that 5.4% (range 0–23%) of their sample had an IDC [619]. IDC use was more common in men than in women (11.5% versus 3.3%). Rates also differed between countries, ranging from 0% in the Netherlands to 23% in Italy. High rates of IDC use in Italy were also reported in data from 12 Home Health Agencies that provided care for 1004 frail older community-dwelling women (mean (SD) age 83.3 (9.5) years). The researchers reported that in this sample the prevalence of incontinent patients with a catheter was 38.1% [608].

Although some frail older adults are catheterised during an admission to acute care, others are admitted with an IDC in situ. Lakhan and colleagues conducted a prospective cohort study to identify the prevalence of geriatric syndromes at preadmission, admission and discharge, and to determine the incidence of new and significant worsening of existing syndromes at admission and discharge. In their sample of 577 patients aged 70 and older who were admitted to a general medical unit of large acute care hospitals, 22/577 (3.8%) had a pre-morbid IDC (within three days prior to the acute illness precipitating admission). IDC rates increased to 98/577 (17%) in the admission period, and decreased to

47/577 (8.1%) at discharge. Although rates of IDC use decreased before patients were discharged from acute care hospitals, more elderly patients were discharged with an IDC than those who were admitted with an IDC [620].

d) IDC for end of life care

Incontinence is experienced by many patients toward the latter stages of a terminal illness. Although IDCs are indicated 'to improve comfort for end of life care if needed' [605], we found little evidence about managing incontinence for end of life care, or about IDC use in this context. According to the findings of one study, involving 61 patients with terminal illness due to cancer admitted to a palliative care unit (PCU), IDCs may be used in up to 75% of such patients [621]. In this study, 38% (n=23) admitted to the PCU had an IDC in situ prior to their admission and another 36% (n=22) were catheterised during their admission. Complications associated with the use of IDCs in this cohort included: bacteriuria (n=28), encrustation (n=8), bladder spasms (n=4), fever (n=2), and urethritis (n=2). Despite these complications, staff cited 'patient comfort' as the main rationale for the use of an IDC. Clearly, further research is warranted to guide clinical care in this area.

- **The appropriateness of IDC use in frail older adults**

Despite guidelines for appropriate IDC use, a number of studies report potentially inappropriate IDC use in older adults. For example, Landi and colleagues report that of their sample of frail older community-dwelling women with urinary incontinence and IDCs, 50% were catheterised without any reasonable justification [608]. Overuse of IDCs is however not limited to community-dwelling frail older adults. Two studies draw attention to potentially inappropriate IDC use for older people admitted to acute care hospital settings. Gokula and colleagues for example found appropriate indications for IDC use for only 46% of 2845 elderly patients admitted to a large teaching hospital in the US [622]. They reported that only 13% of charts contained information on the reason for the catheter and 33% of charts contained no written order for catheterisation. Similar findings were reported for 133 elderly patients who had an IDC inserted whilst inpatients of a 450-bed, tertiary-care university hospital in central Thailand. Twenty-eight percent of medical records lacked information about the reason for the IDC. The presence of urinary incontinence was cited as a reason in 18% of cases [623].

Anomalies in the use of IDCs were also reported by McNulty and colleagues who found that "almost all homes (114/124, 92%) stated they had an infection control policy, however 31% (38/124) had no written policy on urinary catheter care" [615]. In a later qualitative examination of reasons for variation in IDC use in care homes, McNulty and colleagues found that 'care homes with a lower urinary catheterisation prevalence, had a more proactive approach to management of continence, using structured toileting regimes and encouraging residents' mobility' [624] (p. 709).

- **Complications - morbidity and mortality**

The complications associated with IDCs are well documented and are comprehensively addressed in Chapter20….. However, with respect to frail older adults with an IDC, Kunin and colleagues report the morbidity associated with use of an IDC in residents of a skilled nursing facility is threefold even after adjusting for other factors [625]. This finding also holds true for community-dwelling frail older adults with an IDC [608]. Among residents of Department of Veteran Affairs (VA) long term care facilities in the USA, 1205 of 10939 residents had an IDC and of these, 135 (11.2%) had a nursing home-associated infection. Residents with some form of indwelling device had a three-fold increased risk of a nursing home-associated infection ($P < .0001$). These factors make it imperative that IDCs are used to manage incontinence only when other methods of managing have been excluded.

e) Management recommendations

As noted in Chapter 20, IDCs should be avoided wherever possible and only adopted for those in whom alternative strategies are unsuitable or unsatisfactory, after careful assessment of the patient and their particular problem [606]. Interventions designed to minimise IDC in frail older adults are the same as those for other populations of IDC users. Interventions include, but are not limited to: the development and dissemination of guidelines, quality indicators, and regulatory initiatives; educational approaches; and promoting intermittent catheterisation as an alternative method of management. Interventions to minimize and address complications associated with IDCs are comprehensively addressed in Chapter 20.

Another approach designed to decrease the inappropriate use of IDCs, and to ensure optimal IDC management is the use of assessment protocols. Regulatory processes in the USA mandate that all newly admitted Medicare/Medicaid funded residents receive an assessment using a standardised form called the Minimum Data Set (MDS). A further level of assessment is triggered when/if a resident is newly incontinent and the Resident Assessment Instrument Minimum Data Set is completed (RAI-MDS). This assessment information in turn, acts as a prompt for staff to design an individualised care plan based on direct contact with residents, appropriate staff, and through use of observation, interviews and record reviews. The MDS and RAI are now used in a number of other countries, including Canada and Iceland, and other countries have developed their own assessment instruments. Ideally, these assessment

instruments should prompt staff to enquire about whether the residents' IDC is medically warranted, and to identify IDC related problems, and care plans should contain information about an individualised IDC care plan (including the frequency of IDC changes and ongoing maintenance).

The assessment process used in the USA is strengthened by the fact that it is linked to quality indicators. Since, 2005 facilities have been required to use information from the residents' comprehensive assessment to provide assurances that:

- o IDCs are used for only medically valid reasons;
- o IDCs are removed as soon as clinically warranted;
- o efforts are applied to restore or improve bladder function as much as possible; and
- o efforts are made to prevent infection while the IDC is inserted [626].

It remains to be seen if these measures will reduce IDC rates in long-term care, and how they will impact day-to-day IDC use and care at the clinical interface. However, similar regulatory approaches should be considered by government and health agencies in other countries.

f) Intermittent catheterisation as an alternative to IDC in frail older adults

Intermittent catheterisation (IC) involves the act of passing a catheter into the bladder to drain urine via the urethra, or a catheterisable channel such as a Mitrofanoff diversion. It avoids many of the problems associated with IDC. Many patients with neurological urinary incontinence perform IC. While IC is performed using a sterile technique in healthcare environments, some patients intermittently catheterise themselves using a clean technique in their own home environment. Advanced age should not constitute a barrier to IC. Pilloni and colleagues (2005) for example, found that of 21 elderly patients in whom IC was initiated because of voiding dysfunction, 12 learnt to catheterised themselves, seven were catheterised by their partners and two by nurses. The majority (18/21) reported improvements in their quality of life [627].

g) Research recommendations

- Further research is required on:
  - o Rates of IDC use in various populations (especially in community-dwelling frail older adults and those admitted to acute care)
  - o Managing incontinence for end-of-life care
  - o The effectiveness of interventions to minimise inappropriate use of IDCs such as the development and dissemination of guidelines, educational approaches; the development and dissemination of quality indicators; and regulatory initiatives; and intermittent catheterisation Efficacy and effectiveness of specific devices and procedures to prevent complications from long term indwelling catheters in frail elderly

V. NOCTURIA IN THE OLDER ADULT

1. BACKGROUND

Nocturia is defined as waking at night from sleep one or more times to void, with each void being preceded and followed by sleep.[628] Having a standardised definition is meaningful for the field, but this specific definition is problematic for several reasons. While a single episode of awakening to urinate would be considered nocturia, patients are more likely to be experience significant bother and have decreased quality of life [629], or consult a provider about nocturia if they have three or more episodes.[630] Many clinical trials include only participants with two or more episodes [631]. Additionally, if only a void interrupting sleep and preceding sleep counts, the annoying situation of waking to void and not being able to return to sleep again would not be nocturia, but would still be disruptive [632]. This definition does not take into account the wide range of sleep patterns of older adults. Since some older adults will spend six hours sleeping while others might spend twelve hours in bed, having three episodes of nocturia would be very different for these individuals [633].

Several detailed reviews on nocturia [634, 635] and two convened consensus conferences reports [631, 636] have helped summarise and update the current knowledge regarding nocturia. Even with these sources, the prevalence, impact, pathophysiology, diagnostic assessment, and treatment of nocturia differ meaningfully with respect to the older adult and the frail elderly [633] and merit a targeted discussion. As is the case with urinary incontinence, nocturia often results from the reduced physiological reserve of multiple systems. Because of this fact, diagnostic assessment must be detailed and comprehensive, and multi-component interventions may be necessary for successful treatment.

2. QUALITY OF THE DATA

There are multiple, quality sources of epidemiological data across a broad range of countries and cultures regarding the prevalence of nocturia and associated risk factors. There is a smaller, but growing, body of evidence regarding the incidence and impact of nocturia. In particular, studies of the pathophysiology of nocturia in the elderly have generally been small and disease-focused, examining a single, potential underlying cause of nocturia. As with UI, there are limited data on optimal diagnostic assessment, and therefore recommendations are generally based on expert opinion.[628, 637] The evidence base regarding treatment, particularly with

respect to the frail, is somewhat thin. While there are some treatment RCTs, they are small, include few very elderly subjects. The treatment literature regarding vasopressin and its analogues is robust, yet use of the therapy in the older patient continues to be limited because of the side effect of hyponatraemia. We located no randomised controlled trial data on the effectiveness of multi-component interventions for nocturia in the elderly.

3. PREVALENCE, INCIDENCE, AND IMPACT

The prevalence of nocturia increases with age, and has been reported to be as high as 90% for one episode per night in persons over age 80.[638-643] The prevalence of two or more episodes among men between 70 and 79 is nearly 50 percent.[643, 644] This increasing prevalence is largely due to age-related conditions that underlie the pathophysiology of nocturia (see below). With respect to gender, nocturia for young adults is more common in women than in men, but this gender ratio reverses after age 60 when more men have nocturia.[644] For those over 75 years of age, the prevalence of nocturia of at least two or more times is much more common in men (70%) than in women (50%) [645].

While higher age is associated with more nocturia, what happens to nocturia, as an individual ages, is a slightly different question. Nocturia is more prevalent in older populations, yet the concept of incidence of nocturia is difficult as the condition both “begins” and “resolves” over time and varies due to imprecision of self-reporting and estimates as to the frequency over a past period of time. In one recent study, participants recorded their urination frequency and voided volumes. Over a 2-year period, the incidence rate of nocturia of an average of two or more times per night was 23.9% and the resolution rate was 36.7%. For the oldest adults participating (70-78 years), they had the highest nocturia incidence (47.1%) and the lowest resolution rate (26.2%) compared to their younger counterparts [646].

Recent data have also highlighted that the prevalence of nocturia in older adults differs by racial group. Multiple population-based epidemiological studies have shown a higher prevalence of nocturia in older men and women who are African-American when compared to whites [643, 647, 648]. While controlling for socioeconomic factors eliminated the differences in prevalence between non-Hispanic whites and Hispanics, differences persisted, although somewhat attenuated, between blacks and whites [649].

Nocturia is also associated with chronic medical conditions such as hypertension and diabetes,[650, 651] advancing renal insufficiency [652, 653] and cardiovascular disease.[654, 655] Clinically, nocturia may be the herald symptom of significant underlying medical conditions and problems, which, if overlooked, might result in significant morbidity and even mortality [631]. Therefore, an older patient bringing up nocturia should be evaluated not only for the causes of nocturia, but also for unrecognised comorbidity, including cardiovascular disease, sleep apnoea, restless leg syndrome, moderate alcohol usage, poor nocturnal glycaemic control, and conditions causing nighttime pain [631].

Nocturia is associated with other important conditions. Nocturia has been shown to be associated with accidental falls.[185, 656] Frail elderly persons with nocturia, who also have gait and balance disorders and other risk factors for falls, are clearly at increased risk for falls [657], injury and hip fracture [658], and consequent morbidity [659]. Despite these facts, no nocturia treatment trials to date have evaluated any impact on fall reduction. Nocturia also has adverse effects on quality of life [660], including an increased risk of depression and poor self-rated health, probably as the result of the impact on sleep [661]. Adults with nocturia also complain that nocturia “makes them feel old” and they worry about falling at night [662] Older individuals described nocturia as simultaneously debilitating, frustrating, distressing and puzzling [663].

To better appreciate the deleterious effects of nocturia, it is important to understand the effects of disrupted sleep [636, 664] When a group of 1,424 elderly individuals, ages 55–84 were presented with a checklist of symptoms that potentially disrupt sleep, nocturia was chosen by 53% of the sample as a self-perceived cause of “every night or almost every night”. Nocturia was cited four times as frequently as pain, which was the next most identified cause of sleep disruption [665]. There is growing evidence to suggest that bother from nocturia is related to the number of trips to the bathroom, but also with the difficulty experienced in trying to return to sleep.[632, 664, 666] In particular, those with nocturia who report difficulty going back to sleep, the prevalence of falls is higher [666]. While the relationship between nocturia and sleep disruption might appear to be self-evident, other lower urinary tract symptoms are also highly correlated with sleep disturbances. [667]

There has been recent and meaningful development in understanding the impact of nocturia on quality of life. A condition-specific instrument commonly used for assessing the impact of nocturia is the ICIQ-NQOL [668], which was developed using a pool of only men (average age 68.2, age range 32-88) recruited from urology practices. Given the absence of women and the likely predominance of men with benign prostatic enlargement as informants, there remains a chance that the instrument does not broadly represent the experiences of all individuals who have nocturia. Other focus groups and one-on-one interviews performed independently with a broader representation of both men and women did demonstrate similar themes, suggesting content validity.[662] Two missing themes,

however, were that nocturia was an “indication of getting older” and made them fearful of falling. Use of the Nocturia Nocturnal Enuresis and Sleep-interruption Questionnaire, which was specifically developed in older men and older women (60-80), showed a greater impact of nocturia in the younger elderly and a greater bother among women compared to men.[663] Use of the generic quality of life instrument, the 15-D, demonstrated statistically significant and clinically meaningful decreases in 15D score and in all 15D dimensions except eating with increasing nocturia.[629] In this study, older women were less bothered by nocturia than were younger women; older and younger men were equally bothered [629].

Notable recent work has shown nocturia to be associated with mortality [659, 669, 670]. It is unlikely that nocturia directly contributes to mortality; nocturia certainly marks other conditions (poorly controlled diabetes mellitus, congestive heart failure, worsening renal insufficiency) associated with bad outcomes. Whether or not these associated conditions should be statistically controlled for is not clear, as they might represent a part of the causal pathway. The association with mortality when examined across the age spectrum shows a stronger relationship with younger than with older individuals [669]. With careful controlling for comorbidities, this association between mortality and nocturia sometimes remains independently significant [671] and other times does not [672]. Though much of the impact of nocturia is believed to result from its impact on sleep, nocturia remains independently associated with mortality even with controlling for sleep disordered breathing [673].

4. PATHOPHYSIOLOGY

The pathophysiology of nocturia is considered to be multifactorial; this is the case for nocturia in elderly persons as well. In age-adjusted analyses from a large survey in Finland, no single factor related to nocturia was present in greater than 50% of those with nocturia [674]. The factors with the greatest impact at the population level were (urinary) urgency, “benign prostatic hyperplasia”, and snoring for men, and overweight and obesity, urgency, and snoring for women [674].

A commonly used framework for clinical diagnosis and treatment is that nocturia can be related to one or a combination of three primary underlying causes, all of which increase with age: low bladder capacity usually as a component of OAB, DO, urgency UI, or BOO in men; nocturnal polyuria; and primary sleep disorders.[634, 635, 675] Nocturia was shown in retrospective analysis of 213 cases (mean age 72) who had detrusor overactivity, out of a total of 777 men studied using pre-operative urodynamics to be highly associated with volume at which the first detrusor contraction occurred [676]. Somewhat in contrast, in one prospective case series of 987 ambulatory women aged 55-75 years, a higher post void residual (>200 mL, 100-199 mL, 50-99 mL versus <50 mL) was not associated with reporting more nocturia [677].

The proportion of 24-hour urine volume produced at night increases with age, even among healthy older adults free of overt comorbid conditions.[678, 679] Studies of frail elderly have shown that the proportion of urine produced at night is close to 50%, rather than less than 30% as in young healthy adults. [680-682] Nocturnal polyuria (NP) is more common in older compared to younger nocturics [683-685] In some elderly persons, this is due to mobilisation of excess volume caused by peripheral oedema, which may be due to venous insufficiency, medications, and/or heart failure. In the case of calcium channel blockers, women younger than 55 years of age, but not older women or men, were shown to have higher rates of nocturia in cross-sectional analyses [686]. In that same study, both hydrochlorothiazide and loop-diuretic usage in men were associated with higher rates of nocturia.

Some studies have suggested that there is an abnormality in the secretion and/or action of arginine vasopressin (AVP) or a loss of the normal diurnal rhythm (with inappropriately low values at night) in many elderly patients with nocturia. [687, 688], which may approach as many as 4% [687]. Another, however, failed to find an association between AVP deficiency (detected by water deprivation testing) and nocturnal polyuria in a series of elderly persons with nocturia. [689] Other research suggests that some frail elderly persons with nocturia have high atrial natriuretic peptide (ANP) levels at night; [690, 691] however, these investigators did not use echocardiography or brain natriuretic peptide levels to detect occult heart failure.

Sleep disordered breathing and sleep apnoea, have also been associated with nocturia and nocturnal UI in the elderly.[690, 692-694] Community-based elderly populations who have higher levels of sleep disordered breathing (>25 breathing events per hour), have nearly double the number of nocturia episodes compared with those with low rates of sleep apnoea [695]. Nocturia is so tightly associated with sleep apnoea that in a population of adult patients presenting to a sleep clinic, it performed similarly as a screening question for OSA when compared to asking about “snoring’ [696]; whether or not this held true for the subset of older patients was not reported. Whether this relates to increased ANP production,[690] mechanical forces on the bladder generated during apnoea events,[693] or other mechanism(s) is unknown.

5. DIAGNOSTIC ASSESSMENT

The approach to the assessment of nocturia should be similar to that for UI described above. Special considerations include:

- A frequency-volume chart of at least 24 hours duration that includes timing and volume of each void at night as well as during the day, as well as a specific indication of when the individual went to bed with the intention of going to sleep at night and awoke in the morning. Some patients may find this difficult to perform,[697] but face-to-face explanation of the procedure, a hand-held urinal or a receptacle to place in the toilet to measure volumes, and involvement of caregivers may improve compliance and accuracy.

- Additional questions in the history that focus on the possibility of a primary sleep disorder, such as asking about sleep quality, daytime sleepiness, snoring, and leg movements at night (this history is enhanced by questioning the bed partner).

- Additional history and focused physical examination related to volume overload (e.g., lower extremity venous insufficiency, congestive heart failure); in some cases additional testing such as an echocardiogram or a brain natriuretic peptide level may be helpful in ruling out the latter diagnosis.

6. TREATMENT

While many clinical investigations are trials of single agents, experts [633] would argue that treatment of nocturia in elderly patients should be based on a holistic approach informed by identification of multiple potential underlying causes. There is, unfortunately, little high quality evidence for most treatments, and certainly with respect to combined treatments, for nocturia in this age group. As well, cure, or the complete resolution of nocturia, is infrequently achieved in either clinical practice or research.

The most common primary outcome in clinical trials is reduction in nocturia episodes, as measured by voiding diary or self-reported, average nocturia over a given period of time. Some trials have reported the percent of participants who achieving a 33% [698] or 50% [689, 699-702] reduction in nocturia from the baseline level or the percent of individuals having a reduction equal to 1.0 fewer mean nightly episodes of nocturia [699, 701, 702]. There are few treatments that offer robust reductions of nocturia, with most ranging from 0 to 0.8 fewer episodes of nocturia. The net reduction of an intervention, subtracting the benefit seen in the control or placebo arm is often even smaller. Whether this is due to regression to the mean due to random variation in the symptom of nocturia or a result of monitoring and recording night-time voids is unclear. Patient-level outcomes related to general satisfaction questions, nocturia-related bother, and nocturia-specific quality of life are therefore even more meaningful. Most trials examining nocturia as an outcome were performed prior to the validation testing of the ICIQ-NQOL instrument.[668] An additional important target for therapy is reduction in bother due to nocturia. Unfortunately, there have been few meaningful successes in relating the number of nocturia episodes to the hours spent in bed, which may vary considerably in older persons. [633]

There are several approaches to drug therapy for elderly patients with nocturia; most of the published guidelines suggest targeting “primary” or “principal” causes of nocturia (e.g., nocturnal polyuria). Because older adults with nocturia have multiple potential causes, treatment often will require combination treatment. While some trials may report statistical significance for reduction in nocturia, the clinical meaningfulness of these changes is suspect.[703] Although no specific data are available on RCTs of multi-component interventions, elderly patients with nocturia may benefit from an approach to treatment [704] that combines behavioural strategies, therapy for medical and sleep disorders, and nocturia-specific drug therapy. In another uncontrolled study, lifestyle modifications of 1) restriction of fluid intake, 2) refraining from excess hours in bed, 3) moderate daily exercise and 4) keeping warm in bed resulted in a positive reduction of nocturia from 3.6 episodes per night to 2.7 for 56 participants aged 59-85 (mean age 74.5, 84% male) [705]

a) Behavioural approaches and treatment of comorbidity.

The use of specific behavioural strategies (e.g. altering fluid intake, reducing sodium intake, leg elevation for oedema) on nocturia in older patients have largely been made on the basis of consensus. Using bedside commodes or urinals, and minimising the distance necessary to reach a toilet and providing a safe, adequately lit path may be helpful in reducing the risk of night-time falls related to nocturia, especially in those with underlying gait instability and other risk factors for falls.

The first secondary data analysis of a RCT which demonstrated that behavioural therapy, with an emphasis on pelvic floor muscle exercises and urgency suppression strategies, showed that nocturia was reduced in women (mean age 68) with urgency-predominant UI.[699] The median reduction of 0.5 episodes per night was significantly more effective than drug treatment with oxybutynin IR titrated from 2.5mg per day to 5.0 mg three times a day, (0.3 episodes) or placebo (no reduction). A second secondary data analysis of an RCT, that did not show benefit with respect to the primary endpoint of urgency incontinence in women (mean age 55), did not show benefit of behavioural therapy when added to tolterodine 4 mg LA for nocturia. [706] An additional RCT in men (mean age 64) examined the impact of the addition of either titrated bladder relaxant therapy (oxybutynin XL 5-30mg) versus behavioural therapy for pelvic floor muscle exercise in whose 24 hour urinary frequency was not resolved with alpha-blocker therapy. In this trial, nocturia was a secondary outcome. In this study, the behavioral group showed greater reductions in nocturia (mean

= -0.70 vs. -0.32 episodes/night; P = .05) [707]. There are currently no trials of pelvic floor muscle exercises or urgency suppression strategies where individuals were enrolled on the basis of having nocturia with reduction in nocturia as the primary outcome.

b) Pharmacotherapy

1. Antimuscarinic therapy

Members of a recent nocturia consensus conference agreed on the following statements with regards to overactive bladder and antimuscarinics: 1) most patients with nocturia do not have overactive bladder; 2) most patients with OAB do have nocturia; 3) antimuscarinics are not usually efficacious for nocturia; and 4) antimuscarinics may be effective for nocturnal voids due to urgency.[631] In general, if the history, bladder diary, and physical examination suggest that nocturia is related primarily or in part to OAB/DO/urgency UI, then treatment with an antimuscarinic agent should be considered (see Pharmacological Treatment above). There are several trials examining the effect of antimuscarinics for nocturia reduction, including trials of oxybutynin-IR, [699] solifenacin, [708] and tolterodine [709, 710]. Four recent trials have compared placebo to active drug for nocturia without statistical improvement. [711-714] There is evidence to suggest that these agents may be best used in combination with other therapies [715] rather than as single modality therapy. Even when agents from this category have shown statistically significant reductions in nocturia, the net benefit of reduction in nocturia (above that effect shown with placebo) is only by 0.0 to 0.3 episodes. A recent "positive" trial showed a statistical advantage of solifenacin 10 mg over placebo of a net difference of -0.12 episodes per night.[716] Tolterodine demonstrated statistical reduction in nocturia accompanied by urinary urgency (but not overall nocturia). [710] The clinical importance of nocturnal urgency is evident to the patient with the symptom ("I would like to not wake up and have to rush to the bathroom"), but this outcome is not fully nor well established within the literature. Use of anticholinergic medications should be used with caution in at-risk individuals as they may cause worsening of confusion.

2. Agents directed towards benign prostatic obstruction

Alpha-adrenergic agents used in patients with symptoms suggestive of BPO have a modest impact on nocturia, with a mean reduction of slightly less than one episode per night.[689, 717]. 5-alpha reductase inhibitors [689] and saw palmetto (Serenoa repens, saw palmetto berry extract) [718] have not shown statistical benefit for nocturia except in one study within one subset of participants age >70.[719] This statistical advantage did not persist beyond one year, and the net benefit compared to placebo was a difference of < 0.2 fewer nocturia episodes.

3. Other medication approaches

Among postmenopausal women, one uncontrolled trial of oestradiol in combination with a progestogen showed a dramatic reduction in nocturia over 6 months, [720] but this was not replicated in another RCT. [721] There are few studies that have focused on treatment of nocturia with the use of medications for sleep. One RCT evaluated melatonin for treatment of nocturia associated with BOO in older men. [722] Melatonin showed only a trend towards reduction in nocturia compared to placebo (-.03 and -0.05 episodes from baseline 3.1 episodes, respectively) but did significantly reduce reported bother from nocturia. A second study compared the addition of either melatonin or a sedative hypnotic (rilmazafone) to older men and women (mean age 72) who were already taking a medication for nocturia, and found the addition of either treatment further reduced nocturia one episode (from 3.5 to 2.5 in both groups) [723]. Reducing volume overload associated with lower extremity venous insufficiency or congestive heart failure with a late afternoon dose of a rapid acting diuretic may be helpful in reducing nocturnal polyuria and nocturia in selected patients. [724, 725] Diuretics (specifically bumetanide and furosemide) have been conferred Level 2 evidence, Grade C recommendation by the Committee for Establishment of the Clinical Guidelines for Nocturia of the Neurogenic Bladder Society. [726] Treating sleep apnoea with continuous positive airway pressure can reduce nocturia severity, but these trials have not usually included the frail elderly. [727] Treatment with very short-acting benzodiazepines for patients with primary insomnia, and with dopaminergic agonists for patients with restless leg syndrome, may improve sleep quality, but there are no data to support these approaches.

4. Anti-diuresis treatment Desmopressin

Most older patients with nocturia have increased nocturnal urine output, which is less common in younger patients [685]. This having been said, the value of classification of patients (according to the presence or absence of NP) has not been demonstrated to be a meaningful predictor of efficacy, or lack of benefit, for any treatment, including prediction of response to desmopressin [636]. A large number of studies over the last 20 years have examined the potential role of exogenous AVP (desmopressin or DDAVP) for the treatment of nocturia in older patients [681, 698, 701, 702, 728-743] (**table 10**). While many have been uncontrolled case series involving relatively small numbers of subjects, more are robust RCTs. In some cases, however, the inclusion criteria, outcome measures, and route, dosing, and duration of DDAVP treatment have varied considerably. The first two, large RCTS using oral DDAVP employed essentially identical designs, with one conducted in men [702] and the other in women. [701] While these trials included some patients older

Table 10. Selected studies of desmopressin (DDAVP) for nocturia involving older patients (last 5 years)

Reference No. (Yr.)	Study Design	N	Sex	Age Mean, (SD)	Nocturia Definition	DDAVP Dose[1]	Outcomes	Level of Evidence
van Kerrebroeck 2007 [952]	RCT, placebo controlled Dose titration	127	70%M	63.4 (12.8)	> or =2 voids/night	0.1, 0.2, 0.4 mg	39% reduction in the mean number of nocturnal voids with desmopressin vs. 15% with placebo, p<0.0001 duration of the first sleep period prolonged by 108 min with desmopressin vs. 41 min with placebo; p<0.0001)	2
Johnson 2007 [953]	double-blinded, placebo-controlled, crossover trial of individually titrated oral ddAVP.	14	NS	74 (5)	any nighttime void between going to bed and morning awakening	0.1, 0.2, 0.4 mg	NUV in subjects receiving ddAVP treatment was significantly lower than at baseline (197mL reduction,) and than in subjects taking placebo (126mL less,). NUVof subjects at baseline and of those taking placebo were not significantly different	3
Wang 2011 [738]	long-term efficacy and safety of low dose oral desmopressin in elderly patients with benign prostatic hyperplasia	126	M	74.5 (5.99)	2 or more voids nightly nocturnal polyuria =nocturnal uri ne volume greater than 30% of total daily urine volume	0.1	decrease of 2 or more voids per night) achieved by 35 (61.40%) patients receiving desmopressin and by 8 (13.80%) on placebo (p _0.001).	2
Fu 2011 [740]	randomized double-blind treatment period. with DDAVP and staggered furosemide	80	58 men and 22 women,	67 (8)	at least two voids per night	0.1, 0.2, 0.4mg	46% patients in the study group compared with 4 (10%) patients in the control group reported that the treatment had a 50% or greater reduction in the number of nocturnal voids	2

than 75, the mean age of the participants was closer to “middle” rather than “old” age (65 and 57, respectively). Both found significant reductions in nocturia and nocturnal urine volume, and increases in mean duration of self-reported first night-time sleep episode. However, there were some unusual elements of the trial design. The randomised controlled portion was preceded by an open-label dose-titration run-in, with the subsequent exclusion of subjects who did not experience >20% reduction in nocturnal urine volume or who were intolerant to the medication. Although this approach may be useful for targeting therapy in clinical practice, it raises questions about selection bias and the generalisability of the results. Most individuals in DDAVP oral tablet trials were titrated up to an oral dosage of 0.4 mg, [701, 702] yet older patients can have a significant reduction in night-time urine with much lower doses of 0.1 or 0.2 mg orally.[738, 739, 744]. A major concern related to DDAVP treatment in elderly patients is fluid retention (which can exacerbate underlying cardiovascular disease) and hyponatraemia. In one study, one of the 57 individuals randomized to 0.1 mg DDAVP for year was described as having a “consciousness disturbance due to hyponatraemia (116 mmol/l)” which left him unable to “complete the protocol” (Wang 2011). Many older persons may have pre-existent hyponatraemia due to a variety of medical conditions and drugs and will develop renal insufficiency or congestive heart failure. One review [745] found the incidence of hyponatraemia with DDAVP in older persons to be 0-9% (depending on definition), with the exception of the RCT in men discussed above, in which the incidence of any hyponatraemia was 22% (4% with sodium < 130 mmol/L). Because so few frail elderly were included in these trials, the actual incidence of clinically significant hyponatraemia from DDAVP that might occur with monitoring outside of a clinical trial is unknown. A further review of pooled trial results found that the incidence of hyponatraemia in subjects with normal baseline sodium was <1% (3/336 subjects) in persons < 65 and 8% (22/260) in those >65, and 75% (6/8) in older patients with a low baseline serum sodium.[746] Pharmacodynamic studies in younger older men (aged 55-70) found that DDAVP had a prolonged half-life which was in part responsible for hyponatraemia. [747] DDAVP is not useful in frail older persons in nursing homes with nocturia and/or night-time UI because of the lack of efficacy for reducing night-time voids and the very high rate of hyponatraemia [744].

Several attempts at delivering the efficacy of antidiuretic therapy without the side effects have focused on the dosing, mechanism of achieving anti-diuresis, half-life of the agent, and delivery system. Since the last ICI review, data about the efficacy and safety of an orally-disintegrating tablet formulation of DDAVP have been published [698]. The theoretical advantages of such a formulation would be the ability to deliver smaller and consistent level of the drug. The study design evaluated co-primary outcomes of decrease in night-time voids from baseline versus placebo and the ability to achieve a 33% decline in baseline nocturia. Participants were stratified by age <65 and ≥ 65, with 500 individuals over 65 in the study having safety endpoints. At enrolment, all participants needed to have a serum sodium of >135 mmol/L, an estimated creatinine clearance of greater than 60 ml/min (the largest single reason for exclusion during screening, 15%), and a post void residual of less than 150 mL, and, for men only, a peak uroflow of >5 mL/second. The results showed that for men, the minimal effective dosage was 100 microgrammes (-1.38 versus -0.84 for placebo) and for women it was 25 microgrammes (-1.22 versus -0.88 for placebo). Side effects appeared in a dose-dependent fashion, that depended upon both age (older had higher side effects) and gender (women had higher side effects). For those participants over 65 years of age, the following percentages of participants had a reduction of sodium of either 125-130 or <125: on 100 microgrammes, 14.1% and 4.7%; on 50 microgrammes, 6.6% and 2.6%; for 25 microgrammes, 2.6% and 0%. While the 2011 nocturia treatment consensus guidelines [631] stated that ”the mechanisms behind desmopressin-induced hyponatraemia are well understood”, newer information suggests that the hyponatraemia in women is not fully explained by pharmacokinetic profiles [748]. For elderly individuals, antidiuretic therapy via DDAVP orally absorbable tablets still has a narrow therapeutic window where the dosage that allows for efficacy in the absence of meaningful and potentially serious side effects may be difficult to find.

There have also been trials with staggered DDAVP and diuretics, which have greatly reduced nocturia [740]. Of the participants who completed the trial, 5% had hyponatraemia, not counting individuals who had hyponatraemia during run in.

c) Surgical and procedural treatments

Posterior tibial nerve stimulation has been used in OAB trials. A recent trial [749] demonstrated in 214 individuals a favorable outcome for nocturia reduction in the active treatment group (2.9 at baseline to 2.1 with treatment) that was statistically superior to the effect of sham (2.9 to 2.6, net benefit of active over placebo -0.4 reduction). Of note, there were more individuals over 65 years of age (50%) compared to the sham group (41%) biasing against demonstrating benefit if it were true that older adults responded less well; whether or not these gains are maintained without ongoing treatment is not known [750].

Surgical approaches to treatment of nocturia have long been recognized to be effective, yet overall symptoms improve more than does nocturia specifically. The evidence from trials shows that older patients with the highest symptom scores prior to surgery benefit the most from transurethral resection of the prostate [751], yet nocturia often persists and may

be the least responsive symptom for improvement following the procedure [751-753]. Yet, surgery does reduce lower urinary tract symptoms and may result in reductions in nocturia and improvement in symptom specific QOL [754] In one consecutive group of 56 patients treated with either TURP or radical prostatectomy (mean age 69) for persistent symptoms despite six months of medical therapy. The group monitored postoperative nocturia counts, hours of undisturbed sleep, and the ICIQ-NQOL which were compared to baseline. In this uncontrolled series, patients had significant improvements in all measured domains, including a 0.8 episode reduction per night [755]. The NQOL outcome measure was most favorable in individuals with the greatest reductions in nocturia or the most uninterrupted sleep. One study used a retrospective evaluation of 298 patients (mean age 70) over a 10-year period, and found that younger men with lower preoperative urinary maximum flow rates had the best post-operative results [753]. Not surprisingly, symptoms post-operatively were not strongly correlated with objective urodynamic findings [756]. On average, less than half of the men operated on had a reduction of nocturia by 50% or more [753]. In a rare RCT where 66 men, aged 52–81 years (mean 68.6), who were believed to have nocturia solely due to "benign prostatic hyperplasia" and who had received no previous treatments of any type, were randomized in a 1:1 fashion to either alpha-blocker therapy (tamsulosin 0.4 mg) or TURP. The prostate volumes and baseline nocturia nearly differed in a statistically significant manner at baseline (51 cm3 and 2.0 mean nocturia episodes versus 59 cm3 and 2.4 for those allocated to surgery). Both groups had a reduction of nocturia to 1.5 (3 months) and 1.4 (6 months), as well as statistical improvements in the ICIQ-NQOL. No treatment was superior to the other and both were statistically significantly improved from baseline [754].

7. SUMMARY OF EVIDENCE

- Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions. **(Level 2)**
- If OAB, DO, and/or urgency UI is felt to be a major contributor to nocturia, antimuscarinic agents should be considered. **(Level 3)**
- If nocturia is due to insomnia alone, then a very-short acting sedative hypnotic may be considered. **(Level 3)**
- DDAVP should not be used in frail elderly because of the risk of hyponatraemia. **(Level 1)**

8. RECOMMENDATIONS FOR MANAGEMENT

- Nocturia investigations should be carried out utilising both frequency-volume charts and validated questionnaires capturing QoL and bother related specifically to nocturia (e.g. NQoL).

9. RECOMMENDATIONS FOR RESEARCH FOR NOCTURIA IN THE ELDERLY [636]

- Validation and clarification of the definitions of both nocturia (in regards to any night awakening owing to the desire to pass urine, the ICS definition, vs. the more clinically bothersome nocturia, of 2 or more episodes)
- Studies to elucidate the reason for awakening
- Ways in which to understand, and potentially diminish, the robust effect of placebo/control arms
- Epidemiological research regarding studies of nocturia involving the following aspects: incidence/natural history, bother, effect on quality of life
- Research regarding what would be a clinically significant improvement
- Further clinical trials examining the impact of sleep focused treatments
- Trials examining the effects of multiple incremental and multicomponent therapies for nocturia
- Algorithms for both initial and subsequent (e.g., cause-specific) management of frail elderly, and men versus women would seem to be desirable.

VI. MODELS OF CARE FOR THE FRAIL ELDERLY WITH UI

1. BACKGROUND

Globally, frail elderly persons receive personal, nursing and medical care in a variety of healthcare and residential settings that employ many different models of continence care. While there continue to be very few studies, and fewer randomised clinical trials that directly examine these models in relation to UI prevention and management, a discussion of selected models is useful in identifying the challenges and opportunities to improve continence care for this population. This descriptive section briefly outlines four models of UI care particularly relevant to the frail elderly: home care, continence nurse advisors, collaborative practices between advance practice nurses and physicians, and long term institutional care. The care of incontinent frail elders in the acute care and assistive living settings is also discussed. A comprehensive review of global models of care is outside the purview of this section. Of note, we located little new information since the 4th ICI. Our findings were confirmed by a systematic literature review of 7 studies that investigated conservative interventions for frail non-institutionalised older adults, some of whom however lived in assisted living, senior apartments, and homes for the elderly, or attended adult day care [757].

2. HOME CARE

Most care for the frail elderly who live at home is provided by informal caregivers such as spouses,

children, other relatives, and in some cases neighbours or friends. Overall, there has been little research on UI interventions for this population but one trial found that behavioural interventions can be effective in selected frail homebound persons with UI and motivated caregivers [758]. Another trial, included in the systematic literature review mentioned above, found comprehensive geriatric assessment (CGA) was effective in resolving UI in 23% and improving incontinence in 44.6% [759]. Overall, however, the informal nature of care at home may lead to important barriers to effective continence care. Firstly, caregivers may not be available 24 hours per day, and thus regular toileting assistance may only be intermittently available. Toileting programmes (e.g., prompted voiding), intermittent catheterisation, and pessary use therefore may be impossible to implement consistently. Secondly, many caregivers for frail persons are, in fact frail, themselves. Spouses and adult children may have medical illnesses and/or functional problems making toileting assistance physically difficult and continence care stressful for them. An internet-based survey with Japanese family caregivers revealed that caring for a family member with incontinence resulted in significantly higher Zarit Caregiver Burden Interview (ZBI) scores than for those caring for a continent family member [760].) In 11 European regions, informal caregivers caring for incontinent older adults were 2.2 times more likely to report feelings of stress or burden [378]. Thirdly, even among caregivers who are physically capable and available to assist with continence care, negative attitudes, lack of knowledge and educational resources may pose substantial barriers to providing the required care.

Trained, paid caregivers for the frail elderly living at home are variably available throughout the world. Such services may include nurses to teach patients and caregivers UI care and management of intermittent or indwelling catheterisation, health care aides or personal care assistants who can assist with continence care, and provision of continence care supplies (e.g., pads and catheter supplies). In the US, for example, Medicare (health insurance for persons aged > 65) does not pay for ongoing UI care, only some catheter care and supplies and need-based home skilled nursing and physical therapy, and usually only on a limited basis and following hospitalisation. In a survey of Dutch older adults, > 65 years (mean age 80 years, standard deviation 7.2) who were receiving home care agency services, 46% (n=2866) had urinary incontinence. UI type was diagnosed in 49.8%. Types of UI were as follows: 13.1% stress UI, 33.4% urgency UI, 18.1% mixed UI, and 35.4% functional UI. Use of pads was the most commonly used intervention with scheduled toileting the second most frequently used intervention. In addition, for older adults who had a diagnosis for UI type, only 11% received special skin care [492]. In a study with 4010 older adults who were receiving home care, 1478 (36.8%) were incontinent of urine and the use of pads ranged from 29% to 52% among 11 home care sites in Europe [378]. Thus, even for older adults receiving home care, UI management often remains focused on containment by using pads and other protective products. These can be expensive if not provided or reimbursed through available health services or insurance. Research is needed to determine the magnitude of the problem of frail elders who do not engage in practices to protect skin integrity and devise homemade alternatives to pads, which are neither effective, comfortable, nor safe (especially to prevent incontinence-associated dermatitis [761]. A study conducted in the Netherlands with 19 home health agencies found that 38% of agencies documented the input of a continence nurse to care, but no association between quality systems and UI outcomes was found. The authors defined quality systems as management activities designed to monitor, assess and improve the quality of care [762]. With the demand for home care services expected to increase, these agencies will provide services for an increasing number of frail elderly patients with continence concerns.

3. CONTINENCE NURSE ADVISORS AND NURSE-LED MODELS

In many countries (e.g., UK, Australia, Sweden and Canada, among others), continence nurse advisors who can provide extremely valuable services for frail elderly with UI are available. Continence nurse advisors are highly trained in the assessment and management of both urinary and faecal incontinence. They are generally funded by the government and function as public health nurses for a region associated with one or more hospitals. They serve as advisors and provide education to physicians, nurses, and other health care professionals, as well as patients and their caregivers. They may also assist hospital staff in the assessment and management of UI in the hospitalised frail elderly, and coordinate follow up care in the home or in an outpatient clinic. One Canadian study found that continence nurse advisors had a positive impact in improving management of UI in older persons [763]. Data suggest that continence nurse led services are effective for the general population, but there are no specific data for frail older people [764].

4. COLLABORATIVE PRACTICES BETWEEN ADVANCE PRACTICE NURSES AND PHYSICIANS

In many countries, publicly supported continence nurse advisors are not available. However, other models have developed that generally involve collaborative practices between nurses with special interest, advanced training, and expertise in continence care and physicians (usually a urologist, gynaecologist, or geriatrician). These collaborations can be vital for providing optimal continence care for the frail elderly because of the multi-component therapy required. Such nurses may provide reim-

bursable services in private offices and clinics; provide education, consultation, and/or direct services to nursing homes or other long term care facilities, and assisted living facilities; and assist with the assessment and management of UI to frail elders in their homes. The complexity of healthcare delivery systems and needs of medically complex frail older adults are acknowledged in calls for optimal continence care delivered through multidisciplinary teams [404]. An analysis conducted with data from the 2006 National Audit of Continence Care for Older People in England and Wales found that integrated services, those that included organisational structure and clinical care processes for continence care which met national quality standards, provided higher quality of care [268] . Reimbursement for advance practice nurses and their ability to provide direct care independently of a physician varies across countries, and in some case within countries (e.g., in the US their scope of practice can vary by state). Evidence from a randomised controlled trial of a nurse-led continence service (for women aged 40 years and over) revealed clinical and statistically significance decrease in the urinary symptoms of urgency, frequency and UI [765]. The nurses in this study were specially trained, used evidence-based interventions and behavioural techniques with motivation and reinforcement. The nurses also consulted with a medical team. Although this model was used in independently living women, it shows promise for use in community-dwelling frail older people. In some countries there are specialty organisations for continence nursing (e.g., the US, Wound Ostomy Continence Nurses Society and Society of Urological Nurses and Associates; Canada, Canadian Continence Nurse Advisors; UK, Association for Continence Advice). Although little data on the effectiveness of these organisations in terms of improving patient care exist, they are becoming more widespread (e.g., Israel and Italy).

5. INSTITUTIONAL LONG TERM CARE

Long term care for the frail elderly is provided in a variety of types of institutional settings throughout the world. Continence care here is dependent upon many factors, including: type of resident (those requiring long-term skilled and personal care, short-term rehabilitation, post-hospitalisation care); physical environment; the organisational culture and leadership commitment to providing high quality care; the number, education, and motivation of direct care staff; access to physicians with interest in and understanding of continence care; and financial and regulatory incentives to provide appropriate continence care. Nursing home staffing continues to be a major barrier to translating research on prompted voiding and other interventions (see sections on Behavioural interventions and Environmental factors) into practice, and because resource constraints are stringent and will become more challenging with the rapid growth in the frail elderly population [766]. One study found that one staff member to five residents was necessary to implement combined toileting assistance with an exercise programme for physically dependent residents [470]. However, the residents' ability to maintain continence or improve may depend not only on the number of staff available, but also on their knowledge, skill, and interest and how these staff members are deployed. A systematic review on the impact of nursing workload and staffing on establishing healthy work environments for example, found a positive association between the knowledge and level of staff, and patient outcomes. Specifically, a greater proportion of regulated staffing (i.e. registered nurses, enrolled nurses, practical or vocational nurses) is associated with improved outcomes related to the Functional Independence Measure score, the Short Form Health Survey (SF-36) vitality score, patient satisfaction with nursing care, patient adverse events (including atelectasis, pressure ulcers, falls, pneumonia, postsurgical and treatment infection and urinary tract infections) [767]. Moreover, improved patient outcomes in relation to falls, pneumonia, pressure ulcers, urinary tract infection, length of stay and postoperative infection rates are associated with increased hours of registered nurse employment. The section on Interventions with Long-term Care Staff above, reviews studies of interventions with nursing home staff to improve continence care. These interventions have generally met with limited success because they have not incorporated either contextual or patient-level factors into their interventions, but have merely concentrated upon facilitation [768].

Three broad strategies have been employed to improve the quality of continence care for frail elderly nursing homes residents. The first are standardised approaches to identification, assessment, and management of UI. One is the Resident Assessment Instrument for nursing facilities, whose use is mandated in the US and other countries [418].) The Resident Assessment Instrument combines information from the Minimum Data Set (including data on individual resident demographics, medical conditions, function, cognition, and care needs) with Resident Assessment Protocols for specific conditions and impairments. The continence section of the Minimum Data Set is generally accurate in identifying incontinent patients, but not for determining the type or severity of UI or determining especially smaller changes in continence over time [769]. The original version of the Resident Assessment Protocol for UI was partially validated in a sample of approximately 100 frail, incontinent patients in one large academically-affiliated US nursing home [770]. In other countries, such as Australia and the UK, the use of clinical assessment tools in nursing homes is not mandated. They are in certain cases however, linked to accreditation processes and funding, providing a financial incentive for nursing homes to document an assessment and care plan

that addresses residents' continence care needs. The National Audit of continence Care for Older People reported on the extent to which nursing homes adhered to a suite of continence assessment and management standards based on ICI and national criteria [265].

Another approach is national guidance directives, such as that for surveyors who conduct yearly quality evaluations of all US nursing homes. A revision of the US guidance to surveyors for UI and catheter use in 2005 attempted to replace the existing emphasis on nursing documentation of continence care plans with an emphasis on UI assessment and provision of patient-focused care [418]. However, a subsequent study found that both surveyors and nursing home staff did not understand this shift in emphasis, and that the dissonance between these two groups in basic UI knowledge and elements of the guidance was a barrier to any change in quality of UI care [427]. Despite the existence and dissemination of guidelines, several studies document an ongoing discrepancy between their recommendations and regulations and the continence care actually delivered in the US [277, 425, 458, 771] and UK [265, 772].

The second strategy has been the use of principles of continuous quality improvement and total quality management developed for business management [773]. The key elements of these approaches are education and involvement of direct care staff, identification of a "continence champion" and team to implement the programme, and the continuous collection and analysis of quantitative outcome data using principles of statistical quality control. Quality assurance programmes using UI quality indicators have also been proposed [263]. One study successfully used a computerised assessment and quality improvement software program and external oversight to maintain a 50% reduction in UI in eight diverse, geographically dispersed US nursing homes [440]. A second implemented a quality improvement programme in five diverse US nursing homes, but UI reduction was more modest (20-30%) in this effort to translate research into practice [484]. In a recent major quality improvement in NHs initiative, the Centres for Medicare and Medicaid Services (CMS) in the United States use publicly disclosed quality measures (QMs) for nursing homes. Low risk incontinence (i.e., percent of low risk long stay residents with loss of bladder or bowel control) was associated with the percent of residents readmitted and the percent of residents incontinent of urine on admission to the facility [774].

The third approach is a specialty practice exemplar model for continence care, with an academic nursing faculty member with expertise in the assessment and treatment of UI engaged in clinical UI practice in a long-term care facility (see Interventions with Long-term Care Staff, above): graduate nursing students working with this individual focus on the Resident Assessment Protocol for UI. UI assessment and management skills are transferred to the facility nursing staff members through several mechanisms, including staff education and improved continence care systems [398]. This approach to improving continence care in nursing homes can be facilitated through collaborative partnerships between academia and the nursing home sector. Proponents of this type of collaboration claim it has the potential to facilitate culture change in nursing homes; to transform the perceptions and images of nursing homes in academia and the community, as exemplary places for quality and care and quality of life; and to promote evidence-based care, interdisciplinary collaboration, and resident-centred care [775-777]. For example, they can also potentially support the development of clinical leaders to introduce change at the clinical interface [778].

The concept of using clinical leaders, and/or nurses with advanced knowledge and skill, to improve the evaluation and treatment of UI in nursing homes is not new [277, 453, 767, 779, 780]. Watson and colleagues for example report a quasi-experimental pre-post design to test the effectiveness of using nurse practitioners to translate the Agency for Health Care Research and Quality Urinary Incontinence Guideline into practice for residents from nursing homes in upstate New York. Although the intervention was inconsistently implemented, 8.4% of residents' (n=25) became continent: largely due to treatment of reversible causes such as constipation [781].

6. OTHER INSTITUTIONAL SETTINGS

Other institutional settings that warrant attention in the context of models of care for improving the management of UI in frail older adults are: 1) acute care settings and 2) assisted living communities.

Acute care is a form of secondary health care which involves an active approach to managing a short-term, but urgent health problem. It is generally delivered by a range of health care professionals in a hospital setting. Older adults comprise the largest proportion of people admitted to acute care and as the population ages, the number of frail older adults requiring hospitalisation will increase. A recent prospective cohort study of 577 patients (mean age 82 +/- 6.9 years) admitted to general medical wards of three acute care hospitals in Brisbane, Australia, found UI rates of 43.8% (243/555) premorbid, 36.7% (176/479) during admission, and 35.3%(187/530) at discharge [782]. Moreover, of 438 patients at the time of discharge, 38 (12.8%) had new onset UI. One group of patients with a high risk for developing UI in hospital are female hip fracture patients. A secondary analysis of data from 6516 hospitalised women with a fractured hip revealed 21% became incontinent during hospitalisation [783]. Risk factors in this group included admission from a nursing home or other long-term care facility (odds ratio

[OR] 1.68, 95% confidence interval [CI] 1.29–2.19), confusion (OR 3.44, 95% CI 2.79–4.24), use of a wheelchair or device for walking (OR 1.53, 95% CI 1.29–1.83), and prefracture dependence on others for ambulation (OR 2.51, 95% CI 1.64–3.85).

Other research on UI in acute care draws attention to an overreliance on continence aids, and inadequate attention to identifying and addressing potentially contributing factors. For example, Ostaszkiewicz and colleagues conducted a point-prevalence survey of 447 hospitalised older adults in acute and subacute care settings in Australia and found 60% with a continence product or device, however, 50 (41%) patients with an absorbent pad denied having experienced UI or FI in the preceding 24 hours [430]. By contrast, 113 patients (16%) who reported UI or FI in the same period had no continence product or device. Hospital inpatient notes and admission notes also lacked information about patients' continence status. Similar findings were reported for elderly patients admitted to hospitals in Israel [409] Switzerland, [408] , and Italy [784]. Zisberg and colleagues [409] conducted a prospective cohort study of 352 patients aged 70 and older who were continent prior to admission to an acute care hospital. They found, 17.1% developed UI during their hospitalization, and in a multivariate analysis, the use of a urinary catheter or diaper were associated with the development of UI (4.26 95%CI 1.53-11.83 and 2.62 95%CI 1.17-5.87 respectively). Zurcher and colleagues [408] surveyed 78 elderly inpatients in a Swiss hospital and found 41 (51%) screened positive for UI, yet only 10 (24%) of nursing records documented the presence of UI. Moreover, the use of absorbent pads was the only intervention documented. The number of patients who declined to be asked about their continence status was minimal (n=5). Palese and colleagues also drew attention to a mismatch between UI and absorbent pad use, which occurred for 34% of patients admitted to medical wards in two Italian hospitals [784]. Factors that contribute to the lack of screening and assessment of incontinence, and overreliance on containment strategies for UI in acute care include: healthcare practitioners' lack of knowledge and skills, [428, 785-787] negative attitudes toward older adults with incontinence, or the belief that UI is not a priority [788, 789].

Whilst existing research indicates the need for UI to be treated as a potentially preventable complication of hospitalisation, it does not offer specific information about the continence status and continence care needs of hospitalised frail older adults as a specific subgroup. As incident UI is a marker for frailty, and functional decline, it is important to focus clinical and research attention on this vulnerable population [790, 791]. Dowling-Castronovo and colleagues provide a standard of practice protocol for managing UI in older hospitalised adults [792]. However to the best of our knowledge, there is no evaluative research on the use of these or other protocols for managing either daytime or night-time UI in acute care, especially in the frail elderly. There is a similar lack of published literature on models of care. Staff management protocols that involve using clinical champions, goal setting, self monitoring, and industrial quality control techniques, that have been trialled and evaluated in other settings (i.e. nursing homes), may apply to acute care.

Assisted living communities are social care residential models, in which older persons are provided primarily IADL assistance (meals, laundry, cleaning), and are becoming more common (primarily in the developed world). There is substantial variation in the functional status and medical care needs of their residents, the availability of nursing and physician care, reimbursement, regulation, and whether and how residents are allowed to age "in place" versus being transferred to nursing facilities should their care needs substantially increase. In some countries and localities, assisted living residents may substantially resemble the nursing home population. There are no data on the quality of management of UI for frail elderly residing in assisted living facilities, or intervention trials specifically in this population. The US National Association for Continence (www.nafc.org) has published a "blueprint" for continence care in assisting living facilities, based primarily on expert opinion.

7. RESEARCH RECOMMENDATIONS

1. Compare the efficacy of specific models of UI care for the frail elderly around the world.
2. Determine the factors associated with the effectiveness of care models in countries with different health care systems.
3. Develop and evaluate protocols for managing UI in frail elderly persons in acute care.
4. Differentiate frail from non-frail older adults in research on UI.
5. Replicate clinical trials and quality improvement initiatives to reduce urinary incontinence in a variety of healthcare settings with larger samples.
6. Identify specific models of care for UI in frail elderly persons in specific healthcare delivery settings: acute care, nursing home and assistive living, and primary care settings.
7. Determine system-level, group-level and individual-level quality indicators and outcomes for different models of care for UI in frail elderly persons.
8. Determine the factors associated with the effectiveness of care models in countries with different health care systems

C. FAECAL INCONTINENCE

I. BACKGROUND

FI in older people is a distressing and social isolating symptom and is associated with a possible increased risk of morbidity,[320, 793] mortality,[794, 795] and dependency [793, 795-797]. Frailty, defined by having multiple comorbid chronic illnesses and/or limitations to physical activity, is an independent risk factor for FI [798, 799]. Many older individuals with FI will not volunteer the problem to their general practitioner or nurse, and regrettably, health care providers do not routinely enquire about the symptom.[800] This 'hidden problem' can therefore lead to a downward spiral of psychological distress, dependency, and poor health. The condition can especially take its toll on informal care providers of home-dwelling patients, [801] with FI being a reason for requesting nursing home placement [802].

Even when older people are noted by health care professionals to have FI, the condition is often managed with the use of absorptive or containment products, especially in the long-term care setting where it is most prevalent. Current surveys show that the level of awareness regarding appropriate assessment and treatment options is limited among primary care physicians [803]. The importance of identifying treatable causes of FI in frail older people, rather than just managing passively (e.g. pads provision without assessment) is strongly emphasized in national and international guidance,[320, 804] but audits show that adherence to such guidance is generally poor, with non-integrated services, and sub-optimal delivery by professionals of even basic assessment and care [268].

This section covers specific issues for frail older people with FI. Since frail older adults frequently have co-existing urinary incontinence, evaluation and management of urinary incontinence and FI should be considered simultaneously [805-809]. Healthy older people should be managed using the interventions covered in the Chapter 16 on the "Management of Faecal Incontinence."

For the previous ICI report, the literature review covered the period 1966 to 2008. We identified new population-based studies on the prevalence and incidence rates of faecal incontinence specifically including frail, older adults (**Table 11**). Table 10 includes all studies published through December 2011, which met the following criteria: (1) sample representative of the general population (not a convenience sample or sample recruited from a specialty/primary care medical clinic or other setting in which there is a probable selection bias), (2) sample involving specific models of care for the older adult, and (3) sample of specific disease or co-morbid condition (i.e., home care, long term care).

The PUBMED.gov database was searched up to December 2011 using the following keywords:

(i) 'anal, bowel, faecal, faecal' and 'incontinence'

(ii) constipation

(iii) 'urinary' and 'incontinence'

(iv) laxatives, enemas, suppositories

(iv) other relevant phrases such as 'comprehensive geriatric assessment' ' stroke'

(v) level of care, 'nursing home,' institutionalisation', long-term care,' 'acute care,' 'hospitalisation'

Additional articles were identified by examining reference lists, and the Cochrane other recent systematic reviews.

II. PREVALENCE AND RISK FACTORS FOR FAECAL INCONTINENCE

In 2007, the Centre for Disease Control commissioned the University of Minnesota to prepare a systematic review of the prevalence and risk factors associated with FI for the State of the Science Conference on the Prevention of Faecal and Urinary Incontinence [810]. Their inclusion criteria differed from ours and did not focus on the frail older adult. The studies identified in both of these publications were reviewed for this report.

1. PREVALENCE ESTIMATES FOR FAECAL INCONTINENCE

(FI) prevalence estimates for faecal incontinence vary widely: 2.2% to 25% in the general community-dwelling population, 9-30% in older, frail adults, 18% to 33% in acute care settings, and may approach up to 50% in long term care and institutionalised settings. Incident FI varies from 6% to 17% in community dwelling populations, with less information known about incident rates in specific care settings. The variability in the prevalence rates may be related to the case definition and the frequency of FI reported. Case definition may include flatal incontinence, as well as loss of solid and liquid stool. Often, passive FI, or seepage, is not differentiated from solid or liquid stool FI in prevalence studies. A few studies have also defined a category of soiling of underwear only. In this review, FI refers to the loss of solid or liquid stool or mucus. Studies are specified that use other definitions, such as flatal incontinence or anal incontinence and soiling.

2. PREVALENCE AND INCIDENCE ESTIMATES OF FI IN COMMUNITY-DWELLING OLDER ADULTS.

FI is strongly associated with aging in many studies, and studies only involving older adults have higher prevalence estimates. The National Health and Nutrition Examination Survey (NHANES) in

Table 11. Population-based Surveys of FI in Older Adults

Source	Design	Prevalence/Incidence	Risk Factors	Notes
Whitehead et al (2008)	US representative sample of 2229 women and 2079 men, aged 20+ years. FI assessed with the FISI. FI defined as any involuntary loss of mucus, liquid, or solids in the last month.	**Prevalence** among older adults aged 70+: **15.3%** overall No gender differences	Age Loose stool consistency >21 bowel movements/week – women Inability to do activity – women Chronic illnesses – women Poor self-rated health – men Urinary incontinence - men	Cross-sectional, population-based national survey. No subgroup analysis for risk factors in older adults.
Rey et al (2009)	Random sample of 5,400 adults aged 50 yrs and older from Olmstead Co, MN. Respondents (n=1540, 64%) answered questions on FI at baseline in 1993 and 674 responded a mean of 9 years later.	**10-year incidence rate was 7%** for any FI	Urgency with bowel movements Self-reported diarrhoea Incomplete evacuation Pelvic radiation	Community sample, not population-based No separate analyses by gender Mean age of sample at follow up was 67±9 years
Markland et al (2010)	1000 Medicare beneficiaries age 65+ in 3 counties of Alabama. In-person interviews at baseline and 4-years. Gender/race stratified. FI excluded flatus.	**4-year Incidence** rates reported. 17% overall for any FI 6% for monthly FI No gender differences	White race/ethnicity - women Chronic diarrhoea – women Urinary incontinence – men and women Depression – women	Population-based longitudinal study with in-person interviews Mean age of 78 ± 5 years
Joh et al (2010)	Convenience-based survey in adult senior centers and health centers in Korea, n=981, mean age 73.6±6.8 years	**Prevalence of FI in the previous 3 months, 15.5%.** No differences in men and women, p=0.08	Urinary incontinence – men and women Hemorrhoids – men and women Poor self-rated health – men Diabetes – women Infrequent dietary fiber - women	Community sample, not population-based
Sharma et al (2011)	Postal survey of 2000 adults, 18 years and older in New Zealand, mean age 51.6 years	**Prevalence of monthly liquid or solid stool was 12.6%**	Study did not assess risk factors, only variations in prevalence by 3 scales	No gender or age group sub-analyses
AlAmeel (2010)	Population-based Canadian Health and Aging Study, n=8917, among adults 65 years of age and older	**4% overall prevalence rate** for any FI in the past year	Older age More common among women Poorer self-rated health More dependency in ADLs Cognitive impairment	Population-based study No increased mortality or institutionalization after 10 years when adjusting for all significant confounding factors No separate analyses by gender

the United States (US) provides one of the best estimates of FI prevalence to date because it surveyed both sexes, all major races represented in the US, and a range of older adults by age decade (55-69 and 70 years of age and older) [811]. NHANES also provided separate estimates for different types of FI (e.g., solid, liquid, mucus, and flatus) and frequencies of stool loss. The age-adjusted prevalence of FI (defined as accidental loss of solid, liquid, or mucus incontinence in the month preceding the interview) in the non-institutionalised population of the United States is 8.9% of women and 7.7% of men, with higher rates in older adults (15.3% in women and 15.5% in men aged 70 years of age and older). Liquid stool incontinence was the most common type of FI reported in the NHANES data. Rates of FI in older, frail adults are not gender-specific, with recent studies suggesting equal rates of FI among older men and women [797, 798, 811-815], and differences in survey methods make it difficult to interpret observed differences [793, 811, 812, 816-818].

New additions to the literature include prevalence estimates of urinary incontinence and FI in populations receiving specialty services in the home, such as home health care/home visits by physicians and other care providers. Using the Outcome and Assessment Information Set (OASIS), a standardised and administrative assessment tool used to document patient needs in home care settings in the United States, urinary incontinence was identified in 27%-33% of home health care patients and 7%-9% had FI on admission to the home health agency/provider [819].

Rates of incident (i.e., rate of new onset) FI in non-institutionalised populations have been reported in two recent studies [817, 818]. Both studies surveyed older adults in the community and reported FI incidence rates after 4 and 9 years, respectively, from the initial survey period [817, 818]. Incident rates for FI occurring in the last year were 17% (95% confidence interval 13.7% to 20.1%) after 4-years in one study (n=557)[817] and 6.3% (95% confidence interval 4.5% to 8.6%) after 9-years in the other (n=683).[818] For FI occurring at least monthly, the incidence rate was 6% (95% confidence interval 4.0% to 8.3%) after 4-years [817]. Differing FI incidence rates may be due to the age range of those surveyed at baseline. In the Markland *et al* study, the average age of those surveyed was 77.7 years at 4-years, whereas the Rey et al study surveyed adults 50 years and older at baseline. FI incidence rates have also been reported in specific populations followed over varying time periods. Rates of incident FI in institutionalised older adults was 7.5% at 1-year (n=1186), [794] with another study finding an incidence rate of 5.4% 1-year after hospitalisation for an acute brain injury (n=1013),[820] and a smaller study finding a rate of 10.2% 5.5 years after a lateral sphincterotomy for an anal fissure (n=62) [821].

3. PREVALENCE ESTIMATES OF FI IN HOSPITALIZED OLDER ADULTS.

Like the variability of prevalence rates of FI in community-dwelling population, hospitalized older adult populations also vary depending on the type of acute care setting or hospital setting, type of populations being studied (i.e. those under surveillance for certain types of infections), and duration of the hospital stay. Rates of FI in hospital or acute care settings range from 18-33%. In one study, the rates of FI in the acute care setting for adults (mean age of 67 years) was 33% (50/152 with diarrhoea under surveillance for infections) [822]. In another study, FI (17.6%) was almost as common as urinary incontinence (19.7%) in 608 hospitalised adults (age range 4 years to over 80 years) [823]. Older age was associated with a 4-fold increase in FI in hospitalised adults [823].

4. PREVALENCE AND INCIDENCE ESTIMATES OF FI IN LONG-TERM CARE RESIDENTS.

Few studies were identified that reported prevalence rates of FI in nursing home or long-term care resident facilities. Data are often limited by the type of facility described or administrative data that report FI rates [805, 824-828]. Prior estimates of FI in long-term care or institutionalised older adults varied due to the type of facility and administrative data reporting. Recent FI prevalence studies confirm the prior high range of FI (>50% of nursing home residents having FI) reported in the literature [824, 825, 829]. Little is known about the FI incidence rate in this specific population of frail adults, with one study reporting a rate of 20% during a 10-month period after admission [794].

5. FAECAL INCONTINENCE IN OLDER ADULTS – THE “HIDDEN” PROBLEM.

Recent evidence re-affirms that adults with FI do not seek care [830] and that health care practitioners are not likely to inquire or document discussions regarding FI [802,803]. Over 600 geriatricians responded to a US questionnaire on their beliefs, referral patterns, and perceptions on quality of care, and management practices for FI among older adults. Only 54.1% reported screening for FI and over 40% did not feel that FI could be managed conservatively. Only 32.9% believed nursing homes provide good care for FI and 27.1% believed that nursing home care conditions exacerbate FI [831].

Increasing awareness is important aspect of the identification, prevention, and treatment of FI in older adults [320]. Recent public campaigns with public and industry funding have sought to increase awareness of bowel control in the United States and United Kingdom (http://www.bowelcontrol.nih.gov/ and http://www.bowel-control.co.uk). Using appropriate terminology for FI for individuals that is consistent with health literacy levels may be an important factor. Terminology such as "bowel" or "bowel control" may be more appropriate than the term "faecal" or "faecal incontinence." Barriers that prevent adequate identification and treatment include: social and cultural issues about discussing symptoms, perception that treatments may not exist, access to trained health care providers in the community, access to providers in long-term care settings, and access to training and treatment protocols. Given the high prevalence rates of FI in the hospital, home care, and long term care settings, health care practitioners should directly inquire or directly observe bowel control issues and document any findings. Other high risk groups of older adults that should be questioned about bowel control include older adults that have: mobility problems, cognitive impairment/dementia, prior pelvic/lower abdominal radiation exposure, prior anal or rectal surgery, urinary incontinence, chronic constipation, chronic diarrhoea, and co-morbid disorders such as diabetes and stroke.

6. RISK FACTORS ASSOCIATED WITH FI IN OLDER ADULTS.

Age has been established as a risk factor for FI in many population-based studies [797, 808, 811, 832]. Other factors that have been associated with increased rates of FI include: female gender, co-existence of UI, poor general health, physical limitations, cognitive impairment, stool consistency, prior colo-rectal surgery, and high body mass index [798, 833-836]. However, among population-based studies among older adults, risk factors specific to women (e.g. vaginal deliveries, parturition characteristics) are no longer significantly associated with FI when controlling for all other factors [811, 837]. Many diseases and co-morbid disorders are associated with FI and include: diabetes, dementia-related incontinence, irritable bowel syndrome, inflammatory bowel disease, systemic sclerosis, and neurological diseases, such as cerebrovascular disease [797, 818, 833, 838-842]. The association between faecal incontinence and loose stool consistency (diarrhoea) is robust in community-dwelling populations and nursing home studies [811, 817, 818, 826, 836, 837]. As supported by the epidemiological data, the aetiology of faecal incontinence remains multifactorial and treatment depends on the underlying mechanisms or specific co-morbid disorders known to impact bowel function.

III. THE AGEING LOWER BOWEL AND PATHOPHYSIOLOGY IN OLDER ADULTS WITH FAECAL INCONTINENCE

Chapter 4 covers the pathophysiology of FI. This section considers factors specific to frail older people.

1. QUALITY OF DATA

There have been few relevant new studies since the last consultation. The findings from physiological studies of the lower bowel in older adults tend to be variable due to a) a variety of different techniques used in measuring anorectal function, b) unclear definition of the normative range of manometric measures for older people, c) poor matching between cases and controls of clinical factors which may affect gut function (e.g. level of mobility), or inadequate clinical information, d) usually small subject numbers, e) few studies deal with subjects over 80 years, and f) improvements in imaging quality with endoanal ultrasound and MRI. Studies reviewed are cohort case-control to evaluate age-effect [843] [844] [845, 846], young-old healthy subject comparisons [847, 848], and age- and sex-matched case-control studies of continent versus incontinent patients [849-852].

2. ANORECTAL FUNCTION IN HEALTHY OLDER ADULTS

Studies of age effect in healthy volunteers have shown a linear reduction with ageing in squeeze pressures (external anal sphincter tone) in women after the age of 70, and in men from the 9th decade onwards [844] Studies of normal men and women demonstrated a significant but similar linear decrease in anal resting pressure and maximum squeeze pressures in both men and women with increasing age.[853] [854] [855]. Studies of asymptomatic females showed a significant decrease in both anal resting and squeeze pressures with age. [856] [857] [858]. A study comparing young and old continent women found a decrease in anal resting pressure but no decrease in squeeze pressures between the two groups. [852] Age beyond 70 years was associated with reduction in anal resting pressures (internal anal sphincter tone) in both sexes, but to a greater degree in women in some studies [843] [844] [848], but not confirmed in other studies as reaching statistical significance [850, 859] [860].

The internal sphincter thickness and diameter is significantly increased in older versus younger men and women [861] and in nulliparous older women [862]. In addition this was associated with a significant decrease in the external anal sphincter thickness in women [863] [864]. A study of men and women using endoanal MR imaging showed a

significant decrease in the external anal sphincter thickness in men but not women with age [865].

With ageing the enteric nervous system undergoes age-related degeneration. In patients older than 65 years there is >30% loss of enteric neurones when compared to people aged 20 to 35 years. This loss is associated with an increase in fibrous tissue deposition [866]. Increase in thickness of internal sphincter is related to an increase in collagen deposition [867] [868].

There was a significant increase in pudendal nerve latencies with age in women [857] and not men [869].

Rectal motility appears to be unaffected by healthy ageing [847], but there is an age-related increase in anorectal sensitivity thresholds [854] [870] [855]. Rectal compliance was not affected in one study [870] but reduced rectal sensation was associated with reduced rectal compliance in another [858]. Anorectal function in older adults with faecal incontinence.

One study demonstrated prolonged pudendal nerve terminal motor latency (>2.2ms) in 34% of women aged over 50 with FI, though no relationship was observed between pudendal neuropathy and anal resting or squeeze pressures. Advancing age was however related to declining anal resting pressures. [871] Another study similarly found an age-related increase in pudendal neuropathy in incontinent women, again unrelated to squeeze pressures [872]. Single fibre EMG in incontinent patients aged over 78 years showed an increase in polyphasic potentials in the external anal sphincter muscles compared with continent subjects after adjusting for age, indicating some local reinnervation of these muscles following neurogenic damage. [851] A study comparing anorectal function in young (mean age 42) and old (mean age 72) women with FI (patients with constipation and/or pelvic floor dysfunction excluded) showed that older women were more likely to have bilateral pudendal neuropathy, but less likely to have a sphincter deficit of >90 degrees, likely to have had a previous sphincteroplasty and thin perineal body, although the validity of this test is questionable (Committee 7). Anorectal physiology was similar aside from a trend toward lower resting tone in older women [846].

An examination of anorectal function in elderly medically frail incontinent patients and continent age- and sex-matched controls showed that individuals with FI had reduced anal resting pressures. Significantly lower anal resting pressures were found with decreasing mobility in FI elderly [850]. Lower anal resting pressure was correlated with a lower threshold for expulsion of a rectal balloon. Patients with FI and dementia were more likely to exhibit multiple rectal contractions in response to rectal distension, though the role of these 'uninhibited' contractions in causing incontinence was unclear [873].

A similar matched case-control study showed that elderly patients with rectal impaction and soiling had impaired rectal sensation (needing a larger volume before feeling the presence of a rectal balloon and the desire to void), lower rectal pressures during rectal distension, and impaired anal and perianal sensation ('rectal dyschezia') [849]. Resting anal and squeeze pressures were however unimpaired in these patients, and the rectoanal inhibitory response were well-preserved. The authors concluded that overflow FI is primarily due to locally secreted mucus from around an irritative rectal faecal mass leaking out, despite well-preserved anal sphincter integrity.

A study comparing 8 older incontinent women (mean age 71.6 SD 7.5) with 9 older continent women (mean age 71.6 SD 7.5) and 9 younger continent women (mean age 28.7 SD (7.3) found women with FI were more likely to have decreased maximum squeeze pressures and levator ani (LA) defects. (OR 14). LA defects were associated with 26% less force on maximal contraction. Levator and urogenital hiatus measurements on MRI were increased in older women irrespective of continence status. [874]. Older FI females tolerated lower balloon anorectal manometry volumes before urge to defaecate indicative of rectal hypersensitivity [852].

SUMMARY OF EVIDENCE ON FAECAL INCONTINENCE AND THE AGEING GUT

- Anorectal function in healthy older persons is characterised by a tendency towards an age-related reduction in internal anal sphincter tone **(Level 2)**, and a more definite decline in external anal sphincter tone, especially in older women **(Level 3)**, An age-related decline in anorectal sensitivity in women has been observed **(Level 3)**, but rectal motility is well-preserved **(Level 3)**,
- Ageing alone however, appears to have little impact on anorectal function until later old age – from the 7th decade upwards in women and even later in men **(Level 3)**,
- Age-related internal anal sphincter dysfunction (reduced anal resting tone) is an important factor in FI in later old age (Level 3),
- Pudendal neuropathy is an age-related phenomenon in women with FI **(Level 2)**, and a likely predisposing factor for FI **(Level 3)**, although the validity of this test is questioned.
- Stool impaction predisposing to overflow is related to rectal dyschezia in frail older adults, a condition characterised by reduced tone, increased compliance and impaired sensation **(Level 3)**,
- Overflow FI is due primarily to mucus secretion from around a rectal faecal bolus, rather than to impaired sphincter function **(Level 3)**,
- Decrease in mobility is associated with anorectal dysfunction and is a predisposing factor for FI **(Level 3)**,

RECOMMENDATIONS - PATHOPHYSIOLOGY OF FI IN OLDER PEOPLE

1. Overall, the physiological data suggests that FI should not be considered an inevitable consequence of ageing
2. Older adults with FI should be evaluated for age-related reduction in internal and external sphincter function
3. Older patients with FI require a digital examination to identify rectal stool impaction causing overflow
4. Patients who are unaware of the presence of a large faecal bolus in the rectum may have rectal dyschezia, and should be considered at risk of recurrent impaction with overflow

3. CAUSES OF FAECAL INCONTINENCE IN OLDER ADULTS

Stool consistency is important aspect of determining the cause and the associated factors for the evaluation of FI in an older adult [817, 818, 837]. Loose, as well as hard, stool consistency can be related to FI in frail, older adults [794, 825, 875]. Evidence shows that loose stool consistency and chronic diarrhoea are important contributing factors for FI [811, 817, 818, 826, 837]. Loose stool consistency and chronic diarrhoea can result from multiple causes, such as malabsorption syndromes (e.g., lactose intolerance, gluten sensitivity, and fat-malabsorption), acute diarrhoeal illnesses, microcytic colitis, irritable bowel syndrome – with diarrhoea predominant symptoms, and other causes of chronic diarrhoea. Any change in stool consistency along with other warning symptoms (weight loss, bloody stools, change in stool calibre, and painful defaecation) should prompt further evaluation for colorectal cancer. Potential reversible causes of loose stools may include: excessive laxative use, lactose intolerance, drug-related side-effects, bacterial overgrowth, and possible bowel obstruction with “overflow” FI. “Overflow” FI secondary to constipation and stool impaction is also important to consider in older adults, potentially more common in men than women,[876, 877] those with mobility problems, [825, 875, 878] and those that reside in nursing home settings [825, 878].

Overflow incontinence or FI that results from stool impaction can be difficult to diagnose, may be more common in certain frail, older populations, and should be evaluated and treated when suspected. Evidence suggests that constipation and symptoms of constipation are common among nursing home residents with FI [825, 878, 879]. However, the true prevalence of impaction and FI in nursing home residents is not clearly identified. Constipation (according to bowel movement frequency) and associated symptoms (straining and incomplete evacuation) were common among nursing home residents in a 4-site randomized controlled trial to improve FI and urinary incontinence among nursing home resident by giving a multi-component intervention involving toileting assistance, exercise, and dietary snacks [825]. At baseline, 81% of the 111 nursing home study participants had less than 3 bowel movements in 5 days. During the 2-day run-in period where toileting assistance was provided, the number of bowel movements per day increased from 0.3 ± 0.3 to 0.8 ± 1.0 with 11% found to have straining and 21% reporting problems with incomplete evacuation. The average stool consistency rating on the 7-point Bristol Stool Form Scale was 4.2 ± 1.5. Another study that identified factors associated with FI in different health care settings found that 70% of nursing home residents experienced “faecal loading” compared to 63% in rehabilitation wards, 57% in acute care wards, and 20% in the home care setting [878].

Urgency associated with bowel movements is also an important bowel-related factor that should be assessed in older adults. Many studies do not evaluate urgency as an independent risk factor. However, among the studies that evaluated a sense of urgency associated with bowel movements, urgency is consistently and strongly related to FI , having a negative impact on quality of life even after controlling for other known confounding factors [818, 880, 881].

Other bowel-related disorders or complications of prior anorectal surgery can contribute to FI in older adults who otherwise would be continent, especially when functional status, mobility and cognition become impaired. Other bowel related disorders that have been associated with FI in adults (but not limited to the frail older adults) include: haemorrhoids,[876, 882] posterior vaginal prolapse (rectocoele),[837] inflammatory bowel disease,[883] irritable bowel disease,[837, 884] and a strong sense of urgency [880]. Types of prior anorectal surgery that contribute to FI include: haemorrhoid surgery,[876] fistula repair,[885, 886] sphincterotomy for anal fissures,[821] partial or total colectomy,[887] low anorectal resection and re-anastomosis for colo-rectal cancer,[888, 889] prostatectomy,[814] and prior pelvic/perineal radiation [814, 890]. All of these bowel-related disorders and prior surgeries should be part of the focused history in older adults with FI. More studies are needed to identify causal pathways for causing FI in the older adult.

Functional FI, as defined by mobility problems or restraints that restrict accessibility to the toilet despite normal bowel sensation and capacity, is also cited as a common reason for FI in epidemiological studies among community-dwelling older adults and those residing in nursing homes [326, 794, 798, 799, 807, 826-828, 891, 892].

Other causes of FI in older adults can be related to other diseases or co-morbid disorders, especially neurological disease, which increases the risk having FI.

Even after adjusting for age and gender, diabetes mellitus is associated with gastrointestinal symptoms including FI in population-based studies,[813, 840] nursing home residents,[892] and has been associated with impaired rectal sensitivity and sphincter weakness [838].

Neurological diseases that contribute to FI in older adults include cognitive impairment, stroke, traumatic brain injury, and sacral cord dysfunction. Older adults are living longer with significant neurological conditions. Cognitive impairment and dementia have been found to be independent risk factors with FI in older adult populations from epidemiological studies and among those in nursing homes [794, 807, 814, 826]. Having a stroke is an important risk factor for FI, with three and half times the rate of FI, compared to adults who did not have a stroke, in one population-based study [893]. FI affects 30-56% of stroke survivors in the acute period after having a stroke (1-30 days), with a lower prevalence (11%) of FI after 3-months, and 11-22% at 12-months following the initial stroke event [839, 894]. It is unclear whether the functional disability from having a stroke or the disruption in neurological pathways (sensory mechanisms) that promote continence, contributes more to FI among stroke survivors. Traumatic brain injury has also been linked with urinary incontinence and FI, but limited data exist on older adults from registry studies and single site studies [820, 895]. Spinal cord injury (depending on the level of injury) may result in impaired muscular strength of the external anal sphincter, delayed transit time, abnormal defaecation reflexes, and impaired sensation [896].

SUMMARY OF EVIDENCE ON PREVALENCE AND RISK FACTORS FOR FI IN FRAIL OLDER PEOPLE

Summarised below are key points that are specific to the frail elderly population.

- FI affects 1 in 5 older people (aged 65+) living in the community, and half of those reside in care homes **[Level 1]**
- The prevalence of FI increases with age alone, particularly in the 8th decade and beyond **[Level 1]**
- The prevalence of FI is higher in the acute hospital and nursing home setting than in the community **[Level 1]**, thus the group most affected is frail older people.
- The prevalence of FI in frail older men is equal to or greater than in women **[Level 2]**.
- This predominance of older men over women with FI is most striking among nursing home residents **[Level 2]**.
- The prevalence of FI varies dramatically between institutions in nursing home studies **[Level 2]**.
- FI usually coexists with urinary incontinence in frail older people **[Level 1]**
- Aside from age, the following are primary risk factors for FI in older people **[Level 2]**:

  Stool consistency -- Loose stool

  Bowel-related disorders, such has prior rectal surgery

  Impaired mobility

  Dementia

  Neurological disease

  Chronic medical conditions

  Depression

- Loose stool is a primary cause of transient FI in older people **(Level 2)**
- Faecal loading and constipation are clinically linked to FI, but there is little epidemiological work assessing this association (Level 3)
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people **(Level 2)**
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI **(Level 2)**,and there is a tendency toward passive management (e.g. use of pads only without further evaluation) **(Level 2)**.Faecal loading is often present in older care home residents with FI **(Level 2)**
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider for social or cultural reasons, or due to a popular misperception that the condition is part of the aging process and therefore 'nothing can be done about it' **(Level 2)**
- FI is associated with reduced quality of life, and poor health perception **(Level 2)**

RECOMMENDATIONS - IDENTIFYING FAECAL INCONTINENCE IN FRAIL OLDER PEOPLE

- Bowel continence status should be established by direct questioning and/or direct observation in:

  o all nursing and residential home residents

  o hospital inpatients aged 65 and over

  o people aged 80 and beyond living at home

  o older adults with impaired mobility

  o older adults with impaired cognition

  o older adults with neurological disease

- o older adults with chronic disease
- o older adults with constipation

- Primary care staff, hospital ward staff, and long-term care staff should routinely enquire about FI in frail older patients
- Enquiry about FI should be systematic and include stool consistency, severity of FI and impact on activities of daily living and quality of life
- Health care providers should be sensitive to cultural and social barriers discouraging patients from talking about the condition
- Frail older patients with restricted ability to access primary care such as nursing home residents, and those with mobility, chronic illness, or cognitive impairments, should be screened for FI through systematic case-finding methods
- Systematic outreach programmes which make it easier for frail older people and those who care for them to volunteer the problem to their primary care provider should be implemented
- There are significant geographical variations in provision of specialist expertise in bowel care (both medical and nursing) nationally and globally, which may affect case-finding in older people
- Further examination of underlying reasons for the variations in prevalence of FI between nursing homes (standards of care, patient case-mix, reporting) is needed
- UI and FI often coexist; continence care workers (e.g. nurse specialists) should be trained in identification and management of faecal as well as urinary incontinence in older people
- Key requirements to improving detection in the practice setting should be implemented:
  - o education of health care workers to embed both a sense of value in identifying FI, plus confidence that the condition can be treated
  - o protocols should be in place clarifying all details of screening enquiry (who will ask, how to ask, when to ask, and who to ask)
  - o patients and carers should have access to educational materials at the point of enquiry

4. EVALUATION OF FAECAL INCONTINENCE IN OLDER ADULTS

The algorithm contained in this chapter delineates a systematic approach to the clinical evaluation of frail older people with FI.

An initial assessment can be undertaken by any suitably trained health care practitioner, often this will be by either a physician or clinical nurse specialist. In the majority of cases, a clinical evaluation will provide sufficient diagnostic information upon which to base further management. There are available tools which can assist in this process [447]. The use of formal testing is hampered by both lack of relevant data in frail older people and the poor correlation between symptoms and abnormalities [897, 898]. Evidence that the assessment of faecal incontinence in older people is poorly done despite the existence of guidelines has been a persistent finding throughout the history of this chapter [339, 772]. What actions need to be taken to ensure that older people receive assessments which are consistent with current guidelines remain to be defined. There is evidence from a survey of US physicians that the presence of FI makes a referral for nursing home placement more likely than if it is not present [37]. Self reports of bowel symptoms are reliable and reproducible in older people including those in long term care [899-901]. Documentation of the type of incontinence experienced is very important, particularly because of the association between faecal incontinence and loose stool [385]. Faecal urgency is closely associated with diarrhoeal illness whereas constant passive leakage of homogenous liquid stool or stained mucus is more characteristic of overflow incontinence around faecal impaction. People with anal sphincter dysfunction tend to lose small amounts of stool. Urgency faecal incontinence tends to predominate when there is underlying external sphincter weakness and those with internal sphincter weakness experience more passive leakage [902]. People with faecal incontinence due to dementia may pass normal stool, particularly after meals, in response to the gastrocolic reflex. Any assessment of faecal incontinence should also include an assessment for constipation. It is important to recognise the constipation subtype of rectal delay in older people, which is said to affect 21% of the community dwelling elderly and may lead to faecal impaction and overflow incontinence [903]. A prolonged evacuation and feeling of anal blockage with the need to evacuate manually are the hallmark symptoms. A majority of the constipated elderly have evacuation problems rather than low stool frequency [904]. Regardless, the clinical definition of constipation relies upon the finding of an excessive amount of stool in the rectum or colon. An objective assessment is especially important in the frail elderly as they may not be able to communicate their symptoms and may, despite constipation, still have regular bowel movements [905]. The frail older person may also have impaired rectal sensation and be unaware of the existence of a full rectum [906, 907] or be unwell, with confusion (or worsening confusion). Older people are also less likely than the young to report a reduction in bowel frequency, abdominal bloating or positional changes to achieve defaecation [908].

Digital rectal examination can assess to a reasonable degree anal sphincter tone and squeeze pressure and appears to be as good as sphincter ma-

nometry in discriminating continent from incontinent people, although not the frail elderly [909]. Constipated patients with an empty rectum on digital examination may have high impaction.

Radiographs of the abdomen should be requested to establish the diagnosis to assess the extent of faecal loading and to rule out an obstruction or sigmoid volvulus. As with any other person, a change in bowel habit with weight loss, anaemia, rectal pain and faecal incontinence should raise the suspicion of an underlying malignancy [910]. Colorectal cancer is associated with both constipation and use of laxatives, although this risk is likely to be complicated by underlying bowel habit. In a retrospective study of 4798 incident cases of colorectal cancer in people aged 30 – 84 from UK datasets, independent predictors in men and women included family history of gastrointestinal cancer, anaemia, rectal bleeding, abdominal pain, appetite and weight loss. Alcohol consumption and recent change in bowel habit were also predictors in men alone [911].

The single symptom of chronic constipation does not usually warrant colonoscopic investigation, however, in the frailer elderly this may be considered as the index of suspicion may be higher. Given the increased difficulty of adequately preparing frail older people for either endoscopy or barium studies [912]; CT colonography may be considered as an alternative investigation where available [913]. Evaluation of the capacity to successfully toilet should include an assessment of mobility, visual acuity, manual dexterity and cognition. If acceptable to the older person, observing the process of transferring to the toilet, manage their clothing, redress and leave the lavatory is a good measure of ability. Caregivers should additionally be aware of the surroundings in which the frail older person lives in terms of access, lighting, distance and clutter. The design of commodes should also be considered in the light of the individual's capabilities.

Faecal incontinence is also associated with the development of pressure ulcers in older people with impaired mobility although whether this is a causal association is still a matter for debate, [914, 915] however, an assessment of skin integrity and provision of appropriate pressure relief is important. A pelvic examination to rule out posterior compartment prolapse is also important given the association between FI and prolapse in older women [916, 917]. There are no bowel specific quality of life assessments validated for use in the frail elderly.

5. TREATMENT OF FI IN OLDER ADULTS.

a) Quality of data

New trials are included on the treatment of FI in frail, older adults. No trials were identified on the prevention of FI in high risk, older adults. Many studies that include older adults have small sample sizes, inadequate power to detect clinically meaningful differences in outcomes, and biased methodology. Given these limitations, FI treatments applicable to older adults were considered and include: multicomponent treatments for FI, treatments aimed at specific populations of older adults (e.g. nursing home populations and stroke survivors), and percutaneous tibial nerve and sacral neuromodulation for FI. Issues related to surgery, bulking agents, biofeedback, containment, and skin care are discussed in other chapters.

b) Multi-component treatments for FI.

Given the multifactorial causes for FI in older adults, few studies existed in the literature involving multicomponent interventions. In 2006, the Cochrane group reported that available trials for FI do not allow for a definitive assessment of the role of pelvic floor muscle training and/or biofeedback therapy in the treatment of FI. The Cochrane report also noted that insufficient data exists that pelvic floor muscle training or biofeedback is any better than other conservative measures such as medication or education [918]. Since the Cochrane report, a recent study by Heymen et al involved a run-in period to improve stool consistency among adults with weekly FI prior to randomization to pelvic floor muscle training or biofeedback [919]. Among the 168 community-dwelling participants (mean age was not reported), FI frequency decreased from 3.4 to 2.0 days/week (41% reduction) and 35 patients (21%) reported adequate relief at the end of run-in. FI severity scores, as measured with the Faecal Incontinence Severity Index (FISI), decreased from 36.9 at baseline to 31.0 at the end of run-in ($p<0.001$). The run-in phase controlled for the effects of improved medical management to normalize stool consistency and this produced adequate relief of FI for 21% of patients. The remaining participants (n=108, mean age 60 years) were randomized to pelvic floor muscle exercises alone or manometric assisted biofeedback. After 3 months, the participants who received biofeedback treatment had a great improvement in improvements in their FI severity scores ($p=0.01$) and fewer days with FI ($p=0.083$) [919]. An additional study comparing different methods of biofeedback concluded that active sensory training is more effective than sham training for participants with "idiopathic" FI [920]. Others have found that the additional of rectal balloon distension sensitivity training did not improve outcomes [921, 922]. Evidence for biofeedback treatment for improving FI in older adults with cognitive impairment or physical limitations/poor functional status was not found.

A systematic review in 2003 identified three trials that compared loperamide versus placebo without any trials among older adults; one in patients with ileoanal pouches, and two in patients with chronic diarrhoea [923]. No controlled studies were identified during this review using anti-diarrhoea medica-

tions for patients initially presenting with the primary complaint of faecal incontinence and there were no controlled studies investigating the treatment of faecal incontinence in older adult populations. In a double blind randomised crossover trial by Lauti *et al* [2008], fibre supplementation was used along with loperamide and specific diet recommendations in participants with the primary complaint of liquid and solid faecal incontinence [924]. Participants (n=63, mean age 59 ±15 years, 91% women) were randomised in a cross-over trial to loperamide along with fibre supplements and advice sheet on diet versus loperamide with an advice sheet on low residue diet and placebo fibre supplements. There was significant improvement in both groups from baseline to 12 weeks in FI severity without group differences between the two treatments. There were also no adverse events reported and very few participants reported dry mouth (specific amounts not reported). Expert opinion suggests that loperamide should be used with caution and close monitoring for faecal impaction in older adults, especially those with chronic co-morbid disorders.

c) Treatment of FI in nursing home settings.

Treatments for FI in nursing home settings also involved the treatment of constipation and faecal loading or faecal impaction. In a French study among 206 nursing home residents in 4 different homes, lactulose alone was compared to lactulose plus daily suppositories along with weekly tap-water enemas for reducing FI episodes. Although there were no differences between the two groups, residents that achieved complete rectal emptying also reduced the number of FI episodes by 35% while also reducing staff workload by 42% (soiled laundry counts). [879] Recently, Schnelle et al (2010) completed a multi-centre, multi-component intervention for improving FI and constipation in cognitively impaired 112 nursing home residents (mean age 86 ± 10 years) [829]. In this controlled trial in 6 nursing homes in the United States (n=112), the intervention was compared to a usual care control group. The intervention group received toileting assistance, exercise, and choice of food/fluid snacks every 2 hours for 8 hours/day for 3 months. Participants in the intervention group compared to the usual care control group had improvements in bowel movement frequency and the percentage of bowel movements in the toilet ($p<0.01$), but not the frequency of FI episodes determined by direct checks from research staff. Urinary incontinence episodes also improved with this intervention ($p<0.05$). Among the 29 nursing home residents who had anorectal manometry, a dyssynergic defecation pattern was identified in 89%. The authors concluded that this multi-component intervention improved some factors associated with FI in nursing home residents, but further work to improve stool consistency and treatments for dyssynergia may be warranted.

d) Treatment of FI in stroke survivors.

In outpatient and inpatient stroke survivors (n=146), Harari et al (2004) completed a randomised, controlled trial to improve FI and constipation symptoms with an intervention based on education booklet for the patient/caregiver along with treatment recommendations to the health care provider and compared this intervention to a usual care control group [925]. After 6-months and 1-year of follow-up, the intervention group compared to the usual care control group were more likely ($p<0.05$) to have 'normal' rated bowel movements on a 7-day bowel diary and more likely to have an increased bowel frequency ($p<0.05$). The intervention group was also more likely to alter their diet and fluid intake to control their bowels.

e) Sacral Neuromodulation/Percutaneous tibial nerve stimulation for FI in older adults.

Recent prospective multi-centre trial data on sacral neuromodulation with a surgically-implanted device shows significant improvements in FI episodes, symptoms, and quality of life [926]. In the larger, multi-centre studies with data at 2- and 3-years, the mean ages were 54.3 ± 11.3 and 60.5 years (range 30-88 years) without subgroup data on the older age participants [927-929]. Evaluating and selecting older adults and adults with specific neurological conditions who may benefit from permanent implantation is an important consideration [930, 931]. Data on sacral neuromodulation for FI and surgical outcomes including adverse events for frail, older adults is limited [932].

Percutaneous tibial nerve stimulation (PTNS) studies for FI have also reported benefits. Among the 8 small, prospective studies (largest study, n=32), involving a total combined sample size of 129 participants, have significant variation in the study population, with large mean age ranges (38 to 60 years), methodology, and outcome measures [933-940]. One prospective study involving 100 participants with a median age of 57 years found that "urge-related" FI and "mixed" FI were more likely to having improvements in a symptom score than those with "passive" FI [941]. Data from adequately powered randomized controlled trials for PTNS treatment for FI are currently ongoing and will add significantly to the existing evidence [942].

6. SUMMARY OF EVIDENCE ON THE TREATMENT OF FI IN FRAIL OLDER PEOPLE

1. Structured multi-component approaches to bowel care did not reduce the frequency of FI in the nursing home setting, but did improve bowel frequency and number of bowel movements in the toilet **(Level 2)**

2. Older people with FI may benefit from biofeed-

back and sphincter strengthening exercises if they are able to comply **(Level 3)**

3. Loperamide can reduce frequency of FI, particularly when associated with loose stool (once infection and other causes have been excluded) but should be used with caution **(Level 2)**

4. Additional fibre supplementation to loperamide may not improve FI outcomes **(Level 2)**

5. Multi-component structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients **(Level 2)**

6. More data are needed on the use of sacral neuromodulation in specific higher risk older age populations **(Level 4)**

7. RECOMMENDATIONS - TREATMENT OF FI IN FRAIL OLDER PEOPLE (ALL GRADE C)

1. Loperamide is a useful treatment in FI, in the absence of constipation, but should be used with caution in older adults

2. Causes of loose stool must be identified and treated.

3. All frail older people with FI should have structured multidisciplinary assessment and treatment of their bowel problem.

4. Patient and caregiver education (using verbal and written materials) should be undertaken to promote self-management and other coping mechanisms, and where appropriate self-management (e.g. reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odour control, and continence aids is also important.

5. Greater emphasis needs to be placed on systematic and effective management of FI in older people backed up by sound communications between all health care providers, especially in the nursing home and acute hospital setting.

6. Education of health care providers with regards to heightening awareness of the problem plus methods of identification, assessment and management of FI in older people should be broad-ranging and include geriatricians, general practitioners, hospital physicians, hospital, community, general practice and long-term care nurses, and related disciplines (physiotherapists, occupational therapists, dieticians, pharmacists).

7. Cyclical national audit with provider accountability, of current practice in managing FI in older people is needed to lay the ground-work for standardised care, and provide a culture of continuous quality improvement. Such audit tools should be developed using standardised consensus methodologies

8. AREAS FOR FURTHER RESEARCH ON FI IN FRAIL OLDER PEOPLE

1. Trials of laxative and nonpharmacological treatment and prevention of faecal impaction and overflow are needed to optimise standards of prescribing and care.

2. Multicomponent interventions to treat FI in frail older people should be evaluated to assess effective ways of FI management in acute care settings

3. Multidisciplinary study assessing the feasibility and efficacy of a step-wise approach to the management of dementia-related FI in nursing home residents

4. Evaluation of case-finding methods for FI in different settings including the fundamentals of staff education, screening protocols, and patient's educational information would be very informative.

5. Testing the feasibility of providing an integrative approach to assessment of FI in the frail older person, including a range of health and social care providers and different health care settings (acute, intermediate or sub-acute, long-term care and community) would be relevant to national implementation of bowel care improvement programmes.

6. Examination of the variability of FI rates between nursing homes within single nation states, (taking into consideration case-mix) will highlight problems areas both organisationally and clinically. Nursing home administrative factors such as resident: nurse staff ratios should be evaluated as a contributing factor to FI.

7. Further epidemiological studies are required to document causes of FI in frail older people in different health care settings. Such studies should include evaluation of unmet need for patients and caregivers.

8. Evaluation of the pathophysiological basis for high prevalence of FI in older men. Evaluation of potentially preventable causes of loose stools in institutionalised older people, and impact of their treatment on FI.

9. Nurse-led initiatives are needed to develop care pathways for assessing of bowel problems in frail older people with a view to establishing integrated service delivery.

10. Examine the research question, 'Do educational interventions by health care providers to informal carers of home-dwelling older people with FI reduce carer burden and improve quality of life for patient and carer?'

The present chapter would not have been possible without the work of the previous editors, Jean Hay Smith [2008] and Don Wilson [2000, 2004]. They produced the remarkable framework for the present review. Indispensable assistance was also provided by Victoria Mei Lee, Fiona Stewart, Sheila Wallace, and the Cochrane Incontinence Group. Finally, this chapter would not have been possible without the untiring dedication of Mr. Wayne Day.

I. INTRODUCTION

Conservative treatment is any therapy not involving surgical treatment of incontinence. In this chapter update, we cover studies that provide some comparison data between therapy and lifestyle interventions (also called lifestyle interventions), physical therapies, scheduled voiding regimens, complementary and alternative medicines, anti-incontinence devices, supportive rings/pessaries for pelvic organ prolapse (POP) and medications with a direct comparison with conservative management.

Conservative therapies are considered relatively low cost, non-invasive approaches, with minimal adverse effects that are typically guided by a healthcare professional and depend on user participation. It is generally accepted that conservative measures are part of the initial counselling at the primary care level of individuals suffering from either UI or POP. Conservative therapy is also indicated for those for whom other treatments are inappropriate, for example, those unwilling to undergo or unfit for surgery and women who plan future pregnancies (as these may adversely affect surgery). Other indications include individuals awaiting surgery or who wish to delay surgery and those whose symptoms are not serious enough for surgical intervention.

The research base on which to judge the effectiveness of conservative management is growing although some aspects such as lifestyle interventions and alternative and complementary medicines in particular, require considerably more well designed trials. In this chapter we add to what was known in the 2009 4th Edition ICI [1] and integrate the evidence since the last search on treatment of urinary incontinence and pelvic organ prolapse (POP). The updated literature search was conducted from 1 January 2008 to August 2011 of randomised controlled trials (RCTs). (Appendix 2 lists the details of the literature search).

Each section concludes with the level of evidence and factors affecting outcome. Separate chapters in this 5th Edition address incontinence in the elderly, children, pharmacological treatment, products for continence, those with neurological conditions and those suffering from faecal incontinence.

Where summary statistics are presented, the raw data from which these are derived can be found in the tables at the end of the chapter, in trial reports and systematic reviews cited in the chapter. The Chapter is intended as a stand alone document and adds to the comprehensive reports from previous ICI editions.

A.UI IN WOMEN

I. LIFESTYLE INTERVENTIONS

A number of lifestyle factors may play a role in either the development or resolution of UI. Few RCTs have been carried out to assess the effect of a specific lifestyle change on UI. This section will examine the evidence for the association and use of lifestyle interventions in the management of female UI. A summary of the search strategy and inclusion/exclusion criteria is given in Appendix 2.

1. PREVENTION

No RCTs assessing the effect of lifestyle interventions on UI prevention were identified.

2. TREATMENT

Where RCTs are available, these are reviewed. Where there are no RCTs for a particular lifestyle intervention, other types of evidence are considered giving priority to good quality cohort studies.

a) Weight loss

Three RCTs were identified on weight loss. Two specifically recruited incontinent women [2-4]. The third focused on the effect of intensive lifestyle intervention in overweight women with diabetes [5]; this intervention mainly comprised weight loss. Four prospective cohort studies [6-9] evaluated the effect of weight loss. Other study designs were

cross-sectional [10-16], retrospective cohort [17], or case-control studies [18]. The non-RCT evidence will not be reviewed here in light of the available RCT evidence.

1. Quality Of Trials

Sample sizes for the three RCTs were 48 [2], 338 [3,4], and 1,957 [5]. Participant blinding was not possible in any of the three RCTs. Of 48 randomised in one trial, 40 remained in the study at the time of assessment [2]. The Subak [2009] study randomised 338 women, six month incontinence outcome data was available for 304 women (290 had diary data – the primary outcome measure). Participants were followed up at 12 and 18 months, at which time 96% provided urinary incontinence outcome data. In the large RCT with diabetes as the primary focus, 2191 women were enrolled and 234 were excluded because data about UI were not available; the number that dropped out before the endpoint is not detailed for this subpopulation of women.

All three trials used subjective and objective measures including urodynamics, urinary diary and 24 hour pad test. Follow-up periods were three months after completion of a very low calorie liquid diet and exercise [2], six months after completing an intensive group weight intervention programme that included lifestyle and behaviour changes [3], and a mean of 2.9 years after beginning the intervention [5]. In addition, the Subak study population [3,4] was followed up at 12 and 18 months, and is reported in a separate paper [19].

Results

In the 2005 RCT [2] involving 48 participants, median baseline weight (95 kg) and number of incontinent episodes (21 per week) were similar between the groups. Compared to controls (wait list) that did not participate in a weight loss programme, women in the weight loss (liquid diet) group lost 15kg (SD 7) (compared to 0kg (SD 4)) and experienced a 60% reduction in weekly incontinent episodes (compared to 15%).

The Programme to Reduce incontinence by Diet and Exercise (PRIDE) [4,19] randomised 338 overweight incontinent women in a 2:1 ratio to an intensive 6-month group weight intervention programme or usual care, consisting of four information sessions. Women in the intervention group lost a mean of 8% of their body weight from baseline compared with 1.6% in the usual care group after 6 months. Forty one percent of women in the intervention group decreased the weekly number of incontinence episodes by at least 70% compared to a 22% reduction in the usual care group. At 12 months weight loss in the intervention group was 7.5% of their body weight from baseline compared to 1.7% with 46% reporting 70% less incontinence in the weight loss group compared with 31% in usual care. By 18 months weight loss was 5.5% in the intervention group compared to 1.6% with 46% reporting 70% less incontinence episodes compared to 40% in the usual care group.

The RCT from the Diabetes Prevention Programme [5] reporting on 1957 participants found that overweight diabetic women assigned to intensive lifestyle therapy (consisting of low-fat diet, moderately intense exercise for at least 150 minutes per week and a behavioural and educational curriculum) were less likely to be incontinent compared to those assigned to placebo drug with standard lifestyle advice or metformin alone (38.3% versus 45.7% and 48.1%, respectively; p=0.001).

Wing et al (2010a) [19] combined data from the Subak 2009 RCT and Wing (2010b) [20] follow-up of the same sample to determine the magnitude of weight loss associated with significant improvement in urinary incontinence. They combined the intervention and control groups into weight loss categories irrespective of randomisation group. Women who lost 5-10% of their body weight were 2-4 times more likely to achieve a 70% reduction in incontinence episodes compared with those who gained weight at 6, 12 or 18 months. Weight losses larger than 10% did not result in greater improvements in incontinence outcomes. It is important to note that individuals were not randomly assigned to weight loss categories therefore groups may have differed in other ways.

2. Summary

Obesity is an important independent risk factor for the prevalence of UI. Massive weight loss (15 to 20 BMI points) significantly decreases UI in morbidly obese women. (Level of Evidence: 2). Moderate weight loss maybe effective in decreasing UI especially if combined with exercise (seeB.1.2b(i)). **(Level of Evidence: 1).**

3. Recommendations

For morbidly and moderately obese women weight loss should be considered a first line treatment to reduce UI prevalence **(Grade of Recommendation: A).** Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain (and exercise) should receive high research priority.

b) Physical activity

No RCTs exist in which moderate physical activity and its effect on UI is compared to no activity.

1.Quality of data

Two prospective studies assessed the risk of incident UI according to physical activity level, reported as metabolic equivalent task hours per week, in 2,355 women aged 54 to79 years [21] and 30,135 women 37 to 54 years at risk of incident UI [22]. Both

suggested that low levels of physical activity are predictive for the onset of UI in middle aged women or older. In the prospective study of women aged 37-54 repeated physical activity reports over 12 years were averaged to estimate long term activity levels. Over the subsequent 2 years 4081 incident cases were identified with monthly incontinence.

2. Results

In older women enrolled in the Nurses' Health Study, total physical activity (i.e. top versus bottom quintile of metabolic equivalent task hours per week) was significantly associated with a reduced risk of new UI (OR 0.81) in analyses adjusted for confounders. Walking constituted about half of the total physical activity among the participants and was related to a 26% lower risk of developing UI. Total physical activity was not related to the incidence of UUI [21]. These findings were mirrored in younger women enrolled in the same study [22]: the risk of at least monthly UI decreased with increasing quintiles of moderate physical activity.

3. Summary

There is good prospective cohort information suggesting that moderate exercise decreases the incidence of UI in middle-aged and older women; this effect may be mediated by weight control **(Level of Evidence: 3).**

4. Recommendations

Epidemiological evidence is building for an association between moderate physical activity and a reduction in urinary incontinence. There is a need for randomised controlled trials to confirm causality.

c) Physical Forces (exercise and work)

No RCTs exist in which UI prevalence is compared between subjects assigned to heavy work or high impact activity versus sedentary activities

1. Quality of data

Two trials have evaluated the difference in UI prevalence between 305 and 144 women, respectively, engaged in high versus low impact activities [23,24]. In another trial, Bø (2001a) compared 572 athletes ages 15-39 years with 574 controls [25]. Caylet [2006] compared UI prevalence between 157 elite female athletes and 426 women from the general population between ages 18 and 35 [26]. Kruger [2007] conducted a case-control study exploring mechanisms by which athletes might be more likely to experience SUI and compared pelvic organ descent and pubovisceral muscle volume between 24 elite nulliparous athletes and 22 age and BMI matched controls [27]. Eliasson [2005] compared UI at 36 weeks gestation and one year postpartum between 665 primiparous women participating in high-impact, low-impact or no activity [28].

Several cross-sectional studies compared the prevalence of UI with the self-reported level of physical activity. The Norwegian EPINCONT study compared both any and severe UI in 27,936 women according to three levels of high impact physical activity [13]. Another compared UI prevalence and severity in 3,364 women according to physical activity level as assessed by the International Physical Activity Questionnaire [29].

2. Results

Minimal SUI is common in young exercising women [23]. College athletes participating in high impact activities are more likely to report the symptom of SUI during exercise than those participating in low impact exercise [24]. In one trial no difference in UI prevalence was found between elite athletes and controls [25]. Another found that 28% of elite athletes reported UI compared to 10% of controls [26]. There was no difference in UI prevalence between physically active and sedentary controls. In the prospective study of pregnant and postpartum women, high-impact physical activity before pregnancy was associated with more urinary leakage one year postpartum compared to low-impact activity [28].

There is little available information on whether strenuous exercise or activity causes the condition of UI later in life. In a study of 104 women who were Olympians approximately 25 years prior to data collection, those who competed in gymnastics or track and field were not more likely to currently report daily or weekly UI than Olympians who competed in swimming [30].

The EPICONT study reporting on 27,936 women found no difference in either 'any' UI or severe UI in women that reported high impact physical activity one to two hours per week or three or more hours per week compared to those that reported exercised less than one hour per week (after adjusting for age, BMI, parity, coughing and wheezing) [13]. In contrast, Nygaard [2005] reported that UI with physical activity was more common among highly active than less active women (15.9% versus 11.8%; p=0.01) [29]. Additionally, after adjusting for age, parity, comorbidities and other factors, women with very severe UI were more likely to be less active than continent women. Danish nursing assistants, who are exposed to frequent heavy lifting, were more likely to undergo surgery for genital prolapse and/or UI than women in the general population; parity was not controlled for [31].

3. Summary

Strenuous exercise may unmask the symptom of SUI during provocation. There is currently no evidence that strenuous exercise causes the condition of UI. There are scant uncontrolled data that suggests that women engaged in occupations with heavy lifting may be predisposed to genital prolapse and/or UI **(Level of Evidence: 3).**

4. Recommendations

There is a paucity of data about the association of strenuous exercise and lifting and UI, this association should be investigated further.

d) Smoking

There are no RCTs investigating the effect of smoking on UI. There are no trials of the effect of smoking cessation.

1. Quality of data

One case-control study compared incontinent smokers with non-smokers [32], another compared smoking behaviour between continent and incontinent women [33]. Cross sectional studies have evaluated multiple risk factors for UI, including smoking [10,13,16,34-37]. One case-control study evaluated smoking as a risk factor for failure of SUI surgery [38]. One trial of women planning surgery for SUI assessed the association between smoking and severity of UI, defined by mean number of incontinence episodes per day on a bladder diary [39]. An in vitro study assessed the effects of nicotine on bladder muscle contraction [40]. Sample sizes were 189 [32], 1761 [34], 160 [33], 199 [38], 7949 [10], 7338 [35], 3302 [36], 5,488 [37], 27,936 [13], and 83,355 [16].

2. Results

Smokers were more likely to report UI than non-smokers in some studies [13,16,33,35,36], but not others [10,34,37]. Amongst women with SUI, current smoking was positively associated with UI severity after adjusting for confounders [39]. After adjusting for age, parity, type of delivery, and pre-pregnancy BMI, smokers had a 1.3 fold higher RR (95% CI 1.0 to1.8) of reporting UI at 16 weeks gestation than non-smokers [35]. The adjusted OR for moderate or severe UI among women reporting UI was 1.38 (95% CI 1.04 to 1.82) in current smokers, after adjusting for perimenopausal status, BMI, diabetes and ethnicity [36]. In the large population based study by Hannestad et al [13], smoking increased the odds of severe UI (OR 1.4, 95% CI 1.2 to1.6) but not of mild UI. In the case-control study, after adjusting for confounders, smoking was a protective factor against recurrent UI after anti-incontinence surgery [38]. Incontinent smokers were found to have stronger urethral sphincters and lower overall risk profiles than incontinent non-smokers [32]; therefore, the authors proposed that more violent coughing promotes anatomic defects, which allow UI.

Two studies have reproted that nicotine produces phasic contraction of isolated bladder muscle probes in vitro [40,41]. However, Milsom (1993) reported an apparent paradoxical local estrogenic effect of nicotine on the vagina, resulting in a decrease in vaginal pH and an increase in lactobacilli [42].

3. Summary

Data suggest that smoking increases the risk of more severe UI **(Level of Evidence: 3).** Smokers may have a different mechanism causing their UI than non-smokers.

4. Recommendations

Further prospective studies are needed to determine whether smoking cessation prevents the onset, or promotes the resolution, of UI.

e) Dietary factors

1. Diet

No RCT was identified that addressed dietary changes for urinary incontinence alone.

However, a randomised cross over trial examined the effect of a soy-rich diet on urogenital changes including urge incontinence [43]. The study recruited 36 women to undergo two 12 week diet periods, a soy rich diet and a control diet (soy free).

The recent BACHs study group (Boston Area Community Health Survey) [44] undertook an epidemiological, cross sectional, population based study of 2060 women aged 30-79 and used a validated food frequency questionnaire to collect data on dietary intake as well as collecting data on lower urinary tract symptoms (LUTS). In a prospective questionnaire study, Dallosso (2004a) studied the impact of dietary risk factors on the one-year incidence of SUI in women [45] and OAB symptoms [46,47]. Participants completed a 130-item validated food frequency questionnaire.

2. Caffeine

No new studies on caffeine and incontinence were found. One RCT [48] assessed the effects of a caffeine reduction intervention upon frequency, urgency and UUI for those who consumed more than 100mg caffeine daily. The experimental group received bladder training and a caffeine-fading method to decrease caffeine intake to less than 100mg per day, while the control group also received bladder training but no caffeine reduction information. Another RCT [49] used a crossover design to evaluate the effect of caffeine restriction and of increasing and decreasing fluid intake on urinary symptoms over a four-week period in women with urodynamic SUI or DO.

3. Fluid Intake

In one RCT, women with UI were randomly assigned to one of three groups: increase fluid intake by 500 cc, maintain fluid intake at baseline level, or decrease by 300 cc. Participants kept fluid intake and output diaries for five weeks [50]. Another study [51] recruited 24 people to a crossover trial in which they were asked to increase or decrease their fluid intake. Individuals were randomised into two groups,

the groups amended their fluid intake over 4 day blocks, group 1: drinking 25% more (group 2: 25% less) than baseline for 4 days followed by 2 days of normal drinking, 4 days drinking 50% more (group 2: 50% less) than baseline (2 days normal drinking) followed by 4 days drinking 25% less (group 2:25% more) than baseline (2 days normal drinking) and finally 4 days drinking 50% less (group 2: 50% less) than baseline. Any changes in frequency, urgency, nocturia and incontinence episodes were then recorded according to randomised group and stage. Participants completed a 4 day frequency volume chart and a validated ICIQ-OAB

In a large postal survey, 6037 men and women responded to questions about tea, soft drink and alcohol consumption, as well as whether or not they had UI [52].

4. Quality of data

It was not feasible to blind participants in any of the RCTs. Dropout rates were: 8% [43], 22% [48], 37% [49], and 45% [50].

5. Results

(a) Diet: One RCT found no statistical difference in urinary incontinence following a soy-rich diet [43]. Non-RCT data showed that after adjusting for age, physical functioning, SUI at baseline, obesity, smoking and certain dietary factors, the incidence of SUI at one year was increased in women consuming more total fat, saturated fatty acids and monounsaturated fatty acids, as well as those that consumed more carbonated beverages, zinc or vitamin B12 at baseline [45,46]. The incidence of SUI was reduced in those that ate more vegetables, bread and chicken at baseline [46]. Higher intake of vitamin D, protein and potassium were also associated with decreased risk of onset of OAB in women [47]. The 2011 BACHS study [44] found that greater total energy intake was associated with LUTS. The same data source was used to test the hypothesis that carotenoid, vitamin C and calcium intakes were associated with UI in women, they found that high dose vitamin C and calcium were positively associated with incontinence whilst vitamin C from food and drinks were negatively associated with incontinence.

(b) Caffeine: One RCT found a clinical effect of decreasing caffeine, while the other did not. Bryant (2002) reported that women in the intervention group decreased daily caffeine consumption to a mean of 96.5mg, compared to 238.7mg in the control group. The experimental group had statistically significant reduction in urgency episodes (61% versus 12%); the number of Incontinence episodes decreased as well (55% compared to 26% in the controls) but this was not statistically significant. In contrast, while Swithinbank (2005) found no effect of decreasing fluid intakes (see below)or changing from caffeine containing to decaffeinated drinks.

(c) Fluid intake: In an RCT, 32 women were assigned to one of three groups: increase fluid intake by 500cc over baseline, decrease by same amount, or maintain baseline level [50]. While non-adherence to the protocol made results difficult to interpret, the authors reported that 20 women who had fewer incontinent episodes at the end of the trial attributed this to drinking more fluids. Another RCT that used a cross-over design found that when fluid intake was decreased, 39 women with SUI decreased the number of incontinence episodes; similarly, 30 women with DO significantly decreased voiding frequency, urgency and incontinence episodes [49]. Fluid manipulation [51] with a decrease in normal intake by 25% led to a significant reduction in frequency (23%), urgency (34%) and nocturia (7%) but not urinary incontinence. Increases in fluid consumption led to symptom worsening.

After adjusting for age and gender, no association was found between UI and consumption of alcohol [52]. After adjusting for age and fluid intake, consumption of wine, beer or spirits did not increase the incidence of either SUI or OAB (there was a trend towards less SUI in beer drinkers; OR 0.75 (95% CI 0.56 to1.01) for weekly drinkers versus those that drank beer less than monthly) [46]. Similarly, in a large cross-sectional study, there was no association in either unadjusted or adjusted analyses between alcohol consumption and UI [11].

6. Summary

Indications from epidemiological data suggest diet may play a role in urinary incontinence **(Level of Evidence: 3)**. Evidence is building on the role of macronutrient intake and reduction of UI. Fluid intake may play a minor role in the pathogenesis of UI. Caffeine consumption may play a role in exacerbating UI. Small clinical trials do suggest that decreasing caffeine intake improves continence. **(Level of Evidence: 2).**

7. Recommendations

Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than one litre a day **(Grade of Recommendation: B).** Further RCT's to assess the role of diet in urinary incontinence are warranted.

A reduction in caffeine intake is recommended for those with incontinence symptoms **(Grade of Recommendation: B)**. Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

f) Constipation

No published RCTs were found which assessed the effect in adults of regulating bowel function on UI. An observational study compared the self-report of straining as a child with urogynaecological symptoms as an adult [53]. Population-based studies assessed multiple risk factors for UI [54,55].

1. Quality of data

Sample sizes range from 73 for the observational study [53] to 213 in a study correlating the surrogate measures of perineal descent and pudendal neuropathy [56] to 1154 and 1051 in the population-based studies [54] respectively.

2. Results

In a small observational study, 30% of women with SUI and 61% of women with uterovaginal prolapse reported straining at stool as a young adult, compared to 4% of women without urogynaecological symptoms [53]. In a large population-based study of 1154 women over age 60 years, those with UI were slightly more likely to report constipation than those who were continent of urine (31.6% vs 24.7%) [54]. After adjusting for demographic and obstetric confounders, women who reported straining at stool were more likely to report SUI and urgency [55]. There appears to be an association between straining and pudendal nerve function. The mean pudendal nerve terminal motor latency increased after straining, correlated with the amount of descent, and returned to resting by four minutes after a strain [57]. Others found evidence of pudendal neuropathy in only 25% of women with abnormal perineal descent; in this large group of patients with defecating dysfunction no relationship was seen between neuropathy and pelvic descent, leading to the conclusion that pelvic descent and neuropathy may be two independent findings [56].

3. Summary

There is some evidence to suggest that chronic straining may be a risk factor for the development of UI. **(Level of Evidence: 3).** There are no intervention trials that address the effect of resolving constipation on UI.

4. Recommendations

Further research is needed to define the role of straining in the pathogenesis of UI. If the association holds, public education, particularly of parents and paediatricians, is needed to make an impact on the common problem of straining due to constipation in children.

g) Other

There are many other lifestyle interventions suggested either by healthcare professionals or the lay press for the treatment of UI, including reducing emotional stress, wearing non-restrictive clothing, utilising a bedside commode, decreasing lower extremity oedema and treating allergies and coughs. There is no evidence to support these interventions for UI; support for these interventions is all anecdotal in nature.

3. OTHER LUTS

No data was found.

4. FACTORS AFFECTING OUTCOME

No data was found.

II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

Pelvic floor muscle training (PFMT) remains a key factor in the prevention and treatment of UI. Because pelvic floor muscle (PFM) integrity appears to play an important role in the continence mechanism (see report from Committee 4: Pathophysiology), there is a biological rationale to support the use of PFMT in preventing and treating UI in women [58]. The role of PFMT in the treatment of UUI came later, when it was recognized that PFM contraction can also be used to occlude the urethra to prevent leakage during detrusor contraction, as well as inhibit and suppress detrusor contraction.

1. RATIONALE AND PRINCIPLES

a) Biological rationale for PFMT for SUI

The biological rationale for using PFMT to treat SUI is at least three-fold.

First, in healthy continent women, activation of the PFM before or during physical exertion seems to be an automatic anatomic response [59-61]. This PFM 'reflex' contraction is a feed-forward loop and might precede bladder pressure rise by 200-240 milliseconds [62,63]. An intentional and effective PFM contraction, prior to and during effort or exertion, compresses the urethra and increases the urethral pressure, preventing urine leakage [64]. Supporting this rationale, both ultrasonography and MRI studies have demonstrated the cranial and forward movements of the PFM during an active contraction and the resulting impact on the postion of the urethra [65,66]. This active contraction of PFM during activities that cause SUI leakage has been referred toin various ways including counterbracing, perineal pre-contraction, PFM functional training, stress strategy, and the "knack" [67,68]. Miller assessed effectiveness in an RCT and demonstrated that a voluntary PFM contraction before or during coughing can reduce leakage after only one week of training in middle-aged and older women with SUI and in pregnant women with de novo SUI. Performing a rapid, strong, and well-timed PFM contraction seems to actively prevent urethral descent during an intra-abdominal rise in pressure [69]. Thus, the timing of a PFM contraction could be an important factor in the maintenance of urinary continence. Active, volitional contraction of PFM to occlude the urethra during physical activity is now routinely combined with PFM exercise to improve strength and tone. However, the optimal strength required to compress the urethra and prevent urine leakage has yet to been determined.

Second, the bladder neck is supported by a strong, toned PFM (resistant to stretching), limiting its

downward movement during effort and exertion, thereby preventing urine leakage [64,70]. Intensive strength training may reinforce structural support by permanently elevating the levator plate to a higher position inside the pelvis and enhancing the hypertrophy and stiffness of the connective tissues [70]. Anatomical and dynometic differences of the PFM have been demonstrated between continent and incontinent women [71-73].Women with SUI and MUI demonstrate less PFM passive force (tone), maximal strength, rapidity of contraction and endurance as compared to continent women [74,75]. In a pre and post PFM training study using an MRI reconstruction method, a significant reduction in the internal surface area of the levator ani was observed after PFMT; this suggests an increase in passive tone of the levator ani, which in turn is indicative of the state of PFM tone [76] Increased urethral stability at rest and during effort following 14 weeks of supervised PFMT and behavioural modification has been noted [77]. Thus, a growing body of evidence supports the rationale that PFMT improves PFM tone, facilitates more effective automatic motor-unit-firing of the PFM, and thus prevents PFM descent and urine leakage during increased intra-abdominal pressure [78]. Finally, morphological and functional changes after PFMT indicated a relationship between improved PFM coordination and increased PFM mobility and also to striated urethral sphincter hypertrophy [79]. Therefore, PFMT could also contribute to continence through a direct action on the urethral sphincter. However, more research is needed to confirm these results

Finally, there is some evidence that contraction of the transversus abdominus (TrA) muscle is associated with co-activation of the PFM. This has been demonstrated by US, EMG and MRI studies [80-84]. However, a TrA muscle contraction does not appear to elevate the PFM in all women [85] and when it does, it does not appear to be as effective as a direct PFM contraction [83,84]. More research is needed to better understand the relationship between the TrA and the PFM muscles as well as the effect on incontinence of rehabilitating the interaction between TrA muscle and the PFM.

Given the above biological rationale, in treating SUI the objective behind PFMT is to improve the timing (of contraction), strength and stiffness of the PFMs and perhaps urethral sphincter function.

b) Biological rationale for PFMT for UUI

PFMT can also be used in the management of urgency and urge urinary incontinence (UUI). In 1975 Godec observed that a detrusor muscle contraction can be inhibited by a PFM contraction that has been induced by electrical stimulation (EStim) [86] and Burgio demonstrated that a detrusor contraction can be inhibited by a voluntary PFM contraction [87]. During urine storage, bladder distension produces low-level vesical afferent firing, which in turn stimulates the pudendal nerve outflow to the external urethral sphincter thereby increasing intraurethral pressure, an effect he termed a 'guarding reflex' for continence [88]. It is also posited that Barrington's Micturition Centre's excitatory loop switches on when bladder pressures are between five to 25mmHg, while the inhibitory loop is predominantly active above 25mmHg [89]. Inhibition involves an automatic (unconscious) increase in tone for both the PFMs and the urethral striated muscle.

Thus, voluntary PFM contractions may be used, often as part of a broader urge suppression strategy, to treat UUI. Generally, patients are instructed not to rush to the toilet in response to any urge sensation, because it can trigger detrusor contraction and increase intra-abdominal pressure. The strategy involves remaining still, repeatedly contracting PFMs, and waiting for the urge to pass. After inhibiting the urgency to void and the detrusor contraction, the patient can learn to reach the toilet in time to avoid urine leakage. However, the number, the duration, the intensity and the timing of the PFM contraction required to inhibit a detrusor muscle contraction is not known.

This focus on urge suppression strategies, often combined with PFM exercise, is commonly called behavioural training. Behavioural training also involves teaching the concept of using volitional PFM contraction to occlude the urethra and prevent urine loss during uninhibited detrusor contraction. Further, patients can also be taught to be more vigilant about PFM tone when they begin to sense bladder fullness and consciously maintain resting tone rather than allowing the pelvic floor relaxation that immediately precedes and coordinates with detrusor contraction.

c) Principles of skeletal muscle strengthening

The aim of any strengthening programme is to alter muscle morphology by increasing the cross-sectional area, increasing the number and frequency of motor neuron excitations, and improving tone and stiffness. When muscles engage in intense, repetitive tasks that exceed the normal demands of daily activities this stimulates an increase in the muscle fibre size (hypertrophy), which in turn increases muscle bulk. However, hypertrophy is not immediately evident as a training response. An increase in strength is evident long before visible hypertrophy. Early improvements in strength result from neural adaptation, including a greater number of activated motor units, an increased rate of motor unit excitation, more synchronised motor unit firings and more persistent activation of type II motor units [90-92]. Hypertrophy begins only after a minimum of eight weeks of regular and intense strength training [93]. With increased overload, hypertrophy may continue for some years.

There are four principles of strength training: specificity, overload, progression and maintenance [78].

Strength training is specific to the muscle(s) being trained and requires overload (that is, exposing the muscle(s) being trained to a gradual increase in resistance, repetitions or repetition speed). Progression is the extension, through increased resistance, intensity and volume of training, of the initial exercise programme. Finally, maintenance refers to the extent to which the muscle is able to maintain a continued level of strength. In order to achieve an effective strength training programme, the American College of Sports Medicine recommends that all these elements be addressed [94].

d) Principles of behaviour change

PFMT is a treatment that involves changing an individual's behaviour and teaching new skills. Because its effectiveness depends on the active patient participation, including adherence to instructions, clinicians are faced with the challenges of changing the individual's behaviour. Some are self-motivated, but most require assistance. In general, models of healthcare behaviour change rely on providing information and education. But these are usually inadequate in the case of interventions like PFMT that typically take effect gradually and require several weeks at least to reach optimal efficacy.

Much of human learning follows the principles of operant learning, in which behaviour is a function of antecedents and consequences. Antecedents include education, motivating techniques, as well as daily reminders including cues to exercise PFM or to use them volitionally to prevent urine loss with physical activities or in response to urge. Most learning occurs through the consequences of behaviour, i.e., by trial and error and feedback. Thus, people learn how to contract and relax PFMs not only through instructions, but also through various modes of feedback. This can include visual or auditory feedback loops provided by a therapist verbally or through biofeedback, in which physiological parameters are measured and fed back using various instruments. Operant learning principles include the concept of positive reinforcement: positive results reinforce behaviour and it is more likely to be repeated. Behaviours that do not produce the desired results tend to be abandoned. Herein lies the challenge for clinicians using PFMT, to help the patient sustain their efforts for long enough to achieve a result, whether it is a change in muscle strength or improvement in symptoms. Even when they result in short-term improvements, patients in PFMT tend to have difficulty sustaining regular exercise long-term, partly because discontinuing the exercise regimen does not result in immediate regression.

Learning is mediated by individual characteristics, including disposition, attitudes, beliefs, and experiences. Several models of behaviour change have evolved that are relevant for addressing health behaviours. According to one widely-adopted model, Social Cognitive Theory, people will engage in a new behaviour when they believe it will lead to positive outcomes and they believe they are capable of performing the behaviour (concept known as self-efficacy). Factors that may affect the ability to learn new skills and change daily habits fall into several domains, including social, cognitive, physical, emotional, behavioural, and environmental. Clinicians have the opportunity potentially to influence any of these by making an effort to understand the patient's daily life, assessing barriers to change during treatment, and assisting patients with overcoming the impediments they encounter. It is generally accepted that clinicians should promote realistic expectations of treatment and outcome, individualize treatment protocols, and follow-up with patients to assess adherence, monitor progress, encourage persistence, and facilitate long-term behaviour change.

This section presents the evidence for the use of PFMT in the prevention and treatment of UI in women. Questions addressed are:

a) Is PFMT effective in the prevention of UI?

b) Is PFMT better than no treatment, placebo or control treatments in the treatment of UI?

c) Is one type of PFMT programme better than another in the treatment of UI?

d) Is PFMT better than other treatments in the treatment of UI?

e) Does the addition of PFMT to other treatments add any benefit in the treatment of UI?

f) What factors might affect the outcome of PFMT in the treatment of UI?

g) What is the effect of PFMT on other lower urinary tract symptoms?

In this section, the pre-specified primary outcomes of interest were 1) self-reported UI (for prevention studies), 2) self-reported cure or 3) cure and improvement in UI symptoms (for treatment studies). Secondary outcomes of interest were 1) quality of life (prevention and treatment studies) and 2) leakage episodes and amount (treatment studies) [95].

2. PREVENTION AND TREATMENT (PREGNANT AND POSTNATAL WOMEN ONLY)

This subsection specifically considers PFMT for the prevention and treatment of UI in pregnant and postnatal women (called childbearing women in this section). As the physiological changes of childbearing can affect PFM function, it is possible that the effect of PFMT might differ in this group compared to non-childbearing women.

A 2008 Cochrane review in this area analyzed data from 15 trials in 6,181 participants [96]. An additional 6 randomised trials published between 2008 and 2011 were identified and also reviewed

for this subsection (total 21). Similar to methods used in the Cochrane review, trials in this section have been grouped in 3 areas: 1) trials of PFMT for prevention of UI (performed in women without UI symptoms when randomised); 2) trials of PFMT for treatment of UI; and 3) trials of PFMT for the prevention and treatment of UI (participants with and without UI symptoms enrolled). Trials were further separated into those beginning during pregnancy (antenatal) or postnatal.

As in the recently updated Cochrane review, the primary outcome of interest was self-reported UI [97]. Secondary outcomes included condition specific quality of life (e.g. King's Health Questionnaire (KHQ), Incontinence Impact Questionnaire (IIQ), or any other quality of life or health status measure (for example Short Form-36); symptom severity; number of leakage episodes; measures of pelvic floor muscle function; and economic analyses. Other outcomes of interest included adherence measures.

a) Is PFMT effective in the prevention of UI in childbearing women?

There are three grades of prevention: primary, secondary and tertiary. Primary prevention aims to remove the causes of a disease. Secondary prevention focuses on the detection of asymptomatic dysfunction and provides treatment aimed at stopping its progression. Tertiary prevention focuses on existing symptoms to prevent the progression of the disease through treatment. This subsection addresses the question of PFMT effectiveness for primary and secondary prevention of UI in childbearing women. Clinically it can be difficult to effectively screen trial participants to ensure that a disease process is altogether absent (for primary prevention studies) or present, although asymptomatic (for secondary prevention). Trials investigating prevention of UI usually enroll people purely on the basis of the absence of symptoms. Thus, the trials in this section likely represent a combination of primary and secondary prevention effects.

The 2008 Cochrane review [96] included 5 trials addressing prevention of UI in childbearing women [98-102]. Two of the studies were combined prevention/treatment studies, but published or unpublished data were available for women who were continent at recruitment [98,101]. In the study by Sampselle (1998), 54 of 72 women were continent based on a standing stress test at 20 weeks gestation. After drop outs, unpublished data were available from 37 previously continent women (16 PFMT and 21 controls). Mørkved (2003) [101] published data for 207 of 301 women who were continent before pregnancy and at 20 weeks gestation. After dropouts, data were available from 193 previously continent women (94 PFMT and 99 controls). Neither study was powered to detect differences in the previously continent subgroup and the subgroup sizes were small.

One new prevention trial published in 2010 was found [103] and two combined prevention/treatment trials of antenatal PFMT with UI outcomes were published since 2008, but outcome data specific to the women who were continent at baseline were not presented [104,105]. Thus, these two trials and their results are included in the section below on combined prevention/treatment trials.

Five studies [98,99,101-103] recruited nulliparous or primiparous women during pregnancy, and one recruited "pregnant women" [100]. Reilly (2002) recruited primigravid women without a pre-pregnancy or current history of UI, but with bladder neck hypermobility at 18 to 20 weeks gestation. Primigravidae were recruited at 18 [98], 20 [101,103] and 28 weeks [102] gestation.

In all six trials, PFMT began during pregnancy while controls received the usual antenatal care, which may have included advice on PFMT from their maternity caregivers [98,99,101,103] or were asked not to do PFMT [100,102]. There were some variations in the PFMT parameters (intensity and supervision):

•Eight to 12 near-maximal voluntary PFM contractions, held for six to eight seconds, followed by three to four fast contractions at the end of each contraction, twice daily from 20 weeks gestation [101,103]. Also a weekly [101] or monthly [103] exercise class from weeks 20 to 36.

- Eight to 12 PFM contractions, held for six seconds with a two second rest, three sets twice daily, from 18 weeks gestation. Also individual PFMT with physiotherapist during monthly visit [99].
- Up to 30 near-maximal PFM contractions per day from 20 weeks of gestation [98].
- 10 PFM contractions; held for eight seconds each followed by three fast one second contractions; a six-second rest between contractions; for up to 20 weeks. PFMT taught one-on-one with physiotherapist. Weekly clinic appointments (one hour each) for eight weeks, then weekly phone calls [102].
- PFMT not described. Participants were seen twice monthly throughout pregnancy, and every three months postpartum for one year [100].

Correct voluntary PFM contraction was checked prior to training in four [98,101-103].

1. Quality of data

Allocation concealment appeared adequate in four trials [98,99,101,102] and the outcome assessors were blind in five of the six trials [98-101,103]. Dropout rates varied, including 4% [101,102], 14% [99], 36% [98] and as high as 53% [103]. Stothers (2002) did not report any losses to follow up.

Outcomes were measured at various times: 28 and 35 weeks gestation and six weeks postpartum

[102]; six and 12 months postpartum [100]; 34 to 36 weeks gestation then at three months postpartum [99,101,103]; 35 weeks post partum then postpartum at six weeks and six and 12 months [98] with the primary endpoint being 12 months. Reilly [2002] was the only trial with long-term follow up, at four years and more recently at 8 year follow up [106].

2. Results

Pooled data described in this section are reported from the 2008 Cochrane review [96].

(a) Late pregnancy (34 weeks or later): Pooled data from three trials [98,101,102] showed that women in the antenatal PFMT group were 56% less likely to report UI than the controls. Statistically significant heterogeneity was observed in this comparison. The point estimates in all three studies favoured PFMT but these differed considerably. A possible reason for the more pronounced difference between PFMT women and controls in the study by Gorbea Chavez (2004) is that the comparison group was asked not to do PFMT, whereas in the other two controls had usual care that might have included PFMT. In another trial [103] a lower proportion of women in the PFMT group at 36 weeks gestation reported SUI compared to controls, but the difference was not statistically significant.

(b) Early postpartum (up to 12 weeks): Pooled data from two trials showed that PFMT women were around 50% less likely to report UI, compared to the controls (RR 0.50 95% CI 0.31 to 0.80) [98,102].

(c) Mid postpartum (three to six month postpartum): In the pooled analysis, PFMT women were still statistically significantly less likely than controls to report UI, although the difference in risk had reduced to about 30% (RR 0.71 95% CI 0.52 to 0.97) [98-101]. Similar to their results at 36 weeks of pregnancy, Mason et al [103] found fewer women in the PFMT group compared to controls reported SUI symptoms at three months postpartum, but this difference was not statistically significant. Loss to follow-up was high, and this outcome was assessed in only 47% of those with baseline data.

(d) Late postpartum (up to one year postpartum): Too few participants (n=44) were available in 1 trial [98] to determine if there was a difference in prevalence of UI between PFMT women and controls at 12 months postpartum.

(e) Long term (more than one year): At four year follow up, Reilly (2002) reported seven of 42 PFMT women and 26 of 58 controls had symptoms of SUI. However, this apparent benefit for the PFMT group was not seen in a later 8 year follow up study [106]. In that report, 164 (71%) of the initial 230 participants with postnatal data were analyzed, and SUI was reported by 35.4% in the PFMT group versus 38.8% in the control group; 70% of those assessed had had one or more additional deliveries during the follow-up period.

Regarding secondary outcome measures, five of the six trials reported symptom severity data such as frequency or amount of urine leakage. None of the measures, or the ways in which they were reported, were common to the four trials. In general, the data suggested that PFMT women with symptoms of UI might have demonstrated less severe symptoms than the controls. Only Stothers [2002] noted adverse events; two of the 43 PFMT women withdrew due to pelvic floor pain.

Only three trials reported treatment adherence data. Gorbea Chavez (2004) reported that 84% of PFMT women attended seven or eight of the eight physiotherapy appointments. In another, nearly half the women in the PFMT group exercised for 28 days or more; postpartum similar proportions of women in the intervention and control groups were doing occasional or no PFMT (28% and 34% respectively [99] Mason [2010] reported that just 64% of women assigned to the PFMT group attended at least one class, but women in the intervention group reported performing more exercises in a 3-day diary at both 36 weeks of pregnancy and three months postpartum than did controls.

3. Summary

Pregnancy and birth appear to be important factors associated with the development of UI in women. Therefore, all women who have had a child or children might be considered 'at risk' of developing UI at a later date.

Continent pregnant women having their first baby who participated in a more 'intensive and supervised' PFMT programme than the PFMT provided as part of usual care were less likely to experience UI from late pregnancy up to six months postpartum **(Level of Evidence: 1)**. There was not sufficient evidence available to demonstrate whether this benefit persists at 12 months postpartum; results from a single trial suggest the benefit of PFMT is not maintained eight years after treatment or with subsequent deliveries **(Level of Evidence: 2)**. There was no evidence investigating the preventive effects of PFMT in pregnant, previously continent, multiparous women.

4. Recommendations

Continent, pregnant women having their first baby should be offered a supervised (including regular health professional contact) and intensive strengthening antepartum PFMT programme to prevent postpartum UI **(Grade of Recommendation: A)**. The usual or standard approach to PFMT in pregnancy (which is commonly verbal or written instruction without confirmation of correct contraction or supervision of training) needs to be reviewed.

Additional trials with longer-term follow-up (greater than 12 months postnatal) are needed to determine long-term benefits of antenatal PFMT. Further,

large, good-quality RCTs are needed to investigate the effect of antepartum PFMT on preventing postpartum UI in multiparous women.

b) Is PFMT effective in the treatment of UI in childbearing women?

Four studies which addressed the treatment of existing UI after delivery [107-110] were identified and all were included in the 2008 Cochrane review [96]. One study recruited incontinent women during pregnancy [110], while the other three recruited women three months or more after delivery. All four studies recruited a mix of primiparous and multiparous women.

The control groups in three [107,108,110] received standard care, which included ante and postpartum advice on PFMT, whereas the control group in Dumoulin's (2004) study received, in lieu of training, relaxation massages at the same frequency as the PFMT treatments.

The PFMT interventions varied as follows:

- intervention group received either PFMT, or PFMT with vaginal cones, or vaginal cones (VC). PFMT comprised 80 to100 PFM contractions per day (a mix of fast and slow), with three home visits by a nurse, healthcare visitor or continence advisor. The VC group received 15 minutes per day of cone therapy while the combined PFMT/VC group received both interventions [107].
- as above supplemented by instruction from a physiotherapist on four occasions [108].
- PFMT with biofeedback + electrical stimulation (EStim) with or without deep abdominal training. PFMT comprised weekly sessions supervised by physiotherapists for eight weeks with 15 minutes of Estim and 25 minute of PFM exercice with biofeedback including strenghtening and motor relearning exercices [109]
- four one to one and half hour sessions with a physiotherapist (three antepartum and one at six weeks postpartum) but details of the PFMT programme were not given [110]

1. Quality of data

Random allocation concealment was adequate in three of the four trials [107-109] and outcome assessors were blind in two [108,109].

In one trial losses to follow-up were high in all intervention groups (51% PFMT; 63% PFMT/VC; 41% VC). In two others losses to follow-up were 30% [111] and 38% [110]. In contrast, Dumoulin's (2004) trial (which included weekly contacts with a physiotherapist for eight weeks) reported a 6% loss to follow-up. Outcomes were measured outcome 12 months after delivery [107,108], and then 24 to 44 months post-delivery, and six years after the index delivery [111]. Dumoulin (2004) reported outcome nine weeks after intervention began. However as women were recruited at varying lengths of time following delivery (all more than three months postpartum) the data are presented alongside those from Glazener (2001), and Wilson (1998), as long-term post-natal data.

2. Results

In the one study of antepartum PFMT for treatment of UI, no statistically significant difference was reported in the prevalence of UI between PFMT and control groups at 35 weeks, eight weeks postpartum, six months and 12 months postpartum [110].

Pooled data from the three trials of postpartum PFMT found women were about 20% less likely to have UI after treatment compared to the controls (RR 0.79, 95% CI 0.70 to 0.90) [96]. Statistically significant heterogeneity was observed. The treatment effect in the study by Dumoulin (2004) was much greater than that in the other two studies. Possible reasons are that the controls in the study by Dumoulin (2004) were asked not to do PFMT, whereas controls in the other two studies received usual care and both interventions and control groups were also doing PFMT (a mean of 20 versus five PFM contractions per day in Glazener 2001), and 86 versus 35 in Wilson 1998). Another difference was the intensity and supervision of the PFMT intervention; Dumoulin (2004) used a more intensive PFMT programme with adjunctive EStim and BF and physiotherapy appointments once a week for eight weeks, whereas in the other two studies [107,108] women had three or four appointments with a health professional over approximately six months and were asked to do PFMT on their own.

All four treatment trials reported some data on symptom severity such as frequency or amount of urine leakage. None of the measures, or the ways they were reported, was common to the four trials. The data suggested that PFMT women with symptoms of UI might have less severe symptoms than the controls, but this was not a consistent or clear-cut finding. Dumoulin (2004) stated that none of the women in the PFMT group reported any adverse events.

Three trials reported some data related to treatment adherence, one for antepartum PFMT [110] and two for postpartum PFMT [107,108]. In the antepartum study, at 36 weeks gestation 37% of the PFMT women were exercising intensively compared to 14% of the controls. Mean number of PFM voluntary contractions per day at 12 months postpartum were 20 [108] and 86 [107]per day in PFMT women, and 5 and 35 respectively per day in the controls.

Glazener and colleagues followed up women six years after the index delivery. The effect of PFMT on UI was not sustained. At six years, 100 out of the 263 in the intervention group and 99 out of the 253 in the control group experienced UI at least once

per week [111]. However, the women had had an average of 1.5 deliveries since the index delivery.

3. Summary

To date, only one trial has investigated the effect of PFMT for the treatment of UI in pregnant women [110]. This was a moderate-size study that did not report allocation concealment or blinding of the assessors, and did not describe the type of PFMT programme employed. In the absence of any detail on the PFMT programme it is impossible to judge if the intervention had the potential to be effective.

Postpartum women with UI who were randomised to PFMT taught and supervised by a health professional were less likely to be incontinent than controls (standard care or relaxation massage) six to 12 months following delivery **(Level of Evidence: 1)**. Of the three trials, the one that used an intensively supervised strength training programme demonstrated the greatest treatment effect. It is unclear if the benefit of PFMT is maintained over time or with subsequent deliveries **(Level of Evidence: 2).**

For women who have persistent symptoms of UI at three months postpartum PFMT is a more effective treatment than standard postnatal care or relaxation massage; effects might be greater with supervised and intensive strengthening PFMT (with the addition of EStim). It is not clear if the effect can be sustained over the long-term; there is also no data on the effect of short periodic refresher sessions on long-term effect.

4. Recommendations

PFMT should be offered as first line conservative therapy to women with persistent UI symptoms three months after delivery (Grade of Recommendation: A); an 'intensive' PFMT programme (in terms of supervision and exercise content) is likely to increase the treatment effect (Grade of Recommendation: B).

There is a need for at least one large, pragmatic, well-conducted and explicitly reported trial with long term follow-up (five plus years) of postpartum PFMT that investigates the effect of 'intensive' treatment followed by periodic refresher sessions.

c) Is PFMT effective in the mixed prevention and treatment of UI in childbearing women?

Ten trials are included in this section. Of these trials, some women did and some did not have UI at the time of recruitment, i.e. the effect of PFMT included a mix of prevention and treatment. Eight [98,101,112-117] were included in the 2008 Cochrane systematic review [96] and two were more recently published [104,105].

In six, nulliparous or primiparous women were randomised to either supervised antepartum PFMT or usual antepartum care [98,101,104,105,113,116]. The other four randomised nulliparous women during pregnancy [114] or postpartum [112,115,117] to either postpartum PFMT [112,115,117] or usual postpartum care or no PFMT [114].

(a) Antepartum PFMT versus usual care: The interventions of two trials (98,101] in pregnant women have been described in section B.2.1a.

Two new studies were added [104,105]. Ko (2011) recruited nulliparous women at 16-24 weeks gestation. Women in the PFMT group met individually with a physical therapist for instruction, and correct contraction was assessed by observing inward movement of the perineum during contraction. The individual therapy was similar to that used by Reilly (2002) described above, including three sets of eight contractions repeated twice daily. Additional group therapy occurred weekly in 45 minute sessions over a 12 week period. Controls were excluded if they reported previous use of PFMT, but were not specifically discouraged to do PFMT during pregnancy; otherwise they received usual prenatal care. Bø's study (2011) differed in that the primary aim was to assess the effect of regular exercise on weight gain in pregnancy. Primiparous, sedentary women within the first 24 weeks of pregnancy were recruited and randomised to aerobic fitness classes including group instruction and practice of PFMT or usual care (not described). Women in the exercise group were asked to attend two to three 1-hour aerobic fitness classes weekly for at least 12 weeks. The PFMT included verbal instruction and group performance of three sets of eight to twelve contractions, holding six to eight seconds each in sitting, kneeling and standing positions. No individual assessment of the ability to perform a correct contraction was included. In addition, the exercise group was given a PFMT pamphlet that recommended a regimen of three sets of eight to twelve PFM contractions daily.

Hughes (2001) recruited nulliparous women at 20 weeks gestation and women randomised to PFMT attended one individual appointment then, between 22 and 25 weeks gestation, a group PFMT session (maximum six women) with a physiotherapist. No details of the training parameters were reported. Women with no palpable voluntary PFM contraction or a flicker of contraction were randomised. Controls received the usual community antepartum care. In another trial [116], women in the PFMT group were trained to use an Epi-No device (an inflatable vaginal balloon connected to a pressure gauge for visual feedback), 15 minutes daily; for three to six weeks. Controls received no device. The authors' primary interest was in improving the elasticity of the PFM for delivery rather than continence outcomes.

(b) Postpartum PFMT versus usual care or no PFMT: Chiarelli (2002) only included women who had had forceps or ventouse deliveries, or had delivered a baby weighing 4000g or more. Ewings (2005) only included women who had already experienced UI and who were at high risk of UI following childbirth

in accordance with the SIFCRAFT risk scale. The control groups received the usual postpartum care, which included: an invitation to postpartum classes taught by physiotherapists [115], standard ante and postpartum care [112], no PFM re-education from two to 10 months postpartum [114] and verbal promotion of PFM exercises supplemented by a leaflet [117]. In PFMT groups, women were visited by a midwife or physiotherapist on the postnatal ward and were advised to train as follows:

- PFMT exercises as often as remembered and contractions integrated with daily living activities, plus midstream urine stop. Correct PFM contraction was checked on a second visit at eight weeks postpartum [112].
- PFMT exercises with three to six-second holds, three times a day. A variety of adherence strategies were employed (e.g. red stick-up dots, home or hospital visit after eight weeks).
- PFMT programme including 12 visits with a physiotherapist between two and 10 months postpartum, including a 20 minute BF training session and a 15 minute EStim session [114].
- PFMT taught one to one with physiotherapist in hospital in addition to an invitation to attend PFMT class at two and four months postpartum; 21 of 284 women participated in the first class (18%) and only 5 (4%) attended both [117].

1. Quality of data

(a) Antepartum PFMT versus usual care: Three of the six trials had adequate random allocation concealment [98,101,105]. In the others women were allocated at random but it was not clear if allocation was adequately concealed [104,113,116]. Assessors were blinded in four of the six trials [98,101,104,105]. Sample sizes varied: 72 [98], 105 [104], 144 [116], 300 [105], 301 [101], and 1169 [113]. Dropout rates were 14% at 6 weeks postpartum [104], 4% [101] at three months postpartum and ranged from 0% [105] to 34% [113] at six to seven months post-partum. At 12 months, the drop-out rate was 36% [98].

(b) Postpartum PFMT versus usual care or no PFMT: Random allocation concealment was adequate in three trials [112,115,117] but inadequate in Meyer (2001) where alternate assignment was used. Blinding of outcome assessment was adequate in one [115]. Sample sizes were large and varied: 1,800 women [112]; 720 [115]; 234 [117], and 107 [114]. Outcomes were measured at Both the Sleep (1987) and Chiarelli (2005) trials measured outcomes at three months [112,115]; 6 months [117], or 10 months [114]. Lost to follow up ranged from 6% to 19%.

2. Results

(a) Antepartum PFMT versus usual care: As reported by Hay-Smith and colleagues in 2008 [96] pooled data from three trials [98,101,113] showed that women who were randomised to antepartum PFMT had about 10% less risk of UI in late pregnancy. Statistically significant heterogeneity was observed in this comparison. While the point estimates in all three studies favoured PFMT these differed considerably between the trials ; the study by Hughes (2001) carried considerable weight in the pooled analysis, most likely because it was the largest study. One of the differences between the studies by Mørkved (2003) and the other two in this analysis was the PFMT intensity and supervision as reported previously, being more 'intense' in the former. Ko (2011), used a similarly more intense PFMT programme, and also found significantly less UI in the PMFT women at 36 weeks gestation compared to controls (34% vs. 51%, $p< 0.01$). Bø (2011) found no difference in the prevalence of UI in the exercise and control groups in late pregnancy.

In the pooled analyses from Hay-Smith (2008), the prevalence of UI was not statistically significant between PFMT and control groups in the early, [98] mid, [98,101,113] or late postpartum period [98,116]. At 6 weeks and 6 months postpartum, Ko (2011) found less UI in the PFMT compared to control group (25% vs. 35% and 16% vs. 27%, respectively); this difference was of borderline significance ($p=0.06$ at 6 weeks and $p=0.04$ at 6 months postpartum). Bø (2011) found no difference in the prevalence of UI in the exercise and control groups in the early postpartum period.

Symptom severity such as frequency or amount of urine leakage was reported in three trials, but PFMT was not found to be superior to control or vice versa at the primary endpoint for each study [98,112,113]. In another, statistically significant lower Urogenital Distress Inventory Short Form (UDI-6) and IIQ Short Form (IIQ-7) scores in the PFMT group were noted compared to controls at all end-points (late pregnancy and three days, six weeks and six months after delivery, suggesting less bother related to urinary symptoms and less functional impact from UI in the treatment group [105].

Some adherence outcomes were included for four of the six trials: 81% of the PFMT women attended more than half of the weekly classes [101]; 85% and 62-90% of the PFMT women reported performing PFMT at least 75% of the time at 35 weeks gestation and at 1 year postpartum [98]; >80% of the PFMT women attended every group session, and at 36 gestational weeks, 87% reported PFMT practice at least 75% of the time [105]; or 40% of the exercise group attended >80% of the weekly exercise classes [104].

(b) Postpartum PFMT versus usual care or no PFMT: There was no statistically significant difference in the prevalence of UI in women randomised to postpartum PFMT or control in the mid [112,115,117] or late postpartum period [114,115]. Statistically significant heterogeneity was observed in the combined

data for the mid postpartum period, with one study favouring PFMT [115], one neither PFMT nor control and one favouring the control condition [117]. Some potentially important clinical differences were noted between the studies. Firstly, Chiarelli (2002) recommended a PFM strength training programme; neither of the other two studies described their PFMT programme, so it is not possible to determine whether the latter studies could have had an effect or how different the PFMT and control conditions were. Further, Sleep (1987) noted only a moderate difference in the proportion of PFMT women and controls doing some PFMT at three months postpartum while at three months postpartum Chiarelli reported that about half the controls were doing PFMT and an even greater proportion of the PFMT group were exercising. A second difference was that Chiarellirecruited women at potentially increased risk of postnatal UI, such as those who had a large baby or a forceps delivery.

3. Summary

The effect of antepartum PFMT or postpartum PFMT, in groups of women where some did and some did not have prior UI symptoms, varied by study with some showing a benefit on UI prevalence whereas others did not **(Level of Evidence: 2)**. The characteristics of the three trials, all methodologically robust, that demonstrated some effect were:

(a) For antepartum PFMT: pregnant women having their first baby and used intensively supervised strengthening PFMT programmes; PFMT reduced UI prevalence in late pregnancy and three to six months postpartum [101,105], but this was not evident six years after the index delivery [101].

(b) For postpartum PFMT: primiparous and multiparous women at potentially greater risk of postpartum UI after a large baby or forceps delivery, and used a strengthening PFMT programme; PFMT reduced UI prevalence at three months postpartum but not at one year [115].

4. Recommendations

Health providers should carefully consider the cost/benefit of population based approaches to health professional taught antepartum or postpartum PFMT, that is, health professional instruction to all pregnant or postpartum women regardless of their current or prior continence status **(Grade of Recommendation: B).**

Where a population approach is used, the 'best' evidence to date suggests the following: (a) an intervention comprising of a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting at 20-24 weeks gestation for pregnant women having their first baby, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more) **(Grade of Recommendation: C)**

3. PREVENTION (OTHER WOMEN)

Hay-Smith and colleagues [96] have previously reviewed trials of PFMT for the prevention of UI in pregnant, postnatal or childbearing women. No trials investigating the primary/secondary prevention effects of PFMT for UI in non-childbearing women were found. These results were considered in section B.2.1. Prevention of post prostatectomy UI is considered in Section D.2.1.

a) Is PFMT effective in the prevention of UI?

No trials investigating the prevention effects of PFMT for UI in non-childbearing women were found.

4. TREATMENT (WOMEN)

a) Is PFMT better than no treatment, a placebo or a control group treatment?

The recommendations in this section are based on the updated 2011 Cochrane Review [97]. Primary outcomes were 1) patient-reported cure or improvement in symptoms and 2) symptom bother (level of distress) and an incontinence-specific quality-of-life assessment. Secondary outcomes of interest included the number of leakage episodes and pad and paper towel testing. For a comprehensive background to the rationale for treatment of urinary incontinence with PFMT see Dumoulin 2010 [118].

There were 25 RCTs comparing PFMT with no treatment for women with UI identified, of which 7 were excluded: one included women with symptoms of geriatric syndrome that could have influenced the results [119], three compared supervised with unsupervised PFMT [120-122], one abstract that did not clearly state "RCT" [123] and two due to the sham PFMT consisting of strong isometric hip abductor contractions [124,125]. According to EMG, dynamometric and MRI studies, both hip abductions and external rotations result in a synergic contraction of the PFMs [61,74,126,127]. Thus, in all likelihood, these two trials probably compared a direct versus an indirect approach to PFMT.

1. Studies included in the analysis

Among the 18 RCTs, three were not considered in the final analysis because they lacked adequate data [68,128,129].

Of the remaining 16, 12 recruited women with SUI exclusively [67,130-140] and one included women with SUI, with or without UUI. However, only one trial was found for women with mixed urinary incontinence (MUI) and it was thus analysed with the SUI studies [141]. One included older women with UUI with or without SUI (with urge as the predominant type) [142].The remaining two recruited women with a range of diagnoses [119,143].

2. PFMT details

Twelve of the 16 studies provided adequate detail about the type of PFMT program used. In all 12, PFMT was taught by a health professional and in eight, a correct voluntary PFM contraction was confirmed prior to training [67,119,130,134,136,139,140,142,143]. Based on the description of the programmes, two trials had PFMT programmes that clearly targeted coordination [67] or strength training [134]. It was more difficult to categorise the other PFMT programmes, because they were either a mixed (i.e. strength and endurance or strength and coordination) programme or did not provide enough information on the exercise parameters. All PFM exercise programs are presented in **Table 1**.

3. Control group details

Among the 15 studies, the 'control' groups received no treatment in eight [67,130,131,135,136,139,141,143], a placebo drug [142], sham EStim, [132], sham PFMT with placebo drug in one [137], a non-active control intervention such as the use of an anti-incontinence device [134], advice on incontinence pads [132] and general education on healthy aging [119,138,140].

Our ability to consider the combined results from individual studies was limited by: 1) lack of consistency in the choice of outcome measures chosen by the researchers; and in the older studies 2) poor reporting of outcome data (i.e. mean reported without a measure of dispersion) hence some data could not be used in the pooled analysis.

4. Quality of data

In three trials published as conference abstracts, the brevity of the reporting made it difficult to assess data quality [131,135,137]. Only three trials reported adequate random allocation concealment [119,134,140]; 9 reported using blinded outcome assessors [67,119,128,133-135,140-142].

5. Results

There were 16 RCTs comparing PFMT with no treatment, placebo, sham or other non-active control treatments. Two reported data on subjective cure and both found that women in a PFMT group were statistically and significantly more likely to report cure [134,142]. However, the effect size was quite different in the two trials. In the trial exclusive to women with SUI, the PFMT group were about 17 times more likely to report a cure compared to the controls [134], whereas in the study of PFMT women with urge-predominant UI, the women were only about two-and-half times as likely to report a cure [142].

With regard to an individual-perceived cure or improvement, two trials in women with urodynamic SUI [132,134] suggested a greater likelihood of cure or improvement than the single study in women with UUI with or without urodynamic SUI [142].

In five, psychometrically robust questionnaires were used to assess symptom impact. Bø (1999) used the Bristol Female Lower Urinary Tract Symptoms (B-FLUTS) questionnaire, but only reported the lifestyle and sex-life results. Women in the PFMT group were less likely to report that UI symptoms interfered with activities or were problematic post-PFMT. Schagen van Leeuwen (2004) reported a mean change in the Incontinence Quality of Life (I-QoL) score, but it was not clear if the difference, which favoured the PFMT group, was important as the reported means lacked a measure of dispersion. Two used QOL in Persons with Urinary Incontinence I-QoL score and reported a mean change in the QOL favouring PFMT over control [140,143]. Another found a significant difference favouring the PFMT group when the scores for incontinence-related limitations and impact on daily life were compared [139].

Six studies used urinary diaries to count leakage episodes: three days [134,143], seven days [140,144]; and 14 days [141,142]. Effect size was greatest in the Lagro-Janssen's (1991) trial; however, the treatment effect may have been overestimated due to inadequate concealment of random allocation. The point estimates in the other trials were similar and all were statistically significant [134,141-143]. Ultimately, PFMT women experienced approximately 1 to 1.5 less leakage episode per 24 hours as compared to the controls.

Three other studies measured incontinence frequency [119,136,138] with either a four-point ordinal scale (1 =urine loss once a day to 4 urine loss once a month) [136] or a six-point leakage scale to document cure (0 = no urine leakage to 5 = every day) [119,138]. Kim's 2007 study, the post-treatment scores were significantly better for the PFMT group post-treatment compared to the control, while in the 2011 trial 44.1% reported a cure in the PFMT group versus 1.6% in the control group immediately after intervention, a statistically significant difference.

One new trial was added to the section [143] making a total of 9 trials reported on pad and paper towel tests. Eight used "short office-based pad tests" and one used a paper towel test [67] Five involving women with SUI [130,131,134,136,140] dichotomised the short pad test data as either "cured"/ "not cured" [134,136,140]; or "cured and improved"/ "not improved" [130,131,136]. Four of the five found that "cured" or "cured and improved" was statistically and significantly more likely in the PFMT group. One older trial was small and did not find a statistically significant difference (fewer than 10 participants per group) [130,131]. Four reported data as mean and SD [128,134,140,143], and two others as a mean change in pad weight from baseline [135,143]. The two trials in women with urodynamic SUI, found that PFMT women had, on average, about 30g [134] and 12g [140] less urine loss than the controls. In a study of women with unspecified urinary incontinence,

Table 1: Characteristics of studies comparing PFM training to a control.

Study ID	PFM Training Type	Training Program	Training Duration	Notes
Aksac, 2003 [136]	Strength training (20) vs control (10)	VPFMC confirmed by palpation. Set: 10 VPFMC, with 5-second hold and 10-second rest. Progressed at 2 weeks to 10-second hold and 20 second rest. Sets per day: 3	8 weeks	Supervision: Weekly visit Drop out: not stated
Bø, 1999 [134]	Strength training (29) vs control (32)	VPFMC confirmed by palpation. Set: 8 to 12 high-intensity maximal VPFMC with a 6-to-8-second hold followed by 3 to 4 fast contractions at the end of each, and a 6-second rest between maximal contractions. Sets per day: 3. Exercises done in different body positions included supine, kneeling, sitting and standing - all with the legs apart.	6 months	Supervision: Weekly 45 minute exercise class Monthly clinic visit with Physiotherapist Drop out: 4/29 PFMT, 2/32 controls
Burgio 1998 [142]	Combined training (65) vs control (65)	VPFMC taught by trained nurse practitioner. Visit 1: anorectal biofeedback for teaching VPFMC with abdominal muscle relaxation. Visit 2: teaching urge strategies (adaptive response to sensation of urge) such as pause, sit, relaxation but repeated VPFMC to decrease detrusor contraction, urgency and urge incontinence. Visit 3: bladder-sphincter biofeedback for those with < 50% reduction in incontinence episodes to teach VPFMC against increasing fluid volume and increasing urgency. Visit 4: review progress, adapt home programme, Home programme 15 VPFMC 3x day in lying, sitting, standing. Also VPFMC with activities that precipitate incontinence episodes. Slow or interrupt urine stream 1x day	8 weeks	Supervision: 4 clinic visit at 2 weeks intervals Drop out: 4/65: PFMT, 8/65 Control
Burns, 1993 [141]	Endurance training (43) vs control (40)	10 VPFMC with 3-second hold, and 10 VPFMC with 10-second hold. Progressed by 10 per set to daily maximum of 200. Sets per day: 4	8 weeks	Supervision: Weekly exercise reminder cards mailed between visits Weekly clinic visits with nurse Drop out: 10 group not specified
Carneiro 2010 [139]	Combined training (25) vs control (25)	VPFMC taught by a trained physical therapist 1 serie of 8-12 repetitions of 5 VPFMC in the recumbent, sitting, and standing positions, with contractions sustained for 6 to 10 seconds	8 weeks	Supervision: 30 minutes twice weekly Drop out: not reported

Table 1: Characteristics of studies comparing PFM training to a control (continued).

Study ID	PFM Training Type	Training Program	Training Duration	Notes
Castro, 2008 [140]	Combined training (26) vs control (24)	VPFMC taught by trained physiotherapist Sets: 5 VPFMC with 10-second hold, 10 VPFMC with 5-second hold, 20 PFMC with 2-second hold, 20 VPFMC with 1-sec hold, 5 contractions with cough Sets per day: Once, three times per week	6 months	Supervision: 3 group session per week for 6 Months Drop out: 3/26 PFMT, 5/24 controls
Henalla 1989 [130]	Endurance training (26) vs control (25)	Correct VPFMC taught by physiotherapist Sets: 5 VPFMC with 5-second hold. Sets per day: 1 set per hour	12 weeks	Supervision: Weekly clinic visit Drop out: None
Kim 2007 [138]	Combined training (35) vs control (35)	VPFMC taught by trained physiotherapist Sets:10 VPFMC with 3-second hold, 10 VPFMC with 10-second hold in sitting, lying, and standing positions with the legs apart Sets per day: 2 times per week	12 weeks	Supervision: Exercise class twice a week Drop out: 2/35: PFMT, 3/35 Control
Kim, 2011 [119]	Combined training (63) vs control (64)	VPFMC taught by trained physiotherapist Sets:10 VPFMC with 3-second hold, 10 VPFMC with 10-second hold in sitting, lying, and standing positions with the legs apart Sets per day: 2 times per week	3 months	Supervision: Exercise class twice a week Drop out: 2/63: PFMT, 1/63 Control
Lagro Jensen 1991 [133]	Endurance training (54) vs control (56)	VPFMC : 5 to 10 daily sessions of 10 exercises of 6 sec each to be done during usual daily activities.	3 months	Drop out: 1/54: PFMT, 3/56 Control
Miller, 1998 [67]	Coordination training (13) vs control (14)	Voluntary PFM contraction (VPFMC) instructed and confirmed by palpation. Short programme aimed at improving coordination between a VPFMC and a rise in intra-abdominal pressure.	1 week	Dropouts: none
Sari, 2009 [143]	PFMT training (22) vs control (19)	VPMC taught by a nurse Sets : 30 contractions in 1 set (fast and slow contractions in supine, sit- ting, and standing positions progressing up to 10 seconds knack	6 weeks	Supervision: Telephone weekly to insure adherence to PFMT program Drop out: 17/22: PFMT, 17/19 Control

PFMT women had about 5g less urine loss compared to the controls; however, the wide confidence intervals included the possibility of no difference [128]. Sari (2009), evaluating women with SUI and MUI, reported PFMT women had about 14g less urine loss compared to the control. Finally, Bidmead (2002) found women with SUI in PFMT group reported a pad weight change of 13g more than controls, based on a baseline comparison.

The only trial indicating a 24-hour home-based pad test [134] reported data as mean and SD. PFMT women reported about 28g less leakage than the controls but with wide confidence intervals that included the possibility of no difference. The only trial reporting a paper towel test [68,145] for either a moderate or a deep cough reported data as mean wet area with SD: the wet area for PFMT women as compared to the controls was approximately 20cm2 less on a medium cough and 21cm2 less on a deep cough. However, in both cases, the wide confidence intervals included the possibility of no difference.

Five trials have published long-term follow-up results ranging from three and six [141], seven [119], nine [130], 12 months [138], and one and five years [144]. Burns (1993) found that those experiencing mild leakages were more likely to have a return of symptoms in contrast with those experiencing moderate to severe leakages and were more likely to continue execising in order to continue to improve. Henalla (1989) reported 18% who returned the nine-month questionnaire had recurrent symptoms. Five years post-trial, Lagro-Janssen (1991) contacted 101 of the 110 women included in their original trial. Data from the 88 consenting women showed that the proportion of continent women (about 25%) was similar after five years, but the number with severe incontinence and those reporting leakage episodes increased from 3% to 18%. Two thirds of women (67%) remained satisfied with the outcome and did not want further treatment. Kim documented cure at 10 months (2011) and 12 months (2007) post-treatment, according to bladder diary. In the 2007 trial, 55% in the treatment group were cured at 12 months compared to 9.3% in the control; this suggests a greater likelihood of continence after one year in the PFMT group; at 10 months, 39.3% were cured at 7 month in the treatment group compared to 1.6% in the control group [119].

6. Summary

PFMT is better than no treatment, a placebo drug or an inactive control treatment for women with SUI, UUI, or MUI (Level of Evidence: 1). Women treated with PFMT were more likely to report a cure or improvement and a better quality of life; they also indicated fewer daily leakage episodes and had less urine leakage on the pad and paper towel test than those in the control group in immediately after treatment and in the long term. The effect of PFMT in Women with SUI does not seem to decrease with increased age: in trials with older Women with SUI it appeared both primary and secondary outcome measures were comparable to those in trials focused on younger women. Moreover, the treatment effect appears to be enhanced where PFMT is based on sound muscle training principles such as specificity, overload progression, correct contraction confirmed prior to training, and use of the Knack **(Level of Evidence: 4).**

7. Recommendations

Supervised PFMT should be offered as a first-line conservative therapy for women of all ages with SUI, urge or MUI **(Grade of Recommendation: A).**

b) Is one type of PFMT programme better than another?

As discussed in the last section, PFMT is more effective than no treatment, placebo or inactive control treatments for women with urinary incontinence, which leads to another question: What is the most effective PFMT programme? A number of factors can influence the outcome of a PFMT programme such as the way in which it is taught and/or supervised, the parameters of the actual exercises, and adherence to the training regime. In this section, different approaches to PFMT were considered based on a Cochrane systematic review [97]. The review compared the effects of different approaches to PFMT on the management of female SUI, urge, and MUI. From 34 potentially eligible trials thirteen were excluded: 2 because they were still on going and 11 due to inadequate information. The interventions from the 21 included trials are described in detail in **Table 2**.

Among the included trials the following variables were compared:

1. *Supervision of training:* amount of contact with health professional [146-151].
2. *Supervision of training:* individual versus group supervision [146,147,149,152-154].
3. *Exercise programme:* direct versus indirect exercises [124,125,150,152,153,155].
4. *Exercise programme:* generic versus individualised exercises [154].
5. *Exercise programme:* submaximal versus near maximal contractions [156].
6. *Exercise programme:* daily versus 3 times per week [157].
7. *Exercise programme:* addition of upright exercise position [158].
8. *Exercise programme:* addition of strength training to motor learning [159].

9. Exercise programme: addition of abdominal muscle exercises [157].

Table 2 Characteristics of studies comparing different PFMT programs

Study ID	Training Type	Training Program	Training Duration	Notes
Bø, 1990 [146]	Intensive PFMT (23) vs Home PFMT (29)	Intensive PFMT: Home PFMT + 45-minute PFMT exercise course in groups, once a week for 6 months. Course: sets of 8-12 VPFMC with 6-8 second holds in standing, sitting, lying, and kneeling with legs apart; 3-4 fast contractions added after held contraction. Home PFMT: 8-12 maximal VPFMC per set, 3 times a day	6 months	Drop out: Intensive PFMT: 3 Home PFMT:2
Borello-France, 2006 [158]	Supine PFMT (22) vs Different position PFMT (22)	Twice daily VPFMC in a supine position Twice daily VPFMC in a combination of positions: supine, sitting and standing	12 weeks	Drop out: 18%
Delgado, 2009 [161]	PFMT (20) PFMT + resistance (20)	PFMT : As below without device PFMT +resistance ; 5 quick and 5 slow (sustained), high-intensity contractions daily. Advised to hold contractions as long as possible, relaxing their PFM for an equivalent time before repeating the process. Intravaginal resistance: instructions to use the Pelvic-Toner Device concurrently whilst exer- cising.Two clinic visits and one phone call	16 weeks	Drop outs : Total 12/52 Dropouts by group: not stated.
de Oliveira, 2009 [154]	Individual supervised individual PFMT (30) Group supervised PFMT (30)	Individualised programme based on PERFECT scheme. 10 slow and 10 fast contractions with 10-sec rest; 10 alternating fast and slow contractions and 5 slow contractions with a cough VPFMC confirmed by DVP, in 'ortho- static' position. 10 contractions/5-sec hold/5-sec rest; and 20 contractions/1- sec hold/1-sec rest; and 5x strong con- tractions with stimulated cough. 1-minute interval between sets	12 weeks	Drop out: Total : 1 Dropouts by group :: not stated
Felicissimo, 2010 [149]	Unsupervised home PFMT (31) Group supervised and home PFMT (31)	Individual : Correct VPFMC con- firmed. PFMT: 10 contractions with 6- sec hold and 12-sec rest in different positions 9 times per day. Start with 90 contractions in first week, then 180 a day for remaining 7 weeks Group : As above, with addition of twice-weekly 50-min group exercise session	8 weeks	Dropouts: 1/31 unsuper- vised PFMT 2/31 super- vised PFMT

Table 2 Characteristics of studies comparing different PFMT programs (continued)

Study ID	Training Type	Training Program	Training Duration	Notes
Ferguson 1990 [160]	PFMT (10): home training PFMT+ resistance (10):	PFMT : same as below without resistance PFMT + resistance: exercises at home for strength and endurance, using audio-tape to guide exercises at home. Intrav- aginal resistance: use of intravaginal balloon. Weekly phone call	6 weeks	Dropouts: none
Gallo 1997 [162]	PFMT (43) PFMT+ audiotape (43)	Adherence strategy: audiocassette tape for use twice a day (contained verbal instruction and counted aloud 25 consecutive PFM contractions, with 10-sec hold and 10-sec relaxation) Encouraged to exercise 10 minutes twice a day, potential times suggested depending on lifestyle	4 to 6 weeks	Dropouts by group: 9/43 PFMT, 2/43 PFMT + audiotape
Ghoneim, 2005 [125]	PFMT (47) vs Imitation PFMT (50)	PFMT: 3 sets of 10 long VPFMC with 6-8 seconds hold, and 2 sets of 10 rapid VPFMC with 1-2 seconds hold, 4 days weekly + Knack. Imitation PFMT: Hip abductor muscle contraction for 6-8 seconds with feet crossed at the ankles. 3 sets of long and 2 sets of rapid contractions, 4 times weekly.	12 weeks	Drop out: PFMT: 9 Imitation PFMT : 9
Hay-Smith, 2002 [159]	Motor relearning PFMT(62) vs strength training PFMT (61)	Motor relearning: VPFMC in different body positions, preceding and sustained during different provocative activities. Strength training: 10-12 near maximal VPFMC, 6-to-8-second hold with equivalent rest, three times a day, at least three days a week	18 to 20 weeks	Drop out: Less than 5%
Hung, 2010 [150]	Unsupervised home PFMT (35) Supervised “Sapsford” PFMT (35)	Correct VPFMC confirmed. Oral in- struction in PFMT. No other detail given Correct VPFMC confirmed. ’Indirect’ + Participants in this group were ”asked not to perform iso- late voluntary pelvic floor muscle contraction exercise during the intervention period“	18 to 20 weeks	Drop out: Less than 5%
Johnson, 2001 [156]	Maximal PFMT(16) vs Sub-maximal PFMT (16)	Maximal PFMT: 10 minutes, three times a day, at 90% of maximal VPFMC intensity Sub-maximal PFMT: 15 minutes, three times a day, at 60% of maximum VPFMC intensity	6 weeks	Drop out: 14%

Table 2 Characteristics of studies comparing different PFMT programs (continued)

Study ID	Training Type	Training Program	Training Duration	Notes
Konstantinidou, 2007 [147]	PFMT individual (10) vs PFMT + group sessions (12)	PFMT individual: At home, 3 sets of fast contractions and 3-4 sets of slow contractions daily in lying, sitting and standing positions readjusted according to subject's progress. PFMT with group sessions: As above + weekly session in a group of 5	12 weeks	Drop out: PFMT: 5 PFMT + group session: 3
Liebergall 2005 [152]	PFMT (29) Paula method PFMT (30)	Weekly 30-minute lesson for 4 weeks in groups of 5. Encouraged to practise at home 15 min/day. Fortnightly phone call from physiotherapist Taught 'Paula' method of sphincter contraction. Weekly individual 45-min training for 12 weeks. Encouraged to practise daily 15 to 45 min	12 weeks	2/29 PFMT versus 2/ 30 Paula PFMT
Liebergall 2009 [153]	Individually supervised PFMT (117) Individually supervised Paula method PFMT (123):	Weekly individual sessions of 45 minutes and daily home exer- cises for 45 minutes for 12 weeks. Paula method was taught; first 2 steps were 'rhythmically' contracting the PFM 'with gradual intensity'. Last 3 steps in- volved contraction and relaxation of eyelids, movement of the mouth and fingers. VPFMC confirmed, based on ob- servation. 6 group classes (1 to 10 women) of 30 minutes each. Once weekly for first 4 weeks, 2 more classes in last 2 months. Exercises in different positions. Separate contractions of levator ani and anal sphincter. Prolonged, rapid and gradual contractions. 1 to 2 minutes between exercises	12 weeks	36/123 PFMT versus 21/117 Paula PFMT
Ng, 2008 [151]	PFMT (34) PFMT with phone call follow-up (n34)	Not clear if correct VPFMC con- firmed. Home PFMT progressing to 50 to 75 contractions three times a day. Taught urgency strategies. One-hour clinic visits twice a week for 4 weeks with nurse As above, then phone calls twice a week from the nurse after cessation of clinic visits to encourage exercise	6 months	10/44 PFMT versus 10/44 PFMT with phone calls
Ramsay, 1990 [124]	Direct PFMT (22) vs Indirect PFMT (22)	Direct PFMT: 4 maximum VPFMC with 4 second hold and 10 second rest, 1 set every waking hour. Indirect PFMT: As direct PFMT but comprising of hip abductor muscle contrac- tion with feet crossed at the ankles.	3 months	Drop out: None

Table 2 Characteristics of studies comparing different PFMT programs (continued)

Study ID	Training Type	Training Program	Training Duration	Notes
Savage, 2005 [155]	PFMT (4) vs Modified Pilates (6)	PFMT: 6 individual physiotherapy sessions of 30-45 minutes over a 12-weeks + home v PFMC Modified Pilates: Lumbopelvic stability training exercises taught using the modified Pilates method.	12 weeks	Drop out: PFMT: 1 Modified Pilate: 0
Sriboonreung, 2011 [157]	Daily home PFMT (23) Thrice-weekly home PFMT (22)	Eight to 12 maximal contractions with 6 to 8-sec hold with 6 to 8 fast contractions, with 6 to 8-sec rest, daily, 3 times a day As above except 3 sets a day, 3 days a week.	12 weeks	3/23 daily PFMT versus 3/22 thrice weekly PFMT
Sugaya, 2003 [163]	PFMT (23) PFMT + chime device (23)	1 minute of rapid contractions every 2 sec, followed by 1 minute of slow 10-sec contractions with 10-sec rests, performed 3 times a day. Adherence strategy: pocket size device with chime or blinking light to indicate time to exer- cise (3 times a day) and when activated leads person through PFMT programme, and kept record of exercise. Fortnightly follow-up As above with device	8 weeks	3/23 PFMT versus 2/ 23 PFMT with device
Wells, 1999 [129]	PFMT (71) PFMT with intravaginal resistance device (71)	PFMT: minimum of 80 VPFMC with 10- sec hold and 10- sec rest per day distributed in individual pattern throughout the day. Intravaginal resistance: Fitted with vaginal dilator to use as resistive device. Monthly clinic visits As above without device	5 months	30/71 PFMT versus 32/71 PFMT + device
Zanetti, 2007 [148]	PFMT HP unsupervised (21) vs PFMT HP supervised (23)	PFMT unsupervised: 10 VPFMC of 5-second hold and 5-second rest, 20 VPFMC of 2-second hold and 2-second rest, 20 VPFMC of 1 second hold and 1 second rest, and 5 VPFMC of 10-second hold and 10-second rest, followed by 5 strong contractions together with a cough, with one-minute intervals with each set. PFMT supervised: As above + VPFMC performed under guidance from a physiotherapist, twice a week, for 45 minutes.	3 months	Drop out: Not reported

Footnotes PFM = Pelvic floor muscle, VPFMC = voluntary PFM contraction, PFMT = PFM training, HP= Health professional Set = one episode or sequence of PFM contractions or training, including length of time of holding contraction, positions while performing contractions and number of repetitions of contractions.

10. *Exercise programme:* addition of intravaginal resistance device [129,160,161].

11. *Exercise programme:* addition of adherence strategy [162,163].

12. *Exercise programme:* addition of biofeedback: clinic biofeedback [120,141,164-166]; home biofeedback [136,167-169].

1. Quality of data

Of the 21 trials, one was a conference abstract [124] rendering it difficult to assess. Ten of the remaining 20 trials provided sufficient detail of the methods to generate a randomisation to ensure they were genuinely random [134, 148 - 150, 152 - 154, 156, 157, 170]. Of the remaining 10 trials, 3 were clearly not random [147,162,163]. The final 6 provided sufficient detail to ensure that allocation was concealed [125, 134, 150, 153, 159, 161].

Overall, in regard to random allocation and concealment, 6 trials were considered to have a low risk of bias [125, 146, 150, 153, 159, 161] and 4 had a high risk; in the remaining 11, the risk of bias was unclear.

Only three trials clearly stated that the outcome assessment was blinded for one or more of the outcomes of interest [150, 155, 159] and 2 stated that a lack of blind outcome assessment was a limitation [129,157].

None of the included trials was large and nearly two-thirds (13/21) were mid-sized, with only 20 to 50 participants per group. Four had fewer than 20 participants per comparison group [147,155,156,160]; one of which was reported as a pilot study [155]. The largest trial randomised 120 women to each of two trial arms: 240 participants in all [153].

2. Results:

Comparison 1. Supervision of training: amount of contact with health professional

Subgroup 1.1: additional group supervision

Four trials shared similarities in terms of the amount of time and frequency of the extra health professional contact: [146-149]. All four recruited women with urodynamic SUI. Three provided the same home-based PFMT programme and individual supervision to both trial arms, then investigated the effect of adding an additional supervised group exercise session (a 45-minute weekly exercise class [146]; a 50-minute twice-weekly exercise class [149]; a weekly group session [147]. The fourth also added a 45-minute twice-weekly exercise session [148]; however, it was unclear if this was offered individually or as a supervised group exercise session.

Subgroup 1.2: additional phone calls

Ng (2008) recruited women with MUI, offered the same home-based PFMT programme in both trial arms, and investigated the effect of adding twice-weekly phone call subsequent to the initial face-to-face contact with a health professional [151]. This was the only trial included in the second subgroup.

Subgroup 1.3: individual supervision versus no supervision (different PFMT)

In the trial of women with SUI or MUI, both arms differed in the amount of health professional contact and the type of PFMT programme used [150]. This was the only trial in the third subgroup.

- *Cure/no cure*: There was no statistically significant difference in the number of women reporting "no cure" comparing PMFT with and without additional group supervision, subgroup 1 [23,149]. As well, for subgroup 1.3, no difference was found between the supervised and unsupervised groups [150]. Ng [151], subgroup 1.2, reported the odds ratio (95% confidence interval) for the difference between the groups for their responses to 2 items from the BFLUTS (i.e., whether they did or did not have symptoms of SUI or urgency incontinence). For both items, the participants in the 'phone call group' (subgroup 1.2) had lower odds of reporting either SUI or urgency incontinence, suggesting that more women in the phone call group were asymptomatic.

- *No improvement/Improvement:* Women receiving additional group supervision (subgroup 1.1) were less likely to report incontinence [23,147-149]. Hung (2010) found women in the supervised group (subgroup 1.3) were less likely to report no improvement [150].

- *Leakage episodes:* Only one of the 4 trials investigating the effect of 'additional group supervision' (subgroup 1.1) measured leakage episodes [147]; similarly those receiving additional supervision reported fewer leakage episodes per day. Based on the Leakage Index [23,146], leakage was less in the group receiving additional supervision. Hung (2010), subgroup 1.3, also measured leakage episodes and found no differences between the supervised and non-supervised groups.

- *Pad and paper towel tests:* All 4 trials investigating the addition of group supervision used pad tests (90-second [146]; 20 minute [150] one-hour [148]; 24-hour [149]). Due to missing data, it was not possible to estimate differences between the treatment groups; where it was possible to calculate differences, these were not statistically significant.

Comparison 2. Supervision of training: individual versus group

Six trials were included in this comparison; however, each had at least one other difference between

trial arms (i.e., between the subjects and the controls within each trial), hence caution is required in interpreting the data.

Subgroup 2.1: individual versus individual+group supervision

The 3 trials in this subgroup (which were also included in Comparison 1, subgroup 1.1) used the same PFMT programme in both trial arms, supplemented with group supervision in one (in terms of frequency and total time) and individual supervision in the other [146,147,149]. Trials included women with SUI only.

Subgroup 2.2: individual versus group supervision (different PFMT)

The 3 trials in this subgroup differed in both supervision and the PFMT programmes [152-154]. Women with SUI [153,154] or mixed incontinence were included [152].

- *No cure/Cure:* There was no statistically significant difference in the number of women reporting 'no cure' between the group and individual supervision arms [146,149] in subgroup 2.1.
- *No improvement /Improvement:* In subgroup 2.1, women who received group supervision were more likely to report 'improvement' in their incontinence [146,147,149]. In subgroup 2.2, difference between group and individual supervision was found [154].
- *Leakage episodes:* In addition to the group versus individual supervision comparison, two trials measured leakage episodes; one used a different PFMT programme between the trial arms [154] and the other used the same programme for both [147]. De Oliveira [2009] indicated no difference between groups while Konstantinidou [2007] reported that the women who had received group supervision indicated fewer leakage episodes per day.
- *Pad and Paper towel test:* All 3 trials in subgroup 2.1 used pad tests (90-second [146]; and 24-hour [147, 149]). The differences, where they could be calculated, were not statistically significant. All 3 trials in the subgroup 2.2 used a 1-hour pad test; and one used a standardised bladder volume rather than maximum bladder capacity [154]. The overall pattern was one of no difference between the groups.

Comparison 3. Exercise programme: direct versus indirect exercises

This comparison encompassed four subgroups.

Subgroup 3.1: PFMT versus sham/imitation

The first comprised 2 trials in women with SUI that compared PFMT versus sham or imitation PFMT treatments [124,125].

Subgroup 3.2: PFMT versus the 'Paula method'

The second subgroup included 2 trials comparing PFMT versus the 'Paula method' in women with SUI [153] or SUI and mixed incontinence [152].

Subgroup 3.3: PFMT versus the 'Sapsford' approach

The third subgroup contained a single trial that compared PFMT with the 'Sapsford' approach in women with SUI or mixed incontinence [150].

Subgroup 3.4: PFMT versus Pilates

The fourth subgroup also comprised a single trial; a pilot study that compared PFMT versus Pilates in women with SUI [155].

- *No cure/Cure:* No difference between 'direct' PFMT and the 'Sapsford' approach was found in the single trial in subgroup 3.3 [150].
- *No improvement/Improvement:* The pooled data from the two trials in subgroup 3.1 (PFMT versus sham/imitation) did not show a statistically significant difference in favour of either trial arm [124, 125]. In contrast, Hung [2010] in subgroup 3.3 found that women in the 'Sapsford' approach group (with more health professional contact) were more likely to report improvement. Savage [2005], subgroup 3.4, did not report on improvement but, instead indicated there was no difference between the groups in terms of satisfaction.
- *Leakage episodes:* Hung [2010], subgroup 3.3, found no difference between the trial arms (median 0 leaks per day, IQR 0 to 0.3, in both groups). In terms of a less than 50% reduction in leakage frequency, neither Ghoniem [2005], subgroup 3.1, nor Liebergall [2009], subgroup 3.2, found differences between groups in weekly or more frequent incontinence episodes.
- *Pad and paper towel test:* Four trials reported pad test data: 20 minute [150]; 1 hour [152,153]; or type not known [124]. The data of two [150] subgroup 3.3, and subgroup 3.2 [124], could not be used to calculate an estimate of effect. Neither of Liebergall's studies [152,153] found a difference in the mean change from baseline.

Comparison 4. Exercise programme: generic versus individualised exercise

This comparison included one study [154] in which women were randomised to either individualised PFMT provided on a 30-minute twice-weekly clinical visit or to a generic PFMT programme offered through a 45-minute twice-weekly group exercise class.

- *No cure/ Cure:* No data was reported.
- *No improvement/ Improvement:* No difference between the generic and individualised exercise trial arms was reported [154].
- *Leakage episodes:* There were no differences in the number of leakages between the generic and individualised exercise trial arms in a 24-hour trial period [154].
- *Pad and paper towel test*: There was no difference in a 1-hour pad and cough test between the trial arms [154].

Comparison 5. Exercise programme: submaximal versus near maximal contractions

One study assigned women with SUI to PFMT programmes that were the same in all aspects with one arm adding either near maximal PFM contractions or submaximal contractions [156]. Both groups received the same amount of contact from health professionals.

- *Not cured/ Cured:* No data was reported for this outcome.
- *No improvement/ Improvement:* No data was reported for this outcome.
- *Leakage episodes:* No statistically significant differences reported between the exercise groups for leakage episodes in a 24-hour period [156].
- *Pad and paper towel test:* Pad weight (10-hour pad test) did not differ between the groups.

Comparison 6. Exercise programme: daily versus 3 times per week.

A new trial [157] compared PFMT programmes that were the same in all aspects except one group was asked to do daily exercise and the other 3 times a week. Both groups had the same amount of contact with health professionals.

- *Not cured/ Cure:* There was no statistically significant difference between the groups in terms of the number of women who reported 'no cure'.
- *No improvement/ Improvement:* None of the women in either group indicated any significant difference in improvement..
- *Leakage episodes:* No data was reported.
- *Pad and paper towel test:* There was no difference between the groups on a 1-hour pad test.

Comparison 7. Exercise programme: addition of upright exercise position

Two PFMT programmes were compared that were the same in all aspects except one group was asked to exercise only in the supine position while the other alternated exercise sets between the supine, sitting and standing positions [158]. Both groups had the same amount of contact with health professionals.

- *No cure/ Cure:* No data was reported for this outcome.
- *No improvement/ Improvement:* No data was reported for this outcome.
- *Leakage episodes:* There was no statistically significant difference between the exercise groups for leakage episodes in a 24-hour period.
- *Pad and paper towel tests:* There was no difference between the groups for the mean change in pad weight gain on a 1-hour pad test.

Comparison 8. Exercise programme: addition of strength training to motor learning.

Women with SUI or MUI took part in two motor-learning PFMT programmes that were the same in all aspects except one group undetook additional strengthening in PFMT. Both groups had the same amount of contact with health professionals..

- *No cure/ Cure:* There was no difference between the groups in terms of the number of women who reported 'no cure'.
- *No improvement/ Improvement:* There was no difference between the groups in number who reported 'no improvement'. There were no differences in other self-reported improvement outcomes: satisfaction with treatment, comfort with continuing the training and desire for further treatment although in this last, the women in the motor learning PFMT group were less likely to want to continue.
- *Leakage episodes:* There was no statistically significant difference between the groups for the number of leakage episodes per day.
- *Pad and paper towel tests:* There was no difference between the groups on either a paper towel test or a 24-hour pad test.

Comparison 9. Exercise programme: addition of abdominal muscle exercise Sriboonreung (2011) compared two PFMT programmes that were the same in all aspects except one group was asked to undertake additional abdominal muscle exercises (these were not described in further detail) [157]. Both groups had the same amount of contact with health professionals.

- No cure/ Cure: There was no statistically significant difference between the groups in terms of the number who indicated 'no cure'.
- *No improvement/Improvement:* There was no statistically significant difference between the groups.

- *Leakage episodes:* No data were reported.
- *Pad and paper towel tests:* There was no difference between the groups on a 1-hour pad test.

Comparison 10. Exercise programme: addition of intravaginal resistance device One new trial was added to this section [161] for a total of three which compared two PFMT programmes that were the same in all aspects except one group used an intravaginal device design to increase the resistance to the PFM contraction [129,160,161]. The resistance devices included a spring-loaded device with two limbs [161] an intravaginal balloon [160], and a vaginal dilator [129]. In all three, each arm had the same amount of contact with health professionals. The women in one study had SUI [Ferguson 1990] and in the others SUI or MUI [Delgado, 2009; Wells, 1999].

- *No cure/ Cure:* There was no statistically significant difference between the groups in terms of the number of women who indicated 'no cure' [129,161].
- *Not improved/ Improvement:* There was no statistically significant difference between the groups in terms of the number of women who indicated 'no improvement' (129,161].
- *Leakage episodes:* No statistically significant difference between the two treatment groups was found [129].
- *Pad and paper towel tests:* All three reported pad test data (30-minute and 24 hour [160,161] or unspecified duration [129]. None of these found statistically significant differences between the treatment groups.

Comparison 11. Exercise programme: addition of adherence strategy

Adherence strategies such as audiotape [162] or small chiming (alarm) device [163] have been tried. The PFMT programmes were [163] or appeared to be [162] the same for both trial arms. Both trial arms in each study had the same amount of contact with health professionals.

- No cure/Cure: No data was reported for this outcome.
- No improvement/Improvement: The group using the devices was less likely to report 'no improvement' post treatment.
- Leakage episodes: No statistically significant difference was found between the groups for the number of leakage episodes in 24 hours [163].
- Pad and paper towel tests: The average amount of leakage on a 1-hour pad test was less in the groups using the devices post treatment.

Comparison 12 Teaching programme: Addition of biofeedback

No new studies were found that compared biofeedback alone to PFMT plus biofeedback in either the home or clinic. Three studies were excluded based on the BF group differing from the no BF group in terms of treatment intensity (e.g., number of clinic visits) [122,171,172] or supervision (i.e., group versus individual teaching) and absence of between group analyses [173].

Five trials used clinic based BF in the treatment of predominantly SUI symptoms [141,164,165], predominantly UUI [120], or OAB with UUI [166]. In four, the home PFMT programme was the same in both groups, with the addition in one arm of clinic BF once every two weeks [120], once a week [141,165], twice a week [166] or three times a week [164].

Treatment durations in both arms were four [164,165], eight [120,141] and 12 weeks [166]. In one, there was more supervisory HP contact with the BF group than with the PFMT alone group [165].

Of the five clinic based BF trials, three had adequate random allocation concealment [120,141,164,166] and three had blinded outcome assessors [120,164]. Three randomised between 25 and 74 women to each group [120,141,165,166], while others randomised less than 25 women per group [164,165]. Withdrawals or losses to follow up were none [164,165], less than 10% [141], less than 15% [120,165,166]. All women were assessed post-treatment; further follow up was conducted at three and six months [141] or at three months and two to three years [165].

There were no new home based trials added to this section so there remains a total of four. Random allocation concealment was adequate in just one [167], and outcome assessors were blind for some or all of the outcomes in two [167,168]. The number of women allocated to the comparison groups was 20 or less [136,168], 40 women in the BF group and 20 in the PFMT [169] or 50 or more per group [167]. Two had complete data sets on trial completion [136,168], one reported 9% withdrawal [167], and 33% dropped out of another [169].

With regard to clinic BF, two of the five trials reported significantly better outcomes with the addition of BF to PFMT. Based on pad weight in women with urodynamic SUI at one to two years after treatment, five of 19 women in the BF group and none of the 14 women in PFMT reported cure [165]. However, the BF group had 4 treatment sessions whereas the PFMT group had 2-3 sessions. In women with OAB there were changes in the total score on the KHQ with the addition of BF, but no statistically significant differences between the groups on any of the nine subscales [166]. Patient-reported cure or improvement was 50% for the BF

group and 38% for PFMT alone; a statistical comparison was not reported [166].

Three trials, including the two largest trials, reported significant improvements in incontinence with PFMT with or without BF, but no significant differences between groups [120,141,164].

For the home BF trials, only one reported a significant effect for the addition of BF [168]. In the others, including the largest trial [167]both groups had significant improvements, but no differences between groups.

A 2011 Cochrane review on feedback or biofeedback to augment PFMT [174] included 24 trials involving 1,583 women and concluded that women who received PFMT with BF were significantly more likely to report that their UI was cured or improved compared to those who received PFMT alone. However, this review included trials in which the treatment groups differed on parameters other than BF, and the authors caution that women in the BF groups commonly had more contact with the health provider. Thus, more research is needed to determine whether differences are due to BF or other differences such as intensity, approach, or contact with the health professionals.

With regard to clinic based BF, studies were inconsistent. The larger trials indicated no statistically significant differences between BF assisted and non-BF groups for self-reported cure, cure/improvement, or leakage episodes per day or quality of life **(Level of Evidence: 1)**. This pattern appeared to be consistent across trials that recruited women with SUI, UUI, or MUI. There were a similar number of trials addressing the effect of home BF, but fewer data. In a single robust trial there were no statistically significant differences between home BF and non-BF groups for self-reported cure, cure/improvement, or quality of life for women with urodynamic SUI **(Level of Evidence: 2).**

3. Recommendations

Clinicians should provide the most intensive HP led PFMT programme possible within service constraints because HP taught and supervised programmes are better than self-directed programmes, and more HP contact is better than less **(Grade of Recommendation: A).** Although studies are inconsistent, there does not appear to be a clear benefit of adding clinic **(Grade of Recommendation: A)** or home based BF **(Grade of Recommendation: B)** to a PFMT programme.

4. Conclusion

Based on the limited available data it appears that PFMT with regular (e.g. weekly) supervision is better than PFMT with little or no supervision. However, the data were unclear if supervision is more effective in individual or group settings.

Cautiously, we conclude that voluntary PFM contractions are better than exercises that facilitate co-contraction of the PFM muscles (e.g. crossing the ankles and pulling the legs apart). Further, 'indirect' methods (e.g. the 'Paula method' or 'Sapsford' approach) did not appear to be better than direct PFM contractions, noting that some study data were confounded by differences in the amount of contact time with health professionals. Moreover, and tentatively, we found there was no benefit from adding intravaginal devices to increase resistance in PFMT.

This review underlines the fact that existing evidence is insufficient to make any robust recommendations about the best approaches to PFMT, beyond the fact that the amount of health professional contact may influence women's perceptions of their improvement.

5. Implications for research

Comparisons of PFMT approaches are, de facto, comparisons of two active treatments. Therefore, it is difficult to determine which approach is best, unless (a) the differences in outcome are large or (b) the trials are powered to find small to moderate differences in outcomes that would be indicative of the need for larger trials. Although finding the best approach to PFMT has been identified as a high priority research area, large, costly trials may not be the best use of research funds, particularly where the difference in outcomes between two active treatments is expected to be small. Therefore, the highest research priority should be to investigate the effect of supervision on PFMT. In addition to clinical effectiveness, this is an important question because of resource implications, both financial and human, for health-service delivery.

6. Recommendations

Clinicians should provide the most intensive supervision-led PFMT programme possible within service constraints because supervised PFMT programmes are better than those with little or no supervision. (Grade of Recommendation: A).

c) Is PFMT better than other treatments?

Trials were considered for inclusion in this section if they compared PFMT with another stand-alone intervention, e.g. vaginal cones, bladder training, drug therapy. Of note is that there are 37 RCTs comparing PFMT with another stand-alone treatment but few recent studies since the last update. For this review, four were excluded, two as conference abstracts [175,176], one reported in two conference abstracts with inconsistent data [177], and one compared PFMT and vaginal cones versus EStim [178].

The 33 trials addressed the following comparisons:

- PFMT versus vaginal cones (VC) [107, 122, 134, 140, 169, 175, 179-183]

- PFMT versus EStim (EStim) [130, 132, 134, 140, 166, 184-188]
- PFMT versus bladder training (BT) [128,189,190]
- PFMT versus drug [125, 130, 131, 142, 188, 191-193]
- PFMT versus surgery [194]

(a) PFMT versus VC: Eleven trials compared PFMT with VC [107,122,134,140,169,175,179-183,185]. The details of the VC and PFMT programmes for each trial are presented in **Table 4**.

(b) PFMT versus EStim: 10 trials compared PFMT with EStim in women with UI [186] SUI [134, 184, 185], urodynamic SUI [130, 132, 140], mixed UI [187] or OAB [166, 188]. There were different PFMT and EStim protocols in each study.

Two trials used interferential current, two to three times weekly, 30 minutes, 10-50Hz to PFMT (weekly PFM exercise courses and daily home exercises), for four to six weeks [185] or 20 minutes weekly for 10 weeks, 0-100Hz, at maximal tolerated intensity to PFMT (five PFM contractions with five second holds, hourly, every day for 12 weeks) [130]. Another applied external (extra-vaginal and lumbar) electrodes to deliver an unknown type of current (10 minutes, three times weekly, intensity increased until noticeable PFM contraction and patient added voluntary PFM contraction) versus PFMT (no details given), for six weeks [132].

The remaining trials all delivered the stimulation using a vaginal electrode. The comparisons were, in approximately ascending order of duration of EStim:

- 20 minutes, twice weekly, biphasic symmetric intermittent current at 10Hz, pulse duration 400 microseconds, duty cycle 10 seconds on and five off, maximum tolerated intensity, versus PFMT (no details given), for 12 weeks [166]
- 20 minutes, twice per week, biphasic intermittent current at 10Hz, pulse duration 1 millisecond, unidentified number of seconds of contraction and, duty cycle, at maximal tolerated intensity up to 100 mA [188]
- 20 minutes, three times weekly, biphasic intermittent current at 50Hz, pulse duration 0.5 millisecond, 5 second contraction, duty cycle one to two, at maximal tolerated intensity up to 100 mA [140]
- 30 minutes, three times weekly, biphasic intermittent current at 50Hz, pulse duration one millisecond, two second contraction, duty cycle one to two, at maximal tolerated intensity up to 100 mA (for predominant SUI) or the same stimulation at 20Hz (for predominant UUI), versus PFMT (no details given), for eight weeks [186]
- 30 minutes daily, biphasic intermittent current at 50Hz, pulse duration 0.2 milliseconds, individualised duty cycle depending on ability to hold PFM contraction, at maximal tolerated intensity up to120mA, versus PFMT (three times daily, eight to 12 near-maximal PFM contractions with six second hold and six to eight second rest, with three to four fast contractions at the end of every contraction in addition to weekly exercise class), for six months [134]
- up to 60 minutes, twice daily, asymmetric balance biphasic intermittent current at 12.5 and 50Hz, pulse duration 300 microseconds, five second contraction time with two second ramp up and one second ramp down, duty cycle one to two, intensity to 80mA, versus PFMT (daily, 60 slow and quick PFM contractions), for four months [187]
- six to eight hours per night, intermittent current at 12, 20 or 50Hz, versus PFMT (six to eight times daily, five to 10 maximal PFM contractions with five second hold and five seconds rest, and one sub-maximal contraction with 30 to 40 second hold), for six months [184].

Amount of HP contact was the same for both groups in two trials [130,140], greater for EStim in two [132,185], and greater for PFMT in another [134,188]. Any differences were not clear in the other four trials.

(c) PFMT versus BT: Three trials compared PFMT with BT in women with SUI [190], SUI and/or DO [189] or UI [128]. BT comprised a voiding schedule with weekly progression [128,189,190]. Wyman (1998) also included urge inhibition techniques (affirmations, distraction and relaxation). Sherburn trial added to voiding schedule, education on normal bladder control and voiding parameters, skin care, pad usage, fluids and fluid intake, optimal toileting position, voiding dynamics, and relaxation, distraction and breath control as part of the deferral strategies.

In the three trials BT was compared with:

- PFMT with clinic based BF, and a twice daily home PFMT programme of five fast (three second holds) and 20 sustained (10 second holds with 10 second rests) PFM contractions, PFM contraction for urge suppression and with increases in intra-abdominal pressure [Wyman, 1998].
- PFMT with clinic based BF, and daily home PFMT of 30 PFM contractions for strength and endurance (12 second holds) [Yoon, 2003].
- PFMT with weekly group class, and daily home PFMT prgram. The PFMT execise class included intensive PFMT, combining motor control, strength, endurance, power and functional training in a variety of different body positions [Sherburn, 2011].

Treatment duration, and amount of HP contact, was the same in both arms of all three trials, with treatment duration ranging from eight (Yoon, 2003), 12 (Wyman, 1998), and 20 weeks (Sherburn, 2011).

(d) PFMT versus drug therapy: Eight trials compared PFMT to drug therapy in women with SUI [125, 130, 131, 191, 192] or UUI [142, 188, 193, 195, 196].

The trials for SUI used several different drugs. In two, premarin (conjugated equine oestrogens) 2g per night for six or 12 weeks was compared to PFMT [130, 131]. In one of these [130], the PFMT was comprised of a daily home programme of five PFM contractions with five second holds per hour; in the other [131] PFMT was not described. Another trial compared phenylpropanolamine hydrochloride for four weeks versus six months of PFMT (90 to 160 PFM contractions with 10 second hold and 10 second rest distributed throughout the day) [192]. Ishiko [2000] compared clenbuterol (20mg bid) versus PFMT (10 minutes daily), for 12 weeks [191]. One study compared duloxetine (4mg bid, plus sham PFMT) versus PFMT (four times weekly, three sets of 10 six to eight second contractions and two sets of 10 one to two second contractions) for 12 weeks [125].

Three trials on UUI used oxybutynin(193) [142,188,193]. Doses and PFMT programs varied: oxybutynin chloride (2.5mg tid, progressed to maximum 5mg tid) versus PFMT with urge suppression strategies for eight weeks [142]; extended-release oxybutynin (5mg/day) versus PFMT (plus lengthening voiding intervals and urge strategies) for 3 months [193]; and oxybutynin chloride (5mg bid, progressed to maximum 5mg tid) to PFMT (and to functional electrostimulation) for 12 weeks [188].

Four trials had approximately the same amount of HP contact in drug and PFMT groups [125,130,142,191]; in one, this was not clear [130]. Wells [1991] assessed treatment effect after four weeks in the drug group, and six months in the PFMT group. Kafri [2007] provided 5 sessions for the PFMT group, but not for the drug group. Arruda [2008] provided two sessions per week with physiotherapist for the PFMT group and visits every 4 weeks for the drug group.

(e) PFMT versus surgery: Only one trial, published, in 1986, has compared PFMT to surgery [197]. The surgical technique was based on the type of defect identified: Burch colposuspension for anterior suspension defects and vaginal repair for posterior bladder descent. Women with both defects had a combined Burch and vaginal repair procedure. No details on the PFMT parameters were provided; women had five or more group sessions with a physiotherapist.

1. Quality of data

(a) PFMT versus VC: Adequate allocation concealment was reported by five: [107,122,134,140,180]. Three indicated that outcome assessors were blinded [134,140,183]; only some of the outcome assessments were blinded in two [107,122]. Sample sizes ranged from fewer than 40 women [107, 134,140,169,175,179,180,182,183], 50 [181] to 79 per group [122]. There were dropouts in both the PFMT and VC groups in all trials except Gameiro's (2010) [181] where no details were provided or in Cammu's (1998), in which all of the dropouts were from the VC group. Dropout rates were higher in the VC groups for several [169,175,179,180,183]; conversely, they were higher in the PFMT group for others [107,122,134,140,182]. Only one trial reported any follow-up beyond the post-treatment evaluation, and this, at 6 and 12 months post treatment [181].

(b) PFMT versus EStim: Of the eight trials, three reported adequate random allocation concealment and blinding of outcome assessors; samples sizes ranged from 10 to 20 and 35 women per group. Four trials appeared to have no dropouts [130,132,184,187]. Others reported 5% [186], 10% [140], 12% [134,188], 13% [166] and 19% [169]. All women were assessed post treatment; follow up was at nine months and one year [130] and four years [184].

(c) PFMT versus BT: Adequate random allocation concealment was reported in one trial [190]; outcome assessors were blinded in two [128,190]. Samples sizes ranged from 15 to 20 women [128], 43 to PFMT and 41 to BT [190] to 70 women per group. Dropouts were approximately 4% for Wyman (1998) and 12% for Yoon (2003) and 8% for Sherburn (2011). All women were assessed post treatment, and Wyman (1998) followed-up three months later (i.e. six months after treatment began).

(d) PFMT versus drug therapy: Random allocation was concealed in two of the eight trials [125,196]. Outcome assessors were blinded in two [125,142]. Five trials randomised 25 or fewer participants per group [130,131,188,191,193]; one randomised approximately 50 per group [125]. The two largest randomised about 80 [192] or 85 women per group [142]. Dropout rates were: 0% [130], 14% [142], 15.9% [193], 16% [191], 16.9% [196], 25% [192] and 36% [125]. Drop out rates were not reported in two [131,193]. Most trials assessed outcomes immediately post-treatment and three had longer follow up of nine months [130], one year [188], and 21-month [193] although in this last trial most participants had discontinued drug therapy after active intervention.

(e) PFMT versus surgery: It was not clear if allocation was adequately concealed, or if the outcome assessors were blinded. Approximately 25 women were in each comparison group with no dropouts at four months (post treatment assessment). There was further long-term follow-up at one year, then four to eight years [197].

2. Results

(a) PFMT versus VC: The comparative results in seven of the 11 studies were inconsistent. For cure,

one trial favoured PFMT [134]. Six favoured neither PFMT nor VCs [107, 122, 140, 179, 182, 183]. Pooled data from these eight trials showed statistically significant heterogeneity.

For *cure/improvement*, pooled data in six of the 11 trials showed no statistically significant differences. In four, PFMT was better than VCs in terms of daily leakage episodes. And, two others [140,181] no significant differences in terms of incontinence-specific quality of life measures (I-QoL) and the number of incontinence episodes were found.

Three reported adverse effects associated with cones such as the inability to use then, pain, vaginitis, bleeding, a sense of unpleasantness [134,180] or inconvenience [183].

[b) PFMT versus EStim: Pooled data from three trials of women with SUI found self-reported cure was more likely with PFMT [134, 184, 187], although only one found a statistically significant difference when data from the trials was considered individually [134]. It was not clear if the cure data reported by Hofbauer (1990) were derived from a symptom scale or a voiding diary; these data were therefore excluded. Pooled data from three trials in women with also found self-reported cure/improvement was more likely in PFMT women [134,184,185]; again only Bø (1999) found a statistically significant difference when trial data were considered individually. At 6 months, QOL (as measured with I-QoL Questionnaire) increased significantly both in the PFMT group 28.4% and in the EStim group 32.4% but there was no significant difference between the groups [140]. Leakage episodes and quality of life (Social Activity Index) were not statistically significant in one study [134]. At nine months post treatment, Henalla (1989) found that three out of 17 PFMT women and one out of eight in the EStim group reported recurrent symptoms. Side effects related to EStim included vaginal irritation and/or bleeding [134,184,187].

Spruijt [2003] [186] recruited women with SUI, UUI or MUI and Wang (2004) [166] women with UUI. Neither found a statistically significant difference between the groups for self-reported cure/improvement' although Wang indicated women in the PFMT group had statistically significantly fewer leakage episodes per day. EStim produced "physical and emotional stress" in the elderly women in the Spruijit trial. On the KHQ there were no statistically significant differences in general health perception, incontinence impact, role limitation, physical limitation, social limitation, and personal relationship, but the EStim group had statistically significant better scores for emotions, sleep/energy and severity measures. In the Arruda (188) study [188], 52% and 76% of the women randomised to the EStim and PFMT groups, respectively, claimed to be satisfied after 12 weeks of the study treatment period. Further, there was a significant decrease in the urge-incontinence episodes, the daily number of urinary pads. However, there was no significant difference in any of these measures between the groups.

(c) PFMT versus BT: Wyman [1998] [189] recruited women with SUI, UUI or MUI. While more women in the PFMT group reported symptomatic improvement or fewer leakage episodes the difference was not statistically significant post-treatment or three months later. Sherbrun recruited women with SUI. Women in the PFMT group reported significantly lower amounts of leakage on the stress test , improved symptoms and bother and greater perception of change after 5 months than the BT group (Sherburn, 2011). No adverse event data were reported in either trial. Yoon (2003) [128] did not report any data for the outcomes of interest.

(d) PFMT versus drug: Neither of the two trials comparing vaginal oestrogens versus PFMT in women with urodynamic SUI reported data for the outcomes of interest [130,131]. Of those that responded to a follow-up questionnaire at nine months, three out of 17 PFMT women and three women using oestrogens reported recurrent symptoms. Adverse events were not reported in either trial.

Two older trials that compared an adrenergic agonist and PFMT in women with SUI or MUI were previously reported in ICI 2009. No significant differences between groups were reported [129,191].

Duloxetine had a significantly greater impact in decreasing incontinence episodes than PFMT (57% versus 35% median decrease between drug and PFMT respectively) [125]. However post-treatment data collection began immediately after treatment initiation, before the effects of PFMT could be expected to occur. There were no significant differences between the treatments with respect to Incontinence Quality of Life (I-QoL).

In the three trials that compared PFMT to oxybutynin, PFMT groups had similar or better outcomes on most parameters. In the largest of these, a comparison of PFMT and oxybutynin in older women with DO or DO with urodynamic SUI, women in the PFMT group had significantly greater reduction in incontinence episodes compared to those in drug treatment and fewer incontinence episodes per day [142]. Women in PFMT were more likely to report that they were "much better" but cure rates did not differ significantly. Side-effects were common among women in the drug group, particularly dry mouth.

One trial reported that the PFMT group had better outcomes for voiding frequency, but not for incontinence episodes [193]. Follow-up at 21 months showed that the PFMT group maintained or improved their voiding frequency, whereas the drug group regressed to baseline levels. However, most participants had discontinued the drug. Similarly, another trial reported that subjective symptom improvement was almost identical in the PFMT and

drug groups *(77%, 76%, respectively)* [188]. Changes in incontinence episode frequency favored the PFMT group, but were not significantly different.

(e) PFMT versus surgery: At four months PFMT women with urodynamic SUI were less likely to report cure than women who had surgery, although there was no statistically significant difference in the proportions reporting cure/improvement. At 12 months, 10/24 from the PFMT group were satisfied with initial therapy, versus 19/26 randomised to surgery. Long-term data (four to eight years) were not presented by group allocation. Adverse events were associated with surgery: new UUI, retropubic or pelvic pain, or dyspareunia [197].

3. Summary

In the 11 trials that compared PFMT with VCs in women with SUI, no consistent pattern emerged in the data. Further, data on self-reported cure in eight of the trials were inconsistent and there was no difference in the pooled data from six trials for self-reported cure/improvement. Notably, there were in fact fewer daily leakage episodes with PFMT in the pooled data from three trials **(Level of Evidence: 1)**.

PFMT with EStim in women with SUI was compared in six trials. Pooled data demonstrated that self-reported cure and cure/improvement were more likely in PFMT than in EStim groups **(Level of Evidence: 1)**. It is worth noting that only one trial individually demonstrated a statistically significant difference in these outcomes and there was more health professional contact in the PFMT arm. There were no statistically significant differences between PFMT and EStim groups for leakage episodes or quality of life, based on a single trial on MUI **(Level of Evidence: 2)**. In the one trial that recruited women with SUI, UUI or MUI self-reported cure/improvement rates were not statistically significantly different **(Level of Evidence: 2).** Self-reported cure and cure/improvement rates and satisfaction were not statistically significantly different in the 2 trials in women with UUI, although PFMT women had fewer leakage episodes per day, and women in the EStim group had better quality of life in three of the nine domains measured on the KHQ (166). **(Level of Evidence: 2)**. Some women reported adverse events attributable to ES.

PFMT and BT was reported in three but only two included data of interest. In women with SUI, symptomatic improvement, leakage episodes and quality of life were statistically significantly better in the PFMT group **(Level of Evidence: 2)**. In contrast the study that recruited women with SUI, UUI and MUI did not find statistically significant differences between the groups **(Level of Evidence: 2)** .

There is insufficient evidence to determine if PFMT is better than vaginal oestrogens. Neither trial that compared an adrenergic agonist with PFMT in women with SUI or MUI found a difference in self-reported cure/improvement and adrenergic side effects were bothersome **(Level of Evidence: 2)**. One trial of PFMT versus oxybutynin in women with DO or DO with urodynamic SUI found women doing PFMT were more likely to report improvement and have fewer leakage episodes per day after treatment **(Level of Evidence: 2)**. Many women taking oxybutynin reported drug-related side effects. One trial compared a serotonin-norepinephrine reuptake inhibitor (duloxetine) with PFMT and while women who took the drug had fewer leakage episodes, there was no difference in terms of quality of life between the two groups and drug side effects were sufficient to discontinue treatment in some women. **(Level of Evidence: 2)**.

Based on one trial it seemed self-reported cure was more likely after surgery than PFMT for women with urodynamic SUI, but no statistically significant difference in the proportion of women reporting cure/improvement **(Level of Evidence: 2)**. There was insufficient detail about the PFMT programme to make a judgment about how effective it might have been.

4. Recommendations

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised **(Grade of Recommendation: B)**.
- PFMT is better than BT as first line conservative therapy **(Grade of Recommendation: B)**.
- PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug **(Grade of Recommendation: C).**
- PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive **(Grade of Recommendation: C)**.

For women with SUI or MUI:

- PFMT is better than VC as first line conservative therapy **(Grade of Recommendation: B)**.

For women with UUI or MUI:

- PFMT,and BT are effective first line conservative therapy **(Grade of Recommendation: B)**.
- PFMT is better than oxybutynin as first line therapy **(Grade of Recommendation: B)**.

For women with UUI:

- PFMT,and BT are effective first line conservative therapy **(Grade of Recommendation: B)**.

Larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. In planning comparisons researchers should consider carefully the potential impact of dif-

ferent levels of supervisory intensity between groups, particularly in comparisons of conservative therapies. A comparison of surgery and PFMT might be least useful, because PFMT is usually first-line therapy with surgery reserved for those in whom PFMT was unsuccessful or is not the treatment of choice.

d) Does the addition of PFMT to other treatments add benefit?

In this section, the effects of PFMT combined with therapy A versus therapy A alone, are compared to address the additive benefit of PFMT. Nine RCTs were found, and three were excluded: no useable data [198]; men and women and the data were not reported separately [199] and a combination BT/PFMT programme [200].

(a) PFMT⁄VC versus VC: Two trials, in women with urodynamic SUI [201]or SUI [107], compared combined PFMT⁄ VC versus VC. In both arms of each study the recommended VC regime was twice daily for 15 minutes, with cone weight progressing from 20g to 70g [201] or 100g [107]. Both PFMT programmes asked women to do 100 PFM contractions per day with 10 contractions 10 times a day [201], or a combination of fast and slow contractions [107]. Treatment duration was 12 weeks in both arms of both studies.

(b) PFMT⁄EStim versus EStim: No new trials have been published on the topic since the last review. In women with urodynamic SUI, EStim (10 minutes, three times weekly, sufficient intensity to provoke a visible contraction to which the patient added their own PFM contraction, extravaginal and lumbar electrodes) was compared to PFMT⁄ES (daily PFMT home programme (not specified) and a twice weekly exercise class plus the same ES programme) [132]. Treatment duration was six weeks in both arms.

(c) PFMT⁄BT versus BT: No new studies were found. In women with urodynamic SUI, or urodynamic SUI with DO, Wyman (1998) compared BT (progressive voiding schedule, advice on urge inhibition techniques such as affirmations, distraction and relaxation) to PFMT⁄BT (twice daily PFMT, maximum of 10 fast contraction with three second holds and 40 sustained contractions with 10 second holds in addition to bladder training as above). The combined PFMT⁄BT group began with BT and added PFMT in the 3rd week of the intervention. Women in both groups received the same preliminary education programme and treatment duration was 12 weeks in both arms [189].

(d) PFMT⁄drug versus drug: Two previously reported trials compared PFMT⁄drug (beta(2)-adrenergic agonist (clenbuterol); duloxetine) [125,191].

Two new trials compared PFMT⁄drug to drug alone in women with UUI [202,203]. One was a two-stage, multi-site RCTI [203]. In Stage 1, women received tolterodine (4 mg/day) versus tolterodine plus PFMT with urge suppression strategies (behavioural training) for 4 visits over 10 weeks. Stage 2 involved drug discontinuation. PFMT included 3 sessions of 15 exercises daily, starting at 2-seconds duration and progressed to 10 seconds. The other trial [202] was a single-site study of individually-titrated, extended-release oxybutynin (initiated at 5 mg/day and escalated as tolerated to a maximum of 30mg/day) with proactive management of side effects versus oxybutynin plus PFMT with urge suppression strategies for 4 visits across approximately 8 weeks. PFMT was also 3 sessions of 15 exercises daily, starting at an individualized duration and progressed to a maximum of 10 seconds.

1. Quality of data

(a) PFM⁄VC versus VC: Adequate allocation concealment and some outcome assessment was blind in one [107]. Neither of these was clearly reported in the study by another [201]. Sample sizes were approximately 20 women in each comparison group. Dropouts ranged from 63% of the women in the PFM/VC group compared to 41% in the VC group [107] to 30% of the PFM/VC group versus 9% in the VC only group [201].

(b) PFMT⁄ES versus ES: It was not clear if random allocation concealment was adequate or whether assessors were blind [132]. There were only 11 women in each comparison group. There did not appear to be any dropouts.

(c) PFMT⁄BT versus BT: In one, it was not clear if random allocation concealment was adequate; outcome assessors were not blinded [189]. There were 68 women in the BT group and 67 in combination therapy with fewer than 10% dropouts after 12 weeks of treatment. Further follow-up was reported at six months and approximately three years after study entry.

(d) PFMT⁄drug versus drug: Although adequate allocation concealment and blinded assessors where used in three trials [125,202,203] it was not clear in another [191]. Sample sizes varied from 18 women in the drug group and 23 in the combination therapy group [191] with 27% and 17% dropouts respectively, principally because of drug-related side effects. In another, approximately 50 women with SUI were assigned to each group, 30% of whom dropped out of both treatment groups. Burgio (2008) randomised 307 women with urge-predominant UI and had a drop out rate of 8.8% at the end of active treatment (10 weeks). Burgio (2010) randomised 64 women with urge-predominant UI before being stopped for futility and had a drop out rate of 9.4%.

2. Results

(a) PFM⁄VC versus VC: In this comparison, neither of the two trials identified any statistically significant differences between the groups (for patient reported cure, improvement as measured by a Visual Analogue Scale or pad test) and all of the confidence intervals were wide [107,201].

(b) PFMT/ES versus ES: Although Hofbauer (1990) [132] reported cure/improvement, it was not clear whether this was based on data from a symptom scale or a urinary diary. There were no data reported for the other outcomes of interest.

(c) PFMT/BT versus BT: No statistically significant difference was found in one early study [189] between combination versus single therapy in the number of women reporting they were much better or in the number of leakage episodes per day; however more in the combination group reported they were much better at six months post treatment. With regard to quality of life the combination therapy group had statistically significantly better scores on UDI and IIQ after treatment, but there was no statistically significant difference in either measure six months after treatment had begun. Approximately three years later, a similar number in each group had sought further treatment for UI (19 of 48 BT, 18 of 48 PFMT/BT). Of the women who had not sought further treatment, fewer were free of leakage episodes in the BT group (four of 22 in BT group versus eight of 16 in the combination group). Adverse events are not mentioned.

(d) PFMT/drug versus drug:. Ghoniem [2005] [125] reported that the combined treatment was not significantly different from the drug-only-treatment in terms of frequency of incontinence episodes, quality of life (IQOL) and Patient Global Impression of Improvement Scale. Ishiko (2000) [191] did not report data for any of the primary outcomes of interest; 10/13 in the drug group, and 17/19 in the combination therapy group had no leakage episodes per week post treatment, and some reported drug-related side effects sufficient enough to withdraw from treatment

A higher proportion of women in the combined therapy group had a successful outcome, defined as at least 70% reduction in frequency of UI episodes [203]. The combined therapy group also had greater subjective improvement, greater patient satisfaction and greater reductions in symptom distress on validated questionnaires. In another study [202], the groups were so similar on an interim analysis and power calculation that recruitment was stopped early for futility. With the individualized, escalating dose titration and proactive management of side-effects, the drug alone group achieved an 88.5% reduction of incontinence episodes, leaving little room for added benefit.

3. Summary

There were few trials addressing the effect of adding PFMT to another therapy, and only five of the eight studies reported useful data. There appears to be no benefit of adding PFMT to VC or duloxetine respectively in women with SUI [107,125] **(Level of Evidence: 2)**. There may be benefit to adding PFMT to BT for women with urodynamic SUI or SUI with DO in the short term (three months), but it is not clear if this benefit persists at six months or more [189] **(Level of Evidence: 2)**. There is not sufficient evidence to be sure if there is any benefit in adding PFMT to ES. There is a single trial indicating added benefit of PFMT when drug therapy is administered with the usual intensity.

4. Recommendations

For women with SUI or MUI a combination of PFMT/BT may be better than BT alone in the short-term **(Grade of Recommendation: C)**, and a combination of PFMT/drug may be better than drug alone. If a woman is taking duloxetine or using VC, it may not help to add PFMT **(Grade of Recommendation: C)**. However, these recommendations are based on single trials of variable quality and larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. Further, these studies examine the effects of combining therapies as an initial approach. Less is known about the effects of combining therapies in a stepped fashion when women do not achieve the desired outcomes with a single therapy.

5. OTHER LUTS

Seven trials included above reported data for other LUTS, e.g. frequency, nocturia, bladder pain but no new trials were added to this section for the update.

The effect of a PFMT programme on frequency, nocturia and urgency in women with MUI improved self report of symptom bother both frequency and nocturia significantly more in the PFMT group, while urgency persisted [204].

Three trials investigating different type of PFMT programs reported whether women had nocturia [147,150,152,153]. There were few data and some missing, making it difficult to observe a difference between PFMT programs.

A secondary analysis looked at the effect of PFMT versus drug therapy on nocturia in older women with UUI or MUI [142]. The PFMT group reduced nocturia by a median of 0.5 episodes per night; this was significantly more effective than drug treatment.

One trial addressed PFMT versus EStim on urgency symptoms and nocturia in women with DO. There was a significant decrease in urge incontinence episodes in both groups, but no difference between groups. Further, there was a reduction in nocturia frequencies in the EStim group [188].

Finally, one new trial [202] studied the effect of drug therapy alone and combined with PFMT on urgency and 24-voiding frequency in women with urgency – predominant incontinence. Urgency decreased significantly although there was no difference between the two groups.

6. FACTORS AFFECTING OUTCOME

Apart from differences in effect attributed to PFMT or comparison interventions, other factors may affect outcomes. Of particular interest is the effect of older age; this and other factors are considered here.

a) Age

Firstly we looked for trials included above that specifically recruited older woman; there were six. The average age of women in these trials was between 60 and 70 years [120,141,142,192], or over 70 years [186,190] compared with a mean age of 40 to 55 in most other included studies. It was not possible to compare the data from older women with data from younger women for the following comparisons: PFMT versus EStim [186], PFMT versus drug [142,192] and PFMT versus BT [190].

For three comparisons (PFMT versus no treatment [141], PFMT versus placebo/sham/control [120,142], BF assisted PFMT versus PFMT alone [141], there were no clear differences in the size or direction of effect when the data from the trials in older women were compared with data from other trials. The recommendations arising from these comparisons appear to apply to older women. Namely, that PFMT should be offered, as first-line therapy, to all women with SUI, UUI, or MUI.

Secondly, the methods of included trials were checked for use of regression or other methods to investigate association between baseline characteristics (specifically age) and outcome. The literature search also located some papers that reported secondary analysis of data from the included trials. Papers that reported an association between age and outcome, but did not describe the methods of testing association are not discussed here.

Two reports detailed the testing of independent associations between patient characteristics (including age) and outcome [126,205]. In one data was used from PFMT groups in three RCTs [120,121,142]. The individual trials restricted entry to women 55 years and older [120,142] or 40 years and over [121]. In multivariate analysis, age was not a significant predictor of reduction in leakage episodes for PFMT women with SUI, UUI or MUI. In another trial, Hay Smith (2006) investigated the associations between leakage on paper towel test and patient characteristics using data from a trial that compared two approaches to PFMT for Women with SUI [126]. Older age was associated with more leakage in univariate models, but was not significant in multivariate analysis.

One further trial [189] used correlation methods, and one [206] categorised women as successes or failures, to investigate the association between age and outcome. In a secondary analysis [207] of the trial by Wyman [1998] there were no statistically significant correlations between age and reduction in leakage episodes or change in PFM activity after PFMT or BT in women with SUI, UUI or MUI. Bø (1992) characterised participants in the intensive PFMT group as treatment responders or non-responders. Treatment responders were statistically significantly older than borderline responders; there were no non-responders.

Considering the number of included trials, there were few that restricted entry to older women and/or investigated the association between age and treatment outcome. Only two studies have used the most appropriate methods to test independent associations. More research is needed to investigate the association between age and treatment outcome. Neither study using multivariate models found an association between age and outcome, nor was there a reported correlation in another. The two studies that categorised women as treatment successes or failures had conflicting results.

Summary

There is no good evidence to date to suggest that 'healthy' older women with UI do benefit less from PFMT compared to younger women.

b) Other

Aside from age, other factors have the potential to mediate treatment outcome, e.g. baseline UI severity, duration of symptoms and co-morbid conditions. All reports were checked for the methods used to address association between baseline characteristics and treatment outcome. Some appeared to be based on researcher observation; these data are not discussed here. Seven reports of interest were found [118,126,141,171,192,205-208]. A wide range of patient characteristics were considered in these papers; it is not clear whether it is more important to know which baseline characteristics might be predictors of outcome, or which ones might not. To eliminate long lists of non-significant associations, a pragmatic choice was made to report only significant associations although this creates a false impression of some consistent associations. None of the variables discussed here has demonstrated a consistent association with outcome, and all are worthy of further investigation.

Two reports addressed independent associations between patient characteristics and outcome [126,205]. Burgio (2003) used data from PFMT groups in three RCTs [120,121,142]. In multivariate analysis of data from PFMT women with UUI or urge predominant MUI, a 75% reduction in leakage episodes was more likely if women did not use protection (e.g. pads) prior to treatment. Continence (100% reduction in leakage episodes) was more likely if women had fewer Incontinence episodes at baseline and had a lower educational level, but less likely if they had prior UI surgery. For PFMT women with SUI or stress predominant MUI a 75% reduction in leakage episodes was less likely if women had previously been evaluated for UI or had

more than 10 leakage episodes per week pre-treatment. Hay-Smith (2003) investigated the associations between patient characteristics and two outcomes (leakage on paper towel test, self-reported improvement) using data from a trial that compared two approaches to PFMT for Women with SUI. In multivariate models increasing parity was associated with less improvement in leakage symptoms and more risk of leakage on a paper towel test. Shorter symptom duration and higher body mass index were both associated with more improvement in symptoms. Leakage once or more per day was associated with greater risk of leakage on a paper towel test; the reverse was true for women with a history of constipation.

There was no statistically significant correlation between any of the baseline characteristics listed and the two outcomes (reduction in leakage episodes or change in PFM activity) in a secondary analysis [207].

Treatment responders had statistically significantly longer symptom duration, higher body mass index, stronger PFM, and were more motivated (clinician judgement) than borderline responders; there were no non-responders [206].

Two studies examined PFM characteristics as possible predictors of successful response to PFMT [118, 208]. Yoo [2011] reported on biofeedback assisted PFMT. In multivariable regression, the only factor predictive of successful treatment response was change in mean amplitude of tonic contraction after the 8th treatment session. Dumoulin [2010] studied PFM function variables measured by dynamometer in women with postpartum SUI. Treatment success (20-minute pad test volume < 2g) was associated with lower pre-treatment passive force and greater pre-treatment PFM endurance.

Few studies investigated the association between patient characteristics and treatment outcome and no consistent pattern emerged from the available data. Even fewer studies used appropriate methods. More research is needed to test for independent associations between patient characteristics and outcome. Given the few data available, and the methodological limitations of some papers, any patient characteristic described above that was associated with outcome should be considered as a possible rather than established prognostic factor.

Summary

It is not clear if there are any reliable predictors of PFMT outcome. Too few trials have appropriately investigated the association between patient characteristics and outcome to be sure.

III. WEIGHTED VAGINAL CONES (VCS)

Weighted vaginal cones (VCs) were developed as a method for testing PFM function and to provide progressive muscular overload during PFM strengthening exercises [182,209]. In theory, when a cone is inserted into the vagina, the sensation of 'losing the cone' provides strong sensory feedback that prompts the PFMs to contract to prevent the cone from slipping out. Women start in a standing position with a weighted cone held inside the vagina for at least one minute, incrementally adding time and increased cone weight whilst standing or walking. The goal is to walk around for 20 minutes without losing the cone; the gradual increase in cone weight maintains muscle overload over the course of the exercise programme.

There are varous cone weights and sizes (**Figure 1**). However, the effectiveness of the VC training method is unclear. Of note is that the PFM contraction is not the only reason the cone is retained and because orientation of the vagina is not completely vertical, some women can retain the cone without actually contracting the pelvic floor. Radiology has also demonstrated that the cones can rest in a transverse position [210,211]. Depending on the axis of the vagina, women need to produce different force intensities to retain the cone. Thus, using VCs as a measure of PFM function does not appear to be a valid method. Finally, some women may find it impossible to insert the cones due to a narrowed vaginal opening or, conversely, to retain it due to an enlarged vaginal opening, prolapse, or an insufficient PFM contraction, one incapable of holding even the lightest cone.

This section examines the evidence for VCs in the prevention and treatment of UI in women. Questions addressed:

- Are VCs better than no treatment, placebo or control for the prevention of UI?
- Are VCs better than no treatment, placebo or control for the treatment of UI?
- Are VCs as effective as other treatments for the treatment of UI?
- Are VCs combined with PFMT better than PFMT alone for the treatment of UI?

1.PREVENTION

No trials investigating either the primary or secondary prevention effects of training with VCs for women with UI were found. The literature search revealed two reviews on the prevention of UI [159,212]. Of these, only Hay-Smith (2002) considered VC prevention trials; however, none of the trials measured the effect on UI, only PFM activity. Because no continence-related outcomes were measured, these trials are not reviewed here. Further, the most recent Cochrane review of VCs did not address prevention [213], and our search did not revealed any new RCTs on VCs as a preventive treatment.

Figure 1: Weighted vaginal cones

2.TREATMENT

The literature search revealed one systematic review that specifically addressed the effects of VCs in the treatment of UI in women [213]. One new trial [181], the review and three RCTs from ICI 2009 form the basis of this subsection [122,140,181,183].

a) Are VCs better than no treatment, placebo or control treatments?

Four RCTs compared VCs with control treatments for women with UI [107,122,134,140]. Details of the VC programmes for each trial are presented in **Table 3**.

1. Quality of data

All four reported adequate allocation concealment, randomisation and blinding of outcome assessors. Dropout rates were 3% [122], 12% [134], 14% [140], and 40% [107]. In one, the VC group experienced more dropouts (42%) than the control group (22%) [107]. In another, participants in the VC group reported abdominal pain, vaginitis or bleeding and 14 reported problems with self-motivation and difficulty in using the cones [134]. Williams did not report any side effects for either treatment group other than the fact that 2.5% of the women in each of the trial arms reported urinary tract infections (UTI). Wilson [1998] and Castro [2008] did not report any side effects in either group.

2. Results

Women in the VC groups were more likely to report they were cured than the controls (RR 1.98, 95% CI 1.21 to 3.23). The pooled data for self-reported improvement/cure from two trials [122,134] showed statistically significant heterogeneity. Individually, one trial favoured the VC group [134] while the other favoured neither group [122]. VC participants scored better than the controls on the Leakage Index but showed no statistical differences on the Social Activity Index [134]. Further, Castro (2008) [140] reported better incontinence-related QOL in VC participants as compared to the controls on the IQoL questionnaire.

3. Summary

The evidence from these four RCTs suggests that VCs are better than control treatments for subjective reporting of cure or cure/improvement and QoL impact in the treatment of SUI **(Level of Evidence: 1)**. However, VC treatment may be inappropriate in some cases due to potential reported side effects.

4. Recommendations

For women with SUI, VCs with supervised training sessions by a trained health professional can be offered as a first-line conservative therapy to those who can and are prepared to use them **(Grade of Recommendation: B)**; VCs may be inappropriate in some cases due to inability to insert or retain the the cone or because of side effects and discomfort. Trained health professional assessment is recommended **(Grade of Recommendation: D)**

b) Are VCs as effective as other treatments?

VCs have been compared with PFMT and EStim, but not with other therapies such as drug treatment, BT or surgery.

(a) VCs versus PFMT

This comparison has been addressed in Section B2.3c. The details of the VC and PFMT programmes for each trial are presented in **Table 4**.

(b) VCs versus EStim

Five trials compared VCs with EStim [134, 140, 201, 214, 215]. The details of the VC and EStim programmes for each trial are presented in **Table 5**.

1. Quality of data

(a) VCs versus PFMT: See Section B2.3c.

(b) VCs versus EStim

Among the five trials, two [134,140] reported adequate randomisation, allocation concealment and blinding of outcome assessors; blinding was unclear in the other three [201,214,215]. Dropout rates were higher in the VC groups for [201,214,215] but higher in the EStim groups for three [134,140,201].

2. Results

(a) VCs versus PFMT See Section BII4c.

(b)VCs versus EStim

There was no statistically significant difference between VCs and EStim in the pooled data between two trials [134,140] in terms of self-reported cure nor in the pooled data [134,215] for cure/improvement.

Table 3: Characteristics of studies comparing vaginal cones (VCs) and no treatment, placebo or control treatments

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Bø, 1999 [134] Women with urodynamically proven SUI	VCs (29) vs Control treatment (32)	VCs: One daily 20-minute consultation with physiotherapist, 20 min/day; three cylindrical weights: 20, 40 and 70 grams. Control: Used a continence guard (Coloplast AS).	6 months	Subjective Cure: VCs 5/27 vs Control 1/30 RR 5.56 (0.69-44.61) Cure & improvement: VCs 17/27 vs Control 1/30 RR 18.89 (2.69-132.58)	Dropouts: VCs: 2/29 Control: 3/32
Castro, 2008 [140] Women with urodynamically proven stress or mix UI	VCs (27) vs Control treatment (30)	VCs: One training session with a physiotherapist and 3 days/week under a physiotherapist's supervision. Held the heaviest cone 45 minutes. Cylindrical weights 20-100 grams. Control: Untreated, but received motivational once-monthly phone calls.	6 months	Subjective Cure: VC 13/24 vs Control 5/24 RR: 2.6 (1.10-6.16)	Dropouts: VCs: 3/27, 93% compliance Control: 6/30
Williams, 2006 [122] Women with urodynamically proven stress or mix UI	VCs (80) vs Standard care (79)	VCs: One training session with a nurse. Holding heaviest cone they could retain (10-60g) 15 minutes, 2x /day, 7 days/week. Standard care: leaflet detailing PFM anatomy and exercises.	3 months	Cure : VCs 7/80 vs Control 6/79 RR 1.15 (0.41-2.38) Subjective cure or improvement : VCs 30/80 vs Control 34/79 RR 0.87, 95% CI 0.60 to 1.27	Dropouts: VCs: 1/80 Controls: 3/79
Wilson, 1998 [107] Women with symptoms of UI three months postpartum	VCs (36) vs Control treatment (117)	VCs: One training session and 3 follow-up visits with a physiotherapist. Cone held for two 15-min home exercises sessions per day.Nine conical weights: 20-100 grams. Control: Standard post-natal care	9 months	Subjective Cure: VCs 11/21 vs Control 22/91 RR 2.17 (1.25- 3.74)	Dropouts: VCs: 15/36 Control: 26/117

Footnotes: VCs = vaginal cones

Table 4: Characteristics of studies comparing vaginal Cones (VCs) and PFMT

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Arvonen, 2001 [179] Women with symptoms of SUI	PFMT (20) vs VCs (20)	PFMT: Under supervision of a physiotherapist or nurse. PFM contraction in sitting and in standing position twice daily: one daily set of 10 PFM contractions (5 sec on / 5 sec off) and one daily set of 15 (3 sec) submaximal contractions. VCs: Under supervision of a physiotherapist or nurse. Starting with the 65-gram VC, 10 contractions (20 sec on/ 20 sec off); plus a 50-gram VC x15 min while walking, 2x/day; both progressing to 100- and 80-gram VCs, respectively.	4 months	Cure: VCs 4/18 vs PFMT 0/19 RR 9.47(0.55-164.35) Cure or improvement: VCs 11/18 vs PFMT 11/19 RR 1.06 (0.62-1.80)	Dropouts: PFMT: 1/20 VCs: 2/20
Arvonen, 2002 [183] Women with symptoms of SUI	PFMT (12) vs VCs (12)	PFMT: Supervision with physiotherapist, 2 visits. Progressive PFMT in sitting and standing position. PFM contractions of short and long duration or with cough. VCs: Supervision with physiotherapist, 2 visits. Starting with the 65-gram VC, 10 contractions (20 sec on/ 20 sec off), plus a 50-gram VC x15 min while walking, 2x/day; both progressing to 100- and 80-gram VCs, respectively.	4 months	Cure: VCs 2/7 vs PFMT 0/10 RR 6.88 (0.38-124.52) Cure & improvement: VCs 6/7 vs PFMT 9/10 RR 0.95 (0.66-1.37)	Dropouts: PFMT: 2/12 VCs: 5/12
Bø, 1999 [134] Women with urodynamically proven SUI	PFMT (29) vs VCs (27)	PFMT: One consultation with physiotherapist.8-12 PFM contractions, 3x per day, plus 1 group-session/week. VCs: One consultation with physiotherapist. 20 min per day, three cylindrical weights: 20, 40, and 70 grams.	6 months	Subjective Cure: VCs 5/27 vs PFMT 12/25 RR 0.39 (0.16-0.94) Cure & improvement: VCs 17/27 vs PFMT 23/25 RR 0.68 (0.50-0.93)	Dropouts: VCs 2/29 PFMT: 4/29
Cammu, 1998 [180] Women with urodynamically proven stress or SUI	PFMT (30) vs VCs (30)	PFMT: Once weekly, 30-min PFM-training sessions with a physiotherapist, plus individualised home-based PFM exercises. VCs: Initial training plus twice-weekly visit with physiotherapist, in addition to holding the heaviest cone 15 min, 2x daily Five VCs 20-70 grams.	12 weeks	Cure & improvement VCs 17/30 vs PFMT 16/30 RR 1.06 (0.67-1.68)	Dropouts: VCs: 14/30 PFMT: 0/30

Table 4: Characteristics of studies comparing vaginal Cones (VCs) and PFMT (continued)

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Castro, 2008 [140] Women with urodynamically proven stress or mix UI	PFMT (31) vs VCs (27)	PFMT: One training session with physiotherapist plus 3 days/week with physiotherapist supervision. PFM contractions: • 10x, 5sec on/5 sec off • 20 x, 2sec on/2 sec off • 20 x, 1sec on/1 sec off • 5 x, 10sec on/10 sec off • 5 contractions with cough VCs: One training session with physiotherapist plus 3 days/week with physiotherapist supervision.Held the heaviest cone, 45 min. Cylindrical weights: 20-100 grams	6 months	Subjective Cure: VCs 13/24 vs PFMT 15/26 RR 0.94 (0.57-1.54)	Dropouts: VCs: 3/27 & 93% compliance PFMT: 5/31
Gameiro, 2010 [181] Women with predominent symptoms of SUI	PFMT (52) vs VCs (51)	PFMT: Once weekly, 45-min session of PFMT2 series of 10 PFM contractions (short and long) VCs:Once weekly, 45min session of VCs. Walked 1 minute, coughed 3 times and ascended and descended a 2-step stair 10 times. Cylindrical weights: 20-70 grams	12 weeks	Cure: VCs 36/51 vs PFMT 26/52 RR 1.41 (1.02-1.95) Cure & improvement: VCs 27/51vs PFMT 22/52 RR 1.25 (0.83-1.88)	Dropouts: No details provided
Haken, 1991 [175] Women with urodynamically proven stress UI	PFMT (31) vs VCs (33)	PFMT: 5 contractions, 10 times per day VCs: Hold for 15 min, 2x/day 5 cylindrical weights: 20-70 grams	10 weeks	Cure: details not reported	Dropouts: VCs: 8/31 PFMT: 3/33
Laycock, 2001 [185] Women with urodynamically proven stress UI	PFMT (20) vs cones (41)	PFMT: Supervision with physiotherapist. PFM exercises lying, sitting and standing, 10 min/day VCs: 10 minutes per day with VC	3 months	No data reported on subjective cure or improvement	Dropouts: VCs: 11/41 PFMT: 4/20

Table 4: Characteristics of studies comparing vaginal Cones (VCs) and PFMT (continued)

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Peattie, 1988 [182] Women with urodynamically proven stress UI	PFMT (22) vs VCs (22)	PFMT: 3 PFM training sessions. VCs: twice/day held cone for 15 min. Weekly phone calls Nine conical weights: 20-100 grams	4 weeks	Cure: VCs 12/17 vs PFMT 10/16 RR 1.13 (0.69-1.84)	Dropouts: VCs: 5/22 PFMT: 6/22
Williams, 2006 [122] Women with urodynamically proven stress or mix UI	PFMT (77) vs VCs (80)	PFMT: initial +bi-weekly training session with nurse 4 sets/day, PFM exercise program progressed according to Oxford scale VC: One training session with nurse. Held heaviest cone (10-60g) 15 minutes, 2x /day.	3 months	Cure: VCs 7/80 vs PFMT 4/79 RR 1.73 (0.53-5.67) Cure or improvement: VCs 51/80 vs PFMT 47/79 RR 1.07 (0.84-1.37)	Dropouts: VCs: 1/80 PFMT: 2/79
Wilson, 1998 [107] Women with symptoms of UI three months postpartum	PFMT (39) vs VCs (36)	PFMT: One training session with 3 follow-up sessions, fast and slow contractions (100 per day) VCs: One training session and 3 follow-up visits with physiotherapist. Held the cone for two 15-min sessions /day. Nine cone weights: 20-100 grams	9 months	Cure: VCs 11/21 vs PFMT 10/19 RR 1.00 (0.55-1.80)	Dropouts: VCs: 15/36 PFMT: 20/39

Table: 5 Characteristics of studies comparing vaginal cones and electrical stimulation (Estim)

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Bø, 1999 [134] Women with urodynamically proven SUI	VCs (29) vs EStim (32)	VCs: One consultation with physiotherapist. 20 min/day, three cylindrical weights: 20, 40 & 70 grams EStim: One consultation with physiotherapist; 30 min of transvaginal EStim per day: biphasic intermittent current, 50Hz, pulse width of 0.2ms, current intensity 0-120mA, on/off time in line with each woman's ability	6 months	Subjective Cure: VCs 5/27 vs EStim3/25 RR: 1.54 (0.41-5.80) Cure & improvement: 17/27 cone vs 16/25 EStim RR: 0.98 (0.65-1.49) Cure & improvement, on pad test: VCs18/27 vs EStim 19/25 RR: 0.88 (0.62-1.24)	Dropouts: VCs: 2/29 EStim: 7/32
Castro, 2008 [140] Women with urodynamically proven stress or mix UI	VCs (27) vs EStim(30)	VCs: One training session with physiotherapist plus 3 days/week with physiotherapist supervision. Held the heaviest cone 45 min. Cylindrical weights: 20-100 grams EStim: 20 min of transvaginal EStim, 3 times/ week: biphasic square current 50Hz, pulse width of 0.5ms, current intensity 0-100mA, and cycle of 5 sec. on/10 sec off.	6 months	Subjective Cure: VCs 13/24 vs Estim 15/27 RR: 0.97 (0.59-1.61)	Dropouts: VCs: 3/27 plus 93% compliance EStim: 3/30
Delneri, 2000 [214] Women with signs and symptoms of SUI	VCs (10) vs EStim (10)	VCs: Initial training Used VCs 25-35 min/day, increasing cone weight progressively. 5 plastic cones: 20-70 grams EStim: Two15-min transvaginal EStim sessions daily, 5x per week: biphasic square current 20Hz and 50Hz, duty cycle 4/8, at maximum tolerated intensity.	VCs: 4 weeks EStim: 12 sessions in 16 days	No outcome of interest	Dropouts: VCs: 2/10 EStim: 0/10
Olah, 1990 [215] Women with symptoms of SUI	VCs (24) vs EStim (30)	VCs: Instructed by a physiotherapist once per week for 4 weeks plus15 min, 2x/day home exercises; Nine cones: 20-100 grams EStim: Instructed by a physiotherapist 3x per week for 4 weeks. Interferential current with 4 external vacuum electrodes. Frequency 0-100Hz, maximal tolerated intensity for 15 min.	4 weeks	Cure and improvement: VCs 6/24 vs EStim21/30 RR: 0.36 (.17-0.74) Cure & improvement, on pad test: VCs 12/24 vs EStim 23/30 RR: 0.65 (0.42-1.02)	Dropouts: VCs: 5/24 EStim: 2/30
Wise, 1993 [201] Women with urody-namically proven stress and genuine stress incontinence	VCs (21) vs EStim (20)	VCs: Used VCs, 15 min, 2x/day,increasing cone weight progressively. EStim: 20 min of transvaginal EStim, daily: biphasic square current 20Hz, pulse width of 0.75ms, current intensity 0-90mA	12 weeks	Cure & improvement, on pad test: VCs 14/21 vs EStim 12/20 RR 1.11 (0.70-1.78)	Dropouts: VCs: 2/21 EStim: 4/20

Footnotes: VCs = vaginal cones, Estim = Electrical stimulation

No differences were reported on the I-QoL questionnaire or in the number of leakage episodes on a 7-day bladder diary evaluation (mean and standard deviations: cones 1.5 ±1.8 vs. EStim 2.3 ±5.5) [140]. Bø [1999] also found no differences in daily leakage episodes on a 7-day bladder diary.

Discomfort or side effects between EStim and VC are reported to be similar [140,214] . One study described women who were unable to use the VCs because of vaginal size [215] and another reported tenderness and bleeding, discomfort or motivational and other difficulties in using the EStim [134]. In the VC group, one participant reported abdominal pain, two vaginitis and one bleeding; 14 reported motivational problems and difficulty using the cones.

3. Summary

Overall, the pooled data for VCs and EStim demonstrated no statistically significant differences between the groups in terms of a self-reported cure, a cure/improvement, incontinence-specific QOL measures or the number of leakage episodes **(Level of Evidence: 1)**. Additionally, both the VC and EStim groups reported adverse events.

4. Recommendations

VCs and EStim seem equally effective in the treatment of SUI and MUI, but the side effects and discomfort caused by the VCs and EStim limit their utility in clinical practice **(Grade of Recommendation: B)**.

c) Are VCs combined with PFMT better than PFMT alone?

Two trials compared a combined PFMT/VCs to PFMT alone (107,216] Details of the PFMT/VCs and PFMT are presented in **Table 6**. None of the outcomes used in the two trials overlapped.

1. Quality of data

Allocation concealment was clear in one and some outcomes had blinded assessors [107,216], but neither of these variables was clearly reported the other [216].

2. Results

No statistically significant differences were detected for either cure or cure/improvement after 12 weeks in either study. Dropout rates in both trials were higher in the combined PFMT/VCs group.

3. Summary

The limited available evidence suggested no benefit from adding VCs to PFMT for women with SUI **(Level of Evidence: 2)**.

4. Recommendations

If this combined intervention proves to be of interest to women, then more research is needed to confirm or refute the advantages of adding VCs to PFMT.

3. OTHER LOWER URINARY TRACT SYMPTOMS (LUTS)

Two trials included in the VC section reported data on other LUTS: urgency and nocturia [122], nocturia [181]. In the Williams [2006] study, there were no differences between VC, control and PFMT group after intervention for urgency or nocturia. Gameiro [2010] however, noted a significant reduction in nocturia after treatment in both VC and PFMT groups, but no significant difference between groups.

4. FACTORS AFFECTING OUTCOME

None of the trials above addressed the effect of age or other factors on the outcome of VC training. Nonetheless, it is worth noting that in the 22 trials included in this section, on average, 24% of the women being treated with VCs (range 0 to 63%) withdrew or dropped out. Although few trials examined the causes of attrition, among those that reported causal factors low compliance, motivational problems, unpleasantness, aesthetic dislike, discomfort, and bleeding were indicated although no one reason predominated.

IV. ELECTRICAL STIMULATION (ESTIM)

The literature concerning EStim in the management of UI remains difficult to interpret, due to the lack of a well-substantiated biological rationale underpinning the use of EStim[217]. However, the theoretical basis of stimulation interventions is emerging with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. The mechanisms of action may vary depending on the cause(s) of UI and the structure(s) being targeted e.g. PFM or detrusor, peripheral or central nervous system. In general, the aim of EStim for women with SUI appears to be to improve the function of the PFM, while for women with UUI the objective seems to be to inhibit detrusor overactivity (DO).

EStim is provided by clinic-based mains powered machines or portable battery powered stimulators (Figure 2) with a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 3). Without a clear biological rationale it is difficult to make rationale choices about different ways of delivering EStim. Additional confusion is created by the relatively rapid developments in the area of EStim, and a wide variety of stimulation devices and protocols have been developed even for the same condition. For example, in the last 30 years or so women with SUI have been treated with a wide variety of EStim ranging from general anaesthetic for 20 minutes [168], to six months of low intensity stimulation at 10 Hz using a vaginal electrode [1,218].

Finally, the nomenclature used to describe EStim remains inconsistent. EStim has not only been described based on the type of current being used

Table 6: Characteristics of studies comparing PFMT + vaginal cones vs PFMT

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Pieber, 1995 [216] Women with urodynamically proven SUI, premenauposal	PFMT+ VCs (21) Vs PFMT (25)	PFMT+VCs: Instruction on PFMT by physiotherapist plus visits with physiotherapist every 2-4 weeks; 100 PFM contractions plus Knack, daily Held the VCs for 15 min/day. Five cone weights: 20-70 grams PFMT: Instruction on PFMT by physiotherapist. 100 PFM contractions/day + Knack; visits with physiotherapist every 2-4 weeks	3 months	Subjective Cure: PFMT+VCs 5/21 vs PFMT 3/25 RR: 1.98 (0.54-7.34) Cure and improvement: PFMT+VCs 11/21 vs PFMT 12/25 RR 1.09 (0.61-1.94)	Dropouts: PFMT+VCs : 8/21 PFMT: 9/25
Wilson, 1998 [107] Women with symptoms of UI three months postpartum	PFMT+VCs (38) vs PFMT (39)	PFMT+VCs: One training session with a physiotherapist plus 3 follow-up visits. 100 fast and slow contractions per day PFMT: One training session with 3 follow-up sessions, fast and slow contractions (100 per day)	9 months	Subjective Cure: PFMT+VCs 6/14 vs PFMT 10/19 RR: 0.81 (0.39-1.71)	Dropouts: PFMT+VC: 24/38 PFMT: 20/39

Footnotes: PFMT= pelvic floor muscle training, VCs = vaginal cones, Estim = Electrical stimulation

(e.g. faradic, interferential), but also on the structures targeted (e.g. neuromuscular), the current intensity (e.g. low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g. neuromodulation). In the absence of agreement of how best to classify EStim, no attempts were made to classify different types of EStim.

This section presents the evidence for the use of EStim in the prevention and treatment of UI in women. Questions addressed are:

- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?
- What is the effect of EStim on other LUTS?
- What factors might affect the outcome of EStim in the treatment of UI?

Eligible interventions were non-invasive EStim without implanted electrodes. (Magnetic stimulation is described in Section B.5.0.) Other criteria for inclusion were (1) randomised or quasi-randomised (lternate allocation) trial design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women (within 12 months of childbirth). Trial data reported in conference abstracts as well as full-text papers were included. EStim compared with PFMT and vaginal cones are covered in previous sections (sections B.2 and B.3). This section focuses on EStim compared with other conservative treatments or no active treatment.

Figure 2: EStim machine

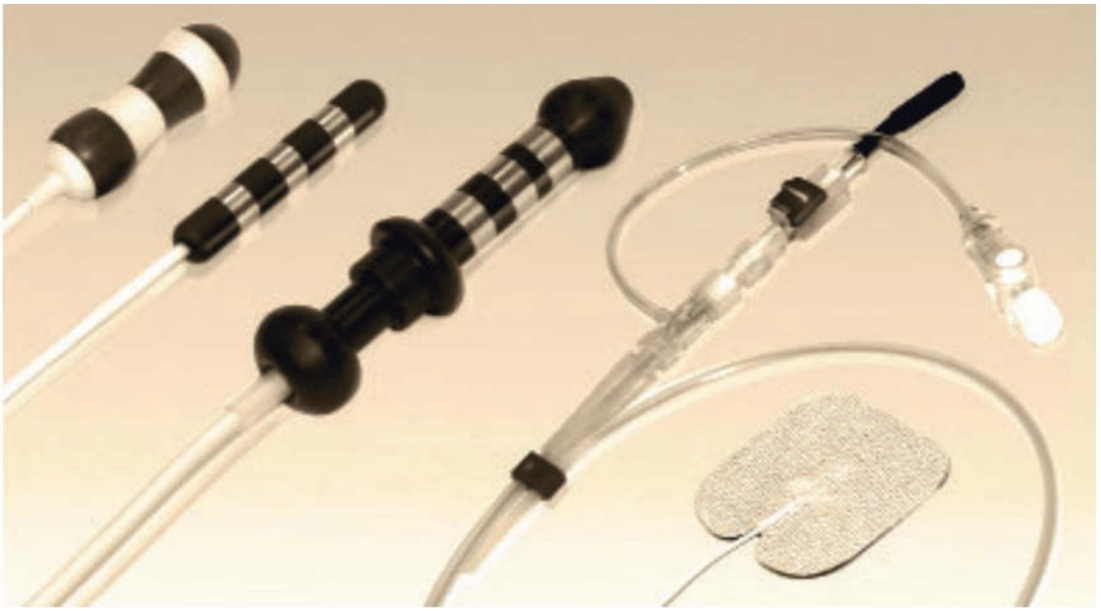

Figure 3 : Vaginal, rectal (anal), and skin electrodes for electrical stimulation

The primary outcomes were cure rates (the number of women cured), and improvement rates (the number of women improved, including cure). There was considerable variability in the way these outcomes were measured. Women's self-report was given priority but for studies in which it was not reported, the rate based on diaries was used as a proxy; where diary data were also not reported, the rate based on pad tests or any other definitions chosen by the trialists was used [219]. Data on health-related quality of life and adverse effects were also extracted. Data at the end of the prescribed treatment phase, or at the first outcome measurement, if later, were used in the analysis. Any treatment effects shown are likely to reflect maximum effect of each intervention. Data from further follow-ups were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a predominant symptom of SUI (as defined by trialists), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trialists), (3) other studies of UI in which neither stress- or urge-UI represented a predominant symptom in the study population, and (4) studies of OAB or DO in which it was unclear whether all participants had UI.

Single estimates with 95% confidence intervals (CI) were derived for each study comparison using odds ratios (OR) for dichotomous variables or mean difference (MD) for continuous variables. Summary estimates were calculated using random effects models if there was more than one study reporting the same outcome (meta-analysis).

'Risk of bias' in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group [220]. Risk of bias regarding blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

Description of intervention in included studies of EStim

A total of 33 trials were eligible. The electrical stimulation parameters and protocols in this section are summarised in **Table 7**. Some approaches to treatment are now rare, such as the use of faradic current or external electrodes. There was considerable variation in the intervention protocol. Although the biological rationale and purpose of EStim might be different depending on diagnosis, there was no consistency in the EStim protocols used for women with SUI, UUI, MUI, or DO.

In addition, there were three trials that recruited both men and women. These include comparing: EStim (transcutaneous electrical nerve stimulation) with oxybutynin for 13 men and 30 women with idiopathic DO [221]; EStim with sham EStim for 29 men and 39 women with UI due to either idiopathic or neurogenic DO [222]; and EStim and MStim for 15 men and 17 women with UI due to either idiopathic or neurogenic DO [223]. These trials did not differentiate the effects of treatment by gender or by diagnosis and therefore did not contribute to the analysis.

Table 7: Electrical stimulation parameters and protocols in the electrical stimulation (Estim) trials

Study	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration/ Supervision	Target UI
Abel 1997 [232]		Vaginal: 110mA ; anal: 50mA	Duration: 1.0 msec	Single freq: 5Hz	Constant	Anal and vaginal electrode	20min sessions, 1/week: 12wks	UUI
Amaro 2006 [231]		According to tolerance (range 0-100mA)	Duration: 0.1 µsec	Single freq: 4Hz	Single ratio: 1:2 (2s on, 4s off)	Single vaginal electrode	20min sessions, 3/week on alternate days, by nursing staff: 7wks	MUI/UUI
Arruda 2008 [188]	Intermittent biphasic	According to tolerance (range 10-100mA)	Duration: 1.0 msec	Single freq: 10Hz		Single vaginal electrode	20min sessions, 2/week, by physiotherapist: 12wks	DO
Barroso 2004 [229]	Biphasic	Max tolerable intensity (range 0-100mA)	Shape: asymmetric Duration: 300 µsec;	UUI or MUI: 20Hz ; SUI: 50Hz	Single ratio: 1:1 (5s on, 5s off) + 1s rise time	Single vaginal electrode	20min sessions, 2/day, home treatment: 12wks	Any UI
Berghmans 2001* [436]	Biphasic	Max tolerable intensity (range 0-100mA)	Shape: rectangular; Duration: 200 µsec	Freq. stochastic range: 4 - 10Hz		Single vaginal electrode	1/week, office-based and home treatment: 9wks	UUI/DO
Bergmans 2002 [224]	Biphasic	Max tolerable intensity (range 0-100mA)	Shape: rectangular; Duration: 200 µsec	Freq. stochastic range: 4 - 10Hz		Single vaginal electrode	30min sessions, 1x a week, office-based: 9wks ; 20min sessions, 2/day, home treatment: 9wks	DO
Bidmead 2002 [135]						Single vaginal electrode	2/day, home treatment: 9wks	SUI
Blowman 1991 [234]		Until patient is aware of some electrical sensation (not enough to cause PFM contraction, and comfortable enough to be ignored)	Duration: 80µsec	Two freq: 10Hz and 35Hz	Single ratio: 1:1 (4s on, 4s off)	Transcutaneous: cathode over perineum, anode over buttock	lower freq (10Hz): 60min sessions, 1/day, home treatment: 4wks; higher freq (35Hz): 15min sessions, 1/day, home treatment: 2wks	SUI

Table 7: Electrical stimulation parameters and protocols in the electrical stimulation (Estim) trials (continued)

Study	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration/ Supervision	Target UI
Bø 1999 [134]	Intermittent biphasic	Max tolerable intensity to get a contraction (range 0-120mA)	Duration: 0.2msec	Single freq: 50Hz	Individually adapted cycles dependent on voluntary contraction time (On between 0.5-10s, Off between 0-30s)	Single vaginal electrode	30min sessions, 1/day, home treatment (monthy clinic visits): 6mths	SUI
Bower 1998 (226]		Max tolerable intensity	Duration: 200µsec	Suprapubic: 150Hz or sacral: 10Hz		Transcutaneous suprapubic or transcutaneous sacral	Single session?	DO
Brubaker 1997 [227]		Max tolerable intensity (range 0-100mA)	Shape: bipolar square; Duration: 0.1µsec	Single freq: 20Hz	Single ratio: 1:2 (2s on, 4s off)	Single vaginal electrode	20min sessions, 2/day, home treatment: 8wks	SUI/DO
Castro 2008 [140]		Max tolerable intensity (range 0-100mA)	Shape: bipolar square; Duration: 0.5msec	Single freq: 50Hz	Single ratio: 1:2 (5s on, 10s off)	Single vaginal electrode	20min sessions, 3/week, by physiotherapist: 6mths	SUI
Eyjolfsdottir 2009 [235]	Intermittent						15min sessions, 2/day: 9wks	SUI
Goode 2003 [121]	Biphasic	Max tolerable intensity (range 0-100mA)	Duration: 1.0msec	Single freq: 20Hz	Single ratio: 1:1	Single vaginal electrode	15min sessions, every alternate day, home treatment (fortnightly clinic visits): 8wks	SUI/MUI
Haig 1995 [236]	Interferential			Single freq: Freq range: 10-40Hz		Single vaginal electrode	20min sessions, 3x weekly, clinic-based treatment: 1mth (total study period 3mths, Estim done in 2nd month only)	SUI

Table 7: Electrical stimulation parameters and protocols in the electrical stimulation (Estim) trials (continued)

Study	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration/ Supervision	Target UI
Henalla 1989 [130]	Interferential	According to tolerance		Freq range: 0-100Hz			20min sessions, 1/week, clinic-based treatment: 10wks	SUI
Hofbauer 1990 [132]	Faradic (low freqency interrupted direct)	Noticable muscle contraciton (with voluntary PFM contraction				Vaginal, perineal electrodes (active), lumbar electrodes (inactive)	10min sessions, 3/week: 6wks	SUI
Jeyaseelan 2000 [198]				Two freq: low & intermedi-ate		Single vaginal electrode	1hr session, 1/day: 8wks	SUI
Knight 1998 [218] (study arm 1)		Barely perceptible tingling sensation	Duration: 200µsec	Two freq: 10Hz and 35Hz	Single ratio: 1:1 (5s on, 5s off)	Single vaginal electrode	Home treatment : overnight (1/day), 6 months	SUI
Knight 1998 {{78 Knight,S. 1998}} (study arm 2)		Max tolerable intensity + voluntary PFMC	Duration: 250µsec	Two freq: 10Hz and 35Hz	Single ratio: 1:1 (5s on, 5s off)	Single vaginal electrode	Clinic-based treatment: 30min session, 1/day: 6mths (total 16 sessions)	SUI
Laycock 1993 [178]	Interferential (bipolar)	Max tolerable intensity		Freq range: 10-40Hz; and 1Hz to 40Hz		Transcutane-ous electrodes	15mins (first session), 30mins (subsequent sessions): 10 sessions, clinic-based treatment	SUI
Lin 2004 [204]		Range 8-70mA	Duration: 200-500µsec	Freq range: 5-50Hz		Vaginal or anal electrode	20min sessions, 1/day, 5x a week: 4-6 weeks	DO
Lo 2003 [237]		Max tolerable intensity		Freq range: 0-100Hz		Transcutane-ous: 2 anterior, 2 posterior	First session 15 mins; other sessions 30mins, 3/week, by physiothera-pist: 4wks	SUI/UUI

Table 7: Electrical stimulation parameters and protocols in the electrical stimulation (Estim) trials (continued)

Study	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration/ Supervision	Target UI
Lobel 1998* [233]				Freq range: 0-100Hz		Anal and vaginal electrodes	5 wks. Additional 5 wks if any cure or improvement was noted.	DO
Luber 1997 [228]		Adjustable (10-100mA)	Duration: 2msec	Single freq: 50Hz	Single ratio: 1:2 (2s on, 4s off)	Single vaginal electrode	15min sessions, 2/day, home treatment: 12wks	SUI
Sand 1995 [230]		Max tolerable intensity		Two freq: 12.5Hz and 50Hz	Alternating ratio: 1:1 and 1:2	Single vaginal electrode	7 sessions, clinic-based treatment: 15wks (12wks treatment, 2wks before, 1wk after) ; 70hrs total planned	SUI
Schmidt 2009 [173]	Biphasic	Max tolerable intensity without discomfort	Shape: asym-metric; Duration: 300µsec	Single freq: 50Hz		Vaginal (ring electrodes x 2)	12wks	SUI/MUI
Shepherd 1984 [168]	Monophasic	Noticable PFMC	Shape: square	Freq range: 10-50Hz		Anal and vaginal electrodes	A single 20min session under anaesthesia	Any UI
Smith 1996 [187]	Biphasic pulsed	Progressive: 5-25mA	Shape: asymmetric; Duration: 0.3msec	Two freq: 12.5Hz and 50Hz	Single ratio: 1:2	Single vaginal electrode	2/day, home treatment: 4mths	UUI/DO
Tapp 1987* [238]	Faradic low frequency interrupted direct)					Single vaginal electrode	2/week: 1mth	SUI
Tapp 1989 [177]	Faradic (low frequency interrupted direct)							SUI

Table 7: Electrical stimulation parameters and protocols in the electrical stimulation (Estim) trials (continued)

Study	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration/ Supervision	Target UI
Wang 2006 [225]	Biphasic	Max tolerable intensity	Shape: symmetric; Duration: 400µsec	Single freq: 10Hz	Single ratio: 2:1 (10s on, 5s off)	Single vaginal electrode	20min sessions, 2/week, by physiotherapist: 12wks	DO
Wilson 1987 [171] (study arm 1)	Faradic (low frequency interrupted direct)	Max tolerable intensity + PFMC		Low frequency	12 surges, 2 min rest (repeated 3x)	Transcutane-ous sacral; Transcutane-ous perineal	12 sessions, clinic-based treatment: 6wks	SUI
Wilson 1987 [171] (study arm 2)	Interferential (range20-25mA)	Pressure peak 0.25-0.30Pa/cm2 for 15pulses (range20-25mA)		Medium frequency	4000cycles/sec	transcutane-oussuction electrodes (x4)	12 sessions (first session 10min; other sessions 15mins), clinic based treatment: 6wks	SUI
Wise 1993* [201]	Variable	Just below level of discomfort (range= 0-90mA)		Single freq: 20Hz		Single vaginal electrode	20min sessions, daily home treatment: 6wks	DO

*Footnotes: * abstract only; Estim = electrical stimulation, freq= current frequency, PFM = Pelvic floor muscle, PFMC= Pelvic floor muscle contraction, VPFMC= voluntary Pelvic floor muscle contraction*

1. PREVENTION

No published trials were found that investigated either the primary or secondary prevention of UI or LUTS.

2. TREATMENT

a) Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?

Seventeen studies compared EStim with no active treatment. Characteristics of studies comparing EStim with no active treatment are presented in **Table 8**. No active treatment consisted of sham EStim in the majority (11 of 17) of the studies. In others, the 'no active treatment' groups received no treatment [130,224], placebo drugs [225], non-active control intervention such as instruction in the use of an anti-incontinence device [134] or motivational phone calls [140].

One study [226] was a three-arm trial: two of the arms using EStim with either sacral or suprapubic electrodes were combined (N = 32) and compared with the sham ES arm (N = 16). The trial by Brubaker and colleagues [227] included women with SUI or DO with women with SUI comprising the majority of the study sample. Data from this trial therefore contributed to the analysis for SUI.

1. Quality of data (risk of bias)

Three studies [134,225,228] reported adequate methods of allocation concealment, namely opaque (and sealed) envelopes with third party involvement in the allocation procedure. Allocation concealment was assessed as suboptimal in two [168,224] that used opaque or sealed envelopes but with no indication of third party involvement. The remainder did not describe methods used for allocation concealment. Trial results were reported for everyone who entered the trial in three studies [132,224,229] but this was not done in the others.

2. Results

(a) SUI or predominant SUI. Pooled data suggest that cure rates were on average higher for EStim compared with no active treatment but the difference was not statistically significant [132,134,140,178,227,228,230]. Improvement rates were statistically significantly higher for EStim compared with no active treatment [134] [130,132,134,178,227,228,230] although there was some evidence of statistical heterogeneity for the improvement rate (I-squared = 59%).

Adverse effects appeared uncommon. One study reported tenderness and bleeding in 10 of 32 participants using the active EStim device, of which seven withdrew from treatment due to adverse effects [134]. Another study reported that 14 of 35 participants using the active EStim device and seven of 17 participants using the sham device experienced vaginal irritation, pain or infection [230].

Quality of life was reported using diverse measures in three studies. Two of these studies reported statistically significant differences favouring EStim compared with no active treatment: the first [134] used the Social Activity Index, and the second [140] used the I-QoL questionnaire. However, the third study [198] found no significant differences between the groups based on either the Urogenital Distress Inventory or the IIQ.

(b) UUI or predominant UUI. One small study in which all participants had MUI with UUI as a predominant pattern found no significant difference between the groups in cure rates [231] although the confidence interval was wide. Improvement rates were significantly higher for EStim compared with no active treatment based on another small study in which all participants had UUI alone [232]. However, these differences are not informative, because the confidence interval is very wide and the OR is clinically implausible. No information was available on adverse effects and quality of life.

(c) SUI, UUI or MUI. One study [168] that provided information on cure and improvement found no difference between the groups. No information was available on adverse effects and quality of life.

(d) DO (wet or dry). Cure and improvement rates were reported only in one study [225]. There was a statistically significant difference in the improvement rate in favour of the EStim group compared with no active treatment but no difference was found for the cure rate. Caution is required, as the OR is clinically implausible and may be a statistical artefact. Two studies with data on quality of life outcomes reported inconsistent results [224,225]. One study using the KHQ (total score] reported a statistically significant difference favouring EStim compared with no active treatment [225], whereas the other study using the IIQ found no significant difference between the groups [224]. No information was available on adverse effects.

3. Summary

Included studies were generally assessed as having a high risk of bias. EStim might be more effective than no treatment in improving (not necessarily curing) symptoms in women with SUI, UUI or DO, although this may not result in cure **(Level of Evidence: 2**). Information on quality of life was sparsely reported and the limited data that were available were not consistent. Adverse effects appear uncommon but some women experienced discomfort with the treatment device. Few data were available on long-term performance.

4. Recommendations

EStim might be better than no treatment in improving symptoms **(Grade of Recommendation: B)**. However, the recommendation should be viewed with caution until the findings are supported or refuted in

further trials; it would be particularly useful if further trials used a validated and reliable quality life measure as a primary outcome.

b) Is one type of EStim better than another in the treatment of UI?

Four studies compared one approach to EStim versus another; two in women with SUI [171,218] and two in women with DO and sensory urge [226,233]. The characteristics of studies comparing one type of Electrical stimulation with another are presented in **Table 9**. No study focusing on UUI or predominant UUI was identified.

1. Quality of data (risk of bias)

Allocation concealment was inadequate in one study that used consecutive (alternative) assignment (quasi-randomisation) [171]. Allocation concealment was also suboptimal in another study in which sealed consecutively numbered envelopes were used but it was unclear if they were opaque and whether a third party was involved in the allocation procedure [218]. The other two studies did not mention allocation concealment [226,233]. In Lobel (1998) data were reported only for those who completed the trial (37 of 43 randomised). It was unclear in the other three studies if trial results were reported for everyone who entered the trial.

2. Results

(a) SUI. Two studies assessed different variants of EStim performed as an adjunct to PFMT and biofeedback. The first compared faradism with interferential therapy: no difference was found between the groups in improvement rates, both after the supervised treatment phase and at six months after the end of the supervised phase [171]. The second study compared maximal EStim with low intensity EStim with higher improvement rates for maximum EStim either at the end of supervised phase or at 6 months after the supervised phase [218]. No information was available on cure rates, adverse effects or quality of life.

(b) DO (wet or dry). Data were available from one study comparing two groups receiving EStim either once or twice a week (for 10 weeks) [233]. The most common adverse effects reported were discomfort and leg tremor during treatment, and UTI, although it was unclear in which group these adverse effects occurred. No difference was found between the groups on a quality of life questionnaire (not specified). No information was available on cure and improvement rates.

3. Summary

Included studies were generally assessed as having a high risk of bias. There were four small trials comparing different EStim protocols; the clinical heterogeneity between studies meant it was not appropriate to pool the data. Based on a single trial for women with SUI, maximal clinic-based stimulation may be more effective than low-intensity home-based stimulation in improving symptoms, although no data were available on cure rates, quality of life and adverse effects **(Level of Evidence: 2)**. The other studies did not find clinically important differences between stimulation groups; the studies were small and may have been underpowered. Further comparisons of EStim protocols are needed.

4. Recommendations

For women with SUI maximal clinic-based EStim might be better than daily low-intensity home-based EStim in improving symptoms **(Grade of Recommendation: B)**. There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.

c) Is EStim better than other treatments for UI?

EStim has been compared with PFMT, VC, magnetic stimulation (MStim), and drugs. The comparisons of EStim versus PFMT, and EStim versus VC, have been addressed in Sections B.2.3c and B.3.2b, respectively. For the comparison of EStim and MStim, one trial by Yamanishi and colleagues included both men and women with UI due to either idiopathic or urogenital DO [223]. Because data were not reported separately for women with idiopathic DO it is not clear from this trial whether there was any difference in the effect of MStim compared with EStim.

The remainder of this section focuses on studies that compared EStim with medications: vaginal oestrogen (Premarin) for women with SUI [130]; propantheline bromide 7.5 to 45 mg (various dose) two to three times per day for women with UI due to DO (assumed to be predominant UUI) [187]; oxybutynin 5 mg twice [188,201] or 2.5 mg three times per day [225] and tolterodine 2 mg twice per day [204]. Four studies recruited women with DO [201] or OAB [204,225], or both DO and OAB [188] where some but not all had UI. (**See Table 10.**)

1. Quality of data (risk of bias)

Methods used for allocation concealment were adequate in one [225] but unclear in the other five. Trial results were reported for everyone who entered the trial in one study [187] but this was not done in four [130,188,201] and unclear in one [204].

2. Results

(a) SUI. In one small study of 25 women, 32% in the EStim group and 13% in the oestrogen group reported improvement and the difference was statistically significant [130]. At 9 month follow-up, one of the eight women in the EStim group and all three in the oestrogen group who had reported improvement post-treatment had recurrent symptoms. There was no report of adverse effects. No information was available on cure rates or quality of life.

† Publication in Chinese with English abstract. English translation of the main text was not available at the time of writing. Estim = electrical stimulation, OAB= overactive bladder, DO = detrusor overactivity, DI = detrusor instability; SUI = stress urinary incontinence, MUI = mixed urinary incontinence, NR = not reported

(b) Predominant UUI. Based on one older small study that recruited women with UI due to DO (UUI was assumed to be the predominant symptom), there was no evidence of a difference between EStim and propantheline bromide both in terms of cure and improvement [187]. No data were available for adverse effects or quality of life.

(c) DO (wet or dry). In three studies with data on cure or improvement, there was no evidence of a difference in cure or improvement between EStim and oxybutynin [225], or between EStim and tolterodine [188]. In two of these studies cure and improvement were defined in terms of resolution or reduction of urgency symptoms rather than UUI [188,225] whereas the outcomes were not defined in the other [204]. Follow-up data based on one study found that treatment effects persisted over time (one year) in four of the 11 (36%) participants in the EStim group and 10 of the 17 (59%) participants in the oxybutynin group who had reported improvement in the initial treatment phase (three months) but the difference between the groups was not statistically significant [188] .

More women with DO who received drugs, experienced adverse effects than those who did not. The most commonly reported adverse effect in both oxybutynin or tolterodine treatment group was a high percentage of dry mouth [188,204] which was "intolerable" [225] or "unacceptable" [201] in a smaller number. Other drug side effects were constipation, indigestion, nausea, headache, dizziness and blurred vision. There was no report of adverse effects or adverse effects resulting in treatment withdrawal in the EStim group. Quality of life outcomes were reported only in one study using the KHQ (total score) [225]. The study reported a statistically significant difference in favour of EStim over oxybutynin; no further data was provided).

3. Summary

Included studies were generally assessed as having a high risk of bias. With small numbers per comparison group available, there is insufficient evidence to determine if EStim is better than vaginal oestrogens in women with SUI, propantheline bromide in women with UUI, or oxybutynin and tolterodine for DO **(Level of Evidence: 2)**.

4. Recommendation

Based on current evidence medical treatments appear to be no more effective than EStim **(Grade of Recommendation: B)**. This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

d) Does the addition of EStim to other treatments add any benefit in the treatment of UI?

A total of 12 studies assessed the effect of EStim as an adjunct to another treatment, compared with the other treatment alone (**Table 11**). Of these, 10 [121,132,135,173,177,234-238] combined EStim with PFMT (EStim + PFMT vs. PFMT), while the other two studies [171, 218] combined EStim with PFMT and biofeedback (EStim + PFMT + BF vs. PFMT + BF).

Two studies were three-arm trials that included both PFMT and PFMT plus sham EStim as two of the study arms [135,236]. These arms were classified as being equivalent to PFMT and combined in the analysis. In two other three-arm trials two of the study arms involving EStim were also combined [107,218]. In one, ESim arms included faradism and interferential therapy [218]; in another, maximal and low intensity EStim were included [171].

1. Quality of data (risk of bias)

Allocation concealment was inadequate in two studies that used consecutive (alternative) assignment (quasi-randomisation) [171,236]. Allocation concealment was also suboptimal in another two in which sealed consecutively numbered envelopes were used but it was unclear whether they were opaque and whether a third party was involved in the allocation procedure [218,237]. The remainder (66%) did not mention allocation concealment. In six (50%) studies, results were reported for everyone who entered the trial [121,132,173,235,237,238], but this was not done in one [234] and unclear in three others [135,171,218].

2. Results

A. EStim + PFMT vs. PFMT

(a) SUI or predominant SUI. Pooled data found no evidence of a difference between the groups in terms of cure [121,132,177,234,235] or improvement [121,132,177]. Adverse effects were reported in one study [121]; the group randomised to EStim with PFMT recorded four occurrences (6%) of vaginal irritation due to application of EStim devices, compared with none in the PFMT only group. Quality of life was also reported only in one study [121]; the results based on the IIQ found no difference between the groups (no further data was provided).

(b) SUI, UUI and MUI. Data available from one study found no significant difference between the groups for either cure or improvement [237]. One small study using the KHQ reported that quality of life was on average better after EStim compared with no EStim during the treatment and at three-month follow-up [173]. The differences reached statistical significance at three-month follow-up. No adverse effects were reported.

B. EStim + PFMT with biofeedback vs. PFMT with biofeedback

SUI. Pooled data from two studies found no difference between the groups in terms of the improvement rate [171,218]. Improvement rates at six

months after the end of the initial treatment phase did not differ between the groups in either study. No data were available on cure rates, adverse effects and quality of life.

3. Summary

For comparisons of EStim with PFMT versus PFMT alone, there was no evidence of a difference between the groups in women with SUI or MUI (in which SUI was the predominant symptom) **(Level of Evidence: 2)**. There was also no evidence to suggest that the addition of EStim to a BF-assisted PFMT was more effective than BF-assisted PFMT in women with SUI **(Level of Evidence: 2)**. A few women experienced side effects with EStim. There is no evidence to draw any conclusion about the effect of adding EStim to PFMT for women with UUI.

4. Recommendations

The addition of EStim to PFMT or BF-assisted PFMT programmes does not appear to add benefit **(Grade of Recommendation:B)**; this hypothesis needs to be investigated further with high quality trials if it is a clinical/research question of interest to women.

3. OTHER LUTS

No trials were identified that analysed the effect of EStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcomes of EStim. Regarding age, there was no clear indication from the included trials that EStim could not be tolerated by elderly. On this basis there is no reason to exclude older women from studies of EStim, or not to offer EStim as part of a conservative management programme, except where recognised contraindications such as a cardiac pacemaker are present. However, it should be noted that this section considered the effect of EStim from studies recruiting independent, community dwelling women; the frail elderly are considered in the chapter on the elderly.

Of note, in a prospective cohort of 3,198 women treated with home-managed EStim in Norway during 1992-1994, there was no association between self-reported improvement and age [239]. In the same cohort, success rates defined by clinicians were higher in younger individuals but this effect was no longer significant after controlling for other factors.

Aside from age, other factors may have the potential to mediate treatment outcome. On the basis of trial reports to date, it appeared that there was considerable variation in EStim protocols with no consistent pattern emerging. EStim protocols are also often poorly reported, lacking detail of stimulation parameters, devices and methods of delivery. The wide range of protocols that have been tested may have impacted on the effect estimates reported in this section.

It is not clear whether one diagnostic group may benefit more than another from EStim. It has been hypothesised that, in women with SUI who cannot voluntarily contract the PFM to begin a PFMT programme, EStim might help initiate or substitute for a voluntary contraction. However, most studies focusing on the efficacy of EStim do use EStim to initiate or substitute for a voluntary PFM contraction [240]. To date, there has been no trial addressing this hypothesis.

EStim is reported to be unsuccessful in women with major descent of the vagina and prolapse of the uterus [228]. Additionally, denervated PFM muscles might not respond to EStim [241]. This means that in women with reduced or no integrity of the relevant nerve pathways EStim provides no or little chance of cure/improvement [217]. It has also been reported that treatment will fail if EStim does not increase urethral pressure profile, although age, oestrogenisation, and urethral mobility may also affect urethral pressure profile and may influence therapeutic outcome [242]. It is unfortunate that it is difficult to assess individuals easily in the clinical setting with regard to integrity of the sacral arc, and other factors, to determine the suitability of EStim as a treatment modality.

As with all conservative therapy modalities, one of the key factors to the success or failure of EStim is treatment adherence. Some authors commented on adherence or reported adherence data. However, adherence measures were highly variable, making comparison across studies difficult. Adherence to EStim was satisfactory and could be attributed to the physician motivating individuals to continue with EStim if they considered stopping prematurely [229]. 'Excellent' or 'good' adherence was observed in 45% of the study participants in one study and this did not differ between EStim and sham [234]. However, another [243] reported that the proportion of women achieving 80% adherence was lower in the active EStim group (61%) compared with the sham group (89%). Bø [134] reported a 75% adherence rate, although it is not clear how this compares with the non-active control group (instruction in the use of an anti-incontinence device). Nevertheless, adherence to EStim was less than that for PFMT (93%) in the same trial, and the reasons for non-adherence to EStim were a lack of motivation and discomfort. Knight [218] reported adherence to home-based low intensity EStim (72.5%) was somewhat higher than that for clinic-based maximal intensity EStim (percentage not reported).

V. MAGNETIC STIMULATION (MSTIM)

MStim has been developed for noninvasive stimulation of both central and peripheral nervous systems [244]. MStim for the treatment of UI was reported

for the first time in 1999 by Galloway [245]. In contrast to EStim, extracorporeal magnetic innervation (more commonly called magnetic stimulation) stimulates the PFM and sacral nerve roots without insertion of an anal or vaginal probe [246] For treatment, the individual is positioned in a chair. Within the seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit (**Figure 4**). A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the individual's perineum is centred in the middle of the seat, which places the PFM and sphincters directly on the primary axis of the pulsing magnetic field (**Figure 5**). Because of this, all tissues of the perineum can be penetrated by the magnetic field. According to Galloway [1999] no electricity, but only magnetic flux enters the body from the device. Goldberg [2000] has suggested that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue impedance, creating a theoretical advantage in its clinical application compared to EStim as structures such as sacral roots or pudendal nerves can be magnetically stimulated without discomfort or the inconvenience of a vaginal or rectal probe. Conventional magnetic stimulators deliver, at frequencies of 10 to 50 Hz, repetitive pulses of current lasting less than 100 μsec [246] and 275 Φs [245] in duration. Size and strength of the magnetic field is determined by adjustments of this amplitude by the therapist [245].

Possible advantages of MStim are that it is performed through full clothing, needs no probes, skin preparation, or physical or electrical contact with the skin surface. On the other hand, the need for repeated clinic based treatment sessions is a potential disadvantage. In contrast to EStim, MStim lacks portability, although in 2003 [247] reported the development of a portable small electromagnetic device (Pulsegen) for home use that fit into the underwear and was designed for continuous use for up to 8 weeks. Furthermore, because both the depth and width of magnetic field penetration is proportional to coil diameter, the present technology is still best suited for stimulation of a field, rather than a narrowly focused target as the sacral roots or the pudendal nerve [246].

MStim of the sacral nerve roots and pelvic floor is said to be effective for both UUI and SUI [246] , although the mechanism of action is not fully understood [248]. Some authors have suggested that in SUI stimulation of the PFM causes external sphincter contraction [249], acts as a passive PFMT exercise [250], and increases maximal urethral closure pressure [247]. In UUI, MStim might suppress DO through activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibres at the spinal reflex arc, activation of inhibitory hypogastric sympathetic neurons, or a combination of both mechanisms [251]. Stimulation of sympathetic fibres maintaining smooth muscle tone within the intrinsic urethral sphincter and modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root, are also suggested to play a role in this mechanism of action [251].

In this section the evidence is considere for the use of MStim for the prevention and treatment of UI in women. Questions addressed are:

- Is MStim effective in the prevention of UI?
- Is MStim better than no active treatment (placebo, sham, control or no treatment) for the treatment of UI?

- Is one type of MStim better than another in the treatment of UI?
- Is MStim better than other treatments in the treatment of UI?
- Does the addition of MStim to other treatments add any benefit in the treatment of UI?
- What is the effect of MStim on other LUTS?
- What factors might affect the outcome of MStim in the treatment of UI?

Description of intervention

Ten trials were identified. Characteristics of the MStim intervention in the included studies are summarised in **Table 12**. Two further trials that did not specify the gender of the participants were found: a cross-over trial comparing MStim plus PFMT with sham MStim plus PFMT for 56 individuals with UUI (due to DO) or SUI [252]; and a comparison of MStim with sham MStim for 87 participants with UUI (due to DO) or SUI [253]. These trials did not contribute to the analysis. **Table 12** illustrates the intervention characteristics.

1. PREVENTION

No trials investigating the primary or secondary prevention effects of MStim for women with UI were found.

2. TREATMENT

a) Is MStim better than no active treatment (placebo, control or no treatment)?

Nine RCTs comparing MStim with sham for women with UI were found. Characteristics of studies comparing magnetic stimulation with no active treatment are presented in **table 13**. One report by Gilling [2002] [254] was an abstract. The trial, which has not yet been fully published, appears to be related to Gilling [2001] [255] of which a full report was published in 2009 [256] (comparing MStim plus PFMT with PFMT alone), but there was insufficient information to verify this. No data were available for any of the pre-specified outcomes. Of the nine included trials, three assessed the efficacy of a magnetic stimulator developed for home use, whereas in others treatment was provided in the clinic setting [247, 257, 258].

1. Quality of data (risk of bias)

Allocation concealment was considered to be adequate in three (33%) trials that used numbered devices of identical appearance [247, 257, 259], or involved a randomisation list in a locked drawer only accessible to a member who had no other involvement in the trial. Allocation concealment was assessed as being suboptimal in one study [258] that used sealed envelopes but did not mention whether envelopes were opaque nor any involvement of a third party in the allocation process. Another five (56%) did not describe methods used for allocation concealment [254, 260-263]. Two studies reported data for all participants randomised [260, 261]. In three, data were reported only for those participants who completed the study [247, 259, 263]. In particular, in the study by Morris [2007] only 29 of 44 (66%) women randomised completed the study, including 10 women deemed ineligible after randomisation. The number of women lost to follow-up was not clearly reported in the other four (45%) trials [247, 254].

2. Results

(a) SUI. Data on cure and improvement rates were reported in one study [Fujishiro, 2000]: on average active treatment (single session) was better than sham treatment both in terms of cure and improvement but the difference was statistically significant only for improvement. One other study that provided stimulation for three days a week for two weeks (six sessions in all) that also measured cure and improvement did not provide any data but reported no statistically significant differences [262].

Information on quality of life was provided in two studies using different measures [261,262]. One study using the KHQ did not report a total score but scores on all questionnaire items were similar between the groups either at one week or one month after the intervention [262]. The second study did not describe how quality of life was ascertained but reported that mean scores did not differ significantly between the groups [261]. No adverse effects were observed in one of these studies [261].

(b) UUI. Suzuki and colleagues (2007)[263] conducted a cross-over trial including 16 men and 23 women with UUI refractory to PFMT [263]. Participants were randomised to either 10-week active treatment, four-week no treatment and 10-week sham treatment (A-S group) or 10-week sham treatment, four-week no treatment and 10-week active treatment (S-A group). Only quality of life outcomes were reported separately for women, based on the International Consultation on Incontinence-Questionnaire: Short Form (ICIQ-SF), in which lower scores indicate better quality of life. In women in the A-S group, ICIQ-SF scores (mean, SD) decreased from baseline by 4.6 (3.9) at 10 weeks and 3.5 (3.5) at 24 weeks. The corresponding scores in women in the S-A group were 1.3 (2.9) at 10 weeks and 4.5 (4.2) points at 24 weeks. These results were interpreted by the study authors to mean that active MStim was more effective than sham MStim. There was no report of adverse effects.

(c) MUI. In one small study, active treatment resulted in statistically significantly higher improvement rates compared with sham treatment [257]. There were no adverse effects in either group. Information on cure and quality of life was not available.

(d) SUI, UUI, or MUI. One small study reported statistically significant differences in favour of active treatment for cure or improvement [247]. In

Table 12: Characteristics of magnetic stimulation (MStim) in the included studies

Study	Intervention description
But 2003 [247]	Pilsegen device for home use, worn in specially designed underwear day and night for 2 months. Magnetic field intensity B max = 230 µT ±10%. Pulse frequency 10 Hz.
But 2005 [257]	Pilsegen device for home use, worn in specially designed underwear day and night for 2 months. Pulse frequency 18.5 Hz.
Fujishiro 2000 [261)	In prone position, using a rapid rate stimulator with a rapid 90 mm circular coil. Coil fixed over the sacrum to cover the bilateral third sacral foramina. A 15 Hz repetitive magnetic stimulation on the sacral roots with 50% intensity output for 5 seconds per minute for 30 minutes.
Fujishiro 2002[260]	In prone position, using a rapid rate stimulator with a rapid 90 mm cicular coil. Coil fixed over the sacrum to cover the bilateral third sacral foramina. A 15 Hz repetitive magnetic stimulation on the sacral roots with 50% intensity output for 5 seconds per minute for 30 minutes.
Gilling 2001 [255)	NeoContol chair with an inbuilt magnetic coil for 10 minutes at 10 Hz followed by 3-minute rest, and 10 minutes at 50 Hz. Intensity adjusted to the maximum level tolerated. Total: 16 treatments (3 per week) over 6 weeks.
Gilling 2002* [254]	16 treatments
Lee 2004† [264]	Fully clothed and seated on a special chair, 20 minutes, 2-3 times a week for 12 weeks.
Manganotti 2007 [262]	Chair using a rapid rate stimulator with a 90 mm circular coil. Repetitive 15 Hz magnetic stimulation over the distal cauda at 60% intensity for 15 minutes, 3 days/week for 2 weeks.
Morris 2007 [259]	Neocontrol device for two 10-minute periods of stimulation at 10 Hz, at individual maximum tolerance, separated by 2 minutes rest. 20 treatment sessions over 6 weeks, with at least 36-72 hours between sessions.
O'Reilly 2008 [258]	Trans-sacral magnetic stimulator for home use, applied using a small belt device over the S3 and S4 sacral foramina for 20 min each day for 12 weeks. Pulse rate between 5 and 20 Hz with pulse width of 1 ms producing a magnetic field of 200 G.
Suzuki 2007 [263]	Armchair type stimulator. 10Hz continuously with 300 µsec for 20 minutes, 1/week for 10 weeks.

Table 13. Characteristics of studies comparing magnetic stimulation (MStim) with no active treatment

Author	Comparator	N	Study population	Treatment duration (months of treatment or when outcome was measured)	Source of outcome**	
					Cure	Improve-ment
SUI						
Fujishiro 2000 [261]	Sham MStim	62	SUI	1 session (outcome measured at 1 week]	Quantified	Quantified
Gilling 2002 [254]* (ongoing)	Sham MStim	43	SUI	NR	NR	NR
Manganotti 2007 [262] (preliminary investigation)	Sham MStim	20	SUI	0.5(outcome measured at 1 month)	Quantified	Quantified
UUI						
Suzuki 2007 [263] (cross-over trial)	Sham MStim	23	DO with UUI	1.25	NR	NR
MUI						
But 2005 [257]	Sham MStim	39	MUI	2	NR	Patient reported
Any UI						
But 2003 [247]	Sham MStim	55	SUI, UUI or MUI	2	Patient reported	Patient reported
DI/OAB (wet or dry)						
Fujishiro 2002 [260]	Sham MStim	37	DI (UUI or urinary frequency)	1 session (outcome measured at 1 week)	NR	NR
Morris 2007 [259]	Sham MStim	44	Idiopathic DO (some had UUI)	0.75	NR	NR
O'Reilly 2008 [258]	Sham MStim	63	OAB (some had UUI)	3	NR	Patient reported

*Foot notes: NR = not reported; * abstract only; **Source of outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.*

this study, one of 31 women in the active treatment group had lumbar-ischial pain in the right leg and withdrew from treatment, whereas none of 24 women in the sham group experienced any adverse effects. Information on quality of life was not provided.

(e) DO (wet or dry). One small study reported that improvement rates did not differ significantly between active and sham treatments [258]. No information was available regarding cure rates. Quality of life outcomes were reported in three studies using different measures [258-260]. There was no difference between the groups in terms of the IIQ or the Urogenital Distress Inventory [259] or between KHQ or the Australian Quality of Life questionnaire [258]. There was one report of statistically significant better qualify of life scores for treatment than sham, although it was unclear how this was ascertained [260]. No adverse effects were noted.

3. Summary

Since there was little duplication of MStim interventions, or sample populations, in the nine small trials, it was not thought appropriate to combine study findings. For women with SUI a single trial showed that one session of sacral root MStim might be more effective than sham in improving symptoms **(Level of Evidence: 2)**, but another trial suggested that six sessions of a chair-based MStim might be no better than sham **(Level of Evidence: 2)**. For women with UUI, evidence from a small trial suggests that active MStim might result in better quality of life than sham **(Level of Evidence: 2)**, although there is some uncertainty surrounding this. Active MStim was associated with higher cure rates than sham in a small trial with women with MUI **(Level of Evidence: 2)**, and also higher cure and improvement rates in another small trial with women with SUI, UUI or MUI **(Level of Evidence: 2)** but no such difference was observed for women with DO (wet or dry) **(Level of Evidence: 2)**. In general, adverse effects appear uncommon.

4. Recommendations

Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence **(Level of recommendation: D)**.

b) Is one approach to MStim better than another?

One study from Korea [264] compared the effect of pelvic floor MStim with BIOCON compared with stimulation via NEOCONTROL for females with SUI (**Table 14**). This report was published in Korean. Data were extracted only from the abstract and main data tables that were reported in English.

1. Quality of data (risk of bias)

Risk of bias could not be assessed, because the trial was published in the Korean language and English translation was not available at the time of writing.

2. Results

Any UI. No statistical difference was found between the groups in terms of cure of UUI or cure of SUI. Quality of life scores based on the Bristol Female Urinary Tract Symptoms were also similar between the groups.

3. Summary

There is insufficient evidence to determine if one type of MStim is better than another **(Level of Evidence: 2)**. No recommendation is possible **(Level of Recommendation: D)**.

c) Is MStim better than other treatments?

There was a single trial by Yamanishi and colleagues that addressed this comparison [223]. In this trial, MStim was compared with intravaginal EStim in 17 women and 15 men with either idiopathic or neurogenic DO. As data were not reported separately by gender and by diagnosis, it is not clear whether there is any difference in effect of MStim compared to EStim for women with idiopathic DO.

d) Does the addition of MStim to other treatments add any benefit in the treatment of UI?

One trial [255] was identified for this comparison. This report was initially available only as an abstract published in 2001. Subsequently, a full-text publication became available in 2009 [256], although participants were followed up for six months post-intervention and no further follow-up was reported. It should be noted that the aim of the trial was to compare active and sham MStim treatments, rather than to examine the effect of MStim as an adjunct to PFMT. Because trial participants had varying degrees of pre-existing knowledge about their condition and available treatments such as PFMT, low-intensity PFMT supervised by a uro-physiotherapist was added to both groups in order to minimise a potential bias. Characteristics of studies comparing MStim combined with another treatment with the other treatment are presented in **table 15**.

1. Results

SUI. The trial found no statistically significant difference for any outcome between the active and sham groups at eight weeks or 6 months (cure; Incontinence Quality of Life questionnaire, KHQ) [255].

The study authors postulate that PFMT performed in each arm of the trial might have concealed any small additional benefit from MStim. This was supported by a post hoc subgroup analysis which suggested that the women with poor PFM tone at baseline (and therefore unlikely to have performed PFMT properly) did better with active treatment than sham treatment.

2. Recommendation

Based on current evidence **(Level of Evidence: 2)** the addition of MStim to PFMT does not appear

Table 14: Characteristics of studies comparing one type of magnetic stimulation (MStim) with another

Author	Comparator		N	Study population	Treatment duration (months)	Source of outcome**	
						Cure	Improve-ment
Any UI							
Lee 2004† [264]	BIOCON MStim	NEO-CONTROL MStim	49	Any UI	3	Patient reported	NR

*Foot notes: NR = not reported; **Source of outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy. † Publication in Korean with abstract and tables. English translation of the main text was not available at the time of writing.*

Table 15: Characteristics of studies comparing magnetic stimulation (MStim)S combined with another treatment with the other treatment

Author	Comparator		N	Study population	Treatment duration (months)	Source of outcome	
						Cure	Improvement
Gilling 2001 [255]	MStim + low-intensity PFMT	Sham MStim + low-intensity PFMT	70	SUI	0.75 (outcome measured at 2 and 6 months after treatment)	Quantified	NR

*Foot notes: NR = not reported; **Source of outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.*

to be beneficial **(Grade of Recommendation: C)**. This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

3. Other LUTS

No trials were identified that analysed the effect of MStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

4. Factors affecting outcome

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. In one early prospective multi-centre study, factors predicting success of MStim were included [243]. Treatment success was associated with no prior hysterectomy, no prior anti-incontinence operations, UI symptoms for less than 10 years, and no use of medications known to cause UI. Brodak has suggested that detrusor response to stimulation might be better in 'thin' individuals (presumably due to a shorter distance between the stimulating coil and the sacral nerve roots) and at low bladder volumes [265]. Overall, little is known about the factors affecting the outcome of MStim.

VI. SCHEDULED VOIDING REGIMENS

This section examines the evidence on use of scheduled voiding regimes in cognitively intact, non-institutionalised women with UUI, SUI, and MUI and provides recommendations for their use in clinical practice. A summary of the search strategy and inclusion/exclusion criteria for selecting studies for review is provided (See appendix). The chapters on the Frail Elderly and Neurogenic Incontinence provide detailed review of scheduled voiding regimens that are used in those with cognitive impairment, or UI secondary to central nervous system or spinal cord disease.

Scheduled Voiding Regimens

Bladder training is a broad term often used to describe any type of a scheduled toileting intervention. This has created conceptual confusion in interpreting research reports where few details are provided other than the statement that bladder training was used. The types of scheduled voiding regimens can be categorised as: bladder training, timed voiding, habit training, and prompted voiding [266]. Although these regimens share a common feature of a toileting schedule, they differ on the basis of adjustments to the voiding schedule, the active or passive involvement of the patient, the nature of patient education including the teaching of strategies to control urgency and prevent stress leakage, the use of reinforcement techniques, and the nature of the interactions between clinicians and patients. In practice, however, scheduled voiding regimens may share aspects of one or more of these features.

Bladder training

Bladder training (also referred to as bladder drill, bladder discipline, bladder re-education, and bladder re-training) involves a programme of patient education along with a scheduled voiding regimen with gradually progressive voiding intervals. Specific goals of bladder training are to correct faulty habit patterns of frequent urination (if present), improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient confidence in controlling bladder function. The underlying mechanism of how bladder training achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved

cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from better individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the "reserve capacity" of the lower urinary tract system [189,267,268]. A Cochrane review of bladder training was last updated in 2010 [269].

Timed voiding

Timed voiding is a fixed voiding schedule that remains unchanged over the course of treatment [266]. The goal is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity. Timed voiding has been recommended for patients who cannot participate in independent toileting [270]. It also has applicability for use in outpatient settings with incontinent women who have infrequent or irregular voiding patterns [271] and men who are independent in their voiding function [272]. A Cochrane review of timed voiding was last updated in 2009 (published 2010) [273].

Habit training

Habit training is a toileting schedule matched to the individual's voiding pattern based on an their voiding diary. The toileting schedule is assigned to fit a time interval that is shorter than the person's normal voiding pattern and precedes the time period when incontinent episodes are expected. Thus, the voiding interval may be lengthened or shortened throughout the day depending on the patient's voiding pattern with the goal to pre-empt UI. Habit training is usually implemented by caregivers, in institutional settings with cognitively and/or physically impaired adults, but it has also been tested in homebound older adults [274]. It is potentially useful for adults without cognitive or physical impairment, who have a consistent pattern of UI [271].

A Cochrane review on habit training was updated in 2009 and published in 2010 [275] following first publication in 2004. Prior to this, the last literature review was published in 1986 [266]. The Cochrane review identified three trials that described the effects of habit training combined with other treatment components compared to usual care on the frequency and severity of UI [274, 276, 277]. A fourth trial compared habit training alone with habit training and an electronic monitoring device [278]. Participants from the first three trials were primarily care-dependent women with cognitive and/or mobility impairment, and the fourth trial comprised men and women with a mean age of 83 years and thus, did not meet the criteria for this chapter. No studies were located that investigated habit retraining in independent-living women.

Prompted voiding

Prompted voiding refers to a caregiver education programme in combination with a scheduled voiding regimen, typically every two hours. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so [279]. It has been used primarily in institutionalized settings with cognitively and physically impaired older adults. In a 2009 Cochrane review of prompted voiding [279], nine trials were identified involving 674 elderly people, mainly women. These trials did not meet the criteria for this chapter as the samples were drawn from care home settings and comprised elderly individuals with impaired cognitive and/or functional ability.

This section will examine the evidence for the use of timed voiding and bladder training for the prevention and treatment of UI in non-institutionalised women of all ages without cognitive or mobility impairments. However, the majority of evidence available pertains to bladder training thus the effects of bladder training are the focus of this section.

Questions addressed are:

- Can scheduled voiding regimes prevent UI?
- What is the most appropriate bladder training protocol?
- Is bladder training better than no treatment, placebo or control treatments?
- Is bladder training better than other treatments?
- Can any other treatment be added to bladder training to add benefit?
- Does the addition of bladder training to other treatments add any benefit?
- What is the effect of bladder training on other LUTS?
- What factors might affect the outcome of bladder training?

This section is based on previously published systematic reviews, including Cochrane reviews, and additional searches of the literature. Studies that were excluded from prior systematic reviews, due to the inclusion criteria for the review or restriction to RCTs or quasi-RCTs, were also considered. Conference abstracts were considered where adequate information was available.

1. PREVENTION

No trials were identified that examined scheduled voiding regimens as a sole intervention in the prevention of UI.

2. TREATMENT

Three systematic reviews on bladder training were located that provided descriptive synthesis with evidence grading [269, 270, 280]. The third is a published Cochrane review that has been updated in 1999, 2004, 2007, and 2010 [269].

a) What is the most appropriate bladder training (BT) protocol?

No trials were identified that compared two or more methods of bladder training (BT). In the absence of trials comparing two or more approaches, a content analysis of the protocols used in trials investigating the effects of BT was performed. Seventeen trials on BT involving a total of 2462 women were identified. Six of the trials provided no or minimal details regarding the specific BT protocol used [128,269,281-285]. In trials that did provide some description, BT protocols were implemented in several ways.

All protocols involved some type of patient education, namely:

- Brief verbal [282,283] or written instructions [286, 287]
- Verbal, written, and audiovisual instruction [189, 268, 288]
- Introduction to an individual who successfully completed BT [284]

If specified, the education was provided by nurses [128,189,268,281,289,290], or general practitioners [291].

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant's voiding pattern or 30 minutes beyond the participant's average voiding interval [287,292].
- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens [284], after 48 hours of dryness [293], every four to five days [292], or weekly if schedule was well-tolerated [189,268].
- Goals for optimal voiding interval varied from three to four hours.
- Voiding was 'mandatory' with restriction of voiding in between assigned toileting times even if UI occurred [284], a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable [189,268,289], or self-scheduling of voiding with a target goal to reach [286].
- Voids were not scheduled (allowed) during sleeping hours [284]; none of the other protocols identified how voids were handled during sleeping hours.

In some protocols the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation [189, 268, 286, 287, 289], and pelvic floor muscle contraction [189, 281, 287]. In other studies there was encouragement to suppress urge but it was not clear what strategies were used [48, 283, 291]. Feedback techniques included self-monitoring [189, 268, 282, 285, 289], goal setting with feedback of progress [290], and positive reinforcement [189, 268, 292].

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments [48,288,289]
- Fluids allowed up to a certain level (1,500 ml) [293]
- No fluid modifications [189,268,286,291]
- Advice on constipation prevention [289].

Both in and outpatient BT programmes have been used. Early inpatient BT programmes involved five to13 days of hospitalisation to ensure strict protocol adherence [284]. Outpatient programmes are more commonly described and the amount of health professional contact had ranged from weekly visits for six weeks with fortnightly telephone calls for six additional weeks [189], to weekly visits [128,268], fortnightly visits [292], and monthly visits [293].

Overall, there is a lack of consistency in BT protocols. Based on the protocols described, a reasonable outpatient BT protocol is shown in **Figure 6.**

Box: Typical Bladder Training Regimen

- an initial voiding interval typically beginning at one hour during waking hours, which is increased by 15 to 30 minutes per week depending on tolerance of the schedule (such as fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the woman's feeling of control over urgency and confidence to expand the voiding interval), until a two to three hour voiding interval is achieved. A shorter initial voiding interval, e.g. 30 minutes or less, may be necessary for women whose baseline micturition patterns reveal an average daytime voiding interval of less than one hour.
- education about normal bladder control and methods to control urgency such as distraction and relaxation techniques and PFM contraction.
- self- monitoring of voiding behaviour using diaries or logs in order to determine adherence to the schedule, enhance self-awareness, evaluate progress, and determine whether the voiding interval should be changed. **FIGURE 6** from 2009
- a supervising health care professional to monitor progress, suggest adjustments to the voiding interval, and provide positive reinforcement to women undergoing BT at least weekly during the training period.

If there is no improvement after three weeks of BT, re-evaluation is warranted and other treatment

Figure 6: Self-monitoring of voiding behaviour (Courtesy of Dr Jean Wyman, University of Minnesota, USA)

options would be considered. Inpatient BT programmes may follow a more rigid scheduling regimen with progression of the voiding interval on a daily basis.

1. Summary

There is no trial evidence to suggest the most effective method or specific parameters of BT. For those undertaking BT it is likely that more health professional contact will be better than less, based on the developing evidence for PFMT, which like BT, requires behavioural change. The literature suggests several variables that could be investigated in future trials including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

2. Recommendations

It is not clear what the most effective BT parameters are. Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of BT parameters or approach **(Grade of Recommendation: D).** Clinicians should provide the most intensive BT supervision that is possible within service constraints **(Grade of Recommendation: D)**. More research is needed to investigate which BT parameters, supervisory intensity, and adjunctive treatments are most effective. Future trials should include outcomes that matter to patients including the length and frequency of supervisory contact.

b) Is BT better than no treatment, placebo or control treatments?

BT as the sole therapy has been used in the treatment of DO, urodynamic SUI, MUI, UUI, UUI with a stable bladder, and OAB syndrome (also called urgency-frequency syndrome). Individual RCTs that met inclusion criteria and the Cochrane review [269] were used to address the question of whether BT is better than no treatment, placebo, or control treatments for UI.

Five RCTs reporting on 515 women were identified that compared the effect of BT to no treatment or control [128,268,285,289,291]. In one trial, it was not possible to identify the effect of BT alone, because results of participants in the treatment group who received BT (those with UUI or MUI) were combined with those who also received PFMT (SUI participants) [291]. However, in the Cochrane review, additional data were provided by the lead author to describe the women with DO who were randomised to BT versus control. In another trial with three consecutive treatments (self-monitoring, BT, and PFMT; with the decision for which treatments to implement based on participants' goals), it was difficult to discern the effect of BT alone as compared to a control group, because some participants had already undergone lifestyle modifications (caffeine and fluid modifications and constipation advice) and diary keeping in a prior self-monitoring condition [289]. Thus, this trial is not discussed further in this section. A recent trial by Diokno et al 2010 [288] compares group session teaching of a behavioural modification program (BMP) includes both bladder training and pelvic floor muscle training, thus it was not possible to determine the effect of BT alone in this study and it is not included in subsequent discussion.

There were four older trials with analysable data: Jarvis (1980) investigated the effect of an in-patient BT programme in 60 women aged 27 to 79 years with a diagnosis of DO or coexisting SUI, whereas three [128,268,291] examined the effect of an outpatient programme. Fantl (1991) studied the effect of a six week outpatient programme in 123 women aged 55 to 90 years with urodynamic SUI, DO, or both who reported an effect of an eight week outpatient programme in 50 women aged 35 to 55 years with UI (type not identified) who had pad test weights at least 1g or more and 14 or more voids during a two day diary. Lagro-Jansen (1992) studied the effect of an outpatient programme in 18 women aged 20 to 65 years who reported UUI twice or more per month and had urodynamically confirmed DO.

1. Quality of data

In one trial random allocation concealment was inadequate [291]; in the remainder it was not clear if allocation was concealed. One used stratification based on urodynamic diagnosis of urodynamic SUI and/or DO [268]. Blinding of outcome assessors was described in only one trial [128].

Sample sizes in the four analysable trials were 18 [291], 50 [128], 60 [285], and 123 [268]. Fantl (1991) reported a power calculation although details were not described. Losses to follow up were none in one trial, although it was not clear if this was due to having no dropouts or due to lack of reporting [285]. In the other two analysable RCTs, loss to follow up was 6% [268] and 14% [128]. Dropout rates at the immediate follow-up time point seemed similar between the BT and the control groups, ranging from 8% vs. 5%, respectively [268], to 10% versus 14%, respectively [128]. No trials reported whether analyses were based on intent-to-treat principles. Follow-up periods ranged from six [268], eight [128] and 12 weeks [285,291], with an additional evaluation six months [285] and nine months [268], after initiation of treatment. Two trials noted whether there were adverse events with BT [268,285]. No trial reported on adherence.

All of these RCTs, with the exception of the one by Jarvis (1980), were considered in the Cochrane review [269]. The Cochrane reviewers based their conclusions on data available from 172 women in the other three trials.

2. Results

Three of the four RCTs reported statistically significant improvements in the BT group compared to the control group incontinent episodes [268,285,291]; the fourth did not report data on incontinent episodes [128].

Jarvis (1980) reported that 90% of the participants in the treatment group were continent and 83% were symptom free at six months (method for determination of continence and symptom status was not specified but probably self-report) compared to 23% of the control group who were both continent and symptom free. All women who were symptom free after treatment reverted to a normal cystometrogram.

Twelve percent of participants in the treatment group were continent and 75% had reduced their incontinent episodes by at least 50% or more at six weeks, measured by a seven day voiding diary, compared to 3% of controls with no incontinent episodes and 24% with at least 50% reduction in their incontinent episodes [268]. These results were maintained at six months. Women with DO and those with urodynamic SUI with and without DO had similar improvement rates. Participants in the treatment group also significantly decreased the grams of fluid lost on a retrograde pad filling test by 54% with results maintained six months later; this was more pronounced in those who had DO with or without urodynamic stress UI. While some women did revert back to normal bladder function following BT, no relationship was found between changes in urodynamic variables and the number of incontinent episodes [294].

Lagro-Jansen [1992] reported that eight or nine patients in BT perceived improvement of UI compared to none of nine in the control group. Yoon (2003) reported that there was no difference between the BT and control groups in the amount of leaked urine at an immediate follow-up; however, it was not clear if this referred to pad test weights solely or a UI severity score. Conclusions from this trial are uninterpretable because of insufficient power.

The Cochrane review [269] noted that the few data available tend to favour BT; however, the scarcity of data implies that they should be interpreted cautiously.

3. Summary

The few trials available were small and of variable quality, there is minimal Level 1 evidence that BT may be an effective treatment for women with UUI, SUI, and MUI **(Level of Evidence: 1).**

4. Recommendations

BT is an appropriate first line conservative therapy for UI in women **(Grade of Recommendation: A).** Additional high quality studies are needed that examine the effect of BT versus no treatment in treatment of women with UUI, SUI, and MUI.

c) Is BT better than other treatments?

To be included in this section, trials needed to compare BT alone versus another active therapy. For the comparison of BT versus PFMT see B.2.3d. The only other comparison for which trials were found was BT versus drug therapy. Individual trial reports that met inclusion criteria and the Cochrane review [269] were used as the basis of the review of BT versus drug therapy.

Three RCTs were located that compared BT to drug therapy in 322 women [281, 284, 292]. The study by Park and colleagues [281] compared a 12-week BT programme to 2mg tolterodine twice daily in women (ages unknown) with OAB (unclear if UI was present); because there were no findings reported on UI, this trial is discussed in the section on Other LUTS (B.6.3). The two trials included in this section used a combination of flavoxate hydrochloride and imipramine [284], or used immediate-release oxybutynin chloride [292].

1. Quality of data

One trial reported adequate random allocation concealment [292]. Sample sizes were 50 [284] and 79 [292]. Neither trial reported a power calculation;

Follow up periods varied from four [284], six [292], and 12 weeks [284], and six months [292]. Both RCTs evaluated drug tolerability and adverse events. Dropouts were none in one trial; however, it is not clear whether this was a reporting issue [284]. In the other trial loss to follow up was 7% [292]. Neither trial identified whether intent-to-treat principles were followed. The conclusions of the Cochrane review [269] were based on the same trials.

2. Results

One RCT published in 1981 suggested that BT may be superior to drug therapy in women with DO [284]. Inpatient BT was compared to outpatient treatment of 200mg of flavoxate hydrochloride (three times a day) and 25mg of imipramine (three times per day) in 50 women aged 17 to 78 years with DO, and concluded that BT was more effective. In the BT group, significantly more patients (84%) became continent and symptom free (76%) assessed by self-report, as compared to the drug group where 56% became continent and 48% were symptom free at four weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks and more in the BT group perceived that they were cured at the end of the treatment phase and approximately two month after treatment ended. Adverse events included dry mouth, dizziness, headache, nausea, vomiting, and drowsiness in participants who received drug therapy; there were none with BT.

A similar clinical cure rate (i.e. self-reported total disappearance of UUI, no protective pads or further treatment) was reported in outpatient BT women aged 24 to 65 years with DO [292]. 'Clinical cure' was observed in 93% and 62% of patients with DO, 67% and 75% of those with low compliance bladder, and 60% and 81% of those with urgency-frequency syndrome in those randomised to oxybutynin and BT respectively. The relapse rate at six months was higher for the drug group. In the analysis by the Cochrane Group (2010) participants' perception of cure was not statistically significant at the end of the treatment phase but favoured BT six months after the treatment ended. Perceptions of improvement were also higher in the BT group at the end of the treatment phase but this difference was not statistically significant. Adverse events included dry mouth, constipation, nausea and tachycardia in patients who received drug therapy, with none in those who received BT.

3. Summary

It is not clear whether BT is more effective than drug therapy for women with DO or UUI **(Level of Evidence: 1)**. This is consistent with the findings of the Cochrane review [269], which concluded that there was not enough evidence to determine whether first line therapy should be BT or anticholinergic drugs.

4. Recommendations

In a choice between BT and anticholinergic drug for women with DO or UUI, either may be effective **(Grade of Recommendation: B)**. BT may be preferred by some clinicians and women because it does not produce the side effects and adverse events associated with drug therapy **(Grade of Recommendation: D).**

d) Can any other treatment be added to BT to add benefit?

To be included, trials needed to investigate the effects of BT versus BT plus therapy A to address the additive benefit of therapy A. Trials addressing the additional benefit of three other treatments were found: caffeine reduction, PFMT, and drug therapy. The trial addressing the added benefit of caffeine reduction [48] is considered in the section on Lifestyle Interventions (A.I.2d), and the trial addressing the added benefit of PFMT [189] is considered in the section on PFMT (A.II.3e). The trials addressing the added benefit of drug therapy are considered below.

One RCT was found that compared BT alone versus BT with tolterodine (2mg, twice daily) in women with OAB [281]. However, incontinence status of the participants was unknown, and details regarding the study methodology were limited (abstract only). Therefore this trial was not considered further in this section.

A further three RCTs compared BT with placebo drug versus BT with drug therapy in patients with DO. One of these used terodoline (a drug that was withdrawn from the market) [283]. Therefore, this trial was not considered further in this section. In the other two trials the drugs used were imipramine [293] and immediate release oxybutynin [282].

Castleden [1986] studied 34 patients with DO (28 women aged 30 to 91 years and six men). Szonyi [1995} recruited 60 patients aged 70 years and over (56 women, four men). While it is possible that the placebo drug could augment BT, and both these trials included a small number of men in addition to women (and data for women were not reported

separately), a pragmatic decision was made to review these two trials in this section.

1. Quality of data

Adequate random allocation concealment, or blinding was not reported in either study [282,293]. Study size was based on a power calculation in one [282]. Post-treatment follow up periods were variable. One trial evaluated participants at six weeks [282]; 16 were lost to follow up. The other did not have a clear endpoint but followed participants for one to 11 months; one participant was lost to follow-up [293].

2. Results

It was not possible to discern the treatment effects in only women in these two trials, and the findings were inconsistent. More participatents became dry on BT plus imipramine 25mg or more per day (14 of 19) compared to those in the BT plus placebo group (six of 14), but the authors reported that there was no statistically significant difference in outcome between the two groups [293]. One patient in the imipramine group became confused and another complained that the drug made him feel ill. Several patients taking imipramine reported dry mouth and constipation (data not reported), but none on placebo.

No difference was found in a comparison of BT plus 2.5mg of immediate release oxybutynin (twice daily) compared to BT and placebo for reducing incontinent episodes [282]. The authors concluded, however, that the combined therapy group was superior to the BT and placebo group, because it had greater subjective benefit (86% versus 55%), and adverse events were similar in the two groups at 50%.

3. Summary

In two small trials comparing BT plus placebo drug versus BT plus drug in DO, there was a suggestion that the effect of BT might be enhanced by active drug **(Level of Evidence: 2)**. However both trials were small, placebo controlled, conducted in gender mixed sample populations, and the outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with drug therapy.

4. Recommendations

Direct comparisons of BT versus BT with drug are needed to address the question of whether the effect of BT can be augmented by drug therapy.

e) Does the addition of BT to any other treatment add benefit?

To be included, trials needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. Trials were located that investigated the effects of PFMT alone versus PFMT plus BT, and drug therapy alone versus BT plus drug therapy.

A new trial compared Solifenacin (5/10mg) alone with Solifenacin and bladder training [287]. One older study (Wyman 1998) compared BT, PFMT, and combination therapy in 204 community dwelling women aged 45 years and older with SUI and/or DO [189]. Two RCTs were identified that compared BT plus tolterodine (2mg twice daily) [281,286] to drug therapy alone. In one three arm trial [281], women with OAB were enrolled but it was unclear if UI was present. Therefore this trial was not considered further.

1. Quality of data

(a) BT plus PFMT versus PFMT alone: In an early, three arm RCT women were ransomised to PFMT (n=69) or PFMT with BT (n=67) [189]. Outcomes were assessed after the 12 week intervention and three months later. It was not clear if random allocation was adequate or outcome assessors were blind. Study size was based on a power calculation. Losses to follow-up were six at 12 weeks, and 16 three months later.

(b) BT plus drug therapy versus drug therapy alone: Mattiasson [2003] evaluated “simplified” BT (consisting of a one page instruction sheet) in a single blind study of 501 participants (378 women and 123 men) aged 18 years and over with OAB with or without UUI. Allocation concealment, blinding of assessors, and a prior power calculation were not described. Post-treatment follow-up was 12 weeks, and then 24 weeks. Seven participants were lost to follow-up: five in drug therapy and two in combination therapy. Analyses were based on intent-to-treat principles. However, because of reporting issues, it was not possible to discern the effect of treatment in women alone. In 2010, Mattiasson compared solifenacin alone with solifenacin and bladder training in a prospective, parallel group, open label study of 643 men and women with OAB, it was not possible to identify the treatment effect in women alone (85% of sample were women).

2. Results

(a) BT plus PFMT versus PFMT alone: Post-treatment the combination therapy group had significantly fewer incontinence episodes compared to PFMT alone. More women in the combination therapy group than PFMT group reported cure (31% versus 13% respectively), or 50% improvement or more (70% versus 50%). The combination therapy group also reported greater perception of improvement and more satisfaction with treatment than PFMT alone. However, three months later between group differences were not statistically significantly different for cure (27% versus 20%), improvement (59% versus 56%), perception of improvement, or satisfaction with treatment.

(b) BT plus drug therapy versus drug therapy alone: Mattiasson (2003) reported no difference between participants who received brief written BT instructions plus tolterodine versus tolterodine alone with

respect to reducing incontinent episodes (median reduction 87% vs. 81%, respectively). Data were combined for men and women and most data were not presented separately for those who had UI versus those who did not. Mattiasson [2010] reported solifenacin was effective in improving OAB at 8 weeks reducing mean number of micturitions by 2.09, when BT was added there was a further significant improvement reducing episodes by 2.78. Again this study did not present data which enabled analysis of men and women separately.

3. Summary

A single trial found that combining BT with PFMT improves short-term outcomes compared to PFMT alone, but the added benefit did not persist three months later.

There is no evidence for an added benefit of combining brief written BT instructions with tolterodine (2mg twice daily) compared to tolterodine alone for urge incontinence (**Level of Evidence: 2**), although this trial included men and women and it is not known if one gender did better than the other with respect to outcome. The use of BT with solifenacin (5/10mg) adds benefit to symptom reduction at 8 weeks compared to solifenacin alone, mainly to symptoms of frequency (**Level of Evidence 2** – NOTE: This evidence related to men and women)

4. Recommendations

The current evidence is conflicting for the addition of written information on bladder training for women taking an antimuscarinic drug. One trial states no clinical benefit in adding brief written instruction in BT (**Grade of Recommendation: B**), whilst another suggests no significant improvements to urgency and urge incontinence but significant improvements in frequency (**Grade of recommendation: B**). More research is needed using an appropriately supervised BT programme (see B.6.2a) combined with anticholinergic or antimuscarinic drug therapies versus drug alone.

f) Timed voiding

A 2010 Cochrane review on timed voiding for management of UI in adults was recently published [273]. Ostaszkiewicz (2010) considered randomised and quasi-randomised trials only and identified two trials that compared timed voiding combined with additional interventions (including medications) to usual care. Both trials were conducted in nursing facilities and most participants were elderly women with cognitive impairment, therefore neither study recruited participants that met the criteria of interest for this chapter.

Two non-randomised studies that were not included in the Cochrane review reported findings related to the effects of timed voiding in women with UUI, stable bladders with UUI, and MUI [194,295]. Klarskov [1986] reported a consecutive series of 20 women aged 27 to 75 years with a double-blind crossover to compare timed voiding plus anticholinergic drug therapy (terodoline) to timed voiding plus placebo. As terodoline has been withdrawn from the market, this study is not considered further.

1. Quality of data

A 1984 case series report involved 20 women aged 24 to 94 years in women with a mild degree of UI, irregular voiding patterns, and normal urodynamic parameters (UI type not clearly reported) [295]. The voiding schedule consisted of a two hour voiding interval. Follow-up periods ranged from six weeks to eight months after treatment [295].

2. Results

A 79% success rate (not objectively quantified) was reported in the case series. Fifteen patients became totally continent, one had less leakage, three (with neurogenic diseases) remained unchanged, and one patient was lost to follow-up

3. Summary

There are no RCTs, or high quality observational studies, providing evidence on the effects of timed voiding for UI in women. Based upon the data from one small uncontrolled study, it seems a two hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function **(Level of Evidence: 3)**.

4. Recommendations

Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (**Grade of Recommendation: C**). It may also be helpful as an adjunct to other treatment.

3. OTHER LUTS

One trial recruited participants with OAB but the continence status was unclear [281]. BT was compared to tolterodine (2mg, twice daily) or combined BT and tolterodine in women with OAB [281]; this study was reported as a conference abstract. Tolterodine/BT group had greater reductions in diurnal micturition (32.6%), nocturnal micturition (63.2%), urgency scores (63.2%), and bladder symptom improvement rates (69.3%) than those in BT alone or tolterodine alone. However, only the bladder symptom improvement scores were statistically significantly better in the combination therapy group. Thus, it is not clear if BT alone, tolterodine alone, or the combination, is better for LUTS other than UI in women with OAB symptoms.

The most common LUTS, aside from UI, are urgency, daytime (or diurnal) frequency and nocturia. Some trials that contributed to the sections above reported data specifically for these symptoms.

(a) Urgency: Jarvis [1981] compared BT and drug therapy (flavoxate and imipramine), and 16% versus 44% of participants reported they continued to experience urgency post-treatment. Mattiasson [2003] compared BT with tolterodine versus tolterodine alone and patient rating of urgency was somewhat less in the combination therapy group.

(b) Daytime (diurnal) frequency: Data on frequency are more commonly collected that data on urgency. Three trials reported diurnal frequency in comparisons of BT with no treatment. Jarvis [1980] reported a small controlled trial of inpatient bladder drill for DO [285]. After BT 17% in the treatment group and 77% in the control group continued to have symptoms of diurnal frequency. Fantl [1991], in subgroup analyses, found a significant reduction in diurnal frequency in participants with urodynamic SUI who had a baseline diurnal micturition frequency of at least 61 per week, and also in participants with DO with or without urodynamic SUI who had at least 57 diurnal micturitions per week [268]. Finally, Yoon (2003) reported that the BT group significantly reduced diurnal micturitions, whereas the control group deteriorated slightly [128].

Three trials compared BT with drug therapy. Jarvis [1981] reported that 24% of the BT group continued to experience frequency as compared to 48% of the drug group (flavoxate and imipramine) [284]. Columbo (1995) found that diurnal frequency was resolved in 18 (56%) of 32 patients taking oxybutynin versus 20 (69%) of 29 BT patients [292]. Kim SW et al [2008] found improvement in daytime frequency in 15 (65%) cases using bladder training alone and 21 (84%) using BT and propiverine combined.

Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found that there was a greater reduction in diurnal micturition frequencies in participants taking oxybutynin alongside BT compared to those on placebo and BT. Similarly, in a trial of BT plus drug versus drug alone Mattiasson (2003) found that “simplified” BT significantly augmented the effect of tolterodine compared to drug alone for voiding frequency (33% versus 25% improvement, respectively; $p<0.001$).

(c) Nocturia: Three trials reported data on nocturia in comparisons of BT with no treatment. Jarvis (1980) reported a small controlled trial of inpatient bladder drill for DO. After bladder training, there were 11% in the treatment group and 80% in the control group who continued to have symptoms of nocturnal frequency [285]. Fantl [1991] also found significant reductions in nocturnal frequency [268]. In subgroup analyses, nocturnal micturitions were only significantly decreased in women with urodynamic SUI alone, who experienced at least five episodes of nocturia per week, and not in those who had DO. Yoon [2003] reported that the BT group significantly reduced nocturnal micturitions, whereas the control group deteriorated slightly [128].

Two trials compared BT with drug therapy. Jarvis [1981] reported that the 19% of the BT group continued to experience nocturia compared to 68% of the drug group (flavoxate and imipramine) [284]. Columbo [1995] found that nocturia disappeared in three (27%) of 11 patients taking oxybutynin and 11 (61%) of 18 BT patients [292]. Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found no difference in nocturnal micturition frequencies.

1. Summary

Scheduled voiding regimens have been implemented in many forms and with a variety of intensities, ranging from strict in-patient regimens to simple instruction sheets. Most research has examined BT, and most of these trials have recruited women with symptoms of UUI or OAB. It is therefore disappointing that there is so little data about LUTS other than UI. The indications so far are that BT is effective for reducing UI, as well as frequency of micturition. The scant research comparing BT to drug therapy is inconsistent with some evidence for the superiority of each. It is not yet clear whether drug therapy can enhance BT, or whether BT can enhance UI outcomes from drug therapy, although it appears that reductions in frequency of micturition may be greater with the addition of BT.

4. FACTORS AFFECTING OUTCOME

a) Age

With the exception of two RCTs [128, 291] all trials included older women in their study populations. Three specifically recruited elderly women aged 65 to70 years and over [282, 283, 293]; and two recruited women aged 55 years and over [268, 289]. In conducting analyses of factors predicting success, two trials reported that age was not a factor in treatment outcome [189,289].

b) Other

Few trials on BT examined other predictors of treatment response. Several discussed the effect of diagnosis on treatment outcome; two reported that urodynamic diagnosis did not have an effect on treatment outcome as measured by incontinent episodes and the IIQ [189,268]. These RCTs included women with urodynamic SUI, DO, or both diagnoses. BT also led to more clinical cures in one small drug trial. BT in women with sensory urgency (81%) and low compliance bladders (75%) produced better outcomes than in those on oxybutynin immediate release (60%, 67%, respectively); however, oxybutynin led to greater cure rates in patients with DO (93% versus 62%).

VII. COMPLEMENTARY AND ALTERNATIVE MEDICINES

There is minimal evidence that complementary and alternative medicines (CAMs) may influence physiologic function and/or health outcomes. CAMs include

those therapies that are not part of the traditional biomedical model, such as meditation, imagery, hypnosis, acupuncture and naturopathic and herbal remedies. While some consider biofeedback (BF) part of complementary therapy, we have included BF in this chapter as an adjunct to physical therapies.

A search of AMED (Allied and Complementary Medicine) using the key words randomised controlled trials, and urinary incontinence, retrieved 32 records in 2012. One reported a randomised controlled trial investigating the effect of hand acupuncture for female SUI on 52 women randomly assigned to either experimental hand acupuncture or control, assessment was made at 12 weeks and 37% less incontinence was reported in the experiental group. The reporting of this trial did not conform to traditional standards and should be treated with caution, however the undertaking of an RCT in the CAMs literature indicates a move towards the gathering of robust 'main-stream' evidence in this area.

There is a need for well conducted RCT's in the area of CAMs before recommendations can be made.

VIII. SUMMARY AND RECOMMENDATIONS

1. SUMMARY

Whislt the effect of PFMT has received considerable research attention, the effect of lifestyle interventions or prevention trials have not. However even with the number of reasonable trials on conservative management of UI in women, the standards of trial conduct and reporting varied considerably and it is strongly recommended that future randomised trials account for sample size, heterogenity, risk of bias, and followup.

2. RECOMMENDATIONS FOR PRACTICE

- While some recommendations are underpinned by good and consistent evidence of effect,

there are also many recommendations that need further testing because there is insufficient **Level 1 or 2 evidence**. For this update, the recommendations from ICI 2009 remain. These are not based on robust reserach and require further study:

a) Lifestyle Intervention

- Weight loss in obese and morbidly should be considered a first line treatment to reduce UI prevalence **(Grade of Recommendation: A)**.
- Caffeine reduction may help in improving incontinence symptoms **(Grade of Recommendation: B)**
- Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than 30 ml/kg a day **(Grade of Recommendation: B)** Moderate exercise may help in decreasing the incidence of UI; this effect may be mediated by weight control **(Grade of Recommendation: C)**

b) PFMT (principal recommendation)

- Supervised PFMT should be offered as first line conservative therapy to women with stress, urge, or mixed urinary incontinence **(Grade of Recommendation: A)**
- The most intensive PFMT programme possible should be provided (in terms of exercise dose, health professional teaching, and supervision) within service constraints ; health professional taught and supervised programmes are better than self-directed programmes ; more health professional contact is better than less **(Grade of Recommendation: A)**.
- There does not appear to be a clear benefit of adding clinic **(Grade of Recommendation: B)** or home based BF **(Grade of Recommendation: B)** to a PFMT programme.

c) PFMT (other recommendation)

Pregnant women expecting their first baby:

- Intensive strengthening antepartum PFMT, with regular health professional contact to teach and supervise training, to prevent postpartum urinary incontinence **(Grades of Recommendation: A)** (for women continent at 18 weeks) and B (for population approaches, that is intervention offered whether women are continent or not at 20 weeks gestation)

Postnatal women, immediately after delivery:

- Individually taught PFMT programme that incorporates adherence strategies for women who had a vaginal delivery of a large baby (4000g or more) or a forceps delivery **(Grade of Recommendation: C)**

For postnatal women with persistent symptoms of UI three months after delivery:

- PFMT is offered as first line conservative therapy **(Grade of Recommendation: A)**
- The 'best' PFMT programmes are 'intensive' with regard to supervision and exercise content **(Grade of Recommendation: B)**

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised **(Grade of Recommendation: B).**
- PFMT is better than BT as first line conservative therapy **(Grade of Recommendation: B).**

- PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug **(Grade of Recommendation: C).**
- PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive **(Grade of Recommendation: C).**

For women with SUI or MUI:

- PFMT is better than VC as first line conservative therapy **(Grade of Recommendation: B)**.

For women with UUI or MUI:

- PFMT and BT are effective first line conservative therapy **(Grade of Recommendation: B).**
- PFMT is better than oxybutynin as first line therapy **(Grade of Recommendation: B).**

For women with UUI:

- PFMT and BT are effective first line conservative therapy **(Grade of Recommendation: B).**

Vaginal cones:

- For women with SUI, VCs with supervised training sessions by a trained health professional can a first-line therapy to women able and prepared to use them **(Grade of Recommendation: B)**; some women cannot insert or retain the the cone or have side effects and discomfort. Trained health professional assessment is recommended **(Grade of Recommendation: D)**

Electrical stimulation (EStim)

While the usefulness of EStim in practice might be limited because some women cannot use it (due to contraindications), have difficulty using it, or dislike it:

- EStim might be better than no treatment in improving symptoms **(Grade of Recommendation: B).**
- EStim may be equal to other medical treatments **(Grade of Recommendation: B).**
- EStim plus PFMT or BF-assisted PFMT programmes does not appear to add benefit **(Grade of Recommendation: B)**

Magnetic stimulation (MStim)

- Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence **(Level of recommendation: D).**

Bladder training (BT)

With regard to **Grade A** recommendations for BT:

- BT is an appropriate first line treatment for UI in women (Unchanged).

Grade B recommendations (all unchanged from ICI 2009):

- Either BT or antimuscarinic drug may be effective, although BT may be preferred by some because it does not produce side effects and adverse events associated with drug therapy.
- There may be no benefit in adding brief written instruction in BT to drug therapy for incontinence but it mayimprove episodes of frequency.
- A combination of PFMT/BT may be better than PFMT alone in the short-term for women with symptoms of SUI or MUI.

There are two **Grade D recommendations** (unchanged from (C(2009):

- Clinicians and researchers should refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach.
- Health Professionals should provide the most intensive BT supervision that is possible within service constraints.

Timed voiding (unchanged)

- Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns **(Grade of Recommendation: C).**

IX. FUTURE RESEARCH DIRECTIONS

Conservative management of incontinence is ripe for future research directions. Research that is urgently needed, in the opinion of the committee members, is highlighted with the use of *italics*. There are a few recommendations that apply to all further studies:

- All future trials must be designed, implemented and reported in ways that maximise their usefulness in practice; this includes being well powered, with longer term follow up, with evaluation of cost- effectiveness and planned secondary analysis of trial data to investigate factors affecting outcome. Readers are referred to the revised CONSORT statement for guidance (http://www.consort-statement.org/)

a) Lifestyle Intervention:

- Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain (and exercise) should receive high research priority.

- Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.
- Further research is needed to define the role of straining in the pathogenesis of UI.
- Studies to establish whether heavy exertion is an etiologic factor in the pathogenesis of UI and whether changing exertions can alleviate established UI.
- Prospective studies on the effect of smoking cessation on the prevention or resolution of UI.
- Separate investigations of the impact of lifestyle interventions on nocturia, diurnal frequency, urgency and UUI to delineate whether certain interventions preferentially affect different areas of OAB.

b) Pelvic floor muscle training (PFMT)

In antenatal and postnatal women, trials are needed to investigate the effects of:

- Antepartum PFMT on preventing postpartum UI in multiparous women.
- Postpartum PFMT programme (suitable exercise dose and supervision) in the long term (five plus years).
- Periodic refresher sessions after an initial supervised postpartum PFMT programme, in the long term (five plus years).

In all women, trials are needed to investigate:

- The effect of different supervisory intensity in PFMT program. In addition to clinical effectiveness, this is an important question because of resource implications, both financial and human, for health-service delivery.
- Whether clinic BF may benefit certain women, such as those with a weak PFM or with difficulty contracting the PFM in isolation.
- Whether the addition of bladder training or medication adds benefit to PFMT.

c) Vaginal cones (VC)

- If the combination of VC with PFMT is an intervention of interest for women then this combination of therapies could be explored further. VC could be used as an overload progression to active PFM strengthening exercises. Thus, a VC programme could be offered to women with a demonstrated minimum PFM strength level and could be aimed at either additional strength training by pulling on the cone for three series of eight to12 contractions daily, or endurance training, using a low-load over a sustained period of time.

d) Electrical stimulation (EStim) and magnetic stimulation (MStim)

- Studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.
- Comparisons of EStim with other treatments such as PFMT, vaginal cones, and bladder training are more important than comparison of EStim with sham.
- EStim as an adjunct to treatments that seem to be effective such as PFMT, vaginal cones, and bladder training.
- MStim protocols, both sacral root MStim and home-based MStim, are worthy of further investigation. Well powered RCT are needed to study the clinical effect of Mstim in different diagnostic group.

e) Scheduled voiding regimes, especially bladder training (BT)

- BT variables to be investigated include the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.
- BT versus another active treatment such as PFMT or drug therapy.
- The potential benefits of combining BT and anticholinergic/antimuscarinic drug need further investigation, including comparisons of BT plus drug versus drug alone, and BT plus drug versus BT alone, or BT vs no treatment.
- Habit training in women with a consistent pattern of UI who are ambulatory and cognitively intact.

B. PELVIC ORGAN PROLAPSE (POP)

Pelvic organ prolapse is characterised by a variety of pelvic floor symptoms. Treatment depends on the severity of the prolapse and its symptoms, and the woman's general health. Conservative treatment is generally considered for those with a mild degree of prolapse, those who wish to have more children, the frail or those unwilling to undergo surgery. Conservative treatment is defined here as lifestyle interventions, physical therapies and pessaries.

The aims of conservative treatment in the management of POP include:

- to prevent the prolapse becoming worse;
- to help decrease the frequency or severity of symptoms caused by prolapse (pelvic heaviness, vaginal symptoms, backache, urinary, bowel and sexual symptoms);
- to avert or delay the need for surgery.

In this section the evidence is applied for the use of conservative treatments in the management of

POP, utilising information from two Cochrane systematic reviews [296,297], and literature identified via a search strategy summarised in Appendix 2.

I. LIFESTYLE INTERVENTIONS

Lifestyle interventions include weight loss, reducing exacerbating activities (e.g. lifting, coughing) and treating constipation and are intended to avoid exacerbation of the prolapse by decreasing intra-abdominal pressure. The extent to which any of these lifestyle interventions are effective in managing prolapse is largely unknown [195].

1. PREVENTION

a) Quality of data

No new intervention studies were identified in this update, however further observational studies have been published and these are reported here and summarised in **Table 16**. In ICI 4th edition, no literature was found relating to the effects of lifestyle change interventions for the prevention of POP. Observational studies were identified that examined the association between factors such as occupation (involving heavy lifting/strenuous physical activity), bodyweight and constipation, and POP.

(a) Association between POP and occupation:

Three new studies investigated the association between occupation and prolapse.

Miedel [298] undertook an assessment of non-obstetric risk factors, including heavy lifting at work, in a population-based, cross-sectional study derived from a sample of 5489 Stockholm women, 30 to 79 years old, who answered a validated questionnaire for the identification of symptomatic prolapse. 69% responded and of those, women who had symptomatic prolapse (n=454) and randomly selected controls (n=405) were given a detailed questionnaire regarding their risk factors, including current or previous occupations that involved heavy lifting (up to 10 kg daily, more than 10 kg) or exposure to vibrations, and participation in low- and high-impact exercise. Only women with intact uteri and no history of surgery for prolapse or incontinence were included (n=273 cases, n=285 controls). Odds ratios and confidence intervals were estimated from multiple logistic regression analysis.

Slieker-ten Hove undertook a cross-sectional study of all female residents between 45 and 85 years old in one Dutch city (n=2979), the results of which were reported in four articles [299-302]. Women received a validated questionnaires via which they were classified as symptomatic (if they reported feeling and/or seeing a vaginal bulge) or non-symptomatic. A response rate of 63% was achieved. Finally 1224 women were included in the analysis (n=142 symptomatic; n=1082 asymptomatic). Multiple logistic regression was used to estimate the odds ratios and confidence intervals for the potential risk factors including current and past heavy physical work [299].

Braekken [303] carried out a one-to-one age and parity matched case-control study (n=49 women with prolapse >=stage II with or without symptoms, and n=49 controls with prolapse stage 0 or I) with recruitment via community gynaecologists and newspaper advertisements. Women had clinical examination, pelvic floor muscle (PFM) function assessment (strength, endurance and vaginal resting pressure in cmH2O) and completed questionnaires including risk factor assessment. The study primarily looked at the association between PFM function and POP, but also measured occupational heavy lifting and BMI as potential risk factors for POP. Heavy occupational work was defined by a positive response to three questions: self-report of physically heavy occupational work; >20 heavy lifts per week; >50% of working time in standing position. One or two positive responses was classified as moderate occupational work. Multivariate logistic regression was used to estimate odds ratios for risk factors.

(b) Association between POP and bodyweight:

Four new studies have addressed the relationship between obesity and prolapse [298, 303-305].

Whitcomb [2009] published a secondary analysis of the data from 1155 obese women from the Kaiser Permanente Continence-Associated Risk Epidemiology Study. Prolapse was identified from responses to a question regarding the sensation of a bulge or something falling out of the vagina. Women were asked to report bother on a visual analogue scale. Multivariable logistic regression was used to assess severity of obesity (obese, severely obese, morbidly obese) as a risk factor for various pelvic floor disorders including prolapse. Models were adjusted for age, parity and mode of delivery.

Washington [2010] reported on a cross-sectional study of all women with pelvic floor disorders (n=971) attending a tertiary urogynaecology centre over one year. Data on POP-Q, PFDI-20, and PFIQ-7 were gathered. Women with POP-Q >=stage II were classed as having prolapse; women with BMI>=30 were classed as obese.

In addition, two studies [298,306] (described above) assessed body mass index as one of several risk factor for prolapse.

(c) Association between POP and bowel function:

Four new studies, one relating to irritable bowel and prolapse [307] and three looking more generally at defecatory problems [298,301,308] were found.

Wang [2010] analysed data from the Reproductive Risks for Incontinence Study addressing the relationship between irritable bowel syndrome and pelvic

Table 16: Characteristics of lifestyle and pelvic organ prolapse studies

Author/ year	Study design	Comparison group	Participants	Risk factors assessed	Subjective and Objective assessment	Objective assessment	Length of follow-up	Results
Badalian 2010 [310]	Cross-sectional, analysis of US National Health and Nutrition Examination Study. Analysis adjusted for age, parity, education, race		Non-pregnant women aged 20 and over, n=1881	Level of vitamin D	Experience of bulge or something falling out		N/A	Vitamin D level was not associated with vaginal bulge
Braekken 2009 [303]	Age and parity matched case-control study		Community and routine Gynae. Population, n=98	PFM function, occupational heavy lifting, BMI		POP-Q		• Heavy occupational work was associated with greater risk of prolapse (>=stage II) • BMI • Weaker PFMs, poorer endurance and lower vaginal resting pressure significantly associated with prolapse >=stage II. Significant interaction between muscle strength and vaginal resting pressure
Braekken 2010 [306]	RCT	PFMT vs control	N=109	N/A	Mouritsen questionnaire PFM function	POP-Q	6 months	PFMT group compared to control group were significantly more likely to have reduced symptom frequency and bother, less likely to have no improvement in POP-Q stage. Change in resting position of the bladder and rectum, were significantly greater in PFMT group; changes in muscles and hiatal area were significantly in favour of the PFMT group.
Miedel 2009 [298]	Cross-sectional, case-control. Analysis adjusted for factors including age, parity and family history of prolapse	Those with vs those without symptomatic prolapse	Population-based, n=359	N/A Occupational heavy lifting BMI bowel	72-item questionnaire		N/A	• Compared to women who did no heavy lifting at work, those lifting weights up to 10kg and over 10 kg had increased risks of symptomatic prolapse • Compared to women of normal weight (BMI 19-25), overweight (BMI 26-30) and obese women (BMI >30) had increased odds of symptomatic prolapse • lack of a normal bowel habit was associated with increased risk of symptomatic prolapse
Moen 2009 [316]	Observational. unadjusted analysis		Women presenting with PFM disorders, n=325	PFM strength (Oxford)		Prolapse stage	N/A	PFM contraction strength was significantly lower in women with prolapse >= stage 2

Table 16: Characteristics of lifestyle and pelvic organ prolapse studies (continued)

Author/ year	Study design	Comparison group	Participants	Risk factors assessed	Subjective and Objective assessment	Objective assessment	Length of follow-up	Results
Saks 2010 [308]	Cross-sectional. Analysis adjusted for age, BMI, presence of apical or anterior prolapse	Those with vs those without obstructive bowel symptoms	Tertiary urogynaecology service, n=331	Obstructive bowel symptoms	PFDI-20	Baden-Walker	N/A	Women with posterior wall prolapse more likely to report obstructive bowel symptoms than those without. Grade of prolapse not significantly associated with obstructive bowel symptoms.
Slieker-ten Hove 2009	Cross-sectional, case-control. Adjusted analysis of occupational lifting only	Symptomatic vs non-symptomatic	Population-based, n=1224, n=469 had POP-Q	Heavy physical work PFM function bowel		POP-Q	N/A	• 24.5% of cases versus 18.9% of controls currently engaged in heavy work (OR 1.48, 95% CI 0.98-2.23). Past heavy work was not a significant risk factor. • Higher stages of prolapse associated with less ability to attain levator closure, and lack of effective involuntary contraction during coughing, but better ability to perform proper straining technique. No association between stage of prolapse and voluntary muscle contraction strength or endurance • no significant association between constipation or straining to defaecate and POP-Q stage
Stupp 2011 [318]	RCT (pilot)	PFMT vs control	N=37	N/A	P-QoL PFM function	POP-Q	14 weeks	PFMT group had significantly greater anatomic improvements in the anterior and posterior vaginal wall prolapses than did the control group and a decrease of symptoms. Also greater improvements in PFM strength, endurance and electromyography parameters
Wang 2010 [307]	Cohort, analysis of RR survey data. Analysis adjusted for age, race, medical history, urinary urgency, UI	Those with vs those without irritable bowel syndrome (IBS)	Racially diverse women, aged 40-69 years, n=2109	IBS	Feeling or seeing a bulge or protrusion		N/A	Risk of symptomatic prolapse significantly greater in group with IBS. Risk of bother with prolapse was also significantly greater in the IBS group.
Washington 2010 [305]	Cross-sectional. Unadjusted analysis of comparable groups	Obese vs non-obese	Tertiary urogynaecology centre, women with pelvic floor disorders, n=971	Obesity (BMI>=30)	PFDI-20, PFIQ-7	POP-Q	N/A	Obese compare to non-obese women were more likely to have prolapse. Significant difference in PFDI-20 but not the prolapse subscale.
Whitcomb 2009 [304]	Cross-sectional, secondary analysis of survey data. Analysis adjusted for age, parity, mode of delivery	Obese vs severely obese vs morbidly obese	Population-based,n=1155 obese women	Obesity	Sensation of bulge or something falling out		N/A	Morbidly obese (but not severely obese) women are at greater risk of bulge than obese women. No difference between obesity groups in terms of bother.

Foot notes: N/A non applicable; PFM= Pelvic floor muscle, PFMT = pelvic floor muscle training,

floor disorders, and the effects of such symptoms on quality of life. RRISK is a racially-diverse cohort of women aged between 40 and 69 years (n=2109). Data were collected by self-administered questionnaires and interviews. IBS status was determined by asking a single question regarding whether a woman had ever been told by a medical doctor that she had IBS. Prolapse was identified by asking about feeling or seeing a bulge or protrusion. Multivariate logistic regression was used to assess factors associated with having IBS including prolapse.

Saks [2010] in a cross-sectional study examined whether there was an association between obstructive defaecatory symptoms and prolapse. Women presenting with prolapse of grade 2 or greater (Baden-Walker system) of any compartment (anterior, posterior, apical) to one tertiary urogynaecology service completed a questionnaire (PFDI-20) that reported pelvic floor symptoms. A multivariate regression analysis was performed, adjusting for confounding variables, the dependent variable being presence of obstructive bowel symptoms (defined as at least moderate bother with one or more of: splinting, straining, incomplete emptying).

Both Miedel [2009] and Slieker-ten Hove [2009] assessed the presence of constipation (<3 bowel movements per week), hard stools and difficult evacuation as risk factors for symptomatic prolapse and changes in POP-Q stage.

(d) Association between POP and nutrition:

Previously one study of women in rural Gambia had been published on the association between prolapse severity and anaemia [309]. A new study by Badalian [310] adressed the association between Vitamin D deficiency and pelvic floor disorders. The authors hypothesised that there is a plausible link between vitamin D deficiency and poor muscle strength since vitamin D receptors are found in human muscle tissue. Over three thousand women aged 20 years or above from the US National Health and Nutrition Examination Study 2005-2006 were selected by probability sampling. Analysis was based on the 1881 non-pregnant women who participated, and who had data on both vitamin D levels and pelvic floor disorders. Prolapse was identified from a positive response to a question on the experience of a bulge or something falling out that is seen or felt in the vaginal area. Level of vitamin D was analysed both as a continuous variable and as a dichotomous variable (>= 30 ng/mL, <30 ng/mL). Analysis included both univariate and multivariate regression models. Models adjusted for age, BMI, parity, education and race.

b) Results

(a) Association between POP and occupation:

In the Miedel study [2009] a total of 655 (76.2%) women returned completed risk factor questionnaires with 558 women included in the analysis (n=273 symptomatic; n=285 controls). Heavy lifting at work was found to be positively linked to symptomatic prolapse in a simple age- and parity-adjusted model. Compared to women who did no heavy lifting at work, those lifting weights up to 10kg had an increased risk of symptomatic prolapse (OR 1.81, 95% CI 1.11–2.95). There was a similar increased risk for those women lifting 10kg or more at work: OR 1.67, 95% CI 1.07–2.61. This finding was confirmed in the multiple logistic regression analysis which indicated eight variables that were significantly associated with symptomatic prolapse. Age, parity, family history of prolapse, increased BMI, the presence of any condition suggestive of deficient connective tissue, fewer years smoking, heavy lifting at work, and abnormal bowel habit were all risk factors for symptomatic prolapse. From this model the results for heavy lifting compared to no heavy lifting were: <10kg OR 1.98, 95% CI 1.10–3.59; >=10kg OR 1.94, 95% CI 1.15–3.27. Thus no clear dose response was confirmed.

Slieker-ten Hove [299] found that current heavy physical work was an independently significant risk factor for symptomatic prolapse; 24.5% of cases versus 18.9% of controls were currently engaged in heavy work. The odds ratio was 1.48 (95% confidence interval 0.98-2.23) and the population attributable risk (PAR) was 8.5%. Other independent risk factors were having POP symptoms during pregnancy and mother having prolapse. Past heavy work was not a significant risk factor.

Braekken [2009] also reported that heavy occupational work, compared to moderate or light occupational work, was associated with greater risk of prolapse >= stage II. BMI and pelvic floor muscle function variables were also significantly associated with risk of prolapse as described in later sections.

Previously the majority of studies (5 out of 6) reported a positive association between occupations associated with lifting and the presence of prolapse. The additional three studies were supportive of an association between current heavy occupational lifting and prolapse, however the odds ratio in one study was only marginally significant.

(b) Association between POP and bodyweight:

Morbidly obese women had significantly increased odds of having prolapse (reported bulge) compared to obese women (Whitcomb, 2009). The odds for severely obese women compared to obese women were not significantly increased. The visual analogue scores for bother with prolapse did not differ significantly between obesity groups. There may be a trend towards increasing prevalence of prolapse with increasing severity of obesity. However this was not reflected in the bother reported.

In the Washington [2010] study of 971 women, 721 met the inclusion criteria and had sufficient data

to be included in the analysis. Mean age was 56.5 years (SD 16.2) and 65.2% were post-menopausal. 35.8% were obese and 62.2% non-obese. The mean BMI was 35.8 (SD 5.4). Stage >=II prolapse was present in 52% of women. No difference in presence of prolapse of stage II or greater was found between obese and non-obese women and similarly for stage 3 or greater prolapse: obese 16.2% vs non-obese 18.4%. Being obese was however associated with more pelvic floor symptom distress: the mean score on the PFDI-20 was significantly higher for obese women compared to non-obese women, due to higher mean scores on subscales for colorectal-anal distress and urinary distress. There was no significant difference between obese and non-obese women in the prolapse-specific subscale of the PFDI-20. The analysis performed was unadjusted, but it was reported that there were no significant differences in age, parity, race, prior pelvic surgery or co-morbidities between the obese and non-obese group.

Miedel [2009] found that although age, parity, and family history of prolapse were the dominating risk factors for symptomatic prolapse, increased BMI was also an independent significant risk factor in the final fully adjusted model (p=0.038). Compared to women of normal weight (BMI 19 to 25), overweight (BMI 26 to 30) and obese women (BMI >30) had increased odds of symptomatic prolapse (OR 1.88 95% CI 1.15 to 3.08 and OR 2.07 95% CI 0.95 to 4.50, respectively).

Braekken [2009] reported that having a BMI of >25 (compared to <=25) was significantly associated with having prolapse >= stage II (OR 5.0, 95% CI 1.1 to 23.0).

In ICI 4th edition the majority of studies (4 out of 6) indicated an association between being overweight and having prolapse. There are now four additional studies to draw on. Each study supported the previous finding.

(c) Association between POP and bowel function:

Symptomatic prolapse in the last 12 months was associated with having inflammatory bowel symptoms (IBS) after adjusting for age, race, medical history, urinary urgency and urinary incontinence: 5% in the no IBS group had symptomatic prolapse compared to 12% in the IBS group. Bother due to prolapse was also significantly associated with IBS. The authors suggest that women with IBS have cycles of constipation which makes them prone to having a weak pelvic floor and prolapse [Wang, 2010].

In the study by Saks [2010], 311 women met the inclusion criteria: mean age 60.5 years (SD 12.5), BMI 27.1 (SD 5.5), and parity 2.6 (SD 1.3). Most women were white (69%) and post-menopausal (79%). Apical prolapse was the most common type (86%), followed by anterior (77%) and posterior (23%). Most had prolapse involving more than one compartment. Nine bowel symptoms were examined and in all cases the prevalence of the symptom was not associated with grade of prolapse. Some obstructive symptoms (splinting, straining, anal incontinence, bulging of rectal tissue) were associated with the presence of a posterior prolapse, but none were associated with the grade of posterior prolapse. In a multivariate regression analysis adjusting for age, BMI and presence of apical or anterior prolapse it was confirmed that women with posterior wall prolapse were more likely to report obstructive bowel symptoms than those who did not have posterior wall prolapse (OR 3.46, 95% CI 1.69 to 7.01). Grade of prolapse (either overall or specifically for the posterior wall) was not significantly associated with obstructive bowel symptoms. The authors concluded that obstructive bowel symptoms often co-exist with posterior vaginal wall prolapse but probably do not cause the symptoms.

Miedel [2009] found all bowel variables were significantly associated with risk of symptomatic prolapse in an age- and parity-adjusted model. In the final multivariable logistic model, one variable remained significant: lack of a normal bowel habit was associated with a two-fold risk of symptomatic prolapse (OR 2.13, 95% CI 1.37 to 3.31).

Slieker-ten Hove [2009] found, in an unadjusted analysis, no significant association between constipation and POP-Q stage, nor straining to defaecate and POP-Q stage.

Previously the evidence was inconclusive with regards to the relationship between constipation and prolapse. There tended to be positive associations with symptoms of prolapse but not anatomical prolapse measures (e.g. POP-Q). Four new studies add some information in this area. The conclusions from these are similar however: significant associations with prolapse symptoms, but no significant associations with prolapse stage.

(d) Association between POP and nutrition:

In the ICI 4th Edition, only one study was found that suggested anaemia was associated with increased odds of having prolapse. A new study by Badalian (2010), looking at the effects on prolapse of vitamin D, found in a univariate analysis that women reporting bulge had higher levels of vitamin D: in women over 50 years old 8.6% reported bulge in the >=30 ng/mL group compared to 3.3% in the <30 ng/mL group. However the model findings suggested that vitamin D level was not associated with vaginal bulge (prolapse): a vitamin D level of 30 ng/mL or more (normal) compared to lower levels had an odds ratio for prolapse of 1.66 (95% CI 0.61 to 4.49). The authors suggest that the small numbers of women reporting prolapse may have been an underestimate due to self-reporting. A significant association between low level of vitamin D and presence of urinary incontinence was reported.

c) Summary

Overall there are still no prospective studies of lifestyle interventions to prevent prolapse.

Some new observational studies were located adding to our knowledge of potentially helpful ways to modify lifestyle risk factors. There is now further evidence that occupations involving heavy lifting/hard physical labour or being overweight may play a role in the development of POP **(Level of Evidence: 3)**.

Constipation is a modifiable risk factor which perhaps has potential to impact on development of prolapse symptoms. However, evidence regarding the association between constipation or straining at stool and prolapse remains conflicting. New studies were reasonably sized and adjusted for covariates.

No further studies on anaemia were found. A study of vitamin D found no association with self-reported bulge.

2. TREATMENT

Previously no studies had been identified that evaluated the effectiveness of lifestyle interventions in the treatment of women with POP. Currently this is still the case.

II. PHYSICAL THERAPIES

The primary physical therapy for POP is PFMT, with or without other adjuncts. PFMT may include PFM assessment and education, PFM exercise instruction, and PFM bracing against increased intra-abdominal pressure, for example when coughing and sneezing (termed “The Knack” [145]). Adjuncts (such as biofeedback) or other physical therapies (such as neuromuscular EStim) may be used. These therapies aim to improve PFM strength, endurance, coordination and function.

The promotion of PFMT for prolapse varies between treatment centres with some providing only a patient information leaflet and others giving individual instruction from a physiotherapist [311]. Research shows that verbal teaching of pelvic floor exercises alone is insufficient [312]. It is suggested that 15% of women are incorrectly ‘bearing down’ when trying to carry out these exercises. In women with prolapse, this could further add to the strain on the area and worsen the condition.

A Cochrane systematic review has indicated that PFMT should be offered as first-line conservative management for urinary stress, urge and mixed incontinence [126]. However, its role in managing prolapse is less well-established [313]. The importance of clarifying the place of PFMT in the prevention and management of prolapse has been highlighted [314,315].

1. PREVENTION

a) Quality of data

No studies have been identified to date that evaluate the role of PFMT in prevention of POP. This lack of evidence was noted by Harvey (2003) in a systematic review of PFMT during and after pregnancy [212].

However, one trial is now underway [http://clinicaltrials.gov/ct2/show/NCT01171846]. Four hundred women originally enrolled in a longitudinal follow-up of post-natal incontinence (including a subgroup involved in a trial of post-natal PFMT), who have not sought treatment for prolapse, have been randomised to receive either a programme of PFMT (individualised physiotherapy appointments, maintenance via Pilates-based classes and annual one-to-one check-ups) or a prolapse prevention advice leaflet. Women are being followed up at 2 years. This trial is due to report in late 2013.

In addition, three more cross-sectional studies have examined the relationship between pelvic floor muscle function and prolapse.

Braekken [2009] conducted a case-control study, in which they examined the association between PFM function and POP, but also measured occupational heavy lifting and BMI as risk factors for POP as reported above.

Moen [2009] [316] undertook an observational study in women presenting with pelvic floor disorders. Women were questioned about their performance of pelvic floor muscle exercises and then were examined to measure pelvic floor muscle contraction strength (Oxford grading scale). Prolapse stage was also recorded. Univariate analysis was performed to assess associations between prolapse stage and muscle strength.

Slieker-ten Hove, as described above, performed a cross-sectional study of women aged 45-85 (n=2979) in one town in the Netherlands [302]. Women completed a validated questionnaire and indicated if they would consent to a vaginal examination. A random sample of consenting women were examined to assess prolapse stage (POP-Q) and pelvic floor muscle function (voluntary muscle contraction and effective involuntary muscle contraction during coughing, relaxation and straining were scored by visual inspection and digital palpation). The chi squared test for trend or ANOVA was used in an unadjusted analysis to assess associations between prolapse stage and pelvic floor muscle variables.

b) Results

In one study [303] weaker pelvic floor muscles, poorer endurance and lower vaginal resting pressure were each significantly associated with greater risk of prolapse >=stage II. There was a significant interaction between muscle strength and vaginal

resting pressure: weak pelvic floor muscles and low vaginal resting pressure giving a higher odds ratio than other combinations. The authors concluded that women with poor PFM function were more likely to experience POP compared with women with good PFM function, and that this supports the hypothesis that PFMT may be important in the prevention and treatment of POP.

In another study [316] of 325 women with a mean age of 57.8 years, 48.9% (159) had prolapse (stage II, III or IV) and 23.4% (76) were able to perform a contraction with strength rated 3, 4 or 5 on the Oxford scale. Pelvic floor muscle contraction strength was significantly lower in women with prolapse >=II compared to women with stage 0 or I prolapse (1.52 versus 1.87, p=0.007).

Slieker-ten Hove [2010] achieved a 62.7% response rate with 1140 women both completing the questionnaire and consenting to a vaginal examination. Of these 1140 women, 800 were randomly selected and 649 then underwent vaginal examination. Fifty four (8.3%) had prolapse. Higher stages of prolapse compared to lower stages were associated with less ability to attain levator closure. Higher stages of prolapse were also associated with lack of effective involuntary contraction during coughing, but better ability to perform proper straining technique. There was no association between stage of prolapse and voluntary muscle contraction strength or endurance. The authors suggest tentatively that strong pelvic floor muscles alone do not prevent the development of prolapse.

c) Summary

Previously one study had reported women with stage II prolapse were better able to elevate their pelvic floor than those with stage III or IV, and hypothesised that poor PFMs may contribute to the development of prolapse. Now additionally three other studies have examined the association between pelvic floor muscle function and prolapse. Two studies had large sample sizes but unadjusted analyses; the third study was smaller but used an adjusted analysis. Two studies suggested the strength of voluntary pelvic floor muscle contractions was negatively associated with prolapse stage, whilst the third did not, but instead found an association between higher stages of prolapse and lack of an effective involuntary contraction.

Currently, there is no evidence from intervention studies regarding the role of PFMT or other physical therapies in the prevention of POP; better PFM function may be associated with less risk of prolapse **(Level of Evidence: 3)**.

2. TREATMENT

a) Quality of data

An evidence-base is now emerging regarding the role of PFMT in the treatment of prolapse, both as a treatment in itself and as an adjunct to surgery. A Cochrane review specifically addressing this question was first published in 2004 and its second update was published in November 2011 [296].

(a) PFMT alone:

Six trials now exist in this area **(Table 17)**, three of which were included in the 4th edition. The three new trials are reported in detail below.

Braekken [2010] undertook a single-centre trial where they randomised 109 women (59 PFMT, 50 control), the results of which were reported in two articles [306,317]. Women had stage I, II or III prolapse of any type (determined by POP-Q), and 63% were reporting symptoms of prolapse. Randomisation was stated as stratified by severity of prolapse. The intervention group women were instructed in PFMT for 6 months (weekly physiotherapy appointments for three months then fortnightly appointments) with home exercise (3 sets of 8-12 close to maximal contractions daily). Both groups were given lifestyle advice and taught “the Knack”. Prolapse stage, prolapse, bladder and bowel symptoms, pelvic floor muscle manometry and ultrasound measurements were taken at 6 months.

The risk of bias was judged to be low. A statistician generated and stored the allocation envelopes. The participant opened the opaque sealed envelope herself. Random permuted blocks were not used which resulted in unequal group sizes. There was a significant difference at baseline between the randomised groups in the prevalence of prolapse symptoms (43/59 PFMT group, 26/50 control group). Pelvic floor ultrasounds were taken and assessed blinded to women’s group in the trial, but pelvic floor assessments were not blinded. Dropouts were adequately reported and the rate was low (2%).

Stupp [2011] randomised women with untreated stage II anterior or posterior prolapse attending a urogynaecology service in Sao Paulo, Brazil [318]. POP symptoms were the women’s main clinical presentation. The PFMT group (n=21) received 6 appointments over 14 weeks with a specialist women’s health physiotherapist at weeks 0, 1, 2, 6, 10 and 14. The first 3 sessions aimed to achieve sensory awareness. A 12-week home exercise program was prescribed and women were encouraged to perform 3 sets of exercises daily. One set was 8-12 MVCs, held for 6-10 secs, double rest times between contractions, followed by 3-5 fast contractions in a row. Fortnightly the same physiotherapist phoned the woman. A standardised lifestyle advice sheet was given to both groups containing global stretching exercises and advice on weight loss, fluid intake, constipation, and avoidance of heavy lifting. No detail was provided of who delivered the intervention e.g. how many physiotherapists. Control group (n=16) received instructions on performing a PFM contraction without a protocol, and a lifestyle advice

Table 17: Characteristics of studies comparing PFMT versus no active treatment for pelvic organ prolapse

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Braekken [306,317]	PFMTvs control (given lifestyle a, taught the Knack)	Weekly physiotherapy appointments for three months then fortnightly visits, with home exercise (3 sets of 8-12 close to maximal contractions daily)	6 months	Reduced frequency of symptoms: PFMT 74% vs control 31%, RR 0.37, 95% CI 0.21 to 0.65) Reduced symptom bother: PFMT 67% vs control 42%, RR 0.56, CI 0.33 to 0.97 POP-Q stage not improved: 47/58 PFMT vs 46/50 control, RR 0.88, CI 0.76 to 1.02	Stage I, II and III prolapse included. Dropout rate 2%
Ghroubi 2008 [437]	PFMT+ healthy living advice vs control	Taught PFMEs (stretch reflex technique) + electrical stimulation + digital biofeedback. 24 sessions, 30 minutes per session. From 10th session 20 contractions per day at home. Lifestyle advice.	unknown	Post-Rx no. with pelvic heaviness; 5/27 PFMT vs 14/20 control, RR 0.26, CI 0.11 to 0.61	Stage I or II cystocele, with or without stage I rectocele. No detail of dropouts.
Hagen 2009 [438]	PFMT vs control (given lifestyle advice leaflet)	5 physiotherapy sessions (weeks 0, 2, 6, 11 and 16). Individualised advice and home exercise programme - 6 sets per day recommended, 1 set = up to 10 max. voluntary contractions, held for up to 10 secs, with 4 secs rest in between, 1 min rest, then 10 or more fast contractions.	16 weeks	Pelvic Organ Prolapse Symptom Score, mean diff. btwn groups in change from baseline: 3.37, CI 0.51 to 6.23 Self-report of no improvement: 7/19 PFMT vs 16/21 control, RR 0.48, CI 0.26 to 0.91 POP-Q stage not improved: 6/11 PFMT vs 9/9, RR 0.57, CI 0.33 to 0.98	Stage I and II prolapse included. Dropouts: PFMT 4, control 3.
Hagen 2011 [296]	PFMT vs control (given lifestyle advice leaflet)	5 physiotherapy sessions (weeks 0, 2, 6, 11 and 16). Individualised advice and home exercise programme – at least 3 sets per day recommended, 1 set = up to 10 max. voluntary contractions, held for up to 10 secs, with 4 secs rest in between, 1 min rest, then 10 or more fast contractions.	16 weeks	Pelvic Organ Prolapse Symptom Score, mean diff. btwn groups in change from baseline at 12 months: 2.37, CI 1.30 to 3.44 (results of statistical modelling subsequent to ICS abstract) POP-Q stage not improved: 135/168 PFMT vs 150/171 control, RR 0.92, CI 0.83 to 1.01	Stage 1, II and III prolapse included. Questionnaire response at 12 months: 67% PFMT, 65% control. 6-month POP-Q attendance: 81% PFMT; 82% control

Table 17: Characteristics of studies comparing PFMT versus no active treatment for pelvic organ prolapse (continued)

Study ID, population	Training Type	Training Program	Training Duration	Effectiveness	Notes
Piya-anant 2003 [439]	PFMT vs control	PFMEs taught on one occasion. If woman unable to perform, attended monthly until could do so. 30 exercises "after one meal every day". Advice on diet and fluid intake.	unknown	PFMT group less likely to have worse prolapse at 24 months follow-up (28%) than those in the control group (72%) (P < 0.05).	These two percentages were the only numeric outcome data reported. Women over 60 years of age, with or without anterior wall prolapse. 88/330 PFMT and 91/324 control did not attend for follow-up.
Stupp 2011 [318]	PFMT vs control (given lifestyle advice sheet)	7 appointments with women's health physiotherapist (weeks 0, 1, 2, 6, 10, 14). 12-week home exercise program was prescribed - 3 sets of exercises daily encouraged: 8-12 MVCs, held for 6-10 secs, double rest times btwn contractions, 3-5 fast contractions in a row. Fortnightly the same physio phoned the woman. Lifestyle advice sheet given to both groups.	14 weeks	POP-Q stage not improved: anterior 6/19 PFMT vs 11/14 control, RR 0.40, CI 0.20 to 0.82; posterior 6/12 PFMT vs 4/5 control, RR 0.63, CI 0.31 to 1.28 Strength (Oxford), mean diff btwn groups post-Rx: 1.5, CI 101 to 1.99 Endurance, mean diff btwn groups post-Rx: 4.4, CI 3.37 to 5.43 MVC, mean diff btwn groups post-Rx: 4.4, CI 1.63 to 7.17	Stage II anterior or posterior prolapse. Stated compliance 100% PFMT and 76.2% control.

Foot notes: MVC = maximum voluntary contraction, PFMT = pelvic floor muscle training, PFME = pelvic floor muscle exercises,

sheet as above. The primary outcome measure was POP-Q performed by one gynaecologist who was blinded to group allocation. Secondary outcomes were: pelvic floor muscle function (strength – Oxford grading, endurance – PERFECT assessment); electrical activity (sEMG); symptom severity. It was stated that compliance in the PFM group was 100% and in the control group 76.2%. 91% in the PFM group adhered to the home exercise programme.

Risk of bias in this study was potentially high: no detail of the randomisation process was given, nor blinding of the outcomes measures, other than POP-Q.

A multicentre trial of PFMT for stage I, II or III prolapse which randomised 477 women has recently been completed [296]. This was a parallel group randomised controlled trial. Women in the intervention group were randomised to PFMT, delivered by a physiotherapist at 5 appointments over 16 weeks, and lifestyle advice. Women in the control group received a Lifestyle Advice Sheet by post only. Women had their prolapse assessed by a gynaecologist (POP-Q system) at baseline and (blinded) 6 months, and completed postal questionnaires at baseline (prior to randomisation) and 6 and 12 months. The primary outcome was prolapse symptom severity (Pelvic Organ Prolapse Symptom Score – POP-SS) at 12 months. Other key outcomes were prolapse severity (POP-Q), women's perceived change in prolapse, uptake of further treatment and cost-effectiveness. Analysis was by intention-to-treat.

The risk of bias was judged to be low. Randomisation was by computer allocation using a remote randomisation service, and groups were comparable at baseline. Outcomes were measured mainly via questionnaire thus avoiding measurement bias. Gynaecologists were blinded to women's trial group when undertaking the follow-up POP-Q assessments. Questionnaire response rates were high at 6 month follow-up (84% intervention; 86% control), but lower at 12 months (67% intervention; 65% control). Rates of attendance for 6-month prolapse assessment and POP-Q were good (81% intervention; 82% control). Compliance with the intervention was high: 80% of women attended 4 or 5 physiotherapy sessions.

(b) PFMT and surgery:

No new evidence to report.

(c) PFMT and pessary:

A feasibility study (the PEPPY study) looking at the possible effects of PFMT with a vaginal pessary in situ has been completed but full results have not yet been published.

(d) Ongoing trials:

There is currently one ongoing RCT (of PFMT as an adjunct to vault prolapse surgery – OPTIMAL) under the direction of the NIH-sponsored Pelvic Floor Disorders Network [319]. This trial compares two methods of suspending the vaginal vault in women undergoing vaginal surgery for POP and additionally will randomise half of the participants to adjunctive post-operative PFM exercises and behavioural therapy and half to routine care. The analysis will assess whether such adjunct therapy improves both anatomic and symptomatic outcomes two years after surgery. The study is expected to be complete by 2012 (the OPTIMAL trial, ClinicalTrials.gov Identifier: NCT00597935).
