A further feasibility study of pre- and post-operative PFMT for women undergoing prolapse repair is underway (the SUPER study: ISRCTN 08203457). This study aims to recruit 30 participants over 3 sites. Participants are randomised to either the intervention group (n=15) or the control group (n=15). Prior to surgery all patients who have agreed to take part are seen by a physiotherapist to complete baseline outcome measures. Those in the intervention group are also seen once pre-operatively by another physiotherapist to be taught pelvic floor muscle exercises. After 6 weeks those in the intervention group are seen for a total of 5 visits over a 16 week period for further instruction in pelvic floor muscle exercises and advice. Both groups complete outcome measures at 6 and 12 months post-surgery.

b) Results

(a) PFMT alone:

In the Braekken trial [306,317], in women with prolapse symptoms at baseline (69/109), those in the PFMT group compared to the control group were significantly more likely to have reduced symptom frequency (74% vs 31%) and bother (67% vs 42%). Fewer women in the PFMT group than the control group had no improvement in POP-Q stage (81% versus 92%). In contrast, no significant difference was noted in the subgroup of women with prolapse beyond the hymen (80% versus 80%). The authors also used ultrasound to measure the position of the bladder and rectum within the pelvis, and the dimensions of the muscles and hiatal area, to indicate the severity of prolapse. They found the change in resting position in standing of the bladder and rectum, compared to baseline, were significantly greater (both were higher) in the intervention group than the control group; and changes in measures of the muscles and hiatal area were also significantly different in favour of the intervention group. Manometry (unblinded) was used to measure contraction strength and endurance and found improvement in strength and endurance were significantly greater in the intervention group compared to the control group. Braekken also reported better urinary outcomes for women in the intervention group in their trial.

Stupp [2011] showed that the intervention group had significantly greater anatomic improvements in anterior and posterior vaginal wall prolapse than did the

control group, and a decrease in symptoms [318]. In addition, the intervention group had greater improvements in muscle strength, endurance, and electromyography parameters compared to the control group.

Hagen [2011] found prolapse symptoms were reduced significantly more in the intervention group compared to the control group at 6 months and 12 months. Change in prolapse stage from baseline to 6-month follow-up showed a marginally significant difference between trial groups: 20% in the intervention group had an improved stage versus 12% in the control group. The majority of women in both groups had no change in their prolapse stage. By 12 months, a significantly greater proportion of control women (55%) reported they had received further treatment for prolapse compared to the intervention women (30%). Control women were significantly more likely than intervention women to report subsequent referral to physiotherapy. Rates for receiving other treatments were similar. When analysis of the primary outcome measure was adjusted for additional treatment received, the estimate of the effect of PFMT at 12 months was greater and comparable with that at 6 months.

ICI 4th edition reported on three trials of PFMT versus control for prolapse that found a positive effect, however two of the trials were small (<25 per arm) and the remaining trial had serious methodological limitations. Results from an additional three trials are now available [296,306,317,318] indicating a benefit on both anatomical and symptom measures of prolapse. Stupp (2011) was a pilot study; the remaining two trials were rigorously conducted trials with large sample sizes which provide level 1 evidence of the effectiveness of PFMT for women with stage I to III prolapse.

c) Summary

Based on previous studies and new evidence from two rigorously conducted trials and a smaller pilot trial, we conclude that PFMT can improve the symptoms of prolapse and the anatomical defects. **(Level of Evidence: 1)**

No further evidence is available regarding the role of PFMT as an adjuct to surgery and thus conclusions are unchanged: pre- and post-operative PFMT may help to improve quality of life and urinary symptoms in women undergoing surgery for POP, but the findings regarding its effects on PFM strength are contradictory. The evidence available however is based on two small trials, one of which included women undergoing surgery for UI and/or prolapse. **(Level of Evidence: 2)**

d) Recommendations

PFMT can improve prolapse symptoms and severity **(Grade of Recommendation: A)**.

Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse **(Grade of Recommendation: C).** Larger trials are needed, and prolapse-specific measures should be primary outcomes in such trials

Future studies of PFMT for POP should aim to reach a consensus on the optimal intervention programme prescribed and might also consider comparisons of individualised training with group training.

III. PESSARIES

Pessaries offer a non-surgical option for the treatment of urinary incontinence and pelvic organ prolapse (POP). Pessary use dates back prior to the days of Hippocrates, and innumerable varieties such as half a pomegranate, a linen tampon soaked with astringent vinegar or a piece of beef have been used. It was only in the 16th century that a device was made specifically to be used as a pessary, as opposed to using naturally occurring objects. Since the 20th century, considerable refinements have occurred and modern pessaries are made from a variety of materials including rubber, clear plastic, soft plastic with metal reinforcements and silicone [320].

A range of vaginal pessaries (**Figure 7**) exist which can be broadly divided into two types: support and space-filling pessaries. Support pessaries lie along the vaginal axis, with the posterior component sitting in the posterior fornix and the anterior component coming to rest just under the symphysis pubis, thus providing a supportive shelf for the descending pelvic organs [321]. As there is no evidence to support the use of a specific type of pessary, choice is based on experience and trial and error. It is generally accepted that the ring pessary should be tried first because of ease of insertion and removal, and if this fails, other pessaries can be used [322]. Clemons [323,324] found that the ring pessary was successful in grades II and III prolapse, but for higher grades, a Gellhorn pessary was more effective. By contrast, a randomised crossover trial of the ring versus the Gellhorn pessary, did not demonstrate any difference in effectiveness between the two types of pessaries [325].

While it is not possible to establish a global perspective of the full extent of pessary use, a survey of the members of the American Urogynecologic Society showed that 75% of members used pessaries as first-line therapy for POP. Ninety two percent of physicians believed that pessaries relieve symptoms associated with POP, while 48% felt that pessaries also had therapeutic benefit in addition to relieving symptoms. No clear consensus emerged regarding the type of pessary or their indications for use [326]. Similarly there are no clear prevailing removal regimes [Cundiff, 2000]. In the United Kingdom, a recent postal survey demonstrated that 87% of consultants use vaginal pessaries for management of POP [327]. Many physicians receive little or no

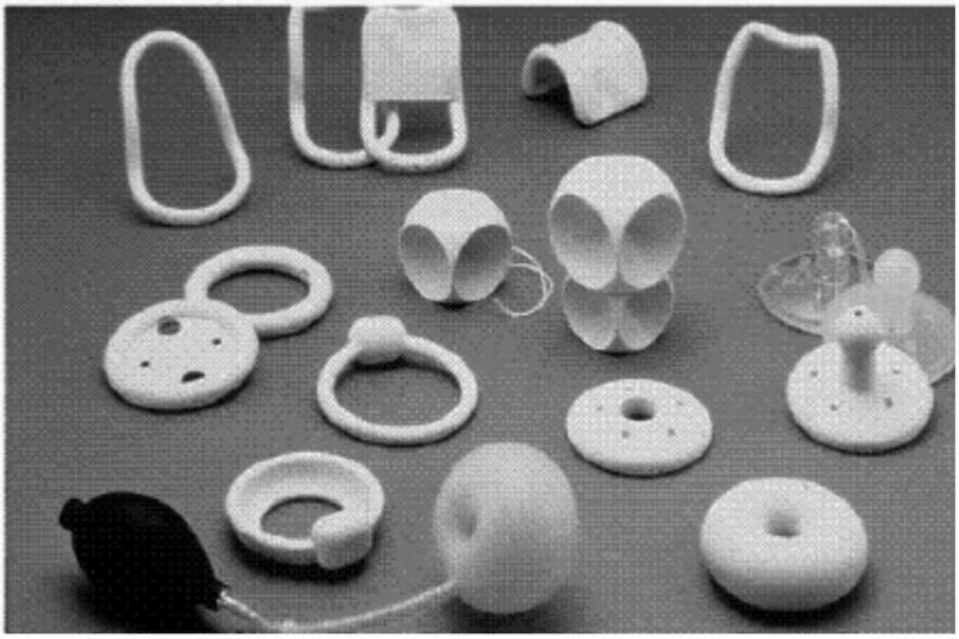

Figure 7 : Range of pessaries (Courtesy of Mediplus Ltd, UK)

training in the use of pessaries [328] and have limited experience with pessary selection and fitting.

Likely candidates for vaginal pessaries are those with co-morbid medical conditions, those who still wish to bear children, as interim relief prior to surgery and for those who prefer non-surgical treatment [314]. Kapoor (2009) demonstrated that when pessaries are offered to patients with symptomatic pelvic organ prolapse, nearly two thirds of women choose a pessary rather than surgery as initial management [329]. Furthermore, a case-control study comparing women who chose pessaries to those who underwent surgery one year after their respective treatment found no difference in prolapse symptoms, bladder, bowel or sexual dysfunction between groups [330]. Thus, although traditionally thought of as treatment only for women deemed unfit for surgery or infirm, pessaries should be considered a viable treatment option for the majority of women in the initial management of POP. Other indications include vaginal laxity, neonatal prolapse mainly seen in association with neural tube defects such as spina bifida and prolapse during pregnancy [322].

Factors that predict the type of treatment chosen for POP have been evaluated in various studies. Powers [2004] [331) noted that patients who refused a pessary were significantly younger and had a higher incidence of urodynamic stress urinary incontinence (SUI). More patients with stage III prolapse refused while more patients with stage IV accepted pessary trial. Heit [2003] [332) found that the probability of choosing a pessary over surgery increased as age increased and decreased as the prolapse severity increased. Clemons 2004 [324] evaluated characteristics that were predictive for pessary usage for up to one year. Age greater than 65 years at the time of pessary insertion and more severe prolapse (Stage III-IV) were more predictive for pessary discontinuation. Brincat [2004] [333] found that women who were sexually active and those with POP were more likely to continue wearing a pessary than women with urinary incontinence. In keeping with this, Ko [2011] [334] found that substantially older women or menopausal women opted for a pessary rather than surgery, and significantly more sexually active women preferred surgery.

Evidence of the effectiveness of pessary use for prolapse can be obtained from a large number of observational studies (prospective and retrospective) and two RCTs (**Table 18 and Table 19**).

1. QUALITY OF DATA

(a) Randomised controlled studies:

One new randomised intervention was found [335] in which the Colpexin Sphere was compared to PFMT in women with stage I and II pelvic organ prolapse on improving pelvic floor muscle strength and reducing symptoms. The device is a spherical

intravaginal device, similar to a pessary, which is placed above the levator musculature and requires active PFM contractions to keep it in place. Its purpose is to reduce the prolapse while facilitating PFM strengthening. Group 1 used Colpexin Sphere with PFMT and the other group did PFMT only for a 16 week period. Outcomes were evaluated at baseline and at 16 weeks for comparison of pelvic floor muscle strength. A total of 50 women were enrolled and 48 women completed the full 16 week assessment which consisted of Colpexin pull through test and a digital test. All assessments were performed by only one investigator who was blinded to the group assigned. The small sample size and the short period of treatment are limitations. In addition, the authors did not report a power calculation. The participants were stratified into two groups by using computer-generated random numbers. Participants within each stratum were randomised by using opaque sealed envelopes to one of two study groups.

No other new randomised contolled trials were found on the use of a pessary compared to another device or treatment protocol. Cundiff [325] conducted the largest multi-centre crossover trial, comparing a ring with support and a gellhorn pessary for the treatment of symptomatic stage II or greater symptomatic prolapse. There were no significant differences between groups in baseline characteristics. Participants were fitted with one of the pessaries for three months, and with the second for a further three months. During each three-month period, data were collected at one, six and twelve weeks from women who had a successful fit. Outcomes were measured at enrolment and three and 12 months, and included objective assessment using POP-Q and subjective assessment using Pelvic Floor Distress Inventory (PFDI), Pelvic Floor Impact Questionnaire (PFIQ), and a sexual function questionnaire. Random allocation was by computer-generated random numbers using permuted blocks of variable size. Opaque, sealed envelopes were used to store the random allocation. Participants and clinicians were not blind to the allocation, but data were coded such that analysis was conducted blind.

(b) Prospective observational cohort studies

Wu [1997] [336] conducted a prospective study of 110 women with symptomatic POP to evaluate a protocol for pessary treatment. After intitial fitting, they were seen at two weeks for re-examination and thereafter at 3-6 month intervals. Handa (2002) [337] described the course of POP amongst 56 women who used a supportive vaginal pessary for at least one year.

In 100 women with prolapse, Clemons [2004] [323], analysed the factors that contributed to successful pessary use. Two publications resulted: one on the symptoms and patient satisfaction at two months on 73 out of the original 100 study women who had a successful pessary fit and the other on the continuation with pessary at one year of the sub-group who were satisfied users [324].

Lukban [2006] [338] described a study of the effectiveness and safety of the Colpexin Sphere device in women (n=39) with prolapse beyond the hymenal ring; all women had grade three or greater prolapse of at least one vaginal compartment (69% cystocele, 44% rectocele, 31% enterocele, 8% vault prolapse, 21% uterine prolapse). Women were instructed to use the Colpexin Sphere only whilst in bed for the first week, and to use continuously thereafter, and were taught PFM exercises to be performed twice daily (PFMT and knee squeezes). The intervention period was 16 weeks. Outcome measures included prolapse stage (modified Baden and Walker classification system), PFM assessment (Brink Scale score), and a Pull Test to measure PFM tone and strength (a tensiometer is used to measure the force required to remove a 35mm sphere from above the levator plate). The small sample size, lack of control group and short follow-up were limitations of the study.

Using the Sheffield Pelvic Organ Prolapse quality of life questionnaire, Fernando [2006] [339] addressed the effectiveness of pessaries in alleviating symptoms associated with POP in a prospective study of 203 consecutive women attending a specialist urogynaecology unit four months after pessary insertion. Abdool [2011] [330] evaluated and compared the effectiveness of pessaries and surgery in patients with pelvic organ prolapse in 554 women one year after treatment. Of these 359 were treated with a vaginal pessary and 195 had surgery. Lone [2011] [340] prospectively evaluated the use of pessaries in 246 women over a 5 year period and identified complication rates and reasons for discontinuing use over the 5 year period. There was an overlap of patients in these studies as they are from one institute. Kuhn [2009] [341] used the same Sheffield Pelvic Organ Prolapse quality of life questionnaire and Female Sexual Function Index questionnaire to evaluate quality of life and pelvic organ and sexual function before and during pessary use in 73 women of whom 31 were sexually active.

Komesu [2007] [342] compared pelvic floor symptom changes in 36 who continued pessary use to 28 who discontinued using the Pelvic Floor Distress Inventory-20 (PFDI-20) before and after pessary use. In the same group of women, they further explored whether patient determined goal achievement was associated with pessary continuation.

Barber [343] undertook a study to evaluate the responsiveness PFDI and PFIQ in women with pop undergoing surgical and non-surgical management. The pessary group consisted of 42 women with stage II or greater prolapse enrolled in an multicentre randomised trial comparing two different pessaries and 64 women with Stage III or greater prolapse who underwent vaginal reconstructive surgery. All subjects completed the questionnaires at baseline and again

either three months (pessary group) or six months (surgery group) after initiation of treatment.

Jones [344] evaluated 90 women who had a pessary inserted for POP at baseline and 3 months after pessary use. Pelvic Floor symptoms were assessed using PDFI scores. In addition they assessed the change in genital hiatus measurements. Logistic regression analysis was used to assess baseline characteristics predictive of continued pessary use.

Patel [345] sought to evaluate whether use of a vaginal pessary would change body image, bother symptoms, and quality of life in women with pelvic organ prolapse. Seventy five women presenting for pessary insertion completed the short forms of Pelvic Floor Distress Inventory-20, Pelvic Floor Impact Questionnaire, and Body Image Scale. After successful pessary insertion and use for at least 3 months, 54 subjects repeated the surveys.

(c) Retrospective studies:

There are several retrospective studies on pessary benefits and outcomes but these are limited by the retrospective study design [334,346-351]. Thus we have chosen not to evaluate them in this review as there are several prospective cohort studies that allow a better assessment of effect.

2. OUTCOME

a) Patient reported outcomes

As can be seen in Table 18, follow-up periods evaluating patient reported quality of life varied from three to 12 months. In most studies a recognised measure of prolapse was used i.e. POP-Q examination, to objectively assess and evaluate the prolapse. One study [342] included patients with prolapse and/or incontinence. Various types of pessaries were used. Validated questionnaires to assess patient related outcome were used in eight studies. Commonly used questionnaires were the Sheffield POP symptom questionnaire, and the Pelvic Floor Distress Inventory (PFDI) and Pelvic Floor Impact Questionnaire (PFIQ). Other questionnaires used were Female Sexual Function Index, Body Image Scale and Kings Health Questionnaire.

A direct comparison between studies is difficult as different outcome measures have been used. When pessary insertion was successful, there appears to be a significant improvement in prolapse symptoms. Cundiff [2007] found significant and clinically significant improvements in majority of the PFDI scales and many PDIQ scales with both pessaries but no difference between the ring or gellhorn pessary. Two prospective studies [343,344] found a significant improvement in the urinary and prolapse scales of the PFDI but not in the colorectal scale 3 months after insertion of pessary compared to baseline. Others [342,345] demonstrated a significant improvement of the PFDI-20 scale 3 months after pessary use.

However data on the questionnaire that measures impact i.e. PFIQ varies as Barber (2006) demonstrated no significant changes in the 3 scales while Patel (2010) showed significant decrease in PFIQ scores and prolapse/vaginal subscale of the PFIQ. Fernando (2006) and Abdool (2011) administered the Sheffield Pelvic Organ Prolapse Quality of Life questionnaire (SPS-Q) at before, 4 monthsand one year after pessary insertion. Two hundred and three patients from the previous study (Fernando) were included in the later paper (Abdool). A significant improvement was seen in prolapse symptoms, bladder and bowel function as seen in Table 18. Contrary to Fernando 's study, Abdool did not demonstrate improvement in bowel evacuation at one year probably as this was only marginally significant (p=0.045) at 4 months.

Women who were sexually active and wore a pessary showed significant improvement in satisfaction of sexual activity at 4 months [339] and at 12 months [330]. Kuhn [341] found a significant improvements in desire, orgasm, lubrication and satisfaction after pessary use. This suggests that a vaginal pessary does not negatively interfere with sexual activity but may even improve sexual function. However, sexual activity is only possible with a ring pessary insitu [330,339]. The other pessaries need to be removed prior to sexual intercourse.

Self-perception of body image is reduced in women with advanced POP [352]. A significant decrease in body image scale scores has been reported indicating an improvement in women's perception of themselves in addition to improvement in PFDI-20 and PFIQ scores at 3 months [345]. However, majority of subjects in this study had stage 3 prolapse, so it is possible that improvements might not be the same for women with less advanced prolapse (i.e., stage 2) and those with urinary incontinence alone.

Two studies [330,343] compared patient related outcome after pessary and surgery use. Abdool demonstrated a significant improvement in prolapse, urinary, bowel and sexual function in both treatment arms but no difference between the two groups. However, Barber (2006) found that subjects in the surgery group had significantly greater improvement in each of the scales of the PFDI and the prolapse and urinary scales of the PFIQ than did the pessary group.

The placebo effect of treatment for prolapse needs further exploration. Komesu [2007] found an improvement in the PFDI-20 total, bladder and prolapse scores in women who discontinued and those who continued pessary use although this was more modest [342]. This could be because of placebo effect or because of conservative interventions such as dietary change and pelvic floor exercises. In the same group they further studied the association between patient determined goal achievement and pessary continuation. Goals commonly listed were

bladder (36%), activity (20%), and general health (13%) and prolapse related (11%). Although goals were found to be variable, women who continued pessary use were more likely to meet one to two goals. Women who attained self-determined goals were more likely to continue pessary use.

1. Success Rates

There is no agreement in the literature on what is considered successful fitting of a pessary. Some consider success if a pessary was perceived comfortable by a patient when retained during valsalva and voiding at the initial visit, while others consider it success if a patient continued to use the pessary until the following visit to the doctor. Therefore, the rates of successful fitting vary between 89% to 8% with the follow-up time to define success ranging from initial fit to 7 years. (**Table 19**). Five studies [333,342,347,349,351] included patients with prolapse and/or incontinence.

Higher success rates for specific types of prolapse (83% for uterine prolapse and 82% for cystocele) are recorded [349]. Comparison of success rates by pessary type was difficult due to use of differing protocols for pessary selection within studies (**Table 19**). Wu [1997] [336] used ring pessaries in 96% of women who were successfully fitted. Similarly, ring pessaries were the primary choice of treatment in other studies [337,339,353]. The fitting protocol used by Mutone [348] specified the ring pessary with support diaphragm in the first instance. Of women who had a successful pessary fitting, ring pessaries were used more often in women with stage II (100%) and stage III (71%) prolapse whereas Gellhorn pessaries were used more often with stage IV (64%) prolapsed [353]. Hanson [2006] found significantly greater success with the ring, ring with support and Gellhorn pessaries than other type of pessaries ($p<0.05$), however only 54% of women in this study had prolapse (the remainder had UI).

Parameters reported as associated with a successful pessary fitting were often contradictory. Hanson [2006], Clemons [2004], and Mutone [2005] reported that patient age was not significantly related to the success of pessary fitting whereas Wu [1997] and Friedman [2010] reported that women who were fitted successfully tended to be older. Mutone [2005] found that women classed as obese were significantly less likely to have a successful fit, whereas Maito [2006] [347] indicated that weight was not a predictor of successful pessary fit.

Clemons 2004 [353] reported no effect on fitting success of previous surgical intervention while others found a significant relationship between unsuccessful fit and previous hysterectomy or prolapse repair [346-348]. Wu [1997] reported that a history of pelvic surgery reduced the probability of a successful pessary fitting from 79% to 67%, although this result was not significant ($p=0.2$). Hanson [2006] found a higher fitting success rate in women with previous abdominal genitourinary surgery (71%) compared to those with a history of genitourinary surgery via the vaginal route (60%). Fernando [2006] found 75% retained the pessary at two weeks, and that failure to retain was associated both with increasing parity and hysterectomy in a multivariate logistic regression analysis; site and type of prolapse did not affect success.

Current hormone use did not predict greater likelihood of fitting success [336,353] whereas use of local oestrogen (with or without systemic HRT) was felt to play an important role in successful pessary fitting [349]. Sexually active women were more likely to continue wearing a pessary for a longer period of time [333,343].

Women with SUI before pessary fitting are reported to have a significantly lower success rate in two trials [336,346] but not in one [324]. Maito [2006] found no significant difference in success rates between women with SUI (94%), POP (89%), or both (81%).

Increasing severity of prolapse did not affect the success of pessary fit [336, 348, 353]. Neither was large genital hiatus [324,348,350], severe vaginal atrophy nor a foreshortened vagina affected success nor was the location of the prolapsed an issue [348]. However, a shorter vaginal length and wider vaginal introitus were associated with an unsuccessful fitting [324,350]. On the other hand, Maito [2006] [347] found mild posterior prolapse to be a significant predictor of successful fit. Clearly, differing techniques, follow up, support and skills affect how well pessaries are tolerated and maintained.

Comparison of long term pessary usage rates was difficult due to differing follow-up periods used in the studies reported. Maito [2006] reported continued pessary use of on average six months (range one to 17 months); discontinuation of pessary use was significantly associated with severe posterior prolapse after adjustment for age. Wu [1997] found that 66% of those who used a pessary for more than one month were still users after 12 months and 53% were still users after 36 months. Lone [2011] prospectively evaluated 246 women who opted to use a vaginal pessary (ring, cube, gellhorn, donut) [340]. One hundred and eighty seven (76%) successfully retained the pessary four weeks after pessary insertion. Over a five year period, 19% of the 187 women were lost too follow-up. Of the 151 women included in the analysis, 13.9% discontinued use at some point after four weeks, whereas 86.1% used the pessary successfully over 5 years. The authors concluded that if the treatment for pessary is successful at four weeks, most women will continue to use the pessary over 5 years without a concomitant increase in complications.

Reasons for failure range from expulsion to complications such as vaginal discharge, erosion, de novo SUI, pain, voiding difficulty and constipation (**Table 19**).

2. Complications

Minor complications after pessary insertion range from vaginal discharge, erosion, de novo SUI, bleeding pain and constipation as can be seen in Table 19. Sarma [2009] [351] reported a complication rate of 56% after pessary use. Rarely major complications may occur. Neglected pessaries present with more serious complications namely fistula formation and peritonitis. Erosion into the bowel or bladder and dense adhesions to other pelvic structures has been reported. Unusual complications of cervical entrapment, small bowel incarceration, and hydronephrosis [354] have been reported.

3. Pelvic Floor Muscle Strength

In a randomised study on the use of Colpexin Sphere [335] a statistically significant improvement in pelvic floor muscle strength was noted as compared with baseline values and at 16 weeks was shown in both groups, with mean difference pull test contraction values of 2.25 + 3.28 N ($P < 0.05$) in the study group and 1.38 + 2.17 N ($P < 0.05$) in the control group. There was no statistically significant difference in improving pelvic floor muscle strength between the study and the control groups. The authors concluded that even though Colpexin Sphere plus pelvic floor exercise improved pelvic floor muscle strength, the improvement was not statistically different from exercise alone

4. Financial implications:

Hullfish [355], developed a Markov decision analysis model to assess and compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy pelvic organ prolapse e.g. expectant management, use of a pessary and surgery obtaining months of quality-adjusted life over one year. Sensitivity analysis was conducted to determine whether the results depended on specific estimates of patient utilities for pessary use, probablitites for complications and other events and estimated costs. Only two treatments i.e. initial pessary use and vaginal reconstructive surgery were found to be efficient choices. Pessary use (including patients that eventually transitioned to surgery) achieved 10.4 quality-adjusted months at a cost of $10,000 per patient, while vaginal reconstructive surgery obtained 11.4 quality adjusted months at a cost of $15,000 per patient. The authors concluded that research is needed to standardise POP outcomes and complication, so that healthcare providers best utilise cost information in balancing the risks and benefits of their treatment decisions.

IV. SUMMARY AND RECOMMENDATIONS

There is growing attention being paid to the effectiveness of conservative interventions for the condition. There are encouraging signs of more rigorous research in this area, with the publication of 4 RCTs [296,306,318,335] in this field since the 4th ICI and 3 more trials awaited.

C.4.1 Recommendations for practice

There is limited Level 1 and Level 2 evidence on which to base recommendations for practice, and most recommendations are, in effect, hypotheses that need further testing in RCTs.

Pelvic floor muscle training (PFMT)

•PFMT can help improve prolapse symptoms and severity **(Grade of Recommendation: A)** (New).

•Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse **(Grade of Recommendation: C)** (Unchanged).

Pessaries

•In a choice between the Gellhorn pessary and a ring with support, either may improve prolapse symptoms and reduce their impact **(Grade of Recommendation: B).**

2. FUTURE RESEARCH DIRECTIONS

a) Lifestyle interventions

- Studies are needed to fully investigate the association between occupation/heavy lifting, bodyweight, constipation and POP. These studies should ensure that:
    - o Occupation, physical activity, bowel function and diet are assessed rigorously, using instruments with sound psychometric properties.
    - o Potential confounding variables are considered.
    - o Attempts are made to overcome some of the obstacles in research in this area such as recall bias inherent in assessing lifetime occupational history, or healthy worker bias which is a problem when attempting to compare POP in women currently employed in heavy labour type jobs versus others.
- Only when the links between various lifestyle factors and POP have been more clearly established can good RCTs be set up to investigate the effects that changes in these lifestyle factors can have on preventing POP.
- Anaemia is a treatable condition, either through diet or medication, and further research on its role in prevention of prolapse is warranted.

b) Pelvic floor muscle training (PFMT)

- Studies are needed to fully investigate the role of physical therapies in the prevention of POP. Such studies should:

Table 18: Characteristics of studies on symptomatic prolapse and pessary

Author/ year	Study design	Comparison group	Partici-pants	Type of pessary	Subjective and Objective assessment	Objective assessment	Length of follow-up	Improvement in symptoms
Abdool et al 2011 [330]	Prospective observational cohort case controlled	Pessary treatment compared to surgery	359	Ring, Gellhorn, Cube, Donut	Sheffield prolapse questionnaire	Baden-Walker	12 months	Awareness of lump, prolapse coming out of vagina, dragging pain in lower abdomen, low back pain, voiding difficulty, need to push prolapse to void, urinary urgency, fecal urgency, improvement in sexual satisfaction, interference with physical activity and quality of life
Barber et al 2006 [343]	Prospective observational cohort case controlled	Pessary treatment (3 months) compared to surgery (6 months) for pelvic organ prolapse	Pessary (n= 42) Surgery (n=64)	Ring and Gellhorn	PFDI and PFIQ	POP-Q	3 months for pessary	Significant improvement in prolapse and urinary scales of the PFDI. No change in the colorectal scale. No change in the PFIQ scales
Clemons et al 2004 [323]	Prospective observational cohort	N/A	100	Ring and Gellhorn	Not validated	POP-Q	2 months	Bulge (90% to 3%) Pressure (49% to 3%) Discharge (12% to 0%) Splinting (14% to 0%) SUI 45% UI 46% Voiding difficulty 53%
Cundiff et al 2007 [325]	Randomised cross-over	Ring with support to Gellhorn	134	Ring with support to Gellhorn	PFDI,PFIQ, Sexual Function Question-naire	POP-Q	6 months	Statistically and clinically significant improvements in majority of the PFDI and many PFIQ scales in both pessaries, but no clinically significant differences between the two pessaries
Fernando et al 2006 [339]	Prospective observa-tional cohort	N/A	203	Ring, Gellhorn, Cube, Donut	Sheffield prolapse questionnaire	Baden Walker	4 months	Awareness of lump (71%), Prolapse coming out of vagina (52%), Vaginal soreness (21%), Dragging sesation in lower abdomen 24%), Lower back ache (30%), Difficulty emptying bladder (40%), Push prolapse to void (29%), urinary urgency (38%), Urge urinary incontinence (29%), Stress urinary incontinence (40%), Incomplete emptying of bowels (28%), Rectal digitation to empty bowels (12%), Vaginal digitation to empty bowel (7%), Faecal urgency (30%), Urge faecal incontinence (20%), Frequency of sexual intercourse (16%),Improvement in sexual satisfaction (11%)

Table 18: Characteristics of studies on symptomatic prolapse and pessary (continued)

Author/ year	Study design	Comparison group	Partici-pants	Type of pessary	Subjective and Objective assessment	Objective assessment	Length of follow-up	Improvement in symptoms
Jones et al 2008 [344]	Prospective observa-tional cohort	N/A	90	Ring, Inconti-nence ring, Gellhorn, Oval	PFDI	POP-Q	3 months	Improvement in the overall PFDI scale and all subscales with the exception of colorectal distress inventory
Komesu et al 2007* [342]	Prospective observa-tional cohort	Compare PF symptoms in patients who continue and discon-tinue pessary use	64	Choice of pessary left to discretion of the provider	PFDI-20	POP-Q	6-12 months	In the continuation group final PFDI-20 total, bladder and prolapse scale scores were better than the discontinuation group.
Kuhn et al 2009 [341,344]	Prospective observa-tional cohort	N/A	73	Cube	Female Sexual Function Index, Sheffield question-naire, Kings Health Questionnaire	POP-Q	3 months	Improvement in feeling of bulge, improvement in stool outlet problems, overactive bladder symptoms. Improve-ment in sexual desire, orgasm, lubrica-tion, satisfaction after therapy
Patel et al 2010 [345]	Prospective observa-tional cohort	N/A	75	Ring, Ring with support, Gellhorn	Body Image Scale (BIS) and PFDI-20, PFIQ, Prolapse subscale of PFIQ	POP-Q	3 months	Improvement in body image scale scores, PFDI-20 scores, PFIQ scores

Wu et al 1997 [336]	110	Ring with and without diaphragm, Cube	Prospective observational cohort	Initial visit	81 (74%)	Failure to sustain support of the prolapse, intolerable urinary incontinence, vaginal discharge, pelvic pain, vaginal abrasions and erosions	Younger women, previous pelvic surgery, history of stress incontinence prior to pessary insertion

*Foot notes: N\A = not applicable; N/R = not reported,*Includes patients with incontinence and/or prolapse; ** women who discontinued pessary usage after two weeks and within the first two 2 months; ***Predictors identified at one year*

- Consider the exact nature and timing of any physical therapies.
- Ensure that the effects of lifestyle factors and other potential confounding variables are taken into account.

• Further trials are needed to add to the evidence regarding:

- The effectiveness of PFMT for different stages and types of prolapse.
- The role of PFMT as an adjunct to prolapse surgery.

• There are no trials that address the following comparisons of interest:

- Low versus high intensity supervision of PFMT
- Individual versus group PFMT.
- PFMT versus surgery.
- PFMT versus pessary.

c) Pessaries

• There remains a pressing need for well-designed RCTs to examine the effects of using the wide variety of different pessaries in the treatment of POP. Such studies need to:

- Address optimal pessary effectiveness, including the symptomatic and therapeutic benefits of pessaries as well as the indications for use, pessary fit, replacement and care.
- Adopt consistent protocols regarding choice of pessary.
- Allow sufficient follow-up periods.

• Randomisation may not be appropriate but efforts should be made to match the characteristics of the treatment groups being compared. Comparisons of interest are:

- Pessaries versus surgery.
- Pessaries versus physical therapies.
- Pessary in conjunction with PFMT.

The assessment and measurement of POP and the assessment of prolapse symptoms need to be made in a standardised fashion using a validated outcome measure (such as the POP-Q examination). The choice of a single validated symptom tool is problematic at the present time.

C. URINARY INCONTINENCE IN MEN

UI in men remains under-reported and under-studied in comparison to studies including women. The report from the 4th ICI indicated that the prevalence of UI and LUTS in men ranged from eight to 23% depending on the method of data collection, population accessed, and location [1,356). As for previous consultations, despite the prevalence of UI and LUTS in older men, the only aspect which continues to receive systematic consideration with respect to conservative management are post-prostatectomy urinary symptoms. Thus, the major focus of this section is UI after prostatectomy for benign or malignant disease. All prostatectomy types and approaches were considered including radical prostatectomy (open radical retropubic or perineal, laparoscopic, and robotic) or endoscopic procedures (such as transurethral prostatic resection, high intensity microwave therapy).

The PMFT, EStim and MStim interventions in the current review were reorganized to reflect the evolving evidence and emerging directions of research on post-prostatectomy urinary incontinence. Studies of EStim and MStim in men post prostectomy all included PFMT as an intervention as well, so these were combined under PFMT. EStim and MStim studies of non prostatectomy related incontinence or other LUTS were kept in separate sections. As preoperative studies may represent the only truly preventative studies, and studies that only included incontinent men the true treatment studies, the categories of prevention and treatment were changed in the PFMT section. Instead, studies in these sections have been grouped into three types: preoperative interventions, mixed pre and post operatives studies of all men undergoing prostatectomy and studies of post operative interventionsfor men with established incontinence. Studies in the pre and post operative study category are heterogenous in timing of recruitment and intervention, an ongoing concern in this research area.

Aetiology of UI after prostatectomy

For purposes of the current review, the reader is directed to the report from the 3rd and 4th ICI (1,356) in which the aetiology of UI after prostatectomy is covered in detail (see report from Committee 13: Surgery for urinary incontinence in men). In brief, risk factors which have been repeatedly identified for UI after radical prostatectomy and transurethral resection of prostate (TURP) are abnormalities of detrusor contractility [357] and age [358]. Other related factors include neurovascular injury during surgery, previous TURP [359], preoperative radiotherapy, trauma, spinal cord lesion, new obstruction such as prostatic regrowth, bladder neck contracture, urethral stricture, Parkinson's disease [360,361], dementia, and medications [356].

Treatment

The primary conservative treatment for UI after prostatectomy remains physical therapies with or without some form of Biofeedback (BF). PFMT, along with

anal EStim, BF or transcutaneous electrical nerve stimulation (TENS), MStim, and even pharmaceuticals have all been utilised and reported as modestly successful in some trials and not in others.

A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed. No other types of study design were considered. The report of the 4th ICI (1) identified 14 relevant RCTs on conservative management of UI post radical prostatectomy (n= 12) or TURP (n=2) [362-375). For this review, nine new published trials [376-384], and seven abstracts [385-391] were found, 14 in men undergoing radical prostatectomy, two in men undergoing TURP. One was excluded as it was a study in progress [388], and one [386] was found to be the same study as one of the published trials [384]. Thus, 14 trials were added to the current evidence base for a total of 32 RCTs on some aspect of continence treatment after radical prostatectomy and four on treatment after TURP. **Table 20** provides summary information on the trials.

I. LIFESTYLE INTERVENTIONS

Lifestyle recommendations such as smoking cessation, healthy eating, appropriate body weight, avoiding excessive caffeine or alcohol are all part of a primary care approach and are intended to be preventative in the onset of obesity, cardiovascular disease, diabetes. Whether these factors have a direct impact on continence is suggested but not known. To date, no trials have addressed the topic of lifestyle interventions alone for men with UI. Nevertheless, in practice, it seems reasonable to offer advice on healthy lifestyle choices that may reduce or delay the onset of continence problems.

II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

The quality of trials included in this update of PFMT has improved from earlier ICI reports although heterogeneity and varying outcome measures continue affect the ability to compare trial findings.

1. PREOPERATIVE RP PFMT

Trials in this section compared preoperative interventions. Two new studies were identified as focusing on preoperative PFMT [385,389].

Delmastro [2010] report a trial in which men undergoing radical prostatectomy were randomised preoperatively to PFMT plus proprioceptive training (n=60) vs PFMT alone (n=57). The authors present a novel arguement that proprioceptive training of the agonist and antagonist muscle activity preoperatively may affect acute adaptive responsiveness, enhancing the effectiveness of PFMT in men undergoing radical prostatectomy. Outcomes were measured at baseline (preop) and 4,8, and 24 weeks post surgery; Although the authors report significant differences in outcomes favouring the intervention group (PFMT plus proprioceptive training) the report of the study was available in abstract form only, and details of the randomization technique and data were not available. This study represents an innovative theoretical perspective, but further investigation and testing is needed to establish efficacy of the treatment approach.

Tobia [2008] (article translated from Spanish) randomised 38 men to to preoperative kinesic perineal exercises (n=19) or no preoperative treatment (n=19). Using DRE and perinemeter plus 'low to medium frequency EStim', participants undertook 'kinestetic exercises', practiced daily at home 7-10 times. No futher details of the intervention were provided such as the number of times the participants visisted the therapist, how participants were randomised, assessors blinded. Nor was continence defined. The authors reported no difference between groups in continence at 14, 30 or 60 days post catheter removal.

2. PREOPERATIVE AND/OR POSTOPERATIVE RP PFMT, POST RP CONTINENCE STATUS NOT ESTABLISHED PRIOR TO INTERVENTION

Trials in this section addressed the effect of PFMT initiated preoperatively and/or postoperatively but before post op continence/incontinence was established. In these studies, men were recruited preoperatively or immediately postoperatively and the investigators compared a treatment group that received the intervention preoperatively and/or postoperatively RP to a group receiving an intervention only post operatively. Post operative interventions were often described as usual care. Nine trials from the previous review [210,362,369,370,372,375,392-394] and one new study [382] are included for a total of 10 trials in this category. One study in abstract form [388] was not included as it described a study in progress with no findings presented.

a) Preoperative PFMT instruction with postoperative home PFMT versus control

No new trials were added to this section. Three were all addressed in the ICI 2009 chapter [1,362,392,393]. Two utilised preoperative BF assisted instruction in PFMT followed by postoperative self-PFMT at home, compared to postoperative verbal instruction [362] or usual postoperative exercise advice [392]. The other study (abstract only), assigned participants to PFMT plus BF (method/type not described) or PFMT alone plus home exercises. Primary outcomes were pads or bladder diary.

1. Quality of data

Of the three trials in this subsection, only one [392] reported adequate random allocation concealment. With regard to blinding of outcome assessment, Bales [2000] attempted to control for bias in outcome

Table 20: Characteristics of male urinary incontinence studies

Primary Author	Timing of interven-tion	Open/lap/robotic	Design	Intervention	Randomization	Blinding	Findings	Definition of Incontinence
Centemero, 2010 [382]	Pre Op Post Op	RRP open	Pre Op/post PFME vs Post Op only; Enrolled > 4 weeks Pre Op. RP.	N=118 T: (n=59 no dropouts) Pre/post BF PFMT 2x/wk 30 min intensive PFMT with PT + 30 min at home; 48 hr post catheter removal 2x/wk x 4 wks + home PFMT until dry; Focussed on "tonic fibres of the superficial perineal musculature". C Group: (n=59 no dropouts) Post Op PFMT (method not described)	block randomisation in blocks of 10 in sequentially numbered sealed envelopes; power analysis SS 118.	surgeons blinded.	At 1 & 3 months T group more likely to be continent (44%, 59% vs 20%, 37%); on pad test: 25%, 17% vs 34%, 32% > 150 gm. Nb no other pad test data provided. Conclude that Pre Op PFMT self reported continence higher in treatment group.	Self report Continence = 0 leakage on bladder diary & negative stress test; ICS male SF; PGI-I .
Delmastro, 2010 [385] (abstract only SIUD)	Pre Op		Intensive Pre Op PFMT + proprioceptive training vs two groups Pre OP PFMT vs N=112. Enrolled Pre Op or actively (time Pre Op not given).	T group (n=60; 10 dropouts); 10 hr individual PFMT sessions + 3 1 hr group sessions + home training; control (n=57; 13 dropouts) PFMT and "no proprioceptive training" (but this is not described); Post Op both groups received verbal info.	not described	PT blinded.	At baseline (Pre Op) & 4,8,24 wks post surgery; reports significant difference favouring treatment but no data provided.	Continence: 1 or less pads per day; pF strength, endurance & function; Post Op patient global impression of improvement (PGI-I).
Dubbelman, 2010 [379]	Post Op	RRP open	Post Op RP two groups 1 day Pre OP all men received verbal instruction from a PT plus written materials 1 wk after catheter removal; PFME with PT + home exercises/written materials vs written materials alone. Enrolled men with > 1 gram urine loss on 1 hour pad test 1 week after catheter removal.	N=79 T group (n=44;33 complete) C group (n=35; 33 complete)	1:1 randomisation 1 wk post catheter removal; sealed envelope open by trial nurse after pad test result.	trial nurse not involved in intervention; PT unaware of outcome data of either group; power analysis done - needed 96 per arm.	At 1,4,8,12,26 wks; at 26 wks on 1 and 24 hr pad test 30% vs 27% were continent; no significant difference in time to continence; amt of urine lost at baseline a significant predictor of continence at 6/12.	Continence < 4 gm on 24 hr pad test; < 1 gm on 1 hr pad test; 1 hr pad test dry (<1g), mild (< 10 g), moderate (10-50 g), severe (>50 g).

Table 20: Characteristics of male urinary incontinence studies (continued)

Primary Author	Timing of interven-tion	Open/lap/robotic	Design	Intervention	Randomization	Blinding	Findings	Definition of Incontinence
Glazener, 2011 [377]	Post Op	TURP	Post Op: TURP two groups 6 weeks post surgery: PFMT vs written material. Enrolled men reporting incontinence on screening questions 6 weeks postop.	N=442 T group (n=220; 194 complete); C group (n=222; 203 complete)	Remote computed randomization independent of clinical collaborators.	Intervention could not be masked from participants and therapists. Clerk entering data blind to allocation.	At 12 months T group 65% incontinent vs 62% C group (RR1.06; CI 0.91 - 1.23).	Any positive response to either of 2 screening questions from the ICIQ-UI SF questionnaire.
Glazener, 2011 [376]	Post Op	Open & lap RP	Post Op: RP two group 6 wks post surgery; Post Op PFMT +/-BF or written material. Enrolled men reporting incontinence on screening questions 6 weeks Post Op.	N=411 T group (n=205; 196 complete) = PT sessions over 3 month period + home exercises; C group (n=206; 195 complete)	Remote computed randomization independent of clinical collaborators.	Intervention could not be masked from participants and therapists. Clerk entering data blind to allocation.	At 12 months T group 76% incontinent vs 77% C group (RR0.97; CI 0.87 - 1.09).	Any positive response to either of 2 screening questions from the ICIQ-UI SF questionnaire.
Goode, 2011 [380]	Post Op	RP open	Post Op (1-17 yrs post surgery) Three groups: PFMT + behavioural therapy (BT); BT + ES + BF; no intervention.	N=208 --T group 1 (n=70; 47 completed) 4 sessions PFMT + BT x 8 wks plus home management; T group 2 (n=70; 40 completed) BT + ES + BF office + home; C group (n=68; 64 completed): no intervention (on wait list)	3 sites; stratified by site; computer generated list; group assignment in sealed envelope opened at randomisation.	Staff scoring of bladder diaries were blinded.	At 2, 6, 12 months 8 wks UI recorded on 7 day bladder diary; both T groups improved: incontinence episodes per wk at baseline and 8 wks: 28, 26, 24 vs 13, 12, 21;also improved % UI episodes no difference between treatment groups; no benefit of adding ES to PFMT. Full data provided for 2 months only, not 6 and 12 months. QOL results modest changes.	Continence: % reduction of UI on 7 day bladder diary; IIQ-7; SF-36; AUA Symptom score
Marchiori, 2010 [387]	Post Op	RP open or lap	one month post catheter removal intensive PFMT with BF + ES vs oral & written info + home exercises.	N=332 Both groups received written and DRE teaching of PFMT on day of catheter removal. Control group continued with home exercises; T group did home exercises plus received daily BF + ES x 15 mins at the hospital clinic x 2-3 wks.	not described	not described	FUp at 1 yr; self report of UI at 3, 6, 12 mon; median continence achievement 44+/-2 days vs 76 +/-4 days in favour of intensive treatment; all subjects were 'dry' by 12/12..	Continence = < 2 mini pads per day; ICI-Q; RAND 36 (only 10% of subjects completed Questionnaires).

Table 20: Characteristics of male urinary incontinence studies (continued)

Primary Author	Timing of interven-tion	Open/lap/robotic	Design	Intervention	Randomization	Blinding	Findings	Definition of Incontinence
Mariotti, 2009 [384]	Post Op	RP Open	Post Op RP PFMT + ES + BF vs verbal & written info from Urologist. Enrolled 7 days post catheter removal.	N=60 (all completed) T Group (n=30) PFME + ES + BF 2x/wk x 6/52; BF x 15 mins then ES x 20 mins (anal) @ 30 Hz x 10 min; 50 Hz x 10 min; µs 300 pulse duration; max current 24 MA; BF 1 channel perineal; 1 channel abd. C group (n=30): verbal and written info from urologist.	not described	not described	Mean time to continence: 8 +/-6.49 wks vs 13.88 +/-8.32 wks in favour of treatment; at 6/12 3.3% vs 33% had UI in favour of treatment. By 12/12 no difference.	Continence 24 hr pad test < 2 gm; no. of pads; ICS-male Q; voiding diary. Eval at baseline, 2, 4 wks; 2.3.4.5.6 months post enrolment.
Park, 2011 [390] (abstract only)	Post Op	RP tech-nique not stated	Active overall exercise vs PFMT alone N=49 Enrolled Pre OP, interventions postop. Sciarra, 2009 [386] (abstract only) Same paper as Mariotti.	Post Op		Post RP FES + BF vs written and verbal information	N=60 T group: FES + BF 7 days post catheter removal 2x/wk x 6 wks; C group: written & verbal info	not described	not described	Mean time to continence	Continence = 0 pads; Eval at 2,4 wks and 2,3,4,5,6 months; 24 hr pad test; ICS-UI questionnaire; bladder diary.
Tibaek, 2007 [381]	Pre Op Post op	TURP	Pre/post Op two group PFMT Pre Op + home exercises or post Op verbal instructions. Pre Op enrollment of men scheduled for TURP.	N=58 T group (n=26; 26 completed): Pre Op PFMT 1:1 x 1 hr; 3 hr group session; home exercises and verbal Post Op; C group (n=23; 23 completed) received verbal instructions post op.	not described	PT assessing;	At 2, 4, 12 wks post op; increased PF strength but no differences in Symptom scores, pad test or pd use. Incontinence per se not measured.	Danish Prostate Sx score; 3 day diary; pad test.
Tobia 2008 [389] (English abstract only; Spanish translated)	Pre Op	RP not described	Pre Op kinesthetic perineal exercises treatment vs no kinesthetic training. Pre Op enrollment of men scheduled for RP.	T group: N=19 kinesthetic training C: group (n=19) no training. Method not described.	not described	not described	At 14, 30 & 60 days post op no difference between groups.	% continent.

Table 20: Characteristics of male urinary incontinence studies (continued)

Primary Author	Timing of interven-tion	Open/lap/robotic	Design	Intervention	Randomization	Blinding	Findings	Definition of Incontinence
Voorham-vander Zalm, 2010 [388] (abstract only) Not included - study in progress.	Pre Op Post Op		Pre Op PFMT vs control (standard care not described). Pre Op enrollment of men scheduled laparoscopic RP.	T group: not described	not described	not described	Pre Op; 6 wks, 3, 6, 9, 12 mons post op; findings not presented - study in progress (author contacted for more information).	Pelvic Floor Inventories (PelFIs); pelvic floor exam; KHQ, IPSS, voiding diary; 24 hr pad test
Yamanishi, 2010 [378]	Post Op	RRP open	two group Post Op PFMT + ES or control (sham ES) enrolled 1 week post catheter removal. Only included subjects with UI > 200 gm on 24 hr pad test 1 week after catheter removal.	N=56; T group (n=26 22 completed): Estim 2x/day x 15 mins by anal electrode 50 Hz with 300 µs pulse duration; max output 70 mA (5 secs on/off) -- does not state if this was home based or clinic; C group: sham ES (n=30; 25 completed) .	By computer connected to stimulation device; power calculation 22/group.	Subjects and Physicians blinded.	At 1, 3, 6 mon significant difference favouring treatment: 36%, 63%, 81%, 86% vs 4%, 16%,44%, 86% were continent. No difference at 12 months Post Op.	PFMT
Zellner, 2011 [383] (in German, translation available)	Post Op	RRP open	Three groups Whole body vibration; PFMT with BF + ES; PFMT alone enrolled on day 22 post surgery	N=75 C group: n= 25 PFMT from physio with individual & group therapy (not described); T Group (1) n=25 Standard care plus ES + BF via recall probe 420-N=75 unit Myo daily x 20 mins (not stated if at home or in the clinic); T Group (2) n=25 whole body vibration: vibration plate with vertical sinusoidal oscillations, Hz 20 to stimulate all body muscles including pelvic floor.	not described	not described	No differences between Standard group & PF/ES group (both improved); not stated if all completed. Not clear when outcomes were assessed - appears to be at end of 3 wk intervention period. Subjects mildly incontinent based on pad test (not clear if 24 or 1 hr).	IPSS; pad test; uroflow and voided volume; PFM strength
Zhang, 2008 [391] (abstract only)	Post Op		Post Op combined PFMT and social support in group. Enrolled men incontinent post prostatectomy.	T group: (n=14) 6 biweekly group sessions + PFMT + BF; C Group (n=15): PFMT at home.	not described	not described	at 3 months post treatment less UI and fewer pads favouring Treatment (50% vs 84%); decreased urge (71% vs 38%); improved depression and Sx distress.	VAS 0-10; pad count.

assessment by having a nurse not directly involved in the study interview the subjects. It is not clear whether he/she was blinded to allocation group. Burgio [2006] had outcomes assessors blinded to group assignment and described dropouts.

2. Results

Burgio [2006] reported a statistically significant difference in favour of PFMT in time to regain continence and proportion of men with severe or continual leakage measured by voiding diary at six months, PFMT (59%) versus controls (78%); additional data provided by the authors on the 24 hour pad test did not indicate a difference between groups. Bales [2000] found no significant group difference on participant report of number of pads used or time to return to continence. Lilli [2006] did not find a difference between participants who received BF in addition to PFMT at any of the time points; at six months, 71% and 67% respectively dry and no use of pads. In the Lilli trial both groups received intervention and it is not clear how intensive the pre-operative PFMT instruction was.

D.2.2b Pre-operative PFMT instruction followed by supervised post-operative PFMT versus post-operative PFMT

One new trial was added to this subsection, making a total of four studies included [369,370,372,382]. Centemero (2010) randomised 118 men more than four weeks preoperatively, with the treatment group receiving twice weekly BF (anal probe) intensive PFMT with a physical therapist plus home exercise and repeated the twice weekly sessions for four weeks post operatively with home exercise until dry. The control group received only post operative PFMT. Outcomes were self report of leakage on bladder diary and provocative (stress) pad test. As reported in ICI 2009 [1], one trial compared active pre- and post-operative PFMT programme to no PFMT instruction [372] and two others pre- and post-operative instruction versus post-operative instruction [369,370]. Participants in one trial [372] had two pre-operative and four post-operative sessions of anal probe BF plus post-operative home PFMT using an exercise ball, or no intervention (similar to Burgio (2006) above). Continence was assessed by pads report and continence questionnaires at six, 12, 16, 20, 28 and 52 weeks post surgery. Sueppel (2001) randomised 16 men (no dropouts) to two pre-operative and five post-operative sessions of anal probe BF or five post-operative sessions plus home PFMT. Continence and quality of life were assessed by AUA symptom score and quality of life questionnaire, pad count, 45 minute standardised pad test, and a leakage questionnaire at six weeks and one year post surgery In another [369] all participants had one session of pre-operative instruction using BF and verbal coaching and were then randomised to intervention or control groups. The intervention group (n=26) practised PFMT daily with a home BF unit (anal probe) from week 3 to 12 after surgery, whereas the control group (n=24) only followed written instructions. Both groups completed questionnaires, pad counts, and 24 hour pad tests at two, five and 12 weeks post-operatively.

Quality of data

Centemero [2010] had surgeons blinded to group allocation and reported no dropouts. Sueppel [2001] indicated incomplete data but did not describe dropouts. Two did not provide any information [372].

Results

Treatment group was more likely to be continent at one and three months post operatively measured by leakage recorded on a bladder diary (44%, 59% vs 20%, 37%) and on pad test (25%, 17% vs 34%, 32% > 150 gm) [382]. More men were continent in the pre and post treatment group at 12 weeks but there was no statistically significant difference at any other time point to 12 months [372] . Sueppel [2001] reported that at one year the pre and post treatment group had less leakage on a standardised 45 minute pad test compared to the postoperative group (mean 2.8g (range 0.0-13.0g) versus 33.3g (range 0 to 194g) and Mathewson-Chapman [1997] found no statistically significant differences between groups at any of the time points.

c) Post-operative PFMT immediately after catheter removal (no pre-operative instruction)

No new trials were found comparing post operative PFMT immediately post catheter removal. Three previously reported trials in ICI 2009 commenced post-operative PFMT immediately after catheter removal [210, 375, 394]. A total of 524 men were randomised to PFMT programme or no formal instruction Filocamo [2005], weekly 45 minute PFMT guided by a physiotherapist or one PFMT training session then home exercises [210] or PFMT with verbal and written instructions intensive postoperative physiotherapy for three days, a post-discharge rehabilitation programme for three weeks, and a three month home PFMT programme with twice daily with EStim or PFMT with EStim and BF [375]. Outcomes in the studies varied from ICS Male Questionnaire (ICS MaleQ), pad count, and pad test (one and 24 hours), self-report of no pads, and PFM strength.

1. Quality of data

In one study, surgeons were blinded to group allocation [210]. Another had data analysed by a professional statistician [375]. Dropouts were described by two [210] and number of dropouts was provided by one [375] but reasons were not described. ITT analysis was decribed by two [394].

2. Results

One trial [394] favoured treatment at three and 6 months for self-reported ‘completely dry’. Differences between treatment and control were 96% versus 65%

at six months and at one year 99% and 88% (not significant). There were no significant differences between groups on 24 hour pad test (Filocamo, personal communication). Overgård (2008) reported no difference between groups for proportion dry (no pads) or 24 hour pad test at three months; however, at 12 months, the proportion of continent men was statistically significantly greater in the treatment group (33/36; 96%) versus the control (28/39; 72%). PFM strength and 24 hour pad test results did not differ between groups at any of the time points. Of note is that 20 participants in the treatment group did not receive face to face instruction due to distance from facility but rather followed detailed instructions provided on a DVD. Wille (2003) found more men in the PFMT/EStim group reported recovery compared to PFMT alone, but the difference was not statistically significantly different (OR 0.48, 95% CI 0.21 to 1.09).

3. Summary

A total of 10 trials were found applying a variety of pre- or post-operative PFMT based interventions (or a combination of both). Any differences between experimental and control groups were modest and short term; differences did not appear to be sustained up to 12 months post surgery. A particular challenge in evaluating the trials was that participant reported outcomes in three of the studies [210, 392, 394] all indicate some level of improvement in the treatment groups; however, there were no clear differences in pad test results in any of the trials. Because all the studies reviewed were generally small, varied in design, and had different outcome measures, it is difficult to interpret them as a whole. Whilst the evidence that therapist delivered PFMT with or without BF before or after surgery improves continence recovery after radical prostatectomy remains inconsistent, there is some suggestion that men who undergo some sort of conservative management including PFMT will achieve continence in a shorter time frame than non-treated men but that this difference is not significant at 12 months post surgery **(Level of Evidence: 2)**.

Further discussion is needed on the outcomes of most importance. It is possible that the emphasis on quantitative outcomes is not meaningful to participants; men appear to find therapy personally helpful and value the direction provided by a therapist.

4. Recommendations

Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful **(Grade of Recommendation: B)**; whether this is in the form of 'hands on' therapy of verbal instruction and support remains unclear. Studies comparing the effectiveness of pre- versus post-operative PFMT, and the number of sessions required, are needed so that practitioners may advise men about pre-operative preparation and budget conscious health boards can make informed decisions on programme funding. In designing such studies, the natural history of UI after radical prostatectomy must be taken into account because the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

3. POSTOPERATIVE RP PFMT FOR INCONTINENT MEN

a) PFMT with digital rectal feedback (DRE) after radical prostatectomy

Two additional trials were identified for this update [376,379] resulting in a total of five trials as Dubbelman [2004] is considered a duplicate [367, 368, 376, 379, 395, 396] in which PFMT was taught using digital rectal feedback (DRE) in at least one arm.

In the largest RCT to date, 411 men who had undergone open or laproscopic RP and who reported incontinence 6 weeks after surgery were randomised to lifestyle information leaflet or leaflet plus 4 sessions of PFMT with a continence physiotherapist or nurse and home exercises (2,376]. PFMT regime was three maximum strength contractions with 10 second break between each lying, sitting and standing twice daily plus submaximal contractions when walking. DRE was used to assess strength of contraction during training sessions. Dubbelman [2010] randomised 79 men who were incontinent one week after catheter removal to physiotherapist guided PFMT using DRE to to written material only. Treatment group received nine 30 minute sessions plus daily home exercises and written material provided one day prior to surgery; the control group received only the written material. This trial appears to be the same as the 2004 report by the authors which was a poster at the ICS [395].

Joseph [2000] randomised a mixed group of 10 men (four radical retropubic prostatectomy and six radical perineal prostatectomy) to weekly verbal teaching plus DRE or BF assisted PFMT over a four week period. Manassero [2007] randomised 107 (94 completed) men to urologist taught PFMT using DRE (unclear how often) plus daily home exercises for up to a year; the control group did not receive any instruction. Participants were assessed at one, three, six and 12 months with a home pad test, VAS and DRE. In Moore [1999] 63 men (58 completed) were randomised to one of three groups: control (written materials only and no therapist contact), PFMT using DRE, or PFMT augmented with EStim via anal probe. Both treatment groups met with the therapist twice a week for up to 12 weeks.

1. Quality of data

Three trials [368, 376, 379] reported adequate random allocation concealment. Data were collected by blinded assessors in two [379,396]. In another, data were collected and outcomes as-

sessed by the primary investigator who had a direct involvement in the trial, although treatment was provided by a therapist blinded to the control group outcomes [368]. Three trials described reasons for dropout [368, 376, 396] but only Glazener [2011] indicated how withdrawals/dropouts were dealt with in the analysis and provided intention to treat analysis. Dubbelman [2010] conducted a power analysis for sample size, but fell short of recruiting the target number.

There was considerable variation in the type and intensity of interventions, follow-up ranged from six and a half months to 12 months, and primary outcomes varied from pad test, pad count or subject report.

2. Results

Between them, the five trials,considering Dubbelman [2004] as a duplicate, had over 600 participants with complete data. Four of the five studies did not find statistically significant differences between the groups. Outcomes included one and 24 hour pad tests, voiding diary or quality of life (IIQ-7). No differences were reported between groups at 1, 4, 8, 12 and 26 weeks on one and 24 hour pad test as well as no difference in time to continence [379]; between treatment and control groups in participant reports of any incontinence or severe incontinence at 12 months [376]; or in pad test between PFMT and PFMT with EStim groups [368]. In a small study of 10 participants no differences between treatment and control groups were found [367].

One research group reported a difference between groups [396]. There was a statistically significant difference in proportion of continent subjects (<2g on 24 hour pad test) in the PFMT group at three, six and 12 months (54%, 33%, 17% compared to 78%, 60%, and 53% for the controls), with 9/54 versus 21/40 incontinent at 12 months.

3. Summary

The most recent and largest trials [376, 379, 396], which compared PFMT taught by DRE or no instruction used different approaches to defining and measuring continence and showed conflicting results. Whereas Mannasero [2007] reported a statistically significant difference in the proportion of continent men (based on 24 hour pad test) in the treatment group at three, six and 12 months the other two found no differences in continence status between groups based on participant report using standardized questionnaires or 24 hour pad test respectively [376, 379]. In the three other smaller and earlier trials, in which the control groups had written or verbal instruction on PFMT, there were no statistically significant differences between groups on pad test. **(Level of Evidence: 2).** Clinical heterogeneity meant that it was difficult to consider the findings from the studies as a whole.

4. Recommendations

Some instruction in PFMT may be helpful; it remains unclear on the objective benefit of the PFMT. Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction **(Grade of Recommendation: B)** is not clear. Further well designed studies using standardized outcome measures and participant input are needed to test this hypothesis.

b) PFMT with BF after radical prostatectomy

No new trials were found under this category although reference Riberio [2008] [397] was a conference abstract and is replaced by Ribeiro [2010] [398]. Thus to date, there are six trials evaluating PFMT with BF compared to a non active or alternate treatment commencing after radical prostatectomy [365, 366, 371, 374, 397-399].

Three compared PFMT with BF versus no treatment, placebo treatment, or usual care [366,374,398] and three compared PFMT with BF versus verbal instruction and home PFMT [365,371,399]. Continence was measured variously by 1 hour, 24, and 48 hour pad test.

1. Quality of data

Two trials appeared to have adequate random allocation and concealment [374,398], although in the latter treatment was provided by the primary investigator who was aware of group assignment. In another [399], therapists were blinded to the results of the control group; pads were weighed by a person unaware of group assignment; data was entered by a data manager. Van Kampen (2000) had pad weights done directly by the individual at home. Dropouts were accounted for and described fully in two [374,399], partially in one [371]. There was a high dropout rate in Franke (2000) and these data were not accounted for in the analysis. There were no reported dropouts two others [365,398]. ITT analysis was described by three [365,374,399].

Continence evaluation was different for each study as well as timing of recruitment and intervention, content of intervention and control treatments. Outcomes varied widely: percentage of participants pad free [366]; one hour pad test [365]; 24 hour pad test (<2g=continent) [374,398]; <8g=continent [399]; and pad test not described [371]. Follow up ranged from 12 weeks to one year.

2. Results

Three trials compared PFMT and BF to a control condition [366,374,398]. At 12 weeks, Ribeiro [2010] reported statistically significant difference in 24 hour pad tests (51g, SD 119 versus 197g, SD 269, p=0.026), but there was no statistically significant difference at six months post surgery. In another study [374] at 8 weeks, there was a statistically significant difference in mean urine loss (30g treatment; 82g control). By 12 weeks this difference

was no longer statistically significant but the proportion of treatment group participants reporting continence compared to control (88% versus 56%) was statistically significant ; no differences were found beyond three months. One other trial reported no difference between groups on 24 hour pad test or pad-free rates but sample was small and dropout rate nearly 50% [366].

None of the three trials that utilised PFMT and BF versus verbal or written instruction on home PFMT showed statistically significant differences between the groups. Outcomes were measured using one hour pad test or number of pads [365], 24 hour pad test, International Prostate Symptom Score (IPSS), or subjective report of continence at eight, 12, 16, 18, or 52 weeks [399], and pad test at 12 weeks [371].

3. Summary

Health professional instruction in PFMT with BF when compared with control conditions seemed to reduce the amount of leakage in the early weeks of recovery (up to three months). However, comparisons of PFMT with clinic BF versus PFMT at home did not find similar differences. Based on the current evidence the addition of EStim or BF does not appear to improve continence outcomes over and above PFMT. **(Level of Evidence: 2).** However, BF may be less difficult for the therapist than DRE.

It seems men who participate in PFMT compared to no active treatment might have less leakage in the first three months postoperatively. To the individual, this early improvement may be important in activity, well-being, and socialising. Such concepts require further investigation.

4. Recommendations

The use of BF in clinic, over and above home PFMT, is currently a therapist/individual decision based on economics and preference. **(Grade of Recommendation: B)**.

c) PFMT plus or minus BF with EStim or MStim after radical prostatectomy

The most notable addition to the evidence base in this section is five new trials which combined EStim with PFMT for men incontinent post radical prostatectomy [378, 380, 383, 384, 387] with four of these including BF as part of the intervention. These five trials were added to two RCTs previously included in the EStim section [400]. Opsomer [1994] compared intensive PFMT plus EStim (once a week) plus BF versus simple PFMT in 43 men. As it was not possible to differentiate the effects of additive EStim (method not described) from adjunctive BF this study was not further considered for this section.

Two studies [400] previously reported and one new [378] reported comparisons of PFMT to PFMT plus EStim and recruited men with severe post prostatectomy UI one week after catheter removal (more than 200 gm of urine lost daily on pad test). In the Yamanishi trial, men were randomised into active EStim group (n=26) or sham EStim (n=30) by computerized random assessment through a connection to the stimulation device. All men had PFMT by nurses (verbal and written information) and were coached to continue this though the study period. Active EStim was 50 Hz with a 300 µsecond pulse duration, 5 seconds on/5 seconds off duty cycle and maximum output of 70 mA. Men receiving sham EStim received limited stimulation at 3 mA with a 2 seconds on/13 seconds off duty cycle. Treatment continued until the incontinence was cured or the 12 month study period ended.

Moore [1999] compared standard treatment (verbal and written instructions about PFMT) versus intensive PFMT, versus intensive PFMT plus rectal EStim in 63 men with UI median of 8 weeks (range 4-241) post radical prostatectomy. EStim was provided by a surface anal electrode, with intensity to induce visual lifting of the levator ani. Stimulation parameters were 50Hz, biphasic pulse shape with one second burst, a one second pulse width and one second pulse trains. All therapy was performed by one experienced physiotherapist. Hoffmann [2004] compared percutaneous EStim plus PFMT versus anal EStim plus PFMT versus PFMT alone in men with post-prostatectomy incontinence; this trial allocated 60 men per group, the intervention was for four weeks, and each individual was followed up for three months. PFMT consisted of a “specialized program” of “continence training”, lifestyle changes, osteopathy and “Feldenkrais Lehre” three times/week in the clinic and three times/day at home, with a daily maintenance home programme after finishing the therapy. In comparing PFMT with BF plus EStim, three trials [383,384,387] included men one to four weeks after catheter removal and one [380] enrolled men at least one year after surgery. Mariotti [2009] compared PFMT with BF plus EStim to a control group which received only verbal and written information from a urologist. Randomisation occurred one week after catheter removal, and severity of incontinence among participants at enrolment varied from 20-1500 gm of urine lost on 24 hour pad test. Men in the intervention group received 12 treatment sessions (twice weekly for 6 weeks) of PFMT with BF and EStim from a single clinician. EStim was delivered by anal surface electrode at 30 Hz for 10 minutes and 50 Hz for the following 10 minutes, 300 µsecond pulse duration and a maximum output of 24 mA. BF was via perineal and abdominal surface electrodes. The frequency details of home PFMT were not provided. Marchiori [2010] randomised 332 men one month after catheter removal to intensive PFMT with BF plus EStim or a control group that received only verbal and written instruction and home exercises. This study was available only as an abstract, and the intervention was not fully described.

Zellner [2011] [383] used a three group design in which men on Day 22 post surgery were randomised to PFMT, PFMT plus EStim and Biofeedback (Myo-420 unitR via rectal probe) or whole body vibration daily at 20 Hz on a vibration plate (Fitvibe MedicalR) plus exercises (not described). Each group was in contact with the therapist over a 3-4 week period and had home exercises prescribed (protocols not described). Outcomes were testosterone, blood sugar, IPSS, pad count, and pad test. This trial was translated from German for this review.

Goode [2011] recruited 208 men with post radical prostatectomy incontinence persisting at least one year after surgery (range 1-17 years) and conducted a three group comparison of behaviour therapy BT that included PFMT, bladder control techniques and fluid management, BT/PFMT plus EStim and control (delayed treatment) [380]. Four visits two weeks apart to teach PFMT were provided for instruction from physician investigators or nurse practitioners. Anal palpation was used during instruction. The second group (BT plus) received BT with added in office dual channel biofeedback with either perianal surface or anal probe and 15 minutes of daily home EStim via anal probe with setting at 20 Hz, pulse width 1 millesecond, duty cycle of 5 seconds on and 15 seconds off and current up to 100 mA (adjusted by participant). The control group received office visits only for 8 weeks to monitor bladder diaries, and were provided with a choice of treatment after 8 weeks.

In a three arm trial [401] electrical stimulation (EStim), magnetic stimulation (MStim) and verbal/written instruction in PFMT were compared in 36 men with post RP incontinence. Home EStim comprised 15 minutes of twice daily stimulation for one month, at maximum tolerable level of intensity. For MStim, treatment sessions were 20 minutes, twice a week for two months, with stimulating intensity gradually increased up to the tolerable level. PFMT consisted of PFM exercises in supine position with instructions how to contract the anal muscles selectively. Verbal and written instructions for home practice were given to the men. Participants were followed up for six months.

1. Quality of data

Blinding, dropouts and continence evaluation

Three studies had adequate concealment of randomisation [368,378,380]; one included a power calculation, and adherence to protocol was monitored using patient-recorded diaries. Five participants dropped out, three in PFMT/EStim and two in the PFMT group. In one participant dropout was related to the use of EStim (rectal pain) [368]. Goode (2011) included a power calculation and stratified participants by site, incontinence type and severity. Randomization was conducted via a computer generated random assignment schedule. Sealed envelopes with group assignments were opened sequentially at the time of randomization. There were 23/70 dropouts in the BT group, 30/70 dropout in the BT plus EStim plus BF group and 4/68 in the group that received no intervention. Dropouts were explained and analysis was by intention to treat. Interventions were not concealed as physician investigators were involved in delivery of interventions. Yamanishi [2010] used a computer generated random assignment that connected to the EStim devices, thereby blinding participants, physicians and staff to assignment. Dropouts included 4/26 in the active EStim group and 5/30 in the sham EStim group.

Randomisation details were not provided in two trials [384,401]. In the Mariotti trial , intervention was directed by the lead author, therefore there was no blinding of the researcher to the intervention group. A power analysis was performed to determine sample size. All participants completed the study. Another [400] did not make clear if allocation was concealed or if observers were blinded. Dropouts were 22/60 in the anal EStim/PFMT group, 4/60 in the percutaneous EStim/PFMT group and 0/60 in the PFMT group. Marchiori [2010] data was available only in abstract form and details of randomization and blinding are not described. In theYokoyama trial, the number of treatments, duration and intensity seemed to be different between groups.

2. Results

In comparisons of PFMT +/- EStim, 9/60 men in the anal EStim/PFMT group reported recovery, versus 11/60 in the percutaneous EStim/PFMT group; data were not reported for the PFMT only group [400]. For comparisons of PFMT to PFMT plus EStim and BF, Goode [2011] found that both treatment groups (BT/PFMTand BT/PFMT plus EStim and BF) reported a statistically significant reduction in incontinence episodes at 8 weeks compared to the control group as recorded on bladder diaries. Both treatment groups maintained improvement at six and twelve months, although there were no statistically significant differences between treatment groups. No comparison to the control group was made after 8 weeks.

Pad test results were not consistent. Using a 24 hour pad test [368] one reported a decrease of urine loss favouring PFMT over EStim/PFMT; another found that at three months 77% in EStim/PFMT group were continent versus 65% in the PFMT group, with 82% and 77% continent respectively after 12 months [375]. None of these differences at any of the time points were statistically significant. Yamamishi [2010] reported more men in the active EStim group were continent (less than 8 gm urine lost on 24 hour pad test) at 1, 3 and 6 months than those in the sham EStim group (4%, 16%, 44% versus 36%, 63%, 81% respectively), although there was no difference at 12 months (86% continent in both groups).

For comparisons of PFMT plus EStim and BF, men in the treatment group who received PFMT plus EStim

and BF had a shorter mean time to continence (urine loss less than 2 gm on 24 hour pad test) than those in the control group (8 weeks versus 13.88 weeks) [384]. At six months, 3.3% of the intervention group and 33.3% of the control group were still incontinent, at 12 months there was no difference between the groups. A shorter time to continence favouring intervention group receiving PFMT with EStim and BF (44 days intervention group vs 76 days control group), was reported with all participants continent (2 mini pads or less per day) at 12 months [384].

EStim was associated with adverse events. Discomfort [378,400], urethral stricture [378], or bladder neck contractures [368]. Whether the EStim caused the strictures or contractures is debatable.

Yokoyama (2004) reported that at one month, urine loss on 24 hour pad test was 72g, 83g and 175g (FES, ExMI, and control groups respectively (EStim versus PFMT, $p<0.05$), and was 54g, 18g and 92g respectively at two months (MStim versus PFMT $p<0.05$). At six months mean loss was less than 10g in all groups. No complications were noted in any of the groups. The authors concluded that both MStim and EStim offered earlier continence compared with PFMT after radical prostatectomy.

Zellner [2011] (translated from German) reported no difference between control and the PFMT/BF/EStim groups based on IPSS, pad test, and pad count but the whole body vibration group (FitVibe medicalTM) had a statistically significant decrease in pad test results from 41 g pre therapy to 11g post relative to the other two groups. Whole body vibration was not described in detail.

3. Summary

Seven RCTs investigated the addition of EStim to PFMT plus or minus BF for men with post-prostatectomy incontinence. Data suggested no further benefit of EStim when added to PFMT over PFMT alone, although EStim may help achieve continence earlier in men with severe incontinence post prostatectomy; the numbers in each trial were relatively small. **(Level of Evidence: 2)**

4. Recommendations

For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme **(Grade of Recommendation: B).**

d) PFMT compared to other interventions after radical prostatectomy

Two new trials were identified that combined PFMT postoperatively with other novel interventions in men with post prostatectomy incontinence [390,391]. Park [2011] compared PFMT to an overall 12 week exercise program plus PFMT in 49 men over 65 years after RP, reporting that the exercise (treatment) group had an earlier return to continence on pad test and self report. Zhang [2008] randomised 29 men to PFMT + BF plus six biweekly meetings of a support group (n=14) or to a control group which had only the PFMT +BF. The treatment group reported less UI on VAS rating scale (3.2 vs 4.7), less pad use (50% vs 84.6%), and had better adherence to the PFMT regime. Both trials were available only in abstract form, and details on baseline incontinence, randomisation, blinding and data were not provided.

4. PREOPERATIVE TURP PFMT

Little study has been dedicated to UI after TURP. In fact, the issue has been largely ignored, perhaps because the incidence of UI after TURP is reported to be very low.

5. PREOPERATIVE AND/OR POSTOPERATIVE TURP PFMT

In previous consultations, two trials were potentially eligible for inclusion [367], but the latter trial was grouped with studies of PFMT after radical prostatectomy because the 11 participants comprised one following TURP and 10 following radical prostatectomy.

One new trial on TURP pre and post operatively was added [381].

Men undergoing TURP were randomised preoperatively to a treatment group (n=26) which involved preoperative PFMT of 1 hour individual and a 3 hour group session along with home exercises compared to control group (n=23) which received verbal information only post operatively. Outcome was symptoms as measured by the Danish Prostate Score. Three day bladder diaries and a pad test were also identified as measurements in the study but data from these were not included in the published report, therefore the effect on incontinence is not clear. An earlier trial included men booked for TURP [373]. At the baseline preoperative visit, PFM strength, tone and grading were established with a DRE. There were weekly follow up sessions for four weeks post TURP. It was unclear what information, if any, the control group received.

Quality of data

It was unclear if random allocation was concealed or outcome assessment blinded, and the proportion of dropouts was not stated.

Results

While there were statistically significant differences in UI and post micturition dribble as measured by voiding diary and IPSS, there was no statistically significant difference at four weeks.

Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if PFMT reduces

UI following TURP. More systematic investigation of the the natural history of UI after TURP is probably needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

6. POSTOPERATIVE TURP PFMT FOR INCONTINENT MEN

Only one study was identified which included men incontinent after TURP. Glazener [376] randomised 442 men post TURP who reported incontinence 6 weeks after surgery. All men received a lifestyle information leaflet; those assigned to the invention group had four 1:1 sessions with specialist continence physiotherapist or nurse. PFMT regime was three maximum strength contractions with 10 second break between each practiced lying, sitting, and standing twice daily plus submaximal contractions when walking plus home exercises. DRE was used to assess strength of contraction during training sessions.

7. PFMT FOR OTHER LUTS

Post micturition dribble (PMD) is an annoying problem experienced by many men of all ages likely due to a failure of the bulbocavernosus muscle to evacuate the bulbar portion of the urethra, causing pooling of urine in the bulbar urethra which then dribbles with movement.

The 4rd ICI identified two RCTs on conservative management of PMD [364,402] and no further trials were found for the past two updates. No trials were found on prevention of PMD and it is unlikely that such studies would be undertaken because of the longitudinal nature of such an exploration.

a) PFMT for post micturition dribble (PMD)

Two RCTs totalling 85 participants who had not undergone prostatectomy have been reported in which PFMT and/or urethral milking were compared to verbal instruction and lifestyle changes [364,402]. In one men were assigned: daily PFMT, urethral milking, or lifestyle changes using four hour pad test at five, nine, and 13 weeks. In another study on erectile dysfunction [403], over 65% of participants also complained of PMD and were randomised to PFMT using BF (5 weekly treatments plus home exercises) or lifestyle advice. Outcome was patient report using a standardised questionnaire administered by an interviewer unaware of group assignment.

1. Quality of data

It was not clear if allocation was adequately concealed in either study. In both studies data collection was done by the researchers but data analysis was done by a separate party.

2. Results

Paterson [1997] found both PFMT and urethral milking were equally effective and better than lifestyle changes. Dorey [2004] found that the PFMT group not only reported a significant improvement in erectile function measured by International Index of Erectile Function ($p=0.001$) but also a significant improvement in PMD measured by standardised questionnaire (67% improved in treatment group compared to 7% of controls; $p<0.002$).

3. Summary

Based on two small studies, it seems that PFMT and urethral milking might both be effective in the control of the annoying symptom of PMD **(Level of Evidence: 2).**

4. Recommendations

Men can be offered instruction to do a strong PFM contraction immediately after voiding, or urethral massage to empty the urethra, to improve symptoms of PMD **(Grade of Recommendation: C)**.

8. FACTORS AFFECTING OUTCOME

Based on the current evidence, it appears that time from surgery to implementation of exercises does affect outcome and that by three months after surgery less improvement is noted. Future trials could consider analysis to evaluate the effect of length of time from prostatectomy surgery, co-morbid conditions, prior pelvic surgery, and medications (including smoking and alcohol use) on treatment outcome.

III. ELECTRICAL STIMULATION (ESTIM)

EStim (EStim) is reported to be effective in the treatment of UUI but no better than PFMT alone for men with SUI [242,404,405].

Symptoms of DO and UUI can be associated with neurogenic disorders and to bladder outlet obstruction such as benign prostatic hyperplasia; in some men the cause is unknown. It is believed that EStim for UUI acts through reflex inhibition of pelvic efferents or activation of hypogastric efferents through stimulation of the afferent input in the sacral route [223,405].

SUI is rare unless iatrogenic with radical prostatectomy, pelvic surgery or radiation, or TURP [368,406-408]. DO, poor compliance and decreased contractility may also be factors related to post-prostatectomy incontinence [368, 409]. For male SUI, EStim could be used to enhance sensory response to contraction of the PFMs in the same way as female SUI [410,411]. As a stand alone therapy it is unclear whether EStim enhances continence recovery [375,412]. It has been postulated that continence is regained more rapidly [413] and the duration of the application of EStim is reduced when PFMT is augmented with EStim [413,414]. EStim is also believed to be more effective in participants who are initially unable to identify and contract the correct PFMs [415]. Interestingly, it is generally agreed amongst those using

EStim that it should be avoided for those with carcinoma of the bladder for fear that EStim may increase abnormal cell activity [403]. Although there are no data to confirm or refute this, many physiotherapists are unwilling to use EStim for individuals with cancer and, therefore, post radical prostatectomy. Further research is needed to clarify this risk.

This section will examine evidence for the use of EStim for the prevention and treatment of UI in men. Questions addressed are:

- What is the most appropriate EStim protocol?
- Can EStim prevent UI?
- Is EStim better than no treatment, placebo or control treatments for UI?
- Is EStim better than other treatments?
- Does the addition of EStim to other treatments add any benefit?
- What is the effect of EStim on LUTS other than UI?
- What factors might affect the outcome of EStim?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see Appendix 2). No other types of study design were considered. Since the 3rd ICI only one new RCT [400] was identified and included in this chapter. A previous relevant Cochrane systematic [412] was updated and contributed to this section [416].

1. PREVENTION OF UI

There have been no studies on the effect of EStim for prevention of non postprostatectomy UUI or SUI in men.

2. TREATMENT OF UI

In the 4th ICI, one systematic review was identified [412], along with nine RCTs [221-223,368,371,375,400,401,404]. An abstract of a trial [417] reported data for men, but the separate effects of EStim could not be assessed and the study was excluded.

a) Is EStim better than no treatment, placebo or control treatments?

No new studies were identified that compared EStim with no treatment or a control. Two earlier placebo controlled trials both included men and women. One included 29 men and 39 women with UUI [222,404]and the other 30 women and five men with SUI [404]. In the latter trial, four men had post-prostatectomy incontinence and one had sphincter deficiency due to sacral cord tumour.

1. Quality of data

Both trials blinded participants and doctors to treatment allocation [222,404]. For EStim in UUI, three participants (8%) in the active group and one (3%) in the sham group dropped out, and two in each group discontinued the treatment due to adverse events (5.4% and 6.5% respectively). For EStim in SUI, two of 35 participants (6%) dropped out and none had adverse events.

2. Results

(a) Men with UUI: The authors reported statistically significant differences in cure (22% active and 4% sham) and improvement rates (81% active and 35% sham) between the groups; data were not differentiated for men and women [222].

(b) Men with SUI: None of the participants in the sham group were cured or improved. One man in the active EStim group was cured and a second was improved; five men participated in the study but it was not clear how many were allocated to sham and how many to active EStim.

3. Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if EStim, as a stand alone treatment for male UUI or SUI, is better than no treatment, placebo or control treatments.

b) Is one approach to EStim better than another?

EStim protocols for men are similar to those for women and like protocols in women vary widely. Intermittent, short-term stimulation (or maximal EStim) using a portable stimulation device at home or in clinic is most common [368,375,401]. Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region.

For the treatment of SUI (and post-prostatectomy incontinence) EStim amy be combined with PFMT or monotherapy. Usually a rectal electrode is used, and the stimulation artificially stimulates the pudendal nerve and its branches to cause direct reflex responses of the urethral and periurethral striated muscles [368,400,401].

Frequencies of 14Hz have been used for UUI [400], while 20Hz [401], 27Hz [375] and 50Hz [368] have been used for SUI. Pulse form is mostly biphasic; pulse width varies and includes 300 microseconds [401], 250 milliseconds [400][401], one [368] and five seconds [375]. Duration of the stimulation varies as well, from 15 minutes [375] to 30 minutes [368], and from twice daily [375] to twice weekly [368]. Duration of treatment has ranged from one month [401], to three months [375].

1. Summary

So far, no studies comparing EStim protocols have been identified. The most appropriate EStim protocol for different types of symptoms is unknown. EStim protocols for men have been developed from studies in women. The variability in the findings of

the trials included in the remainder of this section may in part be due to differences in the effectiveness of the wide range of protocols that have been tested. There are many differences in clinical application that have not yet been investigated. Some populations or subgroups of men may benefit from EStim more than others, but this observation has not yet been investigated.

c) Is EStim better than other treatments?

No new trials were found comparing EStim with other treatments making a total of two comparing EStim with MStim [223] or medication [221] in men and women with UUI. One evaluated EStim with MStim for inhibition of DO in a urodynamic study of 32 participants (15 males, 17 females) [223]. The other compared EStim (TENS) with medication (oxybutynin) for UUI in 43 participants (13 men, 30 women) with DO [221]. Results were not reported by gender. Oxybutynin was started at a dose of 2.5mg orally twice daily and titrated to 5mg orally three times daily by day seven. Dual channel TENS with two self-adhesive pads connected to the stimulator and applied bilaterally over the perianal region (S2 to S3 dermatome) was used. Stimulation parameters were set at a frequency of 20Hz and a pulse width of 0.2msecs on a continuous mode. TENS duration was up to six hours daily.

1. Quality of data

Random allocation concealment was adequate; results were not reported by gender [222]; another did not provide information about randomisation procedure, random allocation concealment, blinding of observers, or drop-outs [221].

2. Results

In the urodynamic study of EStim versus MStim in men with DO, bladder capacity at first desire to void and maximum cystometric capacity increased significantly in both groups compared to baseline; the increase in maximum cystometric capacity was statistically significantly greater in the MStim (106%, SD 130) than the EStim group (16%, SD 34).

EStim and medication improved subjective parameters but only oxybutynin showed statistically significant improvements in objective urodynamic parameters such as bladder volume at first desire to void and at first overactive detrusor contraction [221].

3. Summary

There were few men in either of the two trials comparing EStim and MStim, the single trial comparing EStim with verbal/written instruction in PFMT, or single crossover trial comparing EStim with oxybutynin. In the absence of sufficient data it is not known if EStim is better than MStim or written/verbal instruction in PFMT or oxybutynin for UI in men.

d) Does the addition of EStim to other treatments add benefit?

Four RCTs have been identified investigating the addition of EStim to other treatments for men with post-prostatectomy incontinence [368,371,375,400] and are discussed under the PFMT section on post-prostatectomy incontinence. No studies of EStim being added to other treatments for UUI and SUI were identified.

3. OTHER LUTS

No studies were identified which addressed this comparison in men.

4. FACTORS AFFECTING OUTCOME

a) Age

There are no comparisons of the effects of EStim for UI between younger and older men. While many EStim studies include participants over 50 years most studies don't include those over about 80 years [418]. In the studies of EStim for post-prostatectomy incontinence in this chapter the mean age of men is about 66 years. Although post-prostatectomy studies have included older men it may be unwise to extrapolate the effects of EStim in older men with SUI to older men with UUI, because in the former UI is usually as a result of sphincter incompetence whereas in the latter the symptoms are those of an OAB.

b) Other

Many other factors, such as types of electrodes, intensity, frequency and duration of stimulation, electrode positioning, the number of treatment sessions, diagnosis and underlying cause, participant selection, and treatment adherence are plausible factors affecting outcome. Little is known about the effect of any of these and there are no trials investigating these factors in males.

IV. MAGNETIC STIMULATION (MSTIM)

Background information about extra corporeal magnetic innervation, more commonly called magnetic stimulatio n (MStim), has been given in the section on MStim for women (see B5). MStim has also been used in men; it is unclear whether the mode of action and effects of MStim are similar in men and women. In men, MStim is used to treat UI after radical prostatectomy [401,419] and for the inhibition of DO [223].

The questions to be addressed are the same as those for women (see B5). Since the 4th ICI no further RCTs were found. Suzuki [2007] compared the effect of MStim versus sham MStim for UUI in 39 individuals (23 females and 16 males). The study was not included in the review below because both groups also received PFMT, and data were not reported separately for men and women [263].

1. PREVENTION OF UI

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

2. TREATMENT OF UI

Three treatment RCTs were identified; two published articles [223,401] and one abstract of an ongoing study without data [419]. The first trial [223] included both men and women with UI; because the effects of MStim might be different between sexes (due to differences in the underlying aetiology of symptoms) this study has only contributed to the analysis where the researchers' differentiated the effects of treatment in men and women.

a) Is MStim better than no treatment, placebo or control treatment?

No studies were found addressing this question.

b) Is one approach to MStim better than another?

No studies were found addressing this question.

c) Is MStim better than other treatments?

Two studies were identified [223]. Both compared MStim with EStim; the latter also compared MStim and PFMT. Readers are referred to section D.3.2c for a description of these studies, findings, and summary.

3. OTHER LUTS

No studies were found.

4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. The relationship between age (or any other factor, such as treatment parameters, treatment adherence, or diagnosis) and the outcome of MStim has yet to be determined.

V. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens include bladder training , timed voiding, habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to indicate that scheduled voiding regimens, especially bladder training and timed voiding, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to the literature on their use in women.

1. PREVENTION OF UI

No trials investigating the preventive effects of scheduled voiding regimens for men with UI were found.

2. TREATMENT OF UI

Since the 4th ICI in 2009, there have been no new reports of bladder training that have included men. Of the five that have included men, most had only a small number of men in the sample [48,282,283,286,293]. Two observational studies, but no RCTs, were found regarding timed voiding. No studies were located that addressed habit training or prompted voiding in men.

a) Bladder training

A total of five RCTs involving 142 men met the criteria for inclusion in this review. All trials (previously described in section B6) had predominantly female participants; one RCT compared bladder training (BT) to BT plus caffeine reduction (seven men, 86 women) [48]; and three RCTs compared BT plus placebo drug versus anticholinergic drug therapy (six men, 28 women [293]; four men, 30 women [283]; two men, 58 women [282]. The largest RCT compared drug therapy alone (tolterodine) to drug therapy plus BT (123 men, 378 women) [286]. A sixth study was located that compared BT supplemented with drug therapy after three months, but it was excluded from review because the full length report was in Japanese and an English translation was not available [420].

As none of the trials reported outcome data separately for men, and with the proportion of male participants being so small (3%, [282]; 8%, [48]; 12%, [283]; 8%, [293]; 25%, [286], there is insufficient evidence available to comment on the effectiveness of BT in men.

b) Timed voiding

No new trials were found on timed voiding. There are two clinical series that investigated timed voiding in men only [272,421]. In the first, timed voiding was initiatied in incontinent men in a geriatric hospital [421] and in the other men with persistent post-prostatectomy incontinence [272]. Outcomes were measured by a two week voiding diary kept at baseline and during two weeks of timed voiding by patients diagnosed with SUI, UUI, and/or continual leakage.

1. Quality of data

Both studies used a clinical series design and patients in both subsequently received other treatment if they were not adequately improved. In the Sogbein study, nurses checked the patients' clothing for wetness at each two-hour voiding interval and recorded the results. Data in the Burgio study were based on bladder diaries completed by the patients. Reasons for drop-out [421]and non-adherence [272]were provided.

2. Results

In one study an 85% improvement rate in UI was reported [421]. In the second, the two hour timed voiding schedule was used with only 12 out of 20 men, because they were either already on a voiding schedule, unwilling to go on a voiding schedule, or were noncompliant [272]. In five men with SUI,

there was a 29% decrease of incontinent episodes; in three men with UUI, two improved and one dramatically regressed producing a 33% increase in incontinent episodes. In four patients with continual leakage, there was no reduction in percentage of wet intervals.

3. Summary

With limited **Level 3** evidence (and no higher order evidence), there is insufficient evidence available to comment on the effectiveness of TV in men.

3. OTHER LUTS

No studies were identified in men.

4. FACTORS AFFECTING OUTCOME

a) Age

No new trials were found addressing outcome. The five RCTs involving bladder training included older men, as well as women. Three specifically recruited adults aged over 65 years [282, 283, 293]. The largest trial recruited men with a median age of 62 years. There was no subgroup analysis related to age and gender effects, so it is not possible to draw conclusions regarding the effect of BT in older men [286]. Voiding regimens are of particular interest for the elderly, but some are effective in younger patients with UI [266].

b) Other

No studies were identified on other factors affecting outcome of BT or prompted voiding in men.

Individuals who appear to benefit most from scheduled voiding regimens are highly motivated without cognitive deficits. Men and women with SUI and UUI have benefited, whereas patients with severe sphincter damage (e.g. after radical prostatectomy) generally do not [Hadley, 1986].

VI. COMPLEMENTARY AND ALTERNATIVE MEDICINES

Therapies include acupuncture, relaxation, meditation, imagery, hypnosis, naturopathic and herbal remedies, but only trials of acupuncture therapy have been found in men with UI. Therefore, only acupuncture will be considered in the remainder of this section.

Acupuncture is a traditional Chinese modality and has been used for the treatment of urinary disturbances. Acupuncture has been reported to relieve OAB symptoms including UI due to spinal cord injury [422], and idiopathic DO or MUI [423,424].

1. PREVENTION OF UI

No studies were identified on the preventative role of complementary therapies in men.

2. TREATMENT UI

Acupuncture may improve urodynamic parameters such as sphincter function [425,426] or bladder capacity in men with UUI (Honjo, 2000; Kitakoji, 1995). It is a form of somatic sensory stimulation [Bergstrom, 2000]. The mechanism by which acupuncture inhibits DO remains unclear, but suppression of the spinal and supraspinal reflexes that lead to detrusor contractions is considered one of the most important mechanisms [427,428] or release of endorphins [Bergstrom, 2000]. There has been no report on the effects of acupuncture for male SUI or post-prostatectomy incontinence.

a) What is the most effective acupuncture protocol?

Acupuncture has been carried out with disposable stainless steel needles (0.3mm in diameter, 60mm in length) inserted into the bilateral BL-33 points on the skin of the third posterior sacral foramina [422,423,429] or several other points (BL-31,32, 21, 23, SP-6, KI-3, LI-11,CV-1,2,4,5) [430], and usually performed once or twice weekly [422-424,429,431]. Acupuncture protocols vary and there is no apparent consensus between investigators. It is not known if any acupuncture protocol is more effective than another.

b) Acupuncture versus no treatment, sham acupuncture or any other treatment

No new studies were identifified. Only one RCT has been identified including both men and women [432], but there is no study exclusively for men. In a randomised, placebo-controlled, single-blind study among 20 elderly patients (three males, 17 females) Ellis (1990) showed that the frequency of voiding at night was reduced after acupuncture. Uncontrolled studies suggest improved symptoms post acupuncture [422,423].

The evidence of the effectiveness of acupuncture for men with UI is limited by the lacked of controlled studies. To date, the studies are small, objective measures of UI are not included and long-term follow-up is lacking. Uncontrolled studies suggest that RCTs of acupuncture in the treatment of UI in men are warranted.

3. OTHER LUTS

No new trials were found in this category. In the one trial in men with sensory urgency after TURP [431]a significant improvement was reported by acupuncture reflexotherapy (EStim of somatic and auricular points) in terms of IPSS, QOL scores, decrease of daytime frequency and nocturia, but no improvements with the use of placebo or oxybutynin.

4. FACTORS AFFECTING OUTCOME

Aside from Ellis [1990], reported above, who specifically recruited elderly participants there is a lack of

evidence about the effect of any prognostic factor for the outcome of complementary therapies in men.

VII. SUMMARY

Despite the prevalence of UI and LUTS in older men, the only group that has received much attention in research is men following radical prostatectomy. Overall, the effect of conservative treatment (lifestyle interventions, physical therapies, schedule voiding regimes, complementary therapies) for men has received much less research attention compared to women.

1. RECOMMENDATIONS FOR PRACTICE

There is generally insufficient Level 1 or 2 evidence on which to base recommendations for practice, and most recommendations are, in effect hypotheses, that need further testing in research.

Lifestyle interventions

- It seems reasonable for health professionals to offer men advice on healthy lifestyle choices that may reduce or delay the onset co-morbid conditions that are risk factors for incontinence **(Grade of Recommendation: D)** (Unchanged).

Pelvic floor muscle training (PFMT)

- Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful **(Grade of Recommendation: B)** (Unchanged).
- It is not clear whether PFMT taught by digital rectal examination (DRE) offers any benefit over and above verbal or written instruction in PFMT **(Grade of Recommendation: B)** (Unchanged).
- The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference **(Grade of Recommendation: B)** (Unchanged).
- Use of a strong pelvic floor muscle contraction immediately after voiding, or urethral massage to empty the urethra, can improve symptoms of post micturition dribble **(Grade of Recommendation: C)** (Unchanged).

EStim (EStim)

- For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme **(Grade of Recommendation: B)** (Unchanged).

2. FUTURE RESEARCH DIRECTIONS

There is much scope for research on the effects of conservative therapies for UI and LUTS in men. Research that is urgently needed, in the opinion of committee members, is highlighted with the use of italics. There are a few recommendations that apply to all future studies in men, namely:

- All future intervention studies must be designed to allow standardised and comprehensive reporting of results based on the ICS and CONSORT recommendations.
- The natural history of UI after radical prostatectomy must be taken into account in study design as the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.
- More research is needed to find out what are the most important outcomes for men with UI, so such measures can be incorporated as the primary outcome measures in further trials.
- Data are needed to establish to the cost, and cost effectiveness, of conservative therapies in men with UI.
- Surgical approaches with laparoscopy or robotics offer promising improvements in visualisation for nerve-sparing procedures; further research should address continence and erectile function after these newer surgical procedures.

a) Lifestyle interventions

- To date, no trials have addressed the topic of lifestyle interventions for men with UI.
- The effects of interventions such as weight and caffeine reduction, both of which show some evidence of benefit in women, are priorities for future research.

b) Pelvic floor muscle training (PFMT)

- Further studies to test the hypothesis that preoperative proprioceptive training plus PFMT is more effective than PFMT alone to prevent UI in men undergoing radial prostatectomy.
- A comparison of preoperative versus postoperative PFMT verbal and written feedback to reduce prevalence and severity of UI following radical prostatectomy is needed.
- Methods of PFMT instruction and supervision require further investigation. Two areas of research interest are:
    - Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction.
    - The effect of group exercise. Because of the peer support that men may receive from participating in a group (433] this might be useful after radical prostatectomy; three reported that support in the post operative period may be important to healthy recovery [368,371,391].

- More systematic investigation of the the natural history of UI after TURP is needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

- The relationship between age, or any other factor, and the outcome of PFMT for UI in men has yet to be determined.

c) Electrical stimulation (EStim) and magnetic stimulation (MStim)

- It is not known if pre or postoperative EStim or MStim has a role in reducing UI after radical prostatectomy.

- RCTs in larger samples, with long-term follow up, are needed to investigate all aspects of the effectiveness of EStim and MStim as a treatment for UI in men, including:

    - o Either type of stimulation versus no treatment, sham stimulation or other control conditions.

    - o Comparisons of both EStim and MStim protocols.

    - o EStim versus MStim.

    - o Either type of stimulation versus medication.

    - o Whether the addition of either type of stimulation to other treatments adds benefit, in particular the addition of stimulation to PFMT.

- The effect of age, and other factors, on outcome of stimulation. Elderly men may have more comorbid conditions than young men and a more pragmatic approach to inclusion in EStim studies is needed.

d) Scheduled voiding regimens

In the absence of trials exclusively in men, or trials that report data separately for men and women, there is a pressing need for high quality RCTs with an appropriate sample size and long-term follow up to address the effects of BT, Timed voiding, habit training and prompted voiding in men suffering from UI.

APPENDIX 1

TERMINOLOGY

Pelvic Floor Muscle Therapy (PFMT): any programme of repetitious, voluntary PFM contractions taught by a healthcare professional. It is the PFMs, not pelvic muscles in general, which are the target of the intervention. This broad definition accommodates variations in the PFMT end-goal, type of supervision (e.g. individual or group sessions) and the exercise programme (e.g. variations in frequency, intensity, number of contractions and duration of training). It may include the use of PFM contractions for urge suppression and to prevent stress leakage, under the term "the knack".

PFMT is used in preference to other previously-used terms such as Kegel's Exercises, pelvic floor exercises and PFM exercises. The term 'Kegel's Exercises' is no longer appropriate because it refers to Kegel's original exercise programme of 500 contractions per day (58). Current PFM programmes are very different from the one originally prescribed by Kegel (1948).

"Training" is also viewed as a more appropriate word than "exercise". The term "exercise" is commonly interpreted as one training episode or a single muscle action, whereas, "training" encompasses repeated exercises over a sustained period of time.

APPENDIX 2

REVIEW OF THE LITERATURE/SEARCH TERMS

A systematic search of studies up to the end of August 2011 was conducted. Only papers published in English or in a language for which a translator could be found were included. Relevant systematic reviews and reports of RCTs and quasi-RCTs were included. Therefore, only Level 1 evidence is considered in this section and recommendations are based on the findings of existing up-to-date systematic reviews and more recent RCTs.

Several Cochrane reviews were critical to the rigour of the present chapter: UI prevention (96,170); management of urinary continence in women (97,126,213); management of urinary incontinence in men (412,416); management of pelvic organ prolapse (296,297); habit training and timed voiding (273,275); and bladder training (269). Pre-specified outcomes of interest were urinary continence (for prevention studies), urinary continence, patient symptoms, quality-of-life measures and pad tests (for treatment studies).

Data for SUI were taken from a recent UK Health Technology Assessment (HTA) on non-surgical interventions for stress urinary incontinence in women (219). This was supplemented with additional studies for SUI completed after publication of this HTA, and studies for UUI and other LUTS, located through additional literature searching conducted in the Cochrane Incontinence Group Specialised Register as part of an ongoing Cochrane review. The same methods used in the HTA for data collection and analysis for SUI were applied to the studies on UUI and LUTS.

Criteria for inclusion were (1) randomised or quasi-randomised (alternate allocation) trial study design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women. Retrospective data was not included. 'Risk of bias' in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group (220). Risk of bias due to blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

The Consort Statement Checklist was used to determine the quality each study (434). Empirical evidence indicates that two elements of trial quality, allocation concealment and double blinding, are important for estimating treatment effect with precision. Trials with inadequate or unclear concealment of allocation appear to overestimate treatment effect by about 30% and trials that are not double-blinded overestimate effect by about 15% (435). Therefore, trials that reported adequate allocation concealment have been noted. Although it is often difficult or impossible to blind patients to PFMT, trials that reported blinding of the outcome assessment have also been noted. Readers may wish to consider these factors in their interpretation of the data.

The search terms may be seen at http://hdl.handle.net/10402/era.26262. (Click on the "download" link, top right.)

I. INTRODUCTION

Surgery for male incontinence is an important aspect of treatment with the changing demographics of society and the continuing large numbers of men undergoing surgery and other treatments for prostate cancer.

Basic evaluation of the patient is similar to other areas of incontinence and includes primarily a clinical approach with history, pad testing, frequency-volume chart or bladder diary, and physical examination. Since most of the surgeries apply to patients with incontinence after other operations or trauma, other investigations such as radiographic imaging of the lower urinary tract, cystoscopy, and urodynamic studies may provide important information for the treating clinician.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment is indicated following similar strategies applied in post-prostate cancer treatment incontinence i.e. slings and artificial urinary sphincter (AUS).

Radical prostatectomy for prostate cancer is performed far more frequently now than 15 to 20 years ago, with nearly two-thirds of surgical cases being performed via the robotic-assisted laparoscopic approach in the United States [1]. Approximately 5-25% of patients will experience incontinence that fails to improve with conservative management, and a substantial minority will ultimately undergo surgical treatment [2]. The AUS has provided a satisfactory result in most cases, regardless of the degree of urinary incontinence, with a positive impact on quality of life. Sling procedures have emerged as an efficacious treatment in the majority of men with mild to moderate stress urinary incontinence, however, they have not proven predictably successful in men with higher degrees of incontinence. Injectable agents have not shown durable long-term results. Volume adjustable balloons have been limited in their utility due to a high complication rate. Newer techniques involving adjustable urethral slings have demonstrated efficacy similar to that of non-adjustable slings, with the potential advantage of postoperative alterations in sling tensioning (tightening) but a higher complication rate.

Stratification of treatment based on the degree of stress incontinence is now feasible. Men with milder degrees of incontinence and normal bladder function are candidates for either artificial urinary sphincter placement or sling surgery, each with similar success rates. Sling surgery appears to have a lower risk of surgical complications in this population. Patient preference may be for a sling versus a mechanical device [3]. On the other hand, with more severe incontinence, AUS surgery has a more predictable success profile than does sling surgery.

Incontinence following radiation therapy, cryosurgery, high-intensity focused ultrasound, other pelvic operations and trauma is a particularly challenging problem because of tissue damage inside and outside the lower urinary tract. In such instances, periurethral bulking, sling procedures, and inflatable periurethral balloons have generally proven inefficacious and worsening of incontinence may happen after such surgery. The AUS is the most successful surgical procedure in this setting, but is associated with a higher rate of complications compared to implantation following surgery in the absence of adjuvant cancer therapy. With tissue damage beyond the urinary sphincter, other surgical approaches may be necessary. Patients with unresolved problems from pediatric age and with associated incontinence from detrusor overactivity may benefit from a variety of complex reconstructive surgical procedures. Other complicated problems encountered include urethrocutaneous fistulae, and fistulae between the prostate, bladder neck, or urethra and rectum. Surgical reconstruction, in experienced hands, often in a staged manner, is usually successful.

With decades of worldwide use of the AUS in the surgical management of male incontinence, its complications and their management are well known. Durability of the device is an important aspect that impacts on outcome and cost of treatment. A growing body of literature regarding male sling surgery, its indications, factors affecting outcome, and complications and their management,

has changed the landscape of incontinence surgery over the past 5 years.

Although the literature is replete with well-done cohort studies, there is a continuing need for prospective randomized clinical trials, especially needed for adequate comparisons among surgical techniques.

MATERIALS AND METHODS

The committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Third Consultation [4] for non-neurogenic male incontinence. Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the committee and included in the chapter.

The incontinence problems were classified according to their etiology, i.e. either primarily sphincter or bladder related, and are listed in **Table 1**. Treatment of fistulae is covered separately.

Specific recommendations are made on the basis of published results and determined by the levels of evidence. Consensus of the committee determined the recommendations, which are found at the end of the chapter. Recommendations for future research are also included.

II. EVALUATION PRIOR TO SURGICAL THERAPY

Recommendations for evaluation prior surgery have not changed substantially from the last edition in 2009 [5]. A basic history and physical is the cornerstone of this evaluation. The history should focus on the precipitating events (surgery, trauma, etc) that led to the incontinence, the evolution over time of the leakage symptoms (has there been improvement, etc), what precipitates the leakage (straining, cough, exercise, etc – suggestive of stress urinary incontinence (SUI) or the sudden onset of urgency, the sense of needing to void immediately, particularly in the absence of any physical activity – suggestive of urgency incontinence) as well as other potential comorbidities. A general sense of the degree of bother of these symptoms, sexual function and pad use is important as well. The physical examination should note any gross urine leakage per meatus with patient straining or coughing as well as general characteristics of the lower abdomen, perineal area and penis and scrotum. Assessment of hand function is important to assess manual dexterity for manipulation of an implanted device. A brief neuro-urological examination (perineal sensation, anal tone, voluntary contraction and relaxation of the anal sphincter, bulbocavernosus reflex [6]) should be performed. A urinalysis to rule out infection or signs of inflammation or hematuria should be obtained.

A frequency-volume chart [7], or bladder diary (indicating daytime and nighttime frequency of micturition, incontinence episodes, voided volumes, 24-hour urinary output, etc.) is also helpful. According to Wyman et al. [8] the 7-day diary can be considered as the gold standard for voiding diaries. Schick et al. [9] demonstrated that a 4 day frequency-volume chart gives a reliable snapshot of the patient's situation. A pad test quantifies the severity of incontinence and may be the most objective measure of the incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis of urinary incontinence because it is the most reproducible. [10] The 1-hour pad test may be used because it is easily done and standardized, however there is no strict

parallel with the 24-hour pad test and it may underestimate the weakness of the sphincter in the later part of the day. A pad test may be helpful in quantifying leak in AUS failures.

The ICIQ-SF (short form) questionnaire (www.iciq.net) can be recommended for the assessment of the man's incontinence, and has been used in RCTs of treatment for post prostatectomy incontinence.

Postvoid residual urine measurement is a good estimation of voiding efficiency [11,12]. These basic investigations are recommended in incontinent males prior to surgical therapy.

Blood testing (BUN, creatinine, glucose) is recommended only if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented by the frequency-volume chart [13].

Further evaluation should be adapted to the particular patient. Cysto¬urethroscopy will verify the integrity of the urethral wall (anterior aspect of the distal sphincteric mechanism in post-TURP incontinence [14], erosion by the cuff of the artificial sphincter), and the status of the bladder (trabeculation, stone, diverticula, etc). It will allow observation of the urethral sphincter and voluntary contraction on the part of the patient, if done under local anaesthesia. The presence or absence of urethral, prostatic, or bladder neck stenosis is also necessary to ascertain prior to incontinence surgery, especially in patients who have undergone treatment for prostate cancer.

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of incontinence following artificial sphincter implantation when during the original procedure the hydraulic system was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons [15]. **Figure 1** illustrates the case of a young spina bifida patient in whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Second KUB compared to previous one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is suspected [16], e.g.: following abdominoperineal resection of the rectum. Cystourethrography may be used to demonstrate a fistula, stricture or urethral diverticulum e.g., following healing of the urethral wall erosion caused by the cuff of the artificial urinary sphincter (**Figure 2**). Ultrasound is widely used not only to evaluate the upper urinary tract, but also to evaluate postvoid residual urine. The sensitivity of 66.7% and specificity of 96.5% when post-void residual is 100 ml or more is adequate for routine clinical use [17]. It has been shown to be cost-effective when compared to catheterization [18]. Other modalities, for example transurethral ultrasound [19] and magnetic resonance imaging of the external sphincter are still under development.

URODYNAMIC TESTING

Urodynamic studies (UDS) have traditionally been performed in men under consideration for invasive treatment in order to assess Valsalva Leak Point Pressure (VLPP), detrusor overactivity and bladder compliance. However, there are now several studies, which call into question the use of routine UDS in men with pure SUI. These studies will be commented on at the end of this section.

When performing UDS there are specific issues that must be considered. In patients with incontinence secondary to radical prostatectomy who developed bladder neck stenosis, the urethral catheter can create obstruction giving false values for Valsalva leak

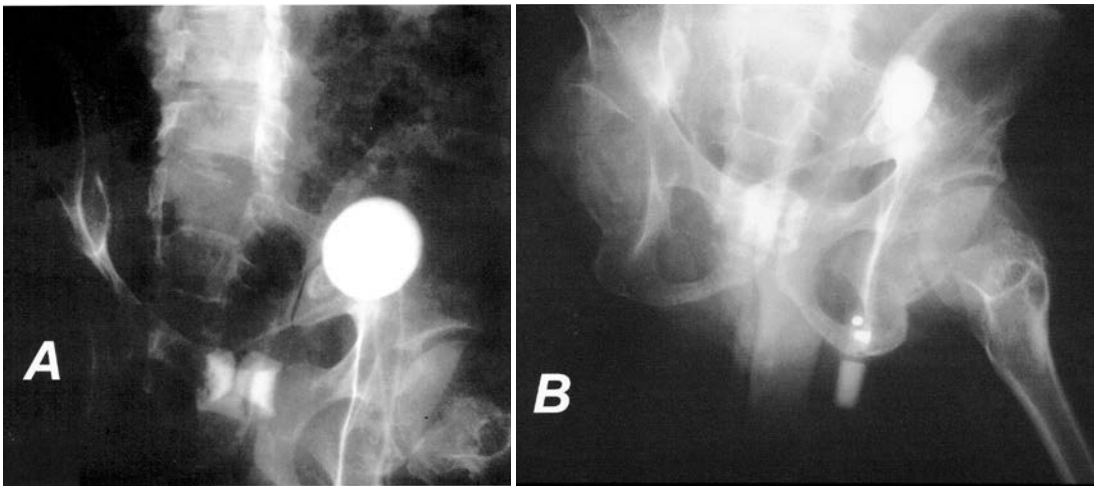

Figure 1. Young spina bifida patient who had a bladder neck artificial sphincter implanted. After more than 10 years, he became incontinent. Early abdominal plain film, A, shows a full reservoir. After leakage started abdominal plain film, B, demonstrates loss of fluid from the reservoir.

point pressure (VLPP). Sphincter weakness can be documented by the Valsalva [20] or cough or abdominal leak point pressure [21]. Catheter size seems to have a significant influence even with a small size 7-F urethral catheter [22], and the correlation is extremely high between the test-retest leak point pressure when the same size of catheter is used [23,24]. In male patients, abdominal leak point pressure may be evaluated via a rectal catheter because a urethral catheter is much more likely to invalidate VLPP measurements than it does in female [25]. It has become evident that bladder volume influences VLPP, i.e. it decreases with bladder filling [26-28]. However, this observation is not consistent [29]. Unfortunately, there is no agreed standardization of the technique at the present time which somewhat limits its usefulness [30]. Measurement of leak point volume may also provide information on the functional capacity of the bladder [31].

Retrograde leak point pressure has been used to study incontinence following placement of an artificial sphincter [32,33]. It correlates with the lowest abdominal leak point pressure [34]. The intraoperative use of this technique has been proposed and this allows early recognition of intraoperative urethral injury and mechanical malfunction [35]. Intraoperative retrograde perfusion sphincterometry may be helpful to determine the appropriate tension on male slings [36]. Similarly, others have utilized repeated intraoperative abdominal leak point pressure (ALPP) measurements to adjust the tension for male slings [37]. Electrophysiologic studies, mainly sphincter electromyography, may be useful to document denervation of the pelvic floor when nerve injury or neuropathology is suspected [38].

Detrusor function is best evaluated by multichannel urodynamics. Its main purpose is to detect detrusor overactivity and/or decreased compliance during bladder filling. It can be coupled with fluoroscopic imaging, video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound [39,40]. Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry [41] but at present its use is controversial [42].

Non-invasive pressure-flow urodynamic evaluation based on Doppler ultrasound seems to have potential for diagnosing bladder outlet obstruction [43]. However invasive pressure-flow studies are still the gold standard in the incontinent male to rule out bladder outlet obstruction accompanied by detrusor overactivity [44] which in turn can cause incontinence.

In most recently published studies, urodynamic testing has been done prior to surgery [45-49]. Cystoscopy is frequently done as well [48,50-54]. However, as noted above, there are some reports that question the value of urodynamics studies in predicting outcomes after surgery. Thiel et al. [55] found no evidence that patients with detrusor overactivity, early first sensation of filling, decreased compliance or low bladder capacity had worse outcomes after artificial sphincter placement in 86 men. Trigo Rocha et al. [56] also found that preoperative urodynamic findings such as detrusor overactivity, impaired detrusor contraction, low Valsalva leak pressure, bladder outlet obstruction, and mildly reduced compliance did not lead to a poor outcome after artificial sphincter implantation. Ballert et al. [57] studied the association between preoperative detrusor overactivit and postoperative outcome after male sling surgery and found no difference in the number of pads used postoperatively. Preoperative detrusor overactivity was not associated with worse postoperative outcomes. Finally, Lai et al. [58] reviewed 129 patients with post-prostatectomy incontinence, all of whom had multichannel videourodynamics, and noted that the presence of adverse preoperative urodynamic features (such as detrusor overactivity, early sensation of desire to void, reduced cystometric capacity of <200cc, low abdominal LPP <30 cm H2O, low maximum flow <10cm H2O and poor bladder contractility) did not negatively affect the continence results after AUS implantation.

The proposed evaluation of the incontinent male is summarized in **Table 2**.

III. INCONTINENCE AFTER RADICAL PROSTATECTOMY FOR PROSTATE CANCER

1. INCIDENCE AND PREVALENCE

Urinary incontinence occurring after radical prostatectomy (RP) is a substantial problem. Despite improvements in continence preservation [59] during the 1990's and 2000's primarily due to a better

Table 2: Evaluation prior to surgical therapy

understanding of the pathophysiology and improvements in surgical technique, continence rates have generally plateaued over the past decade. As RP has continued to increase in popularity as a treatment for prostate cancer, especially with the advent of robotic-assisted surgery, the prevalence of post prostatectomy incontinence (PPI) has increased in developed countries, which has led to an overall increase in the number of patients affected.

Data from large multicenter studies and prostate cancer databases suggest that following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of post prostatectomy incontinence (PPI) depends on the definition of urinary incontinence and the length of follow-up. [60-62] In addition to numerous definitions of incontinence, the tools used to evaluate incontinence vary from self-administered validated and non-validated questionnaires, to interviews from a data manager, to response to the surgeon's inquiry, to insurance data base inquiries regarding secondary surgical procedures. It should be noted that SUI also affects men who have not had surgery for prostate cancer, occurring at a baseline prevalence of 1.3%-4.8% [63,64]. In addition, men with prostate cancer who choose radiation therapy, androgen ablation, or even watchful waiting also develop urinary incontinence, recently reported at rates of up to 12%, 11%, and 3%, respectively [65,66]. In addition to urinary incontinence, bothersome lower urinary tract symptoms may affect patients following any treatment (or even watchful waiting) for prostate cancer.

Typically, reports of large cohorts use definitions that include "total control/perfect continence/dry", "occasional leakage but no pad", and "less than one pad". Because 1/3 to 1/2 of men who do not wear pads will have occasional leakage of urine [60,67] it is important to distinguish among those men who leak enough to require pad use versus those who do not, as it has been demonstrated that health related quality of life (QOL) is strongly correlated with the level of incontinence. Wearing one pad, even if this pad is considered "a security pad", more significantly affects the quality of life than wearing no pad at all [68,69]. In addition, not all men who leak will elect to have further treatment. Most large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery. [70-73] Several large cohort studies are listed in **Table 3** [62,67,69,74-92].

Another bothersome type of incontinence occurring during orgasm in men post-prostatectomy has been termed 'climacturia' and may significantly affect the quality of men with post-prostatectomy potency [93].

2. RISK FACTORS

Reported risk factors for incontinence following radical prostatectomy include patient age at surgery, socio-economic status, preoperative continence status, obesity, pre-surgical bladder dysfunction, stage of disease, surgical technique (including nerve sparing, bladder neck preservation, and posterior reconstruction of Denonvilliers' musculofascial plate, anterior periurethral suspension sutures [94,95], prior radiation therapy, preoperative length and intraoperative preservation of the membranous urethra, prior transurethral resection of the prostate (TURP), postoperative radiation or cryotherapy, and vascular comorbidities. However, various studies have come to conflicting conclusions regarding the importance of specific risk factors. Predisposing factors contributing to incontinence after TURP have been less clearly defined, probably because the incidence is so low, (and the plethora of minimally invasive therapies is reducing the popularity of TURP surgery), making the accumulation of large prospective series of this type of incontinence difficult. However, previous external beam radiation and prior brachytherapy does predispose to post-TURP incontinence (Section VII in this chapter).

Pre-operative urinary incontinence has been reported as a risk factor for post-operative SUI. While preoperative lower urinary tract symptoms, including

urgency incontinence and "overflow incontinence" may improve with de-obstruction secondary to extirpative surgery [96], pre-operative SUI does not improve following RP. Several recent cohort studies have demonstrated that pre-operative sphincteric insufficiency (demonstrated either the pre-existing clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts post-operative SUI. [97,98] Pre-operative bladder dysfunction can also contribute to post-operative incontinence. Pre-existing abnormalities of detrusor function may predispose to leakage following surgery, especially in the setting of neurogenic detrusor overactivity due to Parkinson's disease, dementia or spinal cord injury. [99]

Advancing age as a risk factor is supported by several studies [73,96,100-106]. Steiner, et al found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older [107]. Others have found advancing age and the number of co-morbidities to have a negative impact on the recovering time for continence during the first year after radical prostatectomy [108] although the rate at one and two years did not seem to be significantly affected [109]. Mohamad and colleagues reviewed 16,524 patients who underwent RRP in public hospitals, covering 95% of all procedures in Austria between 1992 and 2003. They found that increasing age was associated with an increased risk of future AUS implantation. In those aged 45-49, 0.5% were bothered enough by PPI to merit AUS placement, while those age 70-74 were five times as likely to undergo AUS placement for PPI.[110] Similarly, Rogers et al. demonstrated that age affected post-operative continence status following laparoscopic RRP. In those < 50 years old, 100% achieved 0-1 pad per day continence at 1 year, which decreased to 91% and 81% for those age 50-59 and > 60 yrs, respectively ($p<0.01$). [111] Nilsson et al. [112] reported that age at surgery predicted in an exponential manner the long-term risk for urinary incontinence, with an estimated relative increase of 6% per year.

In addition to age, overall well-being has also been related to the risk of PPI. For example, a recent study out of Italy demonstrated that both age and Charlson comorbidity index were independent predictors of return to urinary continence [105]. It is especially interesting to note that in this particular cohort study, there were no variables related to the prostate cancer itself that were significantly correlated with urinary continence. A large study from Sweden recently demonstrated that in addition to age as a risk factor (relative risk of 2.4 between the oldest and youngest quartiles), educational level also impacted incontinence, with low educational level, as compared with high education level, being associated with a 2.5 time risk of incontinence[112].

Obesity, especially when coupled with physical inactivity, appears to be a risk factor for PPI in men undergoing RRP. Obesity with a BMI >30 was reported as a risk factor with an incontinence rate of 25.8% versus 8.7% in BMI <30 in a series of 252 men after RRP [113].

Wolin, et al. demonstrated that greater than one year after surgery, obese men were markedly more likely to have urinary incontinence (defined as any pad use) than were non obese men, while this risk was exacerbated by sedentary lifestyle, and ameliorated by at least 1 hour of physical activity per day (preoperatively). Nonobese active men were 26% less likely to have urinary incontinence than obese inactive men. In obese men who were physically active, the relative risk of urinary incontinence was 15% less than in the inactive obese men [114].

Most large series have found no correlation between the stage of disease and incontinence rates [101,102,115-117] Loeb and colleagues specifically demonstrated excellent continence rates even in high risk (high local stage) patients. [118] However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and incontinence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [103]. Yang et al reported that neoadjuvant hormonal ablation was associated with a lower risk of urinary incontinence, and while patients with higher stage disease may have been more likely to receive hormonal ablation pre-operatively, it is not clear that stage of disease was an important risk factor [106].

Regarding surgical technique, the many parameters involved in continence may explain difficulties in understanding the benefit of certain technical points. Bladder neck preservation has been reported to improve continence at 1 month [119] and at 3 months [116] but no difference was found at 6 and 12 months [120,121]. Nerve sparing has no significant impact according to Steiner et al. [107] and Lepor and Kaci [76]. Recently Pick et al. reported that nerve sparing, whether unilateral or bilateral, did not affect continence rates following RALP [122]. Others did find benefit [97]. In particular, Nandipati and colleagues reported that in a cohort of 152 patients followed prospectively, bilateral nerve sparing surgery was associated with a shorter time to regain continence as well as improved long-term continence rates compared to non-nerve sparing surgery. They additionally found that increased age was a risk factor for post-prostatectomy incontinence [123]. Burkhard, et al. similarly demonstrated a positive effect of nerve-sparing surgery on post-operative continence. In a prospective cohort study of 536 patients, PPI developed in 1/75 (1.3%), 11/322 (3.4%), and 19/139 (13.7%) with attempted bilateral, attempted unilateral and without attempted nerve sparing, respectively. Attempted nerve sparing was in fact the only statistically significant factor influencing urinary continence after RRP in this cohort [124]. Two recent reports have linked pre-operative sexual function with post-operative continence. While those who are sexually active pre-operatively may be more likely to have

their cavernosal nerves spared during surgery, it appears that the pre-operative status has a significant effect on post-operative continence rather than the nerve sparing technique [119,122,125].

Within the last decade, laparoscopic and robotic-assisted laparoscopic radical prostatectomy have become standard treatments for men with prostate cancer. Over the past 4 years, the body of available data on post-operative continence has generally demonstrated no obvious differences in continence rates between open and laparoscopic/robotic approaches. Several studies have compared the techniques either prospectively in non-randomized fashion, [85,86,88-91,126,127] or via limited meta-analysis [84,128] and similar continence rates were found. Further prospective comparative studies with open surgery are needed. Currently, a multicenter prospective comparative study of robot assisted laparoscopic and retropubic open radical prostatectomy is underway, with an accrual goal of 2100 patient, with the primary objective of comparing rates of urinary incontinence at 1 year post-operatively [126].

Perineal prostatectomy is done by only a limited number of urologists but is still advocated for markedly obese patients and the continence rate was reported as similar to the retropubic route [79,90,129,130].

3. PATHOPHYSIOLOGY

Post-prostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction or a combination of both. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated [129,131]. Urodynamics demonstrated that the sphincter incompetence occurs as the sole cause in more than two thirds of patients, while isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% [132-135].

Sphincter and bladder dysfunction can coexist in at least one third of incontinent patients. Bladder dysfunction may occur de novo after prostatectomy perhaps induced by bladder denervation; may be caused by outlet obstruction, or may be related to pre-existing factors such as age. Impaired detrusor contractility, which occurs in 29% - 61% of patients (de novo in approximately 47%), and poor compliance, which occurs in 8%-39% of patients (de novo in approximately half), have traditionally been thought to resolve in the majority of patients within 8 months [135,136]. However, two recent prospective urodynamic studies have demonstrated that decreased bladder compliance can occur in up to one-third of patients following RP, and persist in 28% at 36 months, while detrusor underactivity can occur in half of the patients, and persist in 25% at 36 months [136,137]. Decreased sphincter resistance may be due to tissue scarring in some cases and reflected by a low urethral compliance, however this parameter is difficult to measure [132]. Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography, and is clinically suspected when both incontinence and decreased force of stream coexist.

The pre-operative length of the membranous urethra determined on MRI has been shown to be significantly related to time to post-operative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at one year, versus 77% with or less than this length [138]. Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence [97,139,140]. A recent elegant study of intraoperative stretched urethral length (from the urogenital diaphragm to the prostatic apex with cephalad retraction) and cut urethral length (length of preserved urethral stump) during RALP revealed that although in this cohort, MRI urethral length did not correlate well with continence, the intraoperative measurements correlated significantly with time to continence [141]. Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence as well as the extrinsic component responsible for active continence may be involved as has been demonstrated in a urodynamic alpha blockade test [142]. This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Post-operative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory functions [143,144]. In clinical practice, urodynamic evaluation of a urethral weakness may be assessed by resistance to antegrade leakage (ALPP or VLPP), retrograde leakage, or profilometric measurement (MUCP) [145]. However no such parameters have been correlated to outcomes of treatments for the correction of post-prostatectomy incontinence.

The state of a patient's pelvic floor may also influence continence or return to continence after RP. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the post operative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal [146,147]. Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. Another study showed that providing patients with instructions for pelvic floor muscle exercise alone was equivalent to biofeedback or electrical stimulation [148]. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months [149]. On the other hand, a recent trial from Brazil did demonstrate significant difference in 12-month continence rates, quality of life, and lower urinary tract symptoms in general when randomizing patients to biofeedback-

pelvic floor muscle training versus verbal instructions alone [150]. Studies in which physiotherapy was used as a treatment modality for established incontinence have shown more variable results [151-154]. A recent randomized trial of formal one-to-one pelvic-floor muscle training versus advice alone for incontinent men 6 weeks after RP failed to demonstrated any difference in continence rates at 12 months. Nor did the physiotherapy improve SUI after TURP [155].

No medical treatment is available to cure post-prostatectomy incontinence. Duloxetine at 60 mg per day could improve mild or moderate incontinence but half of the patients had some side effects and 25% stopped the treatment because of adverse effects in two short non-randomized series. This treatment is not approved in many countries and could be only a treatment option to improve symptoms in selected patients informed of side effects [156].

4. SURGICAL AND MINIMALLY INVASIVE TREATMENTS

a) Urethral Bulking Agents

Urethral bulking is a minimally invasive treatment proposed for post prostatectomy incontinence, and theoretically works by adding bulk and increasing coaptation at the level of the bladder neck and distal sphincter. It can be done in an office or outpatient setting in a retrograde or antegrade fashion. Several different agents have been used for urethral bulking in men including bovine collagen (Contigen®), silicone macroparticles (Macroplastique®), ethylene vinyl alcohol copolymer (Tegress®), Dextranomer hyaluronic acid (Deflux®), and carbon-coated zirconium beads (Durasphere®). All agents share the similar problems including the need for multiple injections, deterioration of effect over time, and very low cure rates.

For collagen, “success rates” for post-prostatectomy incontinence ranged from 36-69%, with 4-20% of patients reporting being dry [157-164]. Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections were required to achieve modest rates of subjective improvement. There was no advantage of delivery technique (retrograde vs. antegrade). Several authors identified factors which negatively affect results include extensive scarring or stricture formation, previous radiation, and high grade stress incontinence and low ALPP [158,160,161,164]. One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% ‘social continence’ versus 62.5%) [161]. It appears that collagen injection did not adversely affect outcomes of artificial sphincter implantation and did not increase the complication rate [165]. Nor did collagen injection adversely affect the outcome of the bone-anchored male sling (BAMS). [166,167] The cost efficacy of injections remains to be determined. Collagen is no longer available as an injectable agent.

Other bulking agents such as polydimethylsiloxane (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1,3,6, and 12 months respectively [168]. They also noted that a urethral closure pressure of at least 30 cmH2O was essential for success. Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving short-term continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was limited to 3 months.[169] In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the majority had SUI following BPH surgery, with more than1/3 of the cohort suffering from SUI following RRP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52]

With regard to the newer (not FDA approved for male SUI) injectable bulking agents, dextranomer hyaluronic acid has been reported in men with PPI and in men with neurogenic ISD. Four of four patients with PPI failed to improve, and 1 of 2 neurogenic patients (both with detrusor areflexia, wet between catheterizations) failed [170]. With ethylene vinyl alcohol copolymer (Tegress ®) in a report by Hurtado et al., not only was the failure rate high, but also the complication rate was unacceptable. In 17 men, who averaged 1.4 injection sessions followed at a mean of 4 months, 10 had complications, with erosion of injected material in 41.1%, and with only a minority of patients achieving a 50% decrease in leakage [171]. Tegress ®has been withdrawn. Carbon-coated zirconium beads have been similarly reported to be inefficacious, with a recent report of 8 men with mild to moderate incontinence receiving a relatively large average injected volume (23.8 ml), none of whom achieved subjective or objective cure [172].

There has been interest in the use of autologous muscle cells, stem cells, and fibroblasts as an injectable sphincter-restorative agent for PPI. Transurethral injection of living muscle stem cells to reconstitute the deficient urethral sphincter has been reported. Mitterberger and colleagues demonstrated a 67% continence rate at an average of 1 year follow-up in a cohort of men suffering from PPI who were treated with transurethral ultrasound

guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies. 173 An earlier report from the same group demonstrated that men with PPI achieved a 52% dry rate with injection of adult autologous stem cells, which was superior to a similar cohort of men treated with collagen injection.174 However, it must be pointed out that there was a retraction issued by the editors of The Lancet175 for a previous article on the treatment of female SUI with autologous cells published by the same group176. The project was investigated by the AGES PharmMed, a department of the Austrian Government's Agency for Health and Food Safety. The editors stated that in their view "the conclusions of the official investigation pinpoint so many irregularities in the conduct of their work that, taken together, the paper should be retracted from the published record." Current research has focused on the relatively abundant adipose derived stem cells, which are believed to be easier to harvest (higher yield) than are autologous bone-marrow derived stem cells [177].

Conclusion: Bulking agents remain the most minimally invasive treatment for post RP incontinence after conservative measures. All agents for which there is peer-reviewed data available, show only modest success rates with very low cure rates. Effects tend to deteriorate over time. It remains to be seen if improvements in outcomes can be achieved with alternative agents, or if the concept of urethral bulking has achieved its maximal benefit with the agents available now. (Level of evidence 3; Grade of recommendation C)

b) Male Sling

The male sling procedure is based upon the concept of urethral support and external urethral compression, and has established itself as an accepted and efficacious treatment for PPI. The male sling is actually based on the concept similar to that described by Kaufman and associates in the early 1970's [178-180]. At that time a high rate of failure, septic complications and pelvic pain as well as the advent of the mechanical artificial urinary sphincter (AUS) led to the abandonment of the Kaufman prosthesis. Now with the higher prevalence of PPI and patient desire for less invasive surgery and a non-mechanical device the concept has been revisited. Procedures have been developed based on principles used to treat female stress urinary incontinence. These procedures rely on compression from the ventral side of the urethra rather than the circular compression caused by a natural or artificial sphincter. Therefore, most successful sling surgeries rely on a device that is placed under tension, occluding the urethra at rest, and during stress manoeuvres.[181-183]

Schaeffer and Stamey described the bulbourethral sling which uses Dacron bolsters placed under the urethra, which are suspended to the anterior rectus fascia by sutures [184]. Data on this procedure are limited to retrospective analyses from the two authors who described the procedure: it did not gain widespread popularity. In the initial report from 2 centers, 64 patients were included and 56% were "dry" and 8% "improved" at a mean follow up of 22.4 months [184]. Almost one-third needed secondary retightening procedures and patients with radiation fared poorly. Subsequently, Clemens, et al reported a questionnaire-based study of 66 men from a single institution and 41% were cured and 51% improved but mean follow up was only 9.6 months [185]. They also reported that the bulbourethral sling did not cause significant outlet obstruction [186].

The long-term efficacy of the bulbourethral sling was evaluated in 2005, where 95 patients were followed retrospectively at an average of 4 years post-operatively. With follow-up questionnaires returned by 71 patients, the authors found that patients who had undergone radiation, had worse outcomes with only 14% dry and 43% requiring 1 or 2 or fewer pads daily. Moderate to severe pain was reported by 12% of patients after 4 years. Patients who had not had radiation treatment had a cure rate of 42% and 72% used only 0-2 pads per day for mild leakage.[187] Others have described a bulbourethral sling using a polypropylene mesh graft with or without a porcine dermis backing (presumably to reduce the risk of erosion) 53. In two small studies of 9188 and 1653 patients cure rates range from 56-69% and failure rates from 22-25% at a mean follow up of 14 months. John described the bulbourethral composite suspension where porcine dermis is secured to the bulbospongiosus muscle and a 1 cm wide polypropylene sling is placed over this and passed through the retropubic space to emerge from two suprapubic incisions (similar to the tension free vaginal tape procedure in women) 53. He reported a 69% cure and additional 6% improvement in 19 patients, with a mean follow up of 14 months. Eight intraoperative bladder perforations healed without complication.

Xu and colleagues described a bulbourethral composite suspension utilizing a suburethral polyester patch plus a narrow polypropylene tape passed from a perineal incision to a suprapubic incision. At an average of 28 months, 22 (85%) of 26 patients were successfully treated. [189]

A common method of sling fixation involved use of bone anchors. The bone anchored male sling (BAMS) obviated the need for any suprapubic incision for suture passage and fixation. In 2001, Madjar, et al reported on 14 patients with post RP incontinence that underwent the procedure with a synthetic or cadaveric fascial sling 190. At a mean follow up of 12.2 months, 86% were "cured" wearing none or 1 pad. Comiter reported a 76% cure and 14% "substantially improved" rate in 21

men with post prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months 166. In a 2005 update, the same author reported that with a median of 48 months follow-up, 65% of patients remained pad free and 15% required 1 pad per day. [191] Urodynamic follow up in 22 men, revealed that the sling had no substantial effects on voiding function and no one was obstructed postoperatively [192]. Onur and colleagues reported on 46 men with a mean follow-up of 17 months (6-26) [193]. They used different materials for the sling (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis). Overall they reported 41% of patients dry and 35% improved (50% reduction in the number of pads). All patients in whom allograft or xenograft alone was used failed. A 24-month update revealed a patient satisfaction rate of 70% and a 74% improvement in leakage at a median of 24 months.194 Giberti et al195 reported that in 36 men followed for an average of 41 months, 62% were cured and 70% were satisfactorily improved. In the subset who had a synthetic sling implanted, a higher success rate was experienced, with 77% achieving cure. Complications included sling infection in 4.8%, and de novo detrusor overactivity in 7.1%. Carmel et al196 reported that at an average follow up of 36 months, in a cohort of 45 men with moderate to severe PPI, 78% were improved by pad use, 76% had dry ICS 1-hour pad tests, and 72% were satisfied or very satisfied. Infection occurred in 1 patient, and pain resolved in all patients by 12 weeks postoperatively.

However, the morbidity (infection, pubic bone osteitis, perineal pain) related to bone screws coupled with the emergence of effective alternatives has decreased the popularity of the InVance sling.

The transobturator (TO) male sling technique was introduced in 2004 [197] and has since become the most common type implanted for PPI, since the early reports of 2007, [49,197,198]. This approach relies more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than on direct compression of the urethral lumen.[199] Over the past few years, there have been several large case series reporting favorable outcomes. Cornu et al [200] followed 136 men with mild to moderate (< 5 pads per day) PPI for an average of 21 months following implantation of the TO sling. A 78% success rate (based on pad test) was achieved. Rehder et al201 reported their cohort of 118 men with mild to moderate SUI, with a 1-year success rate of 91% at 12 months. Bauer et al202 achieved a success rate of 76%, at a median of 27 months follow-up in 137 men with PPI. In contrast, Gill et al203 reported a subjective success rate of only 51% (PGI-I scale) and objective success rate of 60% (pad use) at a mean follow up of 9 months, and Cornel et al204 reported only 9% of men achieving total dryness at 1 year post-operatively, with a 46% improvement rate.

Membranous rather than bulbar placement of the sling was introduced with the Advance sling with the aim of relocating the urethra in a more proximal direction. However, the concept is controversial as patient anatomy and pathophysiologic modifications are complex. This type of sling surgery close to the membranous urethra requires a deeper dissection compared to bulbar or perineal compression slings.

The I-Stop TOMS sling with four arms and a large surface over the bulbar urethra involves tensioning each corner of the sling. A prospective multicenter study [205] was recently published with 122 patients after minimum follow-up of 12 months for 84% of them, and showed a cure rate of 60% and improvement with only one pad per day in 20%. There were no erosions or acute urinary retention. Wound infection was reported in 2% and all resolved. An “inside-out” TO sling also positioned over the bulbar urethra206 was implanted in 173 men, of whom 49% were cured and an additional 35% improved at a median follow-up of 24 months [207].

In case of failure after sling surgery, no clear guidelines yet exist. Surgical options include repeat sling and balloon or artificial sphincter implant. More studies are needed to document results and predictive factors. With respect to “repeat” TO sling following previous sling failure, Soljanik et al208 reported a cohort of 35 men undergoing a second TO sling. Success rate at 6 months was 79% (46% dry, 33% improved), and was maintained at 76% at a average of 16.6 months, demonstrating that the TO sling may be an effective treatment for managing SUI after a prior failed sling surgery.

Two adjustable retropubic slings have been introduced, with the objective of overcoming potential problems of overcorrection or under correction of continence - the “Argus” [209] and the REMEEX210 slings. In a multicenter trial of the Argus sling in 48 patients211, a 73% continence rate and additional 10% improvement rate was reported after an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent incontinence as well as for urinary retention [211]. In an update reported of 47 patients after a mean follow up of 45 months, 66% were dry and 79% used < 1 pad per day [212]. Hubner’s group [213] reported similarly favorable results, with 79% of 101 men achieving dryness at an average of 2.2 years post-operatively. Thirty-nine per cent required adjustment (10% loosening, 29% tightening) at a mean of 104 days after surgery. Erosion or infection necessitated explantation in 16% at a mean of 1 year. A report from the Netherlands [214] revealed a 72% success rate for the Argus at a median follow up of 27 months. Outcome was

dependent on the degree of pre-operative incontinence, with surgical success in 92% of men with mild leakage (1-2 pads per day), 67% in men with moderate leakage (3-5 pads per day) and 67% in those with severe (> 5 pads per day) incontinence. Explantation was required in 11%, due to infection, erosion, sling rupture or pain. Bladder perforation occurred in 16%, and de novo urethral stricture requiring treatment in 12%. Dalpiaz et al. [215] reported less favorable results, with 79% of 29 patients achieving dryness and 76% satisfaction in the short term, but the dry rate and satisfaction rates deteriorated to 17% and 28% respectively at 35 months. Complications occurred in >80% of cases, with a 35% explanation rate, 14% de novo urgency rate, and a single instance each of urethral stricture and ureteral injury. In a retrospective cohort study of 16 men status post AUS explantation for erosion [216], who were treated with an Argus sling or repeat AUS, men receiving the AUS had a better outcome. Of those who underwent repeat AUS implantation, 63% were cured, and an additional 25% were improved, with only 12% failing. Notably 75% of the Agus patients failed to improve.

In a prospective multicenter Phase II trial of the REMEEX adjustable sling, 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% reporting improvement over baseline158. More recent, but smaller studies have also shown promising results. Navalon Verdejo et al217 reported that 3 of 5 men were dry at an average of 1.4 months, with the other 2 patients experiencing marked improvement. Four of 5 patients experienced recurrent SUI, which was resolved after surgical re-adjustment via the varitensor. A study with lower success rates was reported from Spain with a cohort of 14 men at an average of 18.6 months postoperatively, 42% are dry and 33% are improved218. However, bladder perforation occurred intraoperatively in 29%, sling explantation was required in 21%, urinary retention occurred in 36%, and readjustment was necessary in 83%.

The newest iteration of the male sling is the VIRTUE® Male Sling (Coloplast, Humlebaek, Denmark) an implantable, sub-urethral, permanent, non-absorbable support sling. The sling is a synthetic suburethral mesh of knitted, monofilament polypropylene that measures 5.5 cm x 7 cm, with superior and inferior extension arms. Quadratic fixation is achieved with both transobturator and suprapubic components198. This hybrid sling is based upon the mechanisms of action of the TO sling and the BAMS, providing a broad area of urethral compression and achieving proximal relocation of the membranous urethra. The sling has been shown to increase the retrograde leak pressure in 22 patients from 33.4 to 68.8 cm water after tensioning intraoperatively [36].

Sling results are shown in **Table 4** [45,46,53,184,187-195,209-211,219-222].

1. Sling Complications

Due to the small size of most reported cohort series of BAMS patients, the precise complication rate is 221 not known. However, reports from the largest cohorts of patients reveal an infection rate ranging from 0-6%, and a urethral erosion rate of 0-2%. [46,191,221] Bothersome scrotal pain or numbness affects 16%-72% of patients post-operatively, but has been reported to resolve in nearly all patients by 3 months.[191,195] Postoperative urinary retention was reported in 2-12% of patients. In most cases, it was self-limited and resolved in within 2 weeks [50,194,196,222,223] or rarely required loosening after one month [46].

Infection of the perineal incision/mesh occurred in 3-12%. These infections usually required removal of the implanted sling. Some superficial infections were successfully treated with antibiotics. In men with postoperative mesh infections, 76% (19/25) required surgical explantation of sling [50,191,195,196,221,223,224]. The majority of infections occurred early, however late infections at 3 months and 1 year have been reported [50,196].

Urethral erosion is a well-defined complication in the female SUI population. It has not been frequently reported with BAMS, although theoretically it may be associated with infection necessitating sling removal in some patients [46].

Abnormal postoperative pain or paresthesia is thought to be from compression or intraoperative disruption of the perineal nerves, or from healing around the newly placed bone screws. This complication is difficult to characterize because there is no standard level of pain that is considered abnormal. While some series acknowledged that the majority of patients experience mild pain for 1-3 months after surgery [221], others reported only those with severe pain that required explantation of the sling [222]. The pain generally resolves within 3 months [191,193,196,221,223] although persistent pain beyond 3 months has been reported46,50. Sling removal has been reported in two patients for persistent pain [46,50].

De novo detrusor overactivity or urinary urgency has been reported at 1-14% of patients, and can be treated with oral anticholinergics when necessary. One patient required sling explantation due to this complication [50].

There is a report of early loosening of one of the bone screws [223]. This caused recurrent incontinence and required a second operation to replace the bone screw. Bone screw dislodgement can happen as a late complication and has been reported in 3 patients [191,225].

Table 4. Results of sling procedures in males with stress urinary incontinence

Authors	No. Patients	Mean Follow-up (months)	Sling type	Cured (%)	Improved (%)	Failed (%)

The most common complications reported with the TO sling are perineal pain and urinary retention and studies are needed to establish the best rate between success and side effects among different slings.

Pain beyond the normal perioperative period has been reported to affect 0-20% of patients, and urinary retention has been reported in 3-21% of cases. While incision or explantation for retention is rare, the need for catheterization can persist for up to 12 weeks [200, 201, 226], with rare instances of retention lasting longer than 3 months203. Less commonly experienced is wound infection, with only rare sling infection or erosion requiring explantation [204, 226, 227]. Unlike the BAMS, however, there are occasional instances of worsening incontinence following TO sling placement, which likely occur if the sling is not adequately fixed in position, and allowed to migrate proximally and posterior to the urethra, thereby exerting a pulling tension that opens the dysfunctional urethral sphincter [204,228].

Reported rates of recurrent incontinence following sling surgery are generally low [46,191,194, 208], and it is unclear which patients are amenable to revision surgery. In theory, the adjustable slings are designed to allow increased sling tensioning via a simple adjustment of the tensioning mechanism silicone washer adjustment for the Argus [212], and varitensor adjustment for the REMEEX [229]. But the small sizes of the cohorts, and the limited follow-up of less than 5 years prevent meaningful comparisons of male slings and to the AUS at this time.

Permanent urinary retention is uncommon with male sling surgery, and may be avoided by excluding those patients with detrusor underactivity on preoperative urodynamics.[195,230,231]. However, a recent report from Han et al. [232] found no difference in postoperative residual or urinary retention when comparing 2 groups of men after sling surgery, one with preoperative normal contractility and one with impaired contractility.

2. Predictors Of Success

Several cohort studies have demonstrated that prior radiation therapy is associated with diminished efficacy of the male sling, probably due to urethral fibrosis and inadequate urethral coaptation.[49,187,193,195,207,233-235] Bauer et al [236] recently published their results of a cohort of men undergoing TO sling placement, all of whom had adjuvant radiotherapy following RP. They reported that success was only achieved in 50% of the cohort (cure in 25%), and that only 46% of men reported they were satisfied with the surgical outcome. With respect to the BAMS, Giberti et al. [195] recently reported a markedly lower rate of success in men who had had previous pelvic radiation, with only 15% cure in those patients. The adjustable REMEEX sling also appears to have inferior success in radiated men (60%) compared to patients without radiotherapy (90.2%) [229]. Worsening of incontinence may also occur and patients must be informed of this, especially those with mild incontinence.

The use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material.[193, 195, 221, 237]. The treatment of male SUI with a suburethral sling requires tension that can only be maintained with the use of synthetic material. Pre-treatment severity of incontinence measured by the degree of leakage also appears to influence sling results. Several reports indicate that those with more severe leakage do not achieve similar continence rates when compared to those with milder leakage. [193, 195, 221, 224]. Fischer and colleagues were able to quantify, in prospective fashion, that leakage greater than 423gm on pre-operative pad weight predicted an inferior outcome, compared to those men with less leakage on pre-operative pad weight test. [46] In their report, 62 patients with SUI were followed prospectively. All patients were rigorously evaluated with 24-hour pad test, urodynamics and validated incontinence questionnaires. Success was determined by the Patient Global Impression of Improvement. Overall, 36/62 (58%) of surgeries were successful at a mean follow-up of 15 months. The only preoperative predictive factor was 24-hour pad weight. If pad weight was less than 423 gm, there was a 6-fold greater success rate compared to those with a pre-operative pad weight of greater than 423 gm.

Finally, previous AUS placement and explantation predicts sling failure.[192,216,221]. However, it is not clear if this is directly due to the urethral fibrosis and poor urethral coaptability, and/or if those patients simply suffer from more severe incontinence, which interferes with successful sling surgery.

3. Conclusion

In the intermediate term, the male sling appears to perform well. Slings have surpassed the artificial sphincter as the most common surgical treatment for PPI. The European Association of Urology Guidelines has concluded that there is limited short- term evidence that fixed slings cure PPI, that men with severe incontinence, previous radiotherapy or urethral stricture surgery have poor outcomes and no sling is superior to other slings. Adjustable slings have limited evidence of efficacy. [238] However, in the UK, the National Clinical Guidelines Centre in The Management of Lower Urinary Tract Symptoms in Men has stated that implanted compression devices and slings can be

offered to men with SUI only within the context of a randomized clinical trial [239].

The best candidates appear to be those with lower and moderate degrees of incontinence, who have neither had previous radiation nor AUS placement. With non-circumferential urethral compression, the male sling appears to have a lower risk of urethral erosion and atrophy than does the AUS in the intermediate term. In men with mild to moderate degrees of SUI, or for patients demanding a less invasive procedure or non-mechanical device, the male sling has established itself as a viable alternative to artificial sphincter. When given a choice of surgery, patients have been reported to overwhelmingly choose the male sling over an artificial urinary sphincter. Kumar et al [3] reported that in men with moderate PPI (pad weight 100 to 400 gm/24 hours) who were recommended to receive an AUS or a male sling, 92% opted for the sling. Interestingly, even when the surgeon recommended an AUS for severe leakage (> 400 gm/24 hours), 25% still opted for the sling. While intermediate and long-term data support the BAMS as a durable treatment for PPI, longer term outcomes of the TO sling, pubourethral sling, and quadratic sling are unknown. **(Level of evidence 3; Grade of recommendation C)**

c) Adjustable Balloons

The adjustable balloon procedure is based upon the concept of passive compression of the urethra utilizing two balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial name ACTTM (Adjustable Continence Therapy) was originally conceived and developed for female stress urinary incontinence, and subsequently was applied to male incontinence. The proACT™ device was developed and reported in 2000 [240].

The device consists of a silicone elastomer balloon attached to an injectable titanium port via a silicone tube. A balloon is implanted on either side of the urethra, either under the bladder neck for post-radical prostatectomy incontinence, or under the veru montanum for post TURP-incontinence. The ports are located subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed under general or spinal anesthesia through a short perineal incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation, and then the balloon is pushed along inside the sheath. Fluoroscopic and urethroscopic guidance are used for the procedure. Transrectal ultrasound guided implantation [241] is a possible option. An isotonic medium with sterile water and contrast medium is prepared to fill the balloons with 2 ml during the initial procedure. Then, after a period of time, approximately one month, the balloons are topped up with 1 ml of this solution at each period (maximum filling is 8 ml) until continence is achieved. The adjustment of the filling are volume limited and are carried out step by step in order to obtain a pseudo-capsule surrounding the balloons and therefore to minimize the risk of urethral erosion or migration. Results from 8 prospective studies [48, 51, 242 - 247] reported are shown in **Table 5**. Of 170 patients reported by Hubner [242] and Lebret [51], one-third became pad free. In other studies

Table 5. Results and complications of six prospective series of Adjustable Balloons (proACT) in post-prostatectomy urinary incontinence

Authors	Number of patients	Follow- up (mo)	Number of adjustments (balloon refilling)	Postoperative Complications with explantation (uni or bilateral)	Continence 0 or 1 pad/day	Complete Continence
Hubner[242]	117	13 (3-54)	3 (1-15)	46 %	68 % (46/63)	35 % (22/63) (idem at 1 and 2 years)
Trigo-Rocha[243]	23	22 (6-48)	5 (1-6)	17 %	65 % (15:23)	
Hubner[48]	50 versus 50 (first pts/last pts)	20 vs 23	5 vs 4	58 % vs 24 %	52% vs 60 %	
Cansino Alcaide[244]	69	22 (3-48)	2	12 %	70 %	14 %
Kocjancic[245]	64	20 (12- 62)	3 (0–8)	17 %		67 %
Lebret[51]	62	6	4	31 %	71 %	30 %
Roupret[247]	128	56		18%	68%	66%
Gregori[246]	79	25	3.6	8%		66%

70% of patients utilized 0-1 pads daily [51,242-244]. Mean procedure time of 35 minutes was reported. Along with this improvement in pad use, there were parallel improvements in I-Qol quality of life score [51,242,243]. Based upon these trials, the mean number of post-operative adjustments of the balloon was 3 to 5, with some patients requiring 6 to 8 refillings. In an interesting comparison of the BAMS and ProACT, Crivellaro et al reported their experience of 84 consecutive patients assigned non-randomly to either surgery. Results were similar with respect to success (1 pad or less) with 68% and 64% achieving social continence respectively. However, the explantation rate for the ProACT was more than double that for the BAMS (14% vs. 6%) [248]. Gregori et al [246] recently reported that previous radiotherapy and severe incontinence were associated with higher ProACT failure rates. According to the degree of incontinence, dry rates achieved in patients with mild, moderate, and severe leakage were 85%, 64% and 33%, respectively. Whereas 66% of patients overall realized dryness on a 24-hour pad test, in those patients previously irradiated, the dry rate was only 36%. They therefore considered these pre-operative factors as relative contraindications to ProACT placement. Roupret et al [247] also recently reported a lower success rate in irradiated patients, with continence rates of 46% in radiated patients versus 68% overall. The only reported risk factor for failure or adverse events was prior external beam radiotherapy. Similarly, Kocjanic et al. [245] demonstrated a continence rate of 67% in non-radiated patients, compared to 36% in radiated patients.

1. Complications

The most common peri-operative complications are urethral or bladder perforation, necessitating removal of the implant on the perforated side. However, contralateral implantation was not adversely affected, and repeat ipsilateral implantation was invariably achieved after healing of the urethral or bladder wall. Lebret et al. [51] reported a perforation rate of 10% and Hubner [48] reported a rate of 18% early in their series, but a lower urethral perforation rate in the most recent cases illustrating a relatively short learning curve for optimal balloon placement near the urethral/bladder wall. Temporary urinary retention from presumed obstruction was reported at 5% [48]; removing fluid from the balloon restored voiding.

Device explantation was related to balloon failure, infection, erosion, or migration. The explantation rate ranged from 6 to 58% [48,51,242-247], but decreased with experience [48]. Device removal is straightforward, as a deflated balloon can be explanted transperineally.

As balloon deflation and migration may occur, a long follow-up is required to appreciate this technique over the time.

2. Conclusion

The proACT™ balloon technique appears to be a feasible procedure to improve the continence in short and median term, with better results occurring with more operator experience. Similar to the male sling procedure, appropriate candidates include those with mild to moderate leakage due to intrinsic sphincter deficiency, and no previous radiation. The benefit of an adjustable system should be weighed against the need for multiple sessions of refilling the balloon, and with reported rate of peri-operative and post-operative complications. Longer follow-up is needed before definitive comparison to male sling or artificial sphincter can be made. No recommendation is possible due to variable data on complication rates (12-58%). (**Level of evidence 3, Grade of recommendation D**).

d) Artificial Urinary Sphincter

The artificial urinary sphincter remains the most effective long-term surgical treatment for post RP incontinence due to sphincteric insufficiency. However, due to the cost, the perceived cumbersomeness of the device with resultant patient reluctance to have or inability to use a mechanical implant, and the fear of complications, it is not suitable for all patients. In addition, the development of less invasive techniques (as described above) potentially gives patients new options for treatment. Ultimately the choice of AUS will be based upon patient dexterity, economics, degree of incontinence, previous incontinence surgery, and expectations from surgery. Patient preference was tested in a study by Kumar et al.[3]. Based on the magnitude of their incontinence patients either had an AUS (high grade incontinence) or sling (low grade incontinence) or a choice between the two (moderated grade incontinence) recommended. Outcomes, length of experience and complications were reviewed with the patients. Of interest, all recommended to have a sling chose a sling, 75% recommended to have an AUS had an AUS while of those given a choice 92% chose a sling. This sheds some light on patient preferences in this area.

The AUS has the longest track record of success in the treatment of PPI. Two older studies have reported that about half of the patients with severe incontinence will undergo AUS implantation [249,250]. However, these studies were conducted before male slings and bulking agents became popular, and sling surgery has since surpassed the AUS in number of procedures performed annually. To this end, it is likely that the advent of the male slings has increased the rate of surgery in men with milder incontinence who may not otherwise have opted for an artificially sphincter. The success rates for AUS as defined by a continence status of zero to one pad per day range from 59% to 90% [251, 252], as shown in **Table 6** [56, 251, 253 - 262]. Just as with

Table 6. Results of the artificial urinary sphincter in post-radical prostatectomy incontinence.

Author	No. pts.	Follow-up (yrs.)	0-1 pad/day
Montague [253]	66	3.2	75%
Perez and Webster [251]	49	3.7	85%
Martins and Boyd [254]	28	2	85%
Fleshner and Herschorn [255]	30	3	87%
Mottet, et al [256]	96	1	86%
Madjar, et al [257]	71	7.7	59%
Klijn, et al [258]	27	3	81%
Haab, et al [259]	36	7.2	80%
Trigo Rocha, et al[56]	40	4.5	90%
Kim, et al.[261]	124	6.8	82%
Lai, et al.[262]	218	3.1	69%
Goldwasser [260]	42	1.2	82%

reported rates of incontinence following prostate cancer surgery depend on the definition of incontinence, continence rates with the AUS can vary with the definition of continence, the method of evaluation, and the length of follow-up. The lowest rates are from patient administered questionnaires when pad free rates range from 10-72% [254, 263 - 267]. Nevertheless, high satisfaction rates of 87% to 90% are consistently reported, even without total continence [255, 259, 263].

One potential downside of the AUS is the need for periodic revisions in a number of patients. Revision and explantation rates due to mechanical failure, urethral atrophy, infection and erosion vary considerably among studies with respectively reports of 8-45% and 7-17% [267]. In a large cohort reported by Lai and colleagues [262], non-mechanical failure has decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff and mean time to reoperation was 26.2 months (mean 2-68 months). With a Kaplan-Meier analysis, the overall 5-year expected product survival was 75%. Only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years. Actuarial freedom from revision at 5 years was estimated at 50%-75%. Interestingly, there do not appear to be any urodynamic factors that predict AUS failure in men with ISD. Whereas the male sling has been shown to have inferior success rates in patients with severe leakage, the AUS has been reported to have predictable success regardless of the degree of incontinence and regardless of detrusor underactivity, detrusor overactivity, low abdominal leak point pressure, or diminished compliance [58]. And while the success of the AUS in treating incontinence is not adversely affected by preoperative detrusor overactivity, the rate of persistent overactive bladder symptoms may be high (71%), and patients must be counselled accordingly [268].

The long term efficacy of the AUS was demonstrated by Fulford et al who reported that at 10-15 year followup,269 75% of patients with an implanted AUS either still had or died with a functioning device. Revisions include replacement of the malfunctioning part, cuff replacement, repositioning or downsizing due to urethral atrophy, a second or tandem cuff [270,271] or transcorporal cuff placement [272]. Transcorporal cuff placement, which involves inserting the cuff through the corporal bodies to avoid perforating the dorsal aspect of the urethra, can be particularly useful for patients with prior radiation or urethral erosion; however potency if present may be compromised. Some have advocated tandem cuffs not only as a salvage procedure, but also as a primary procedure for men with severe incontinence [273, 274]. However, O'Connor et al. reported no difference in continence outcome and a higher revision rate in patients undergoing double-cuff implant versus single-cuff after longer follow up [275].

An increased revision rate has been reported for patients who received pelvic radiation [254,27] but was not found in a recent series [252]. The results for continence for radiated patients are variable with some studies showing lower success rates [251,276] while others do not [266]. It has been recommended that such patients have a lower pressure reservoir and/or longer period of deactivation time [254].

CONCLUSION

The AUS remains the gold standard for the treatment of PPI secondary to sphincteric insufficiency in patients with severe incontinence, in those who

have had external beam radiation treatment and in those who have had prior AUS placement. It has the largest body of literature reporting long-term success. The long term success rates and high patient satisfaction seem to outweigh the need for periodic revisions in some patients. Intermediate term data with the male sling demonstrates that the sling is an alternative to the AUS in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility. Overall, the AUS remains the reference standard to which all other treatments must be compared. **(Level of evidence 2; Grade of recommendation B)**

5. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of PPI, either with benign or malignant disease. Therefore, at present guidelines as to timing of the surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. Observational studies of men following prostate cancer surgery typically demonstrate improvement in continence from the early post-operative period until the end of the first year [114]. In addition, it is common for clinical trials of nonoperative management to follow patients for up to 12 months post-operatively, usually with improvement in both the intervention and the control groups during that year of follow up150. In a prospective cohort study of men undergoing RRP, Lepor and Kaci [76] demonstrated continued recovery of continence up to 24 months post-operatively, from 80.6% at 3 months to 95.2% at 12 months, reaching a plateau at 98.5% at 24 months. Other cohort studies have demonstrated a plateau in continence rates at 12 months [277, 278]. Since continence may improve up to 12 months post-operatively, and possibly even until 24 months, it is generally recommended that behavioral/conservative management be utilized during the first year after prostate cancer surgery.

There have been some studies evaluating the effect of early interventional treatment for incontinence. Schneider and colleagues [279] demonstrated a beneficial effect on the earlier return to continence with early injection of periurethral bulking agent. Results were better in the subgroup of 34 patients that were injected early (mean 23 days post-operatively) compared to 10 patients treated at a mean of 26 months post-operatively. It could not be demonstrated, however, that long-term continence is improved by early injection of bulking agent. Similarly, Jones and colleagues [280] demonstrated in a comparative cohort study of RRP patients treated either with or without a simultaneous suburethral sling, that sling placement at the time of RRP resulted in an earlier return to continence. There was no difference after 24 months.

(Level of evidence 3-4; Grade of recommendation C)

IV. INCONTINENCE AFTER PROSTATECTOMY FOR BENIGN DISEASE

1. INCIDENCE AND RISK FACTORS

The incidence of urinary incontinence after prostatectomy for benign disease has been reviewed and described in the AHCPR “Benign Prostatic Hyperplasia” linical Practice Guidelines [281]. The following percentages for stress incontinence and total incontinence, respectively, were reported:

Open surgery (retropubic or transvesical prostatectomy): 1.9% and 0.5%.

TUIP (transurethral incision of the prostate): 1.8% and 0.1%.

TURP (transurethral resection of the prostate): 2.2% and 1.0%.

These figures were based on studies reported before 1990. Several other series were published after 1990. These series were reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. A clear description of the method of follow-up and assessment of the continence status was indicated in only about one third of these studies. The incidence of incontinence after open surgery, TURP, TUIP and HoLEP is low: the reported percentages ranged between 0 and 8.4%. Since the method of assessment of the continence status and the definition of incontinence is rarely stated it is actually not possible to make a distinction between simple stress incontinence and total incontinence. There is generally no clear indication that the incidence is affected by patient age or (resected) prostatic volume. [282] However, a recent study out of Brazil did demonstrate that the rate of urinary incontinence following BPH surgery is higher in older patients. However, most of the increased incidence in incontinence was due to bladder dysfunction rather than to sphincter insufficiency. In a retrospective chart review from Wendt-Nordahl and colleagues [284], the incidence of incontinence following TURP was reported to have decrease over 17 years, from 3.3% in 399 patients operated on between 1987 and 1997, compared to 1.3% in 550 patients operated on from 1997-2004. It is not clear whether this statistically significant ($p< 0.05$) difference was due to improvement in surgical technique or patient characteristics. However both the earlier and later incontinence rates are consistent with those in the AHCPR and AUA guidelines reports.

In 2003, the AUA published guidelines for the management of "benign prostatic hyperplasia" [285]. The estimated frequency of incontinence following TURP was 3% (from 19 trials that included > 5000 patients). However, the Veterans Affairs Cooperative Study, reported an incontinence rate of only 1% in TURP patients, which was not different from the watchful waiting arm [286]. The AUA conducted meta-analysis of RCTs comparing TURP with TUIP or transurethral electrovaporization did not reveal any statistically significant differences in incontinence rates. [285, 287-291] The 2010 AUA updated guideline provided no additional information [292].

Over the past decade, transurethral holmium laser enucleation of the prostate (HoLEP) has become a standard treatment for BPO. Review of RCTs by the AUA as well as a meta-anlaysis of RCTs comparing TURP with HoLEP did not reveal any significant differences in incontinence rates [285,291,293-299]. While incontinence did not increase with age in men undergoing HOLEP with morcelation, it was noted that the overall complication rate - including bladder mucosal injury, urethral stricture disease, and bladder neck stenosis = was higher in patients with prostate volumes > 50 g [300]. Moreover, it does not appear that either bipolar resection of the prostate or photovaporization of the prostate are associated with a substantially different rate of urinary incontinence than are other BPO surgeries [301]. While incontinence following PVP is comparable to that of other BPO surgeries, and more often than not improves over 12-36 months postoperatively with conservative management, the rate of post-operative dysuria is higher than that of TURP, recently reported at a rate of 10.1% [302].

In summary, the incidence of urinary incontinence after open surgery, transurethral resection of the prostate, transurethral incision of the prostate, and holmium laser enucleation of the prostate is low, and does not differ appreciably among the various techniques.

2. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of incontinence, as mentioned above in the section on post-radical prostatectomy. Therefore, at present guidelines as to the timing of surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. (Level of evidence 3-4; Grade of recommendation C)

3. SURGICAL TREATMENT OPTIONS

a) Artificial Sphincter

The literature on this subject was reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. Candidates for treatment with the artificial urinary sphincter (AUS) are patients with incontinence due to intrinsic sphincter deficiency that have normal bladder compliance [303]. Detrusor overactivity is not a contraindication [268]. The AUS has been placed around the bulbar urethra via a perineal route or transverse scrotal routes [304] or around the bladder neck [4, 282, 283]. The above mentioned review of the results obtained with the AUS indicated that more than 70% of the men treated with the AUS for this indication are dry or almost dry after a follow-up of more than 2-3 years. However, most series on the AUS include both post-prostatectomy incontinence for benign and malignant disease [282].

In summary, the AUS is a successful surgical treatment option for post-prostatectomy incontinence. It is the most commonly performed surgery for post-prostatectomy incontinence, with the longest follow-up and therefore longest record of success. (**Level of evidence 2; Grade of recommendation B**)

b) Injectable Agents

Most series include post-prostatectomy incontinence after treatment for benign and malignant disease, with the majority after prostate cancer surgery. For collagen, "success rates" range from 36-69%, with 4-20% of patients reporting being dry. [157-164] Study results are inconsistent with both TURP [305] and radical prostatectomy [306] showing better outcomes.

Other bulking agents such as polydimethylsiloxane PDMS (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration of initial improvements with success rates of 40%, 71%, 33%, and 26% at 1,3,6, and 12 months respectively [168]. As mentioned previously in the section on post-radical prostatectomy incontinence Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively [169]. Follow-up, however, was only 3 months. In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPO surgery, with less than1/3 of the cohort suffering from SUI following RP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52] There has also been some initial work with sphincteric injections of muscle stem cells.[173,174]

Bulking therapy fails in up to 75% of men. Of those who are improved only a minority actually becomes

dry with short-term follow-up. Although bulking therapy may be slightly more efficacious in treating SUI following TURP compared to SUI following prostate cancer surgery, bulking is of limited value in those men with all but minimal SUI. **(Level of evidence 3; Grade of recommendation C)**

c) Male Sling Procedures

Since Frangenheim described his first successful urethral sling suspension for post-traumatic stress urinary incontinence in 1914, various sling materials and surgical methods have been reported [307]. Rectus fascia, as described by Frangenheim, has distinct advantages over alloplastic materials with respect to erosion and infection risks. Allograft off-the-shelf-materials like lyophilized fascia lata have a higher infection risk than does autologous fascia, whereas the use of synthetic materials like polypropylene mesh or polytetrafluoroethylene slings are associated with a higher incidence of urethral erosion [308]. According to various published techniques, the sling can be placed either underneath the bladder neck, the urethral bulb or the membranous portion of the urethra. The principle of continence support is similar for all sling procedures and comprises passive compression of the urethra, which is dependent on the applied sling tension [219]. This mode of action favours sling procedures as a treatment option for intrinsic sphincter deficiency. However, the sling tension needed for restoration of continence has not been standardized, with tensioning techniques ranging from perfusion sphincterometry, to a cough test, to visual approximation, [193, 309] and therefore the success of the procedure probably depends heavily to the surgeon's experience and the degree of sphincteric incompetence. Overcorrection with consequent urinary retention (especially in the setting of detrusor underactivity) and undercorrection with persistent or recurrent incontinence are certainly possible, which may adversely affect continence, bladder emptying, and patient satisfaction. Most series of sling surgeries deal with a preponderance of men following prostate cancer surgery. Therefore, it is difficult to draw conclusions about any differences in sling efficacy between those with SUI following BPH surgery versus those with SUI following RP due to small numbers of BPH patients most the cohort series.

V. INCONTINENCE AFTER EXTERNAL BEAM RADIOTHERAPY ALONE AND IN COMBINATION WITH SURGERY FOR PROSTATE CANCER

The risk of incontinence after external beam radiotherapy (EBRT) for prostate cancer is variable and ranges from 0 to 18.8%. Lawton et al. [310] reported a risk of urinary complications of 7.7% in more than 100 patients, proportional to dose. Perez et al. [311] found incontinence in only 5 of 738 patients. Shipley et al. [312] reviewed more than 2500 cases with an incontinence rate of 0.5%. Similar incidences have been reported in more recent series. Madalinska et al. [77] reported an incidence of 6-7%. With three-dimensional conformal radiotherapy, Weil and colleagues [313] reported no incontinence in 168 consecutive patients and Hanlon et al. [314], in a series of 195 men, found that post treatment urinary symptoms were no different from a control group without cancer. With conformal radiotherapy, Sandhu et al. [315] reported a 9% incidence of stress incontinence in 110 patients. the impact of EBRT followed by prostatic boost, for a total of 66-70 Gy, was evaluated. Scalliet and coworkers [316] reported urinary incontinence in 16% of 230 patients, however, Fransson and colleagues [317] reported an increase in urinary incontinence on a patient-administered symptom bother scale 3 years after treatment in 153 men compared to pretreatment status. The increase was from a mean of 0, at the start to 2 out of 10 at 3 years. Ponholzer et al. [318] reported incontinence in 18.8% of a group of 82 men who were surveyed 4.4 year after EBRT for prostate cancer. Furthermore urinary incontinence worsened from year 2 to year 6 in a cohort of 147 men treated with 3D conformal RT. [319] Budaus et al. [320] conducted a review of radiation series published from 1999-2010 and concluded that early storage symproms are commonly reported but long-term incontinence is not.

Pre-radiotherapy transurethral prostatectomy may be a risk factor for incontinence. Jonler et al. [321] reported an incontinence rate of 11% with pretreatment TURP. Green et al. [322] and Lee et al. [323] also reported a higher risk of incontinence with pretreatment TURP versus those without with 5.4% and 2% respectively. There are no series reported on the treatment of patients who only have incontinence after EBRT.

Salvage or adjuvant radiotherapy is frequently given after radical prostatectomy and the impact on continence is controversial. Petrovich et al. [324] reported no difference in incontinence in 2 cohorts of patients, one with and one without adjuvant radiation. In a follow-up study the same group reported no late toxicity. [325] Fontaine et al. also reported no change in continence status in 16 of 17 men after salvage radiation. [326] However, Petroski et al. reported that postoperative radiotherapy worsened continence in 26% of 129 patients followed for a median of 5 years. [327] On the other hand salvage radical prostatectomy following external beam radiotherapy has been generally reported to have a high incidence of urinary incontinence [328-330] possibly because of radiation induced fibrosis of the external sphincter. [329] Cozzarini et al. demonstrated that older age and greater radiation dose in the salvage setting and younger age and hypertension in the adjuvant setting resulted in worse urinary toxicity. [331]

1. SURGICAL TREATMENT

Results of surgical treatment of incontinence in this setting are based on retrospective clinical series. In the past the most commonly published treatment modality was the artificial urinary sphincter as therapy for sphincter damage. As discussed and referenced in the following paragraphs, the series published contain both patients who had and had not received radiotherapy and collagen injections have also been reported in case series.

There has been a higher reported revision rate for the artificial sphincter following radiotherapy (**Table 7)** [251, 252, 254, 262, 265, 276, 332, 333] compared to low risk patients, 38% versus 22%. Although recent reports dispute the higher rate [252, 262]. However, generally this is due to a higher incidence of erosion and infection as well as urethral atrophy, possibly secondary to radiation induced vasculitic fibrosis of the urethra.254 Radiation may also induce detrusor overactivity or poor compliance leading to urgency incontinence. Recurrence of bladder neck contracture may be more common. [262] Radiation was also identified as a co-morbidity associated with erosion [334] and infection. [335] However, good results are reported, and it is generally recommended that the cuff be inserted outside the radiated field. [336]

Collagen injection has also been reported for incontinence after radical prostatectomy and adjuvant radiation [159,163,305,337-339] or after salvage radical prostatectomy following radiotherapy [166.340] Continence results are poorer compared to those without radiation. [306] Very few patients have been reported on with the use of Macroplastique following radical prostatectomy and adjuvant radiotherapy.

The male perineal bone-anchored sling has been reported in patients following adjuvant RT. In Comiter's group with the perineal compression sling 3/21 with radiation had no adverse sequelae.166 Similarly in the series of Onur et al. radiation did not cause a worse outcome.[193] However, Schaeffer et al. reported that prior irradiation was the only identified factor that predisposed to failure. Their success rate following a single sling procedure was only 29% (2 of 7) for irradiated patients, and the corresponding rate for nonirradiated patients was 68% (39 of 57). [184] They postulated that the sling acts by compressing and elevating the urethra, thereby increasing urethral resistance to abdominal pressures. Theoretically, radiation-induced fibrosis of the urethral and periurethral tissues would make compression and elevation more difficult by reducing tissue compliance and mobility. As mentioned above, the results of AdVance slings, adjustable slings, and adjustable balloons are adversely affected by radiation.

In summary, despite the frequently reported higher incidence of complications of the artificial sphincter in post-prostatectomy patients after adjuvant radiation, it has provided acceptable treatment benefits. Injectable agents have yielded poor results. Other techniques are adversely affected by radiation. (**Level of evidence 3; Grade of recommendation C**)

VI. INCONTINENCE AFTER OTHER TREATMENT FOR PROSTATE CANCER AND NEOBLADDER FOR BLADDER CANCER

1. BRACHYTHERAPY

Brachytherapy is a form of radiation therapy in which radioactive materials are placed directly into the prostate gland. The incidence of incontinence following this modality is given in **Table 8** [341-353] and was previously related to the treatment of post-brachytherapy retention of urine. Numerous series have reported retention to be associated with larger initial prostate volumes. [354] In a systematic review of brachytherapy series, Crook et al. [350] reported the incidence of retention to be 1-14%. Many patients require prolonged or permanent alpha blocker or TURP. The main risk factor for incontinence after brachytherapy is TURP. Hu and Wallner [347] reported on the incidence of urinary incontinence after TURP/TUIP following prostate bracytherapy for prostate cancer. Of the 10 patients who underwent the outlet relaxing procedures for refractory urinary obstruction, 7 developed some degree of permanent urinary incontinence. They surmised that the cause may be multifactorial and may include physical damage to the urinary sphincters and the radiation dose to the urethral region. Surgical therapy when required has included the artificial sphincter. [348] High dose brachytherapy that is administered over a short period of time may have reduced toxicity. [355] Urethrorectal fistula is another complication that has been reported in 1.8% of patients in a large U.S. medicare retrospective review. [348] Salvage brachytherapy leads to a higher rate of urinary tract complications. [330]

2. CRYOSURGICAL ABLATION OF THE PROSTATE

Cryosurgical ablation of the prostate is used for clinically localized prostate cancer either as primary treatment or after unsuccessful external beam radiation therapy. The frequency of the main lower urinary tract complications are listed in **Table 9** [356-369]. The artificial sphincter has been mentioned as one of the treatments for incontinence. [367] Cryotherapy is an adverse factor for collagen injections. Urethrorectal fistulae can also occur in up to 5% of treated patients. Severe incontinence and fistulae that occasionally results may have to be treated with extirpative surgery and diversion. [370]

3. HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU)

Transrectal high-intensity focused ultrasound is another minimally invasive treatment for prostate

Table 7. The artificial sphincter for incontinence after radiotherapy

Study	Numberof patients	Revision rate after radiotherapy	Continence
Martins and Boyd [254]	34/81	38% for whole group	88%
Wang and Hadley [332]	16	25% (Infection and Erosion - 12.5%)	87%
Perez and Webster [251]	11/75	55%	63%

cancer. HIFU destroys prostate cells by coagulative necrosis of the tissue without damaging the structures intervening between the transrectal probe and the target tissue [371]. Reports of efficacy also include morbidity. In a systematic review involving 37 articles/abstracts Rebillard et al. [372] reported that stress incontinence occurs in 6-28%, urethra/bladder neck stenosis in 1-31%, and rectourethral fistula in 0-3% of treated patients. With improvements in techniques the risk of complications is decreasing [372]. In a recent sytematic review from 2000-2011, Cordeiro et al. noted that the rate of incontinence ranged from <1-34.3% [373].

4. INCONTINENCE AFTER NEOBLADDER CONSTRUCTION

The incidence of continence after neobladder construction following radical cystectomy for bladder cancer ranges from 85 to 100% during the day and 55 to 100% at night **Table 10** [374-386]. Most patients achieve daytime continence after one year and nighttime continence after 2 years. Most of the published reports do not comment on specific surgical management and imipramine is mentioned as treatment only occasionally. Martins and Boyd [254] reported on 8 patients treated with the AUS for persistent sphincter weakness incontinence. Six of these underwent revisions, 3 for infection and/or erosion and 3 for inadequate cuff compression. They cautioned against the use of the AUS and suggested alternatives such as intermittent catheterization at night. However, O'Connor and colleagues [387] reported a successful outcome, after AUS, with no complications in 5/5 men with incontinence after neobladder, with a mean follow-up of 22 months and Simma-Chiang et al. [388] reported success in 11/12 men 22 months after AUS implant. The bone-anchored sling has been reported for one case [389] and the AdVance sling for 2 cases [226] Collagen has only been reported in women following neobladder construction.[390]

In summary there are not enough data upon which to recommend definitive surgical therapy, although the artificial sphincter is reasonable. **(Level of evidence 3; Grade of recommendation C-D)**

VII. TRAUMATIC INJURIES OF THE URETHRA AND PELVIC FLOOR

Incontinence following posterior urethral injuries occurs in 0-20% of patients [391,392] and is thought to be due to the extent of injury rather than to the method of management.

The data on surgical treatment are all retrospective case series and the most commonly published surgical therapy is the AUS. The series published contain both patients with and without traumatic injuries. Perez and Webster [251] reported on 27 patients after urethral or bladder neck strictures. The revision rate was 41% and the continence rate was 85%. In a subsequent report from this centre on reoperations the patients with traumatic injuries were not discussed separately. [393] In Montague's [253] series 22 out of 166 patients had incontinence after trauma. He did not separate the results of this group from those of the other patients. Martins and

Table 10. Continence after neobladder construction for bladder cancer

Author	Number of patients	Follow-up (mo)	Continence (%) Day	Night
Alcini et al. [374]	34	12	100	83
Cancrini et al. [375]	89	24 (22% with SUI)	97	83
Elmajian et al. [376]	266	24	85	85
Studer et al. [377]	100	24	92	80
Benson et al. [378]	32	25	94	74

Rogers and Scardino [380]	20	24	90	55
Hautmann et al. [381]	211	36	85	85
Hautmann et al. [382]	363	57	95	95
Steven and Poulsen [383]	166	32.4	100	100 (After 5 years)
Abol-Enein [384]	353	38	93.3	80
Carrion et al. [385]	56 ileum	41	91	68
	57 colon	41	86	68
Nieuwenhuijzen [386]	62	>12	90	67
	50 (sexuality preserving)	>12	96	67

Boyd [254] reported on only one patient out of 81 with a traumatic urethral injury. This patient was dry and required no revisions. Venn at el. [336] reported on 2 with pelvic trauma out of a total of 70. Mundy and Andrich reported successful AUS implant in 7 out of 8 patients after reconstruction for pelvic fracture-related injuries. [394] **(Level of evidence 3; Grade of recommendation C)**

Bladder neck reconstruction by excising the scar and narrowing the calibre was reported by Iselin and Webster [395] in 6 patients who had incontinence with an open bladder neck on cystourethrography, following urethroplasty for traumatic strictures. Bladder neck closure with a Mitrofanoff catheterizable abdominal stoma has also been reported as treatment following severe urethral or bladder trauma. [396] **(Level of evidence 3; Grade of recommendation C)**

For patients with severe bladder neck strictures and incontinence after prostate surgery Meulen et al. [397] and the group from Baylor [262, 398] reported on the use of a Urolume stent with a bulbar artificial sphincter. Alternative management with perineal urethroplasty and subsequent artificial sphincter placement in 6 patients was reported by Simonato et al. [399] **(Level of evidence 3; Grade of recommendation C)**

In summary, the AUS provides a reasonable outcome in appropriate cases. Since there are so few reports of alternative therapies the C recommendations were based primarily on expert opinion as to what is reasonable surgical therapy in very difficult cases.

VIII. CONTINUING PEDIATRIC PROBLEMS INTO ADULTHOOD: THE EXSTROPHY-EPISPADIAS COMPLEX AND OTHER CONGENITAL ANOMALIES

In exstrophy, the bladder plate at birth is smaller than a normal bladder. It is uncertain whether that which does exist is normal. It has been shown that the muscarinic cholinergic and other neuropeptide receptors in exstrophy detrusor muscle are the same as in controls [400, 401]. Microarray analysis shows that the bladders are developmentally immature [402]. The number of number of myelinated nerve fibers in the detrusor is reduced in new born exstrophy bladders compared to that of neonates who had died from cardiac causes (controls) [403]. It seems probable that the spectrum of neurological and morphological changes seen in exstrophy bladders beyond the neonatal period, are largely secondary to the medical management [404].

Control of the bladder outlet depends on proper function of the pelvic floor musculature and of the urethral sphincters. In exstrophy infants who have not had an osteotomy, the pelvic floor muscles have normal bulk, but abnormal orientation, especially in their relationship to the urethra. They are unable, therefore, to contribute very much to urethral continence [405]. The prostate is a flat plate of normal size, lying behind the urethra. It is not wrapped around the urethra [406]. Growth of the prostate at puberty will not improve continence.

The existence of the urethral sphincters is also uncertain. There is no histological study to show their presence or innervation. However, electromyographic studies of continent children have shown normal electrical traces [407].

Epispadias is a very rare condition. There are very few data on the bladder and sphincters for this diagnosis alone. In general the bladder is of better volume and there may be some active sphincter function in those at the better end of the spectrum.

Storage of urine in children with exstrophy depends on creating sufficient bladder outflow resistance that there is a leak point pressure great enough to stretch up the bladder volume. Voiding depends on the ability, either by detrusor or by abdominal wall contraction, to generate enough pressure to overcome a fixed outlet obstruction.

The pediatric literature often refers to patients with exstrophy having a ‘dry interval’ of so many hours. The implication of this is that the bladder has a fixed capacity beyond which the pressure becomes higher than that of the fixed outflow resistance. Providing the child recognizes this point, a visit to the lavatory will avoid incontinence. Patients in many clinical situations to avoid a ‘social or hygienic problem’ use this technique of timed voiding but it does not constitute continence as would be understood by a ‘normal’ person. It is a means of managing poor bladder control. It is rare to find literature on the long-term follow-up of patients with this complex describing ‘normal’ continence. The evidence base is level 3 at best.

1. EARLY MANAGEMENT OF EXSTROPHY AND EPISPADIAS

The early reconstruction of bladder exstrophy is clearly important but not a subject for this chapter. Only an outline will be considered as a basis for discussing problems of continuing incontinence in adolescence and adulthood. Techniques have gradually evolved over the last 100 years since the first (transiently) successful closure described by Trendelenberg in 1906 [408]. The most important development, at least in Western countries, is the concentration of cases in a small number of centers. In the United Kingdom, for example, it is estimated that 12 babies a year are born with exstrophy and all are cared for in two centers.

Broadly, there are three approaches to early reconstruction –

- Staged repair, originally described by Jeffs [409]. Here the principle is to close the bladder in the first operation. The bladder neck and epispadias repair are then done as a second stage.
- Complete primary repair of bladder exstrophy (CPRE) often attributed to Mitchell [410]. The objective is to close the bladder and bladder neck and to repair the epispadias in one operation. Although more than one operation is often needed, the important principle is to create bladder outflow resistance as early as possible. This should allow proper development of bladder volume and compliance. A subsequent bladder neck reconstruction may be needed in up to 40% of children [411].
- Single stage radical soft tissue mobilization (RSTM), usually called the Kelly operation [412]. The entire anterior pelvic contents with blood and nerve supply are mobilized from the pelvic sidewall, reconstructed and repositioned more posteriorly in the pelvis. There is no osteotomy, but the radical mobilization allows abdominal wall closure without osteotomy.

Each of these is subject to many modifications by different surgeons, which makes comparison of results difficult. Not surprisingly, there are no controlled trials. Outcomes have been described from specialist centers with good results and from generalists with, usually less good results.

At the longest follow-up available, the results of these three approaches are very difficult to determine, at least as far as bladder function is concerned. Data beyond the age of 18 are limited, especially for RSTM. Definitive reports in peer-reviewed journals of long-term outcomes from the centers that specifically champion these techniques are lacking. There are reports from other centers of small numbers of patients, but often without the use of a consistent technique.

Approximate figures are given in **Table 11**. Sadly, the results in the world at large are much worse. There are also differences in outcomes in relation to the condition of the kidneys, genitalia, cosmetic appearance and sexual function that are beyond the scope of this chapter.

2. LATE BLADDER FUNCTION

If the figures for continence shown in the table are maintained into adult life and 'partial continence' is not acceptable, no more than 70% of patients will have a native bladder and normal voiding. In reality, this figure is rather optimistic and may be as low as 7% [413].

For the children who have done well, there is some evidence that continence may not be maintained into adulthood. In a follow-up of 56 patients for a minimum of 20 years, 13 were found who where continent and voiding naturally at 10 years old. However, by 20 years old, only three were still in this situation. The remainder were augmented or on CIC or both. The patients had been operated in the 1960s and early 1970s by older techniques than are currently used [414].

Late failure has several possible causes. Possibly the most important is that the outflow resistance generated by bladder neck reconstruction is not sphincteric, but fixed. Voiding is, therefore, always against obstruction. Deterioration in bladder function would come either from detrusor failure or from overactivity. Borer et al found detrusor overactivity in six of 13 children (46%) who had had a staged repair but in none of 19 who had had CPRE [407].

Another problem was identified by Yerkes et al. [415] In an investigation of 18 children who were said by themselves and their parents to be 'continent and voiding well', none were, in fact, voiding normally. Apart from infections, stones and a dry

Table 11. Outcomes of childhood surgery for exstrophy with special reference to continence. Data are best estimates from recent literature from specialist centers. Approximations have been taken as reporting systems are not consistent between papers [412,780,781].
CPRE - Complete primary repair of bladder exstrophy

	Continent, voiding, native bladder	Partial continence, voiding, native bladder	Continent, CIC, native bladder	Continent, CIC, augmented bladder	All other outcomes
Staged repair	70%	10%			20%
CPRE	76%			3%	21%
RSTM	10%	29%	10%		51%

RSTM - Single stage radical soft tissue mobilization

interval of two hours, there were major objective bladder dysfunctions in all patients. Seventy two percent had a residual urine of at least a third of bladder capacity; 70% had a flow rate below 10ml/sec; 30% had staccato stream; and 36% voided by Credé's maneuver.

Finally, there is the problem of the definition of continence. The disciplined life of a closely supervised child may well make a three-hour dry interval seem like continence. It fits in well with the school routine. It does not lie well with the life style of an adolescent. It quickly becomes apparent that the coffee, sodas and alcohol that soon become a part of an adolescent's life expose the fact that they have to make far more visits to the lavatory than their peers or risk being wet. It has been shown that one of the prime desires of exstrophy adolescents is to be 'normal'. This includes being treated as normal and having normal lavatorial habits [416]. This difference from normality may drive some young adults to seek continence surgery even though, by pediatric criteria, they had been classed as continent.

3. MANAGEMENT OF INCONTINENCE

a) Investigation

Standard investigations for incontinence are appropriate for patients with exstrophy. Urodynamic studies have been use to clarify the etiology and have clinical value in management [407,415]. Dave et al. [417] investigated 31 children one year after a modified bladder neck reconstruction. Fifteen had satisfactory continence defined as a dry interval of two hours or more, no stress incontinence and no more than two episodes of nocturnal enuresis per week. The continent children had a better bladder capacity at 162 ml compared to 113ml for those with poor continence or 55ml for the totally incontinent. End filling pressure was around 31cm H_2O for the continent children versus 48 or 41cm for the other two groups. However, involuntary detrusor contractions were seen in a third of the continent group and were associated with a lower than average bladder capacity and less good compliance than the other continent children.

It has been pointed out by Hollowell et al. [418] that even in severely incontinent children who appear to drip continuously, leakage is often due to detrusor overactivity. They found that a leak point pressure (LPP) of at least 10 cmH2O was necessary to allow bladder expansion. However, in some children with a higher LPP than 10, bladder expansion did not occur because detrusor contractions were constantly emptying it.

As in other conditions of bladder abnormality, end filling pressures over 40cmH2O were associated with hydronephrosis (two thirds of patients) [417].

The role of electromyography (EMG) of the sphincters has been reported but not correlated with management or outcomes [407]. In Dave et al's [417] patients only 12 children voided with sustained detrusor contractions and only five voided effectively. Ten children had persistent EMG activity during voiding but no other detectable neurological abnormality. Eight of them had significant residual urine volumes.

Some authors stress the importance of examination under anesthetic. In the assessment of incontinence, the volume of the bladder has some predictive value and is most accurately measured under general anesthesia. Although not statistically significant, children with a bladder capacity before bladder neck reconstruction of less than 25ml do less well than those with larger bladders [407]. Secondly, a transverse oval appearance of the bladder neck is associated with its incompetence and hence incontinence [411].

Complete objective evaluation of bladder function in this manner is particularly important in exstrophy as the description by patients and parents is unreliable [415].

b) Medical Management

The apparent normality of the detrusor muscle at least in infants born with exstrophy, suggests that standard anti-muscarinic drugs should be effective in detrusor overactivity [400]. There have been no disease specific controlled trials, least of all in adults. In children, there has been an uncontrolled trial of imipramine using both clinical and urodynamic criteria to assess response [419]. All of 17 children (mean age 7.9 years) had urodynamically proven detrusor overactivity, small poorly compliant bladders and incontinence. Imipramine 1.5 – 2.0mg/kg was given for a mean of 9.5 months. There was a 40% increase in bladder capacity and a 25% reduction in end filling pressure. Eleven of 17 children had a clinically significant improvement in continence; all of eight children with partial continence (1-2 hr dry interval by day but enuretic) became dry day and night with a dry interval of more than 2hours. Three of nine children with severe incontinence improved. Hydronephrosis improved in three of nine patients. In an editorial comment on this paper, Gearhart stated that he used oxybutynin 0.5mg/kg in combination with imipramine, which 'gave even better results'. No further data were given.

c) Bulking Agents For The Bladder Outflow

In patients with exstrophy who have bladder outflow weakness, there is logic in using injectable bulking agents to increase resistance. Although not mentioned in the literature on this subject, the obvious drawback is that there will be even greater fixed outflow resistance that may limit the opportunity for the action of any active sphincter.

Burki et al. [420] reported the use of polydimethylsiloxane (macroplastique™) in 34 children with exstrophy and 18 with primary epispadias. Apart from bladder neck reconstructions eight had had augmentations. In addition, 14 relied on a Mitrofanoff for self-catheterization. There was no standard technique of injection and the objective seems to have been to put in enough of the bulking agent to produce visual occlusion of the bladder neck area using 2.5 to 7.5 ml. Twenty patients had one injection and the rest had an increasing number up to seven. The follow-up assessment was entirely clinical and there were no urodynamic data. Only 17% were completely dry at a mean of 4.6 years; 33% were reported to be significantly improved. The milder the initial incontinence the better the result, however four of 36 patients who were totally wet did become totally dry. The continence rate was improved by up to four injections but only one patient became dry after more than four (he became dry after six injections). Other bulking agents have been reported including Teflon and collagen but in series of patients with different diagnoses including exstrophy and epispadias.

d) Surgical Management

Adults with exstrophy who have failed to become dry after initial reconstruction and the relatively conservative management of medication and bladder neck bulking have a difficult decision to make. The most elusive outcome is to create a bladder that is continent and from which there is spontaneous voiding. It will be seen that the choice to achieve this result is a second bladder neck reconstruction or insertion of an artificial sphincter. Both of these require a natural bladder of adequate capacity and which retains normal detrusor function. If the bladder is small or of high pressure, there may be some improvement when outflow resistance is increased with a successful bladder neck procedure, though, again, the data come from studies in children and may not be applicable to adults [407]. Otherwise, augmentation will be necessary. The options for augmentation, with or without a Mitrofanoff, are considered elsewhere in this chapter.

A more realistic objective if the urethra is to be used for urinary drainage would be to accept CIC for bladder emptying. If the bladder is inadequate, it can be augmented. However, this option does depend on having a urethra that can be catheterized. This may be difficult after repair of the epispadias and bladder neck initially; after a second bladder neck reconstruction, it may be more difficult.

a) Bladder neck reconstruction: In children who have had a bladder neck reconstruction and failed to become dry, the results of further reconstruction are poor. In adults, data are very limited. In a group of older children (3.2y – 15.5y) the group at the Hospital for Children, Great Ormond Street reported very modest results. There were 20 boys and ten girls most of whom had had several operations apart from the initial bladder neck reconstruction, including injection of bulking agents, augmentation and Mitrofanoff procedures and yet still remained wet. Sixty percent became dry by day (80% of girls but only 50% of boys), but only 50% by night. None could void urethrally and only five performed CIC urethrally. Urethral catheterization was difficult in eight. The authors acknowledged that the outcomes were not good and suggested that closure of the bladder neck might be a better option [421]. In an earlier series from Johns Hopkins all of eight patients achieved a dry interval of three hours or better with a re-do Young-Dees operation but all required CIC [422]. Although these data cannot directly be extrapolated to adults, it seems likely that they are representative of patients with failure of the initial bladder neck reconstruction.

b) Artificial urinary sphincter (AUS): The patient with exstrophy has, by definition, a reconstructed bladder neck and urethra. Such structures are not well suited to the support of an AUS cuff. It is also common for incontinent patients to carry a residual urine and so, with an AUS, would need to use CIC. Even in the earliest reports of the AMS 800 AUS, the results in patients with exstrophy were poor [423]. Again, data on this procedure in adults with exstrophy are limited and often included in series of patients with different diagnoses. In one series of 112 patients without spina bifida, there were 12 with exstrophy and four with epispadias aged four to 17 years old. The AMS 880 AUS was used with 5.5 to 7.5 cm cuffs and 61–70 cm water balloons. The cuff eroded in three of 12 exstrophy patients. Only four were dry and able to void spontaneously all of the time [424]. Herndon et al reported a 20% erosion rate in patients of any diagnosis who had had a bladder neck repair [425].

e) Diversion:

It is beyond the remit of this section to consider urinary diversion for exstrophy in detail. There is a school of thought that the results of exstrophy reconstruction in the long run are so poor that early diversion should be the initial management [426]. The original diversion of choice was a ureterosigmoidostomy, however the results before antibiotics and an understanding of hyperchloremic acidosis were very poor with 50% of children dying before ten years old [427]. With modern management and the use of a de-tubularized rectal pouch, such as the Mainz II, the results are very good and continence rates of 95% day and night are reported [428, 429]. This would certainly be the

management of choice in countries with limited facilities for reconstruction [430]. Surveillance for the development of anastomotic neoplasms from the tenth year after construction is mandatory [431].

Even in exstrophy patients who are continent, very many will have had an intestinal augmentation procedure. If the urethra is continent it may be used for self catheterization. When the urethral reconstruction has failed, either because it is wet or impossible to catheterize, a supra-pubic catheterizable channel, such as a Mitrofanoff, should be formed. The wet urethra is closed at bladder neck level to allow continued seminal ejaculation. If the bladder is too small or of too high pressure, it is augmented with intestine.

In the large series from Baltimore, 91 of 704 (13%) of exstrophy children required such procedures [432]. Of the reconstructed patients, 65% had a bladder neck closure. At a mean follow-up of six years, 93% were continent.

There are no data on the use of these techniques in adults specifically with exstrophy. However, as there are no other alternatives, a reconstruction based on the bladder is the recommended option. Long-term follow-up of intestinal diversions in other situations suggests that stone formation, stomal stenosis, hyperchloremic acidosis are common. Spontaneous rupture, an acute and life-threatening complication is rare. Renal function is preserved at least to ten years [433].

A long-term problem unique to exstrophy patients with a retained bladder is the risk of cancer. At the age of 40, exstrophy patients have a 640 fold increased risk over the normal population of that age. The reported tumors are aggressive and frequently fatal. Histologically, they are a mixture of transitional, squamous and adenomatous, most commonly arising on the bladder neck [434]. To date, the reported cases have been in those whose bladder reconstructions were done in early childhood; it remains to be seen whether those with reconstructions done in the first few days of life will have the same risk. It is important to pay urgent attention to the standard symptoms suggestive of bladder cancer even in young adults with exstrophy.

If the bladder is too small to be useful, or has been removed, one of the standard supra-pubic diversions such as a colonic reservoir can be used. The Mainz II rectal reservoir is an alternative. Ileal conduit is almost never indicated. However, the risk of bladder cancer remains, even if the only remaining part is the bladder neck.

4. RECOMMENDATIONS

The published studies to date are retrospective case series with levels of evidence at best 3 with a **Grade of Recommendation of C and Level of Evidence 3**. The expert opinion of the Committee has resulted in the following recommendations regarding the evaluation and treatment of persisting incontinence in adulthood. **(C)**

- Anti-muscarinic drugs are the first option for detrusor overactivity although there are no data specifically related to exstrophy patients.
- Standard techniques for enlargement of a small or high-pressure bladder are appropriate.
- Bladder neck bulking agents may be effective but continence is unlikely to be achieved if 4 injections have failed
- Re-do bladder neck reconstruction has a high failure rate, and is very unlikely to allow complete, spontaneous voiding. Urethral CIC may be difficult or impossible.
- AUS also has a poor outcome because of erosion, chronic retention and CIC difficulties.
- Supra-pubic continent diversion with or without augmentation and with or without bladder neck closure is the best choice for exstrophy patients with urethral failure. Rectal diversion (eg a Mainz II pouch) should be considered especially in countries with limited medical facilities.
- Patients with exstrophy-epispadias complex should be evaluated and managed in specialized centers
- A universal definition of continence should be established
- Persisting incontinence should be evaluated with urodynamics and its treatment should be individualized based on urodynamic findings
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications
- Comparative studies, including quality of life and psychological assessment, should be undertaken if possible.

IX. DETRUSOR OVERACTIVITY AND REDUCED BLADDER CAPACITY

1. REFRACTORY URGENCY INCONTINENCE AND IDIOPATHIC DETRUSOR OVERACTIVITY

The overactive bladder (OAB) syndrome refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia [435]. Detrusor overactivity (DO) indicates the urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. Idiopathic Detrusor Overactivity (IDO) exists when there is no defined cause. Neurogenic Detrusor Overactivity (NDO) is seen when there is a relevant neurological condition. Ahlberg et al found that 82% of patients initially considered idiopathic on careful searching actually had pathology potentially leading to the problem [436].

Idiopathic detrusor overactivity is a normal situation early in life. Children have urgency incontinence as a stage in acquiring bladder control. The incidence of detrusor overactivity during mid-life years (20 to 60) has been estimated as 10% [437]. In the asymptomatic elderly, detrusor overactivity once again becomes common, occurring in 50% of men over 70 [438]. In the symptomatic elderly, over 75 years old, it can reach 90% in men [439]. Detrusor overactivity may be a cause of severe storage symptoms such as frequency, nocturia, urgency and urgency incontinence. Conservative treatment of these symptoms such as bladder training and pharmacotherapy is discussed in other sections.

Magnetic stimulation has been reported as a non-invasive treatment of DO [440,441]. Bradshaw et al. demonstrated an effect on cystometry with magnetic stimulation and found an improvement in urodynamic parameters but no consistent change in OAB symptoms [442]. Almeida et al.[443] in a prospective urodynamic controlled study of 91 women with UI, found an improvement on DO only in patients with initial bladder contractions greater than 15 cm H2O. There are no other specific data available [444].

The use of intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin was extended to DO of non-neurologic origin after the suggestion that its etiology involved the enhancement of the C-fiber mediated spinal micturition reflex [445] and emerged as a minimally invasive procedure: the results are shown in **Table 12** [446-453]. In spite of promising and controversial results, it is still

Table 12. Intravesical capsaicin and resiniferatoxin for detrusor overactivity (males and females)

Author	No.	Improvement	Duration of effect	Drug and dose	Side effects
Cruz et al.[446]	3 IDO (total of 16, including 3 males)	71% continence (overall total of 14) and 21% improvement	Up to 18 months	Capsaicin 125 ml of 30% alcohol in saline containing 1mM	Intense burning sensation

Liu and Kuo[457]	28	14 (50%)		10 nM RTX weakly for 4 weeks	Transient receptor potential vanilloid subfamily 1 overexpressed in the responders
Palma et al [448]	25 females with idiopathic urgency incontinence	10 (40%) disappearance of urgency incontinence	1 month evaluation only	50 nM RTX	No mention of retention
Rios et al. [453]	58 females With IDO	43% RTX 35 % PlaceboVehicle Improvement -equal (p=0.439)	1 month first evaluation	50nM RTX or 10% ethanol saline solution	Randomized double-blind placebo controlled
Silva et al. [450]	13 IDO (2 men 11 women) (12 incont.)	11 improved (91%) in incontinence 3 (25%) dry	3 months follow up	100 ml 50nM RTX solution 10% ethanol in saline for 30 min	No retention or other problems
Silva et al.[458]	17 IDO (out of 23)	Vehicle 9 (39%) RTX 14 (60%)	Pre-test with vehicle only followed by RTX	Vehicle followed by 100 ml 50nM RTX (patients enrolled in 2005)	No separation of NDO and IDO
Yokoyama et al. 455.[458]	10 (4 men)	5 (2 dry) 50%	3 months follow up	100 ml 50nM RTX for 30 min	Neurometer before and at 30 days

considered experimental and more clinical studies are necessary for it to be licensed [454].

The mechanism of action is still under study. The mean bladder perception threshold is increased only in patients with clinical improvement [455]. The complexity of the mechanism is demonstrated by the presence of vanilloid receptors not only on sensory fibers but also in bladder urothelium and smooth muscle cells [452] and by ineffectiveness in treating an overactive bladder from idiopathic causes or suprapontine lesions with no vanilloid-sensitive fiber-mediated reflex [456]. It has been suggested that over expression of transient receptor potential vanilloid subfamily 1 in the bladder predicts the response [457]. A well designed double-blind placebo-controlled study revealed no difference between placebo ethanol 10% saline solution and 50 nM resiniferatoxin, nevertheless both treatments showed improvement in symptoms of women with IDO [453]. Some placebo-controlled studies either did a quasi randomization458 or did not explain how it was done [452]. Patients with increased bladder sensation without DO presented some improvement in symptoms in a small non placebo controlled series [459]. There are no recent clinical series published and at present time, the use of resiniferatoxin has been restricted to animal studies [460,461].**(levels of evidence 1 – 4; Grade of recommendation D, two level 1 studies have contradictory conclusions**. [452,457])

For symptoms that are refractory to conventional means, 3 interventional treatments have been reported: botulinun-A toxin detrusor injections, neuromodulation, and bladder augmentation.

a) Botulinum toxin A injection in the bladder

The minimal invasiveness of this method makes it very attractive but long-term results in IDO are lacking **Table 13** [462-478]. The effects of its use are still not fully recognized [479], with possible systemic consequences [480-482], such as generalized muscle weakness in a number of patients treated for neurogenic bladder overactivity, and the development of resistance to the drug [483-485]. The FDA conducted a safety review of botulinum toxin products and issued a report that included a “Boxed Warning” highlighting the possibility of life-threatening distant spread of the toxin, a Risk Evaluation and Mitigation Strategy (REMS) with a medication guide to help patients understand the risks and benefits, and changes to the established drug names to reinforce individual potency and lack of interchangeability of the different products and to prevent medication error [486].

Most of the initial experience comes from its use in neurogenic bladders [487-490]. In 2011, OnbotulinumtoxinA was approved by countries in North and South America and Europe for treatment of urinary incontinence in people with neurologic conditions as spinal cord injury or multiple sclerosis. Information about its use in children is scarce [491]. DasGupta et al. [492] published a systematic review on its use in children. They found 225 children in 10 peer-reviewed publications with 165 pediatric patients with neurogenic overactivity (6 studies), 21 patients with idiopathic overactivity (1 study) and 39 patients with voiding dysfunction (3 studies). Only 11 male children with idiopathic OAB were included, limiting conclusions on this subject.

A randomized study comparing the results of botulinum toxin A injections to intravesical resiniferatoxin in NDO showed superior clinical and urodynamic benefit with the use of botulinum toxin [490]. The need for reinjections seems to be overcome by the significant improvement in quality of life of these patients [493-495]. Cost-effectiveness with botulinum toxin A in patients with detrusor overactivity is becoming an important issue with its increasingly widespread use [496]. The number of BTx treatments in the UK has increased dramatically from around 50 in 2000 to 4088 in 2010, making costs an important matter to be considered [497-499]. A 3-year cumulative cost analysis of BTx versus augmentation cystoplasty favoured botulinum toxin injections [500], but longer follow up may change this.

The use of botulinum toxin B (Myobloc – RimabotulinumtoxinB) is less efficient, with duration of action of about 10 weeks [501].

The optimal site of injections, including or not including the trigone, is still under debate [502]. In 2007, Kuo [474], published a study comparing the injections into the detrusor, suburothelial area, and bladder base, with the last location improving urgency but not increasing capacity. Recently Kuo did a single blind, randomized, parallel, actively controlled trial testing 100 U of OnabotulinumtoxinA with patients assigned to receive injection into one of the three following sites: bladder body, 100 U; bladder body, 75 U plus trigone, 25 U; and bladder base, 50 U and trigone, 50 U. He concluded that the injections are a safe and effective treatment for IDO regardless of the injection sites [503]. Manecksha et al [504] performed a study with 500 U of AbobotulinumtoxinA in 22 patients randomized to trigone-included or trigone-sparing detrusor injections. Benefits of trigone included injections were superior to trigone sparing injections for the treatment of refractory IDO and did not cause VUR in this study. A case series of 56 women with IDO underwent submucosa-only injection of 200 U of OnabotulinumtoxinA at 30 sites, showed success in 85.7% at 2 months and 54.3% at 12 months [505]. Initial results of bladder instillation of 300 units of OnabotulinumtoxinA and 50 mL of 50% DMSO in aqueous solution in women with IDO, showed safety and some efficacy that merit further research [506].

Many studies on idiopathic overactive bladder have been done in women [468, 469]. Data are still lacking on dose, concentration, site(s), numbers of injections, long-term efficacy and side effects. Attempts

Table 13. Botulinum Toxin A detrusor injection results

Author	No.	Type of patients	Dose	No. punctures	Results	Comments
Harper et al.[462] Level 3	39 (13 men and 26 women)	Neurogenic and idiopathic origin (not described separately)	200 idiopath 300 neurog	20 to 30 sparing the trigone Flex. cysto.	Increase max bladder volume 174 to 589 ml	
Loch et al.[463] Level 3	30	Neurogenic and idiopathic	200 U	20 injections sparing the trigone	Significant improvement in 67% of the patients - > residual urge	No description of gender or whether NDO
Radziszewski et al. [464] Level 3	12 (6 female and 6 male)	Only idiopathic	Up to 300 U	10-15 injections sparing the trigone	1 months follow up 100% success no residual	Short follow up Inexact criterion of success
Rackley et al.[477] Level 3	18 women	IDO	200-300 U (Botox)	Each 100 U in 1 cc saline, 0.1 cc injections	Improvement 40% frequency 30% urgency	6 months follow up
Rapp et al. [465] Level 3	35 (29 females and 6 males)	6 neurogenic	300 U	30 injections including trigone	34% resolution 26% improvement	40% failure
Kuo, [466] Level 3	30 (12 females and 18 males)	12 neurogenic	200 U	40 injections sparing the trigone	26% resolution 46% improvement	26% failure
Chancellor et al.[467] Level 2/3	10 (2 males and 8 females)	Only idiopathic	100-300 U	20-30 injections only in bladder base and trigone	80% improvement	Control group - 11 neurogenic with 73% improvement
Rajkumar et al.[473] Level 3	15 women	IDO	300 U (Botox)	30 ml – 30 injections	93% improvement	Not randomized prospective study 6 patients with PRV >130 ml
Popat et al.[472] Level 3	31 (18 women and 13 men)	IDO	200 U (Botox)	20 ml – 20 injections	57 % dry at 4 months	19 % needed CISC
Kessler et al.[478] Level 3	11 patients (no gender information – 8 men in total of 22 patients)	IDO	300 U (Botox)	30 ml – 30 injections sparing the trigone	91% dry 5 months duration	Prospective study comparing IDO with NDO 4 high PVR with CSIC (36%)
Werner et al.[782] Level 3	26 women	Only IDO	100 U (Botox)	30 ml- 30 injections	65 % dry at 12 weeks 60% dry at 36 weeks	36 weeks follow up
Schmid et al.[470] Level 3	23 men 77 women	Only IDO	100 U (Botox)	30 ml- 30 injections	88% improved 8% poor results	12 weeks follow-up 4% urinary retention
Kuschel et al.[469] Level 3	26 (only women)	Only idiopathic DO with incontinence	100 U (Botox)	30 ml- 30 injections	11/26 improved (42%) 4 no need further treatment	2-year follow-up 3 complications (1 no response and 2 high PVR)
Jeffery et al. [468] Level 3	25 (only women)	Only idiopathic DO	500 U (Dysport)	20 ml- 20 injections	63% dry – 1 week 32% dry- 3 months	Prospective First study with Dysport
Lee et al. [471] Level 3	13 men 5 women	10 IDO and 8 NDO	50-200 U (NTX component of purified Type A neurotoxin	20-40 injections including trigone Indigocarmine together to check leak	89 % improved	3 months follow-up 6% retention with IC for 12 months
Sahai et al.[476] Level 2	34 patients (16 BTX and 18 placebo) Do not discriminate gender	Only IDO	200 U (Botox) or saline (as placebo)	20 ml – 20 injections	Normalization- Frequency 36% BTX 11% Placebo Urgency No difference Incontinence	12 weeks follow-up Randomized placebo controlled double blind trial Difficult voiding 75% IC 38%

Table 13. Botulinum Toxin A detrusor injection results (continued)

Author	No.	Type of patients	Dose	No. punctures	Results	Comments
Sahai et al. [476] Level 2	34 patients (16 BTX and 18 placebo) Do not discriminate gender	Only IDO	200 U (Botox) or saline (as placebo)	20 ml – 20 injections	Normalization-Frequency 36% BTX 11% Placebo Urgency No difference Incontinence 50% BTX 0% Placebo	12 weeks follow-up Randomized placebo controlled double blind trial Difficult voiding 75% IC 38%
Kuo H-C [474] Level 2	45 patients (gender not specified)	Only IDO	100 U (Botox)	Injections in Detrusor, suburothelial or bladder base	Success 93% Detrusor 80% suburothelial 67% bladder base	Prospective randomized 3 months 4 retentions 14 difficult void
Ghalayini and Al-Ghazo,[475] Level 3	16 patients	IDO	500 U (Dysport)	500 U diluted in 30 ml saline 30 injections	80% of patients satisfied	Prospective study 9 months follow up 1 retention and 4 with PRV >120 ml – 5 ICath
Mohanty et al[783] Level 3	35 women	IDO	200 U Botox	20 ml, 20 injections sparing trigone	85.7% improvement, no adverse effects	Case series No retentions
Kuschel et al[469] Level 3	26 patients (women)	IDO	100 U Botox	30 ml 30 injections	11 re-injections	Case series
Brubaker et al[539] Level 1	43 women (28 Btx and 15 placebo)	IDO	200 U Botox	20-30 injections, sparing trigone	Study stopped – 43% (12 pat.) with large PVR	Randomized double blind placebo controlled
Flynn et al[784] Level 2	22 women (7 placebo and 15, 2 doses of Botox)	IDO	200 or 300 U Botox	10 injections, sparing trigone	6 weeks results only - (improvement) 26% PVR >200 ml 18% infection	Randomized double blind placebo controlled (immediate results)
Sahai et al[536] Level 1	34 patients both sexes	IDO	200U Botox (16 pat) or placebo (18 pat)	20 ml with 20 injections	QoL improved with Botox	Randomized double-blind placebo controlled
Lie et al[785]	19 patients (10 males)	IDO	200 U (onabotulinumtoxi	20 ml, 20 sites sparing trigone	More efficacious in female	Case series 5.2% retention

to determine whether poor responders could be predicted from preoperative urodynamic parameters showed only a very high maximal detrusor pressure over 110 cm H2O as an unfavorable predictor when using 200 units [476]. Studies in women suggest a longer duration of action than its mere motor-nerve blocking potency can explain [469]. Therefore, a dual mechanism of action has been proposed: in addition to binding to cholinergic terminals, it might also affect afferent nerve transmisson, thereby decreasing urgency [507,508]. Kuo evaluated retrospectively the results of 100 U OnabotulinumtoxinA injection in 174 patients (89 males) [509]. Patients who had sensory effects had significantly greater long-term success rates compared to those with motor effects alone. He concluded that improvement of urgency severity seems to be significantly associated with the long-term success of BoNT-A treatment for IDO.

There are two commonly marketed forms of botulinum toxin-A: Botox (Allergan Pharmaceuticals, Irvine, CA, USA), now referred to as OnabotulinumtoxinA, and Dysport (Ipsen Biopharm Ltd., Wrexham, UK), referred to as AbobotulinumtoxinA, as recommended by the US Food and Drug Administration. They require different doses to achieve similar results, in a proportion of approximately 1:3 [510,511]. Other forms of botulinum toxinA do not have enough data in urology to be considered for this report, includng Xeomin (IncobotulinumtoxinA) (Merz, Germany), Prosigne (Lanzhou Institute of Biological Products, China) [512], and Neuronox (Medy-tox, South Korea).

AbobotulinumtoxinA for refractory IDO was published in 2007 with similar results to OnabotulinumtoxinA [468]. Recently, a series of 22 patients with IDO underwent injection of 500 U of AbobotulinumtonA and were randomized to injections including or excluding the trigone [504]. Similar results were obtained regarding side effects (18% retention and no reflux) with the trigone-included group showing better results. Another large case series of 234 patients either with various types of neurogenic bladder dysfunction (NBD) or IDO underwent respectively 500 U and 250 U of AbobotulinumtoxinA including 57 men with IDO. Success was 91% for NBD and 93% for IDO, with 12% retention only in the male patients [513]. In a study using a type A neurotoxin, produced in a medical school laboratory and purified by a procedure using a lactose gel column, Lee at al. [471] reported improvements in 89% of patients treated for incontinence due to IDO and NDO. Mangera et al. [514] did a systematic review on management of lower urinary tract diseases comparing OnbotulinumtoxinA and AbobotulinumtoxinA. They identified good-quality

studies for OnabotulinumtoxinA in adults and lack of such studies for Abobotulinum- toxinA, although this does not imply that OnabotulinumtoxinA is more effective than AbobotulinumtoxinA.

Many studies with botulinum toxin detrusor injection use different outcome measures for results and are variable in reporting the presence of residual urine and the need for intermittent catheterization, but 6-75% of cases may develop a high post void residual urine [469,471,473,476]. A retrospective study looking at risk factors for adverse events in a series of 217 patients treated with OnabotulinuntoxinA showed an overall 63.3% success, with male gender, base line PVR ≥100 ml and dosage >100U as predictors of urinary retention or difficulty voiding. Besides being an alternative for treatment of refractory DO, currently available data do not support superiority of any specific treatment plan, and therapy options should be tailored to the specific patient and physician preference [515]. Higher doses such as 200 units in IDO resulted in incomplete emptying, necessitating intermittent catheterization in 6 out of 16 patients (37.5%) in one study [476]. Sahai suggests a careful follow up of the patients after the injections, starting IC in symptomatic patients if post void residual urine is more than 100-150 ml [516].

Many reports do not separate genders and mix neurogenic and idiopathic etiologies. A large number of publications are reviews of the literature [517-535]. There is a randomized double blind OnabotulinumtoxinA placebo controlled trial showing favourable difference against saline injections for frequency and incontinence, but not for urgency [476]. Quality of life analysis showed improvement even with the occurrence of 38% of urinary retention [536]. In a dose-finding randomized double blind placebo controlled study with a total of 313 IDO patients of both sexes, all OnabotulinumtoxinA dosages (50-300U) were better than placebo, but the 100 and 150 U dosages were best in regard to the balance between efficacy and side effects [537,538]. In women, a placebo controlled randomized study with 200U of OnabotulinumtoxinA for IDO showed a 60% clinical response but was terminated early due to 43% of patients having increased PVR [539].

Conclusions

Efficacy of botulinum toxin A for IDO: **level 1 of evidence, Grade of recommendation A** (for OnabotulinuntoximA). Fewer studies for AbobotulinuntoximA and the lack of studies for other A toxins do not allow similar recommendation.

Dosage of botulinum toxin A for IDO: between 100 and 150 U (for OnabotulinuntoximA). No studies for other types. **Level 1 of evidence; Grade of recommendation A.**

Location of injection: the majority of studies use 20 or 30 injections, and spare the trigone (**Table 13**). Alternative sites such as submucosal or including the trigone, have **levels 2 and 3 of evidence. Grade of recommendation C.**

Predictability of complications: Risk factors for retention or difficulty voiding are: male gender, baseline PVR≥100ml and a dosage >100U. **Level 3 of evidence; Grade of recommendation C** (for OnabotulinuntoximA – for other types, no conclusion possible).

The committee cautions that although the efficacy and safety of botulinum toxin A for IDO is being established there are still concerns regarding the data. Its use in men is not as widely reported as its use in woman; the issue of voiding difficulty and the need for intermittent catheterization has not been addressed in men. There are no long-term or cost effectiveness studies compared to alternatives. Furthermore the recommendations cannot be extended to other toxins due to lack of studies.

b) Electrical stimulation and neuromodulation

Electrical stimulation of the genital area was first used to control incontinence due to DO of different etiologies on an empirical basis [540]. Later, it was suggested that sphincteric contraction induced by electrical stimulation can promote an inhibitory effect on detrusor activity, thus suppressing DO [541]. Many studies of external electrical stimulation for bladder inhibition of idiopathic urgency incontinence have been published, mainly in female patients [542-549]. The results vary from 45% to 85% success, with a mean of 38%, and 26% improved. Electrodes implanted in the pelvic floor, have not yielded good results [547].

Sacral neuromodulation has been reported as alternative therapy for urgency incontinence, urinary retention, chronic pelvic pain, and for simultaneous urinary and fecal incontinence [550]. Good results have also been published in treating neurogenic bladder dysfunction [551,552]. The working mechanism of neuromodulation in the treatment of lower tract dysfunction is still unknown [553,554]. A suggested mechanism is somatic afferent inhibition of sensory processing in the spinal cord [555,556], therefore it may be a centrally acting treatment modality that is different from botulinum toxin, which is an end-organ therapy that specifically targets the bladder [557].

Long-term results suggest a sustained effect on restoring voiding in appropriately selected cases, but a revision rate of 42% at 5-year follow up remains a problem [558]. The 14-year revision rate from a single center was 39%, which decreased after the introduction of new materials [559]. On-demand use, as suggested by Oerlemans et al. [560] may improve this revision rate by prolonging battery life. Its use in refractory idiopathic urgency incontinence has been limited to relatively few patients, mostly women. Bosch and Groen [561] presented results of chronic implantation in 15 women and 3 men, with

an average age of 46 years. Significant improvements in voiding frequency, average voided volume, number of incontinence episodes and number of pads used were found, with no deterioration in response to stimulation with time. However, with subsequent experience in 14 men only 2 patients had a partial response and the rest ultimately failed [562]. Shaker and Hassouna [563] implanted 18 patients with refractory urinary urgency incontinence, but only 2 were in men. Groen, Bosch and van Mastrigt reviewed 33 implanted women and found no effect on urethral resistance and bladder contraction strength, thought to be due to the depressant effect of sacral (S3) nerve neuromodulation on detrusor overactivity [564]. Groenendijk et al in a retrospective study for the Sacral Nerve Stimulation Study Group, reported urodynamic aspects of 111 patients implanted, but only 8 men were included [565]. They found a better result on urgency incontinence in patients without DO. The difference was not significant. This tendency was also found by South et al. in 67 women implanted [566]. Clinical or urodynamic values to predict the outcome of sacral nerve stimulation has been difficult do define. Evaluation of 19 women suggested that urethral overactivity seemed to be a good parameter to predict a favourable outcome [567].

Some studies do not specify the etiology of the DO and neurogenic and non-neurogenic causes are grouped together [563]. Some reports focus on technical or specific aspects of the procedure and the same patients may be included in different publications [565,568-570]. Implantation in children may be feasible in selected cases [571,572] and poorer results are expected in older women [102]. The outcome in older men is unknown since there are no reports.

Table 14 [478,558,573-582] shows recent studies.

Some reports are literature reviews [554,583-585] or detail technical modifications [586,587]. There is one systematic review on efficacy and safety of sacral neuromodulation for urgency incontinence, but 13 of the articles analyzed are abstracts and it is also difficult to ascertain whether the same patients are included in different publications [588].

There are some publications with level [1573,574 or 2562,576,577] evidence and with a grade of recommendation of B. However, due to relatively few men in the clinical trials, and poor results in one of the prospective trials, its general applicability to men with urgency incontinence may be limited. The scenario remains unchanged after about 26,000 patients implanted [589]. In a recent review, Apostolidis [590] concluded that further research is needed to improve patient selection, identify prognostic fac-

Table 14. Neuromodulation for treatment of refractory urgency incontinence due to detrusor overactivity (males and females)

tors, clarify the mechanism of action, and reduce complications and revision rates.

Level of evidence 3. Grade of recommendation C.

c) Surgical treatment by detrusor myectomy and augmentation

Previously used treatments of surgical bladder denervation, open bladder transection, cystolysis, endoscopic phenol injections, hydrostatic bladder distention did not yield good results.

Bladder autoaugmentation or detrusor myectomy has been reported as an alternative to augmentation in neurogenic and non-neurogenic dysfunction. **Table 15** [591-593] shows results of this treatment in patients with non-neurogenic detrusor overactivity. There are few long term results available [593]. The use of silastic intravesical balloon as a scaffold after myectomy seems to improve results in neurogenic patients but was not tested in IDO [594]. Additional and longer-term experience is still required to properly assess this procedure. **(Level of evidence 3; grade of recommendation C-D)**

Enterocystoplasty results are detailed in **table 16** [592,595-601], which includes both male and female patients. Some publications are not clear about the type of surgery specifically done in IDO and about the gender. Good results vary from 58% to 88%, with an average of 77%. Approximately 10 to 75% of patients require intermittent catheterization for bladder emptying. Ileum was the most frequently used bowel segment followed by sigmoid colon, although no scientific reason for the use of any particular segment was given. The surgery, as reported in other sections, has a significant complication rate and should be considered carefully when applying it to these patients. **(Level of evidence 3; grade of recommendation C)**

2. REDUCED BLADDER CAPACITY

Fibrosis of the wall produces a low-volume low-compliant bladder, leading to diminished functional capacity. Symptoms of frequency and nocturia occur as a result of progressive decrease in bladder volume, but urinary incontinence may also be the consequence of a very small capacity, especially if accompanied by urethral weakness. The diagnosis can be suggested by the micturition chart, and confirmed by urodynamics. The causes can be congenital or acquired. Acquired causes include multiple surgeries, inflammatory processes (chronic cystitis, interstitial cystitis, tuberculosis, schistosomiasis, and chemical cystitis) or following radiation.

Bilharzial contracted bladder is a problem that is primarily limited to endemic areas in Africa and the Middle East. Schistosoma haematobium migrates to the veins of the vesical and pelvic plexuses, where the female begins to lay eggs, promoting a initial inflammatory response. As a result, granulomatous lesions form in the lamina propria. Mucosal reactions vary from hyperplasia to polypoid cystitis. A contracted bladder occurs in 2% of cases [602]. Bladder augmentation seems to offer reasonable results in these cases.

Similarly, small fibrotic bladders due to other etiologies can be treated successfully with enterocystoplasty. The results of this surgery are presented in **Table 17** [603-631]. The results are similar in all etiologies except for radiation. The poorer results after radiation may be due to other tissue damage in the surgical area. New conformal techniques for radiotherapy may improve results in the future, so that the need for augmentation cystoplasty decreases.

Almost all of these studies do not distinguish bowel segments or separate males from females in reporting results. Therefore, it is not possible to correlate any particular aspect with the chance of success or failure. However, overall the results seem reasonably good with the exception of patients who have undergone radiation. **(Level of evidence 3; Grade of recommendation C)**

X. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE

Urethrocutaneous or rectourethral fistula may have congenital, inflammatory, neoplastic or traumatic origins. It is important to recognize the varying etiologies because each type may require a different surgical strategy. All reports except one are retrospective case series. The report by Shakespeare et al. [632] is from a prospectively collected data base of patients treated with radiotherapy for prostate cancer. **(Level of evidence 3; grade of recommendation C).**

1. URETHROCUTANEOUS FISTULA (UCF)

a) Acquired UCF

Hidden foreign bodies have been described as a rare cause of both strangulation of the glans penis and urethrocutaneous fistula. Tash and Eid [633] presented the case of a 30-year-old man who developed a urethrocutaneous fistula and penile shaft necrosis after a condom broke during intercourse. Neither the patient nor several physicians could identify the retained ring of condom, which had been buried under newly epithelialized skin. He underwent removal of the foreign body under general anaesthesia, followed 5 months later by a formal urethrocutaneous fistula repair.

Urethroperineal fistula, as a complication of open perineal prostate cryosurgery, occurs as an immediate perioperative complication in 10.7% [634]. Thomas et al. [635] retrospectively evaluated 250 patients after radical perineal prostatectomy and revealed only 1 (0.4%) urethroperineal fistula. Fahal et al. [636] published an unusual complication of mycetoma. The patient had an infection with Actinomadura madurae that involved abdominal wall, perineum and urethra. This resulted in urinary extravasation with a urethrocutaneous fistula.

b) Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography (**Figure 3**), urethroscopy, fistulography, urethral ultrasound or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess [637].

Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure [638]. **(Level of evidence 3; Grade of recommendation C)**

2. RECTOURETHRAL FISTULAS (RUF)

Culp and Calhoon described five basic groups of RUF according to the etiology [639]: congenital, iatrogenic, traumatic, neoplastic, and inflammatory.

Figure 3. Voiding cystourethrogram after incision of the paraurethral abscess

a) Congenital RUF

Endo et al. [640] described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from 1976 to 1995 were analysed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be categorized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down´s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights.

The purpose of Rintala's study was to compare the long-term outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) to that of posterior sagittal anorectoplasty (PSARP). In boys with high anorectal anomalies, PSARP was superior to SP-SAP pullthrough in terms of long-term bowel function and faecal continence [641].

b) Acquired RUF

Acquired RUF may occur after pelvic trauma, surgery of the prostate or rectum, pelvic cancer, radiation (either external beam or brachytherapy),

cryosurgery, prostatic hyperthermia, prostatic high intensity focussed ultrasound (HIFU), inflammatory bowel disease affecting rectum, or rarely prostatic inflammation.

Benchekroun and co-workers [642] report a series of 11 RUF observed over a 25-year period. The etiologies were surgical trauma (5 cases), fracture of the pelvis (2 cases), inflammatory lesions (3 cases), and one fistula was congenital. Colostomy was performed in 2 patients, surgical closure of the fistula was performed in 7 patients: abdominoperineal (3 cases), perineal (2 cases), transperitoneal (1 case) or by transanosphincteric incision (1 case).

In 1972 Smith and Veenema [643] reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only 4 fistulas developed in this group.

Roberts et al. [644] published a series of 11,452 men who underwent open (RRP) or laparoscopic (LRP) radical prostatectomy. Rectal injury occurred in 18 men -12 in the RRP group (0.12%) and 6 in the LRP group (0.47%). When recognized intraoperatively and primarily repaired, rectourethral fistula was prevented in 87.5% of men. Primary repair performed with vascularized tissue interposition prevented rectourethral fistula development. In men with unrecognized rectal injury, the rectourethral fistula tended to persist and eventually required delayed surgical repair. Thomas et al. [645] reported that rectourethral fistulas developed in 13 of 2,447 patients (0.53%) after RP. In 7 of 13 patients (54%) a rectal lesion was primarily closed at radical prostatectomy. With conservative management in 3 patients, all 3 healed spontaneously. None of these patients had fecaluria. Three of the 9 patients 3 (33%) experienced spontaneous fistula closure after temporary colostomy and transurethral catheterization. In this group 6 patients (67%) required additional surgical fistula closure, which was successful in all. Surgical fistula closure (1) without colostomy in presence of fecaluria failed.

The most common single cause of RUF in the series of 23 male patients published by Tiptaft et al. [646] was a fracture of the pelvis and iatrogenic causes (two cases after transurethral prostatic surgery, two cases after open prostatectomy, and three cases after urethral instrumentation. Noldus et al. [647] reported 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino [648] summarized the incidence of rectal injury during RRP in 3834 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4 %.

Nyam et al. [649] reviewed records of all patients who were diagnosed with RUF between January 1981 and December 1995 and 16 males were identified. All patients were interviewed by telephone for follow-up. The mean age was 68 years and the mean follow-up was 80 months. Adenocarcinoma of the prostate in 15 patients and recurrent transitional cell carcinoma of the bladder in one patient were the underlying malignant diseases. Nine patients had had a RRP with 2 fistulas after radiation, 2 after brachytherapy, and 3 after a combination of radiation and brachytherapy. One patient formed a fistula after cystectomy and dilation of a stricture. This heterogenous group of patients received multiple therapies including initial colostomy (7 patients), transanal repair (2 patients), parasacral repair (2 patients), transperineal repair (2 patients), coloanal anastomosis (3 patients), and muscle transposition (3 patients). Four of the patients required a permanent stoma.

Badalament et al. [650] managed one patient (0.4%) with a urethrorectal fistula after cryoablation therapy for prostate cancer. Zippe [651] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter 634 found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al. [652] reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow-up was 33.5 months and RUF occurred in 1%.

Montorsi et al. [653] reported a RUF after transrectal prostatic hyperthermia (43 degree C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month.

Kleinberg et al. [654] summarized results of 31 patients with stage T1 or T2 prostatic carcinoma following CT guided transperineal I_{125} implants and reported that only one patient developed a prostatorectal fistula that was managed with an ileal conduit.

Fengler and Abcarian [655] published their experience of eight patients with RUF in the course of treatment of prostate cancer (3 fistulae after radiation therapy alone, 3 after prostatectomy and 2 after both surgery and radiation therapy). Larson et al. [656] evaluated 5719 patients after radiation for prostate cancer. Ten had documented RUF. Lane et al. [657] treated 21 men with RUF following primary external beam radiotherapy and one after adjuvant external beam radiation therapy for prostate cancer. Time from the last radiation treatment to fistula presentation was 6 months to 20 years. Four patients underwent proctectomy with permanent fecal and urinary diversion. Successful fistula closure was achieved in the 9 patients who underwent urethral reconstruction. Chrouser et al. [658] identified a total of 51 patients with a history of external beam radiation for prostate cancer that subsequently had

a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

Shakespeare et al. [632] reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1455 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. They concluded that gastrointestinal specialists should not perform biopsy of the anterior rectum in patients who have had BT unless there is a very high clinical suspicion of malignancy. Marguet et al. [659] described 6 cases of RUF in patients treated with brachytherapy plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. They also concluded that biopsy of rectal ulcers in the clinical setting of combined radiotherapy should not be performed.

Chang et al. [660] published a case of prostatic malakoplakia masquerading as a rectal tumor due to formation of a fistulous tract to the rectal muscular layers. Cools et al. [661] reported a very uncommon type of fistula between the large bowel and the prostatic urethra due to Crohn's disease. Felipetto et al. [662] described a prostatocutaneous fistula as a complication of pseudomonas prostatitis.

Transrectal high-intensity focused ultrasound (HIFU) destroys prostate cells by coagulative necrosis of the tissue. Recent reports of efficacy also include morbidity. Rebillard et al. [372] reported RUF in 0-3% in a review involving 37 articles/abstracts.

Buckley et al. [663] concluded that there has been a major shift in the cause of RUF from primarily surgical to approximately 50% resulting from radiation/ablation therapy. Surgically induced RUFs typically are small, located in bladder neck/trigonal region and can be closed primarily. Radiation/ablation induced fistula are large (>2 cm), involve the prostatic urethra and are fibrotic often requiring a combination of onlay grafting and interposition muscle flap for closure. The anterior, perineal sphincter-sparing approach may be the optimal approach for closure of most RUF (simple or complex). Lacarriere et al. [664] noted that the use of radiotherapy had a major impact on its prognosis. The flap, which seemed to have the best results, was the gracilis muscle flap.

c) Diagnosis of RUF

RUF may be strongly suspected from the patient's history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Rectal examination, proctoscopy, careful urethroscopy, intraurethral injection of methylene blue dye, radiopaque contrast agent placed into the bladder and then voided usually appears in the rectum on X-ray, are the most important diagnostic steps [637,665] (**Figure 4**).

d) Therapy of RUF

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others [645]. Gibbons 666 stressed the need for a diverting colostomy for 3-4 months.

Figure 4. Cystogram demonstrates a rectourethral fistula that occurred after a laparoscopic radical prostatectomy

However, as surgeons obtained more experience, bowel preparations became standardized, and effective antibiotics were developed, and the enthusiasm for colostomy diminished. Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

e) Surgical Approaches

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (eg. omentum [667], gracilis muscle [668], or scrotal flap [669]) has been described. Surgical approaches include transabdominal, transvesical, or direct exposure of the RUF.

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Rivera et al. [670] staged RUF as: stage I, low (less than 4 cm from anal verge and nonirradiated); stage II, high (more than 4 cm from anal verge and nonirradiated); stage III, small (less than 2 cm irradiated fistula); stage IV, large (more than 2 cm irradiated fistula); and stage V, large (ischial decubitus fistula). Diverting colostomy was performed for stages III to V 6 weeks before definitive therapy. Some of the patients in addition to the RUF will also have urethral strictures that have to managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions. [671]

The surgical approaches including the numbers of reported patients are listed in **Table 18** [639, 642, 643, 646, 647, 655, 665, 669, 672 - 688]

1. Perineal Approach

In 1926, Young [672] dissected the rectum away from sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis, in 1947 [673], described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al. [674] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al. [689] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in **Figure 5**. Pratap et al. [690] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF.

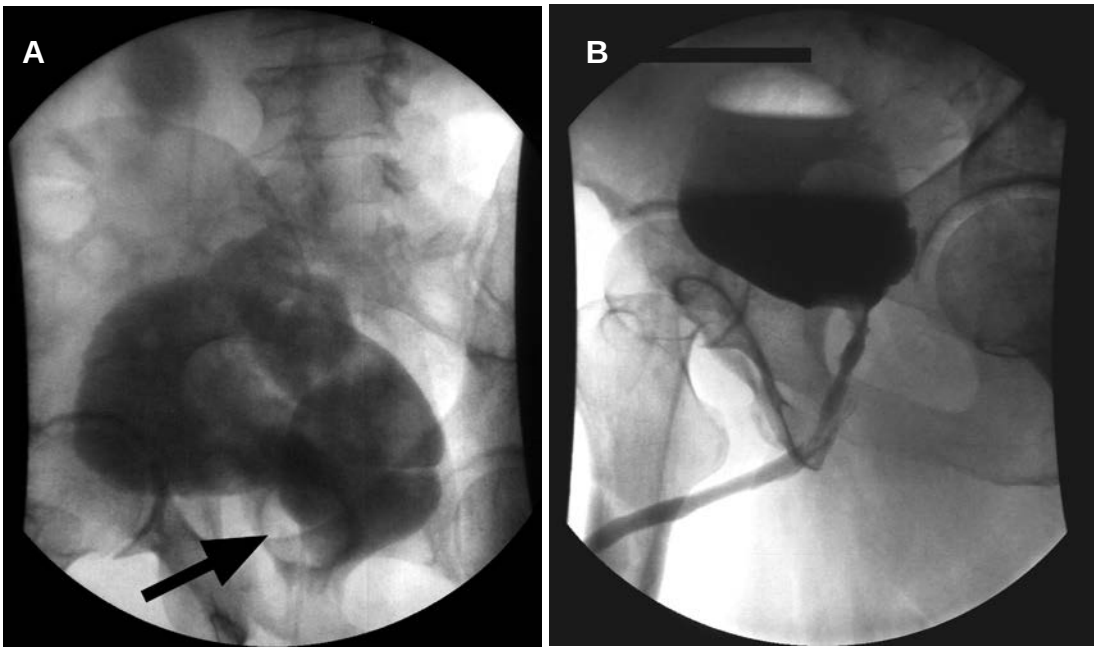

Figure 5A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder.
Figure 5B. Retrograde urethrogram after transperineal closure of RUF

Table 18. Surgical approaches to rectourethral fistulas

Samplaski et al. [691] reported transperineal repair with gracilis muscle interposition in 13 patients with complex RUFs of varying etiologies. One patient developed recurrence. They demonstrated low morbidity, high success rates, and reasonable bowel and bladder function postoperatively.

2. Posterior Sagittal Approach

Kraske in 1885 [692] described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccygectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumour-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson [677] used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

3. Posterior (Parasacrococcygeal) Transsphincteric Approach

In 1969 Kilpatrick and Mason [679] updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated trans-

abdominal or transperineal approaches to RUF. It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum [655]. After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization. After closure of the prostatic urethra it is recommended that the full-thickness rectal wall flaps are close in a "vest over pants" technique (**Figure 6**). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles (**Figure 7**). Fengler and Abcarian [655] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al. [681] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al. [680] in the management of a case of the urethro-prostato-rectal fistula after a gunshot wound.

Stephenson and Middleton [678] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transsphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin [684] reported preliminary experience with the transsphincteric, transanal surgical approach to correct acquired urethrorectal fistula in five men. Mean patient age was 56.6 years (range 37 to 72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1.The time from the diagnosis of urethrorectal fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethrorectal fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al. [693] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn's disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn's disease and in another with ulcerative rectocolitis.

Erickson et al. [694] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the ex-

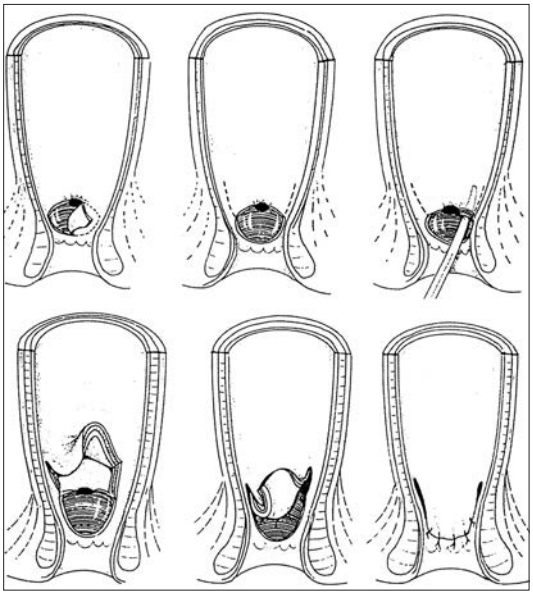

Figure 6. Rectourethral fistula repair. Full thickness rectal wall is mobilized to close in a "vest over pants" technique to close the fistula.

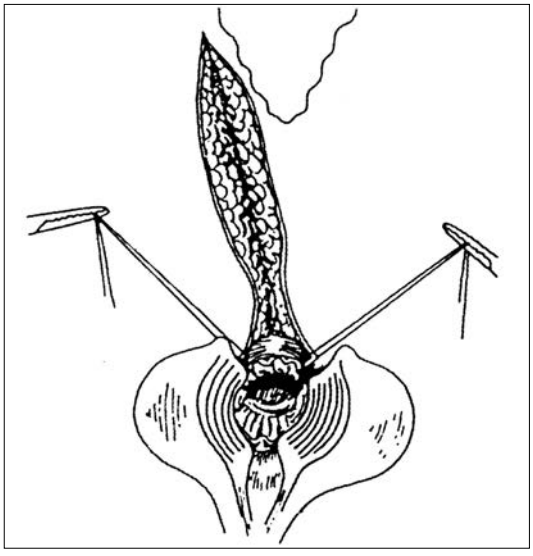

Figure 7. York-Mason approach to a rectourethral fistula via a parasacrococcygeal (transsphincteric) incision. Sutures are used to mark the sphincters. The speculum has been placed at the bottom of the incision and the anterior rectal wall is visible.

aggerated lithotomy position. In a modified prone position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure.

Lorente et al. [695] reported early successful closure in 10 patients with the posterior transsphincteric York-Mason technique, with good recovery of urinary and fecal continence. Pera et al. [696] reported on 5 patients successfully treated after RP with the York Mason technique. They reported minor morbidity and no impairment of continence.

4. Transanal Approach

Parks and Motson [683] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal **(Figures 8** [697] and **9**). They modified the transanal technique by denuding the rectal mu-

B. Intraoperative photograph of transanal rectourethral fistula repair. The anus is held open by the ring retractor to permit direct access to the fistula.
C. Intraoperative view of the rectal mucosal sutures in the rectourethral fistula repair.
D. Retrograde urethrogram 3 months after transanal rectourethral fistula repair. There is no contrast entering the rectum from the urethra. The patient's suprapubic tube was removed and his colostomy was reversed.

cosa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers´ fascia proximal to the fistula for four centimeters. Tiptaft et al. [646] also used a special anal retractor for this surgery.

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al. [647] reported 23 patients (3.9%) with rectal injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seven fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al. [665] treated 30 men with RUF caused by war wounds. He used the method of posterior transsphincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in 'spontaneous' RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

5. Anterior Transphincteric, Transanal Surgical Approach (Astra)

In 1973 Gecelter [685] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The anal sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al. [698] reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by anterior transphincteric, transanal surgical approach (ASTRA).

6. Endoscopic Approach

Wilbert et al. [687] reported two patients with RUF who were repaired endoscopically transanally. The patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum .The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al. [688] used cyanoacrilic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administrated endoscopically through an open-end 6F ureteral catheter. Quinlan et al. [699] presented the case of an iatrogenic fistula in a 71-year-old man treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al. [700] reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM): the RUF occurred after laparoscopic radical prostatectomy. Pigalarga et al. [701] described a case of successful repair of iatrogenic RUF through a multidisciplinary approach consisting of cystoscopy, urethral stent placement, colonoscopy, and transanal endoscopic microsurgery assisted rectal advancement flap.

7. Other Modifications

Youssef et al. [675] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous dartos flap procedure. The RUF resulted from crush pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphyseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous dartos flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous dartos flap may fulfill the principles for successful repair of RUF. Varma et al. [702] also concluded that dartos muscle interposition is a straightforward technique that can result in successful fistula repair. but should not be used in immune-compromised patients or after radiation therapy.

Felipetto et al. [662] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam [703] prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond. Verriello et al. [704] used fibrin sealant (Quixil) to inject it into the fistula tract and a rectal mucosal flap was used to close the internal opening. The fistula healed in few weeks, and the patient remained symptom free after 1 year of follow-up.

Chirica et al. [705] reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex

rectourinary fistulas after radical prostatectomy or following anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7. Lesser et al. [706] reported a case of radiation and salvage cryoablation induced RUF after treatment of prostate cancer which was successfully repaired with a combined endorectal advancement flap with an Alloderm graft.

f) Summary

A review of recent literature shows an increasing number of papers describing treatment. All available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a lack of valid epidemiologic data about the incidence of UCF and RUF. The diagnostic algorithm has not changed in many years.

The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and undiversion). An endoscopic approach using biological sealants is promising. Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF, and the management of these difficult conditions should remain in the hands of experts working in tertiary referral centres. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients.

All reports are still only retrospective case series **(Level of evidence 3; grade of recommendation C).**

XI. THE ARTIFICIAL URINARY SPHINCTER (AUS)

Different devices designed to control urinary incontinence in the male began to appear in the middle of the 18th century [707]. The gold standard today is the artificial urinary sphincter (AUS) designed by F.B. Scott, W.E. Bradley, and G.W. Timm in 1973 [708]. The original model underwent a number of modifications, but the basic principle remained the same. It consists of a fluid filled hydraulic system with a cuff around the urethra, a pressure regulating balloon and an activating device, the pump, placed in the scrotum.

1. AVAILABILITY AND COST

The use of the AUS has increased dramatically since its introduction in 1975 when 90 AUS devices were implanted until 2008 when 4818 procedures were done, with 61% implanted for PPI. [709, 710] In 2005, just over 10% of US urologists perform AUS surgery with the vast majority (92%) performing 5 or fewer surgeries a year and there were only 8 surgeons who implanted 21 or more AUS devices per year. [710]

The results of an e-mail survey among urologists and gynecologists were previously published in the 3rd ICI, whereby members of the International Continence Society were asked if the AUS was available in their country; and if so, what was the price of the device (in US dollars). About 10% of the members responded by email from 31 countries. The high price in some countries at the time (Georgia, Hong-Kong, Romania and Saudi Arabia) precluded its use. Very few gynecologists implant the AUS, probably since the majority of patients receiving the device are male.

2. INDICATIONS

The indication for AUS placement is for the treatment of SUI that is persistently bothersome despite 6-12 months of active conservative management. As the most common cause of SUI in men is iatrogenic injury during prostate cancer surgery, it follows that the most common indication for AUS is post-prostatectomy incontinence (PPI). The use of the AUS for the treatment of PPI varies regionally. For example, within the United States, state-by-state use of the AUS ranges from 1% to 10% of all RRP patients, with an average of 6% of RRP patients ultimately undergoing AUS implantation.[711]

Previous radiotherapy to the pelvis is not a contraindication for AUS placement in males,712 as the ultimate outcome seems to be similar in men whether or not they have received radiation therapy [713], although a higher incidence of urethral atrophy, erosion and infection requiring surgical revision has been reported in irradiated patients compared to those not irradiated (41% vs 11%). Despite this observation, long term continence and patient satisfaction appear not to be adversely affected in the irradiated male patient [713].

The compressive effect of the AUS is temporarily relieved when the patient squeezes the scrotal pump, transferring fluid from the urethral cuff to the pressure-regulating balloon. Subsequently, the bladder can then empty either by bladder contraction and/or by abdominal straining. Accordingly, patients voiding with the Valsalva maneuver because of an underactive or neurologically acontractile bladder, do not seem to be at an increased risk of complications [714]. It should also be noted that patients with previous anti-incontinence procedures show a significantly higher explantation rate [715].

Clinical experience suggests that enterocystoplasty or gastrocystoplasty can be done simultaneously

with the implantation of the AUS [716,717]. However, AUS placement at the time of cystoplasty is associated with earlier infections, especially during the first 3 years post-operatively [718]. In the long-term (> 3 years) the infection rate is the same whether the AUS is implanted after or at the time of cystoplasty. AUS can also be successfully implanted in patients after bladder substitution [387], and in those with locally recurrent prostate cancer with a relatively good prognosis [719], or those with severe post-radical prostatectomy anastomotic stricture in whom a stent has been placed previously [398].

Finally, advanced age is not a contraindication to AUS placement. A retrospective analysis by O'Connor and colleagues of a cohort of men over age 75, revealed excellent success rates, with 21 of 29 men (72%) achieving successful continence. Revision rate was 14% at an average of 5 years follow-up, with 14% requiring explantation, and 21% requiring device deactivation due to deterioration in overall health precluding proper use of the AUS at an average of 47 months after placement [720].

3. SURGICAL TECHNIQUES

The original technique of implantation is illustrated in **Figure 10**. The cuff of the sphincter is placed around the bulbar urethra via a midline perineal incision, while the pressure regulating balloon and the scrotal pump are inserted via a separate inguinal incision. The inguinal incision is carried through the fascia, above the level of the ligament and an area in the prevesical space is bluntly cleared. The pressure-regulating balloon is placed there and filled with 23 cc of saline or contrast after which the fascia is closed. A tunnel is made under Scarpas fascia into the scrotum deep to the dartos fascia where a pocket for the pump is developed. The cuff tubing is transferred from the perineum to the inguinal incision after which the excess tubing is cut off and the appropriate connections are made with the quick connect system.

Another surgical approach has been described using a single, upper transverse scrotal incision which allows the placement of all 3 components of the system, the cuff, the pump in a scrotal pouch, and the reservoir behind the fascia transversalis [304]. Alternatively, the pressure-regulating balloon may be placed through a separate inguinal incision, with the cuff and control pump placed via a single trans-scrotal incision, with the connections among scrotal pump, balloon reservoir, and urethral cuff tubing made in the usual inguinal incision. While the trans-scrotal approach potentially minimizes the invasiveness of the AUS surgery, by limiting the surgical approach to a single incision [304], a few reports have revealed that surgical success might be diminished compared with perineal cuff placement and abdominal balloon reservoir placement [721,722]. A multicenter retrospective study by Henry et al of 158 patients operated on at 4 centers noted that in patients treated with a perineal versus trans-scrotal AUS the perineal group had a completely dry rate of 44%, versus 28% in the scrotal group ($p<0.03$) and had much higher rates of "social continence" as well. Thus the perineal approach for initial artificial urinary sphincter implantation appears to control male stress incontinence better than the trans-scrotal approach.

The trans-scrotal approach appears particularly useful for simultaneous placement of an AUS and inflatable penile prosthesis through a single incision, with Kendirci and colleagues [723] reporting a urethral erosion rate of 9%, an overall revision rate of 14%, and a social continence rate of 100% in 22 patients at 17 months average follow-up. Sellers, et al. [724] recommend the simultaneous surgery for cost-efficacy. They demonstrated a $7,000 cost savings when both devices were implanted simultaneously through a scrotal approach, compared to staged implantation with 2 separate surgeries.

Recent experience with the relatively new 3.5 cm cuff has demonstrated significant efficacy with no increase in complications during 14 months of study at one site [725]. The 3.5 cm cuff has become the predominant size used for primary and revision surgery at that center.

4. COMPLICATIONS

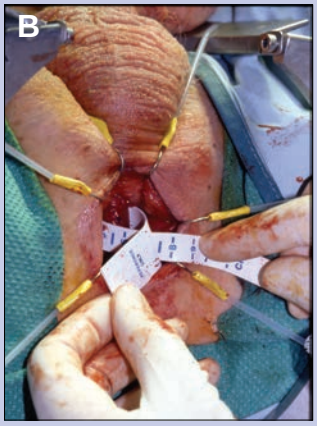
Complications following implantation of the AUS can be divided into the categories of incontinence, erosion and/or infection, and unusual complications. While the number of AUS procedures performed varies geographically throughout the world. Certain "centers of excellence" perform substantially more procedures than do community hospitals [711]. However, the total number of procedures done in a given center does not seem to be a determining risk factor for complications. Comparable erosion/infection rates have been reported from centers with fewer than 50 or more than 100 cases [282]. This suggests that erosion and infection may be more closely related to the physiologic state of the patient rather than the experience of the surgical team, provided standard precautions are strictly applied. Nevertheless, as experience with the AUS has grown the overall revision rate has reportedly decreased [710].

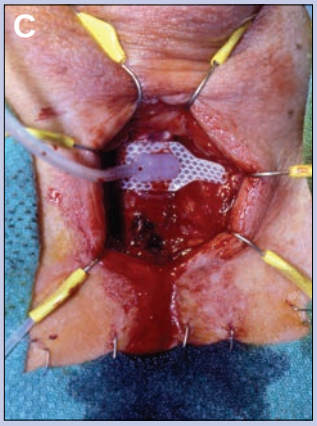
a) Incontinence

Incontinence following implantation of an AUS can result from (1) alteration in bladder function, (2) atrophy of the urethra, or (3) mechanical failure of the device. These causes may co-exist.

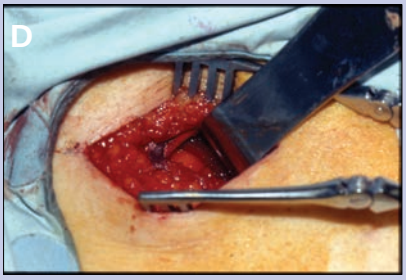
1. Alteration in bladder function

Lai and Boone noted that based on postoperative patient symptoms and the need for anticholinergic medication up to 23% of men undergoing AUS for PPI can develop denovo OAB [268]. UDS were not repeated postoperatively to define the bladder changes associated with this.

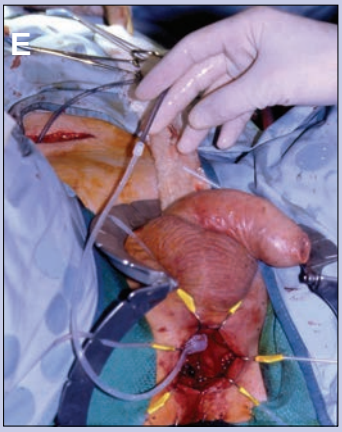


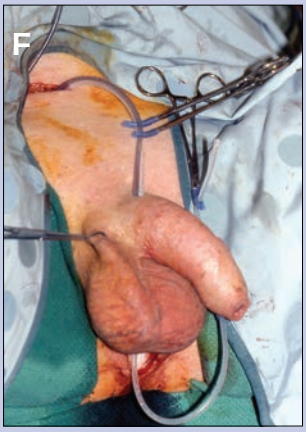


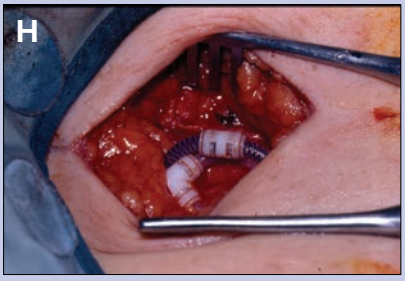
A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to expose the bulbar urethra.
B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size.
C. The belt-like cuff is positioned around the urethra.



D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir.







H. Connectors are placed to join the tubes from the cuff and reservoir to the corresponding tubes from the pump in the RLQ incision.

Figure 10. Artificial Sphincter Technique

Alteration in bladder function has been reported principally in patients with neurogenic bladder dysfunction, especially in children [726-731]. These changes include de novo involuntary detrusor contractions, decrease in bladder compliance, and the development of a high-pressure system, causing incontinence, hydronephrosis and ultimately renal failure. Modifications in detrusor behavior (including its consequences on the upper urinary tract) occur in up to 57% of such cases [726-737]. It should be pointed out, however, that there has never been a published report of hydronephrosis following implantation of an AUS for incontinence after prostatectomy [738]. While the ideal candidates for sphincter implantation are those with an incompetent urethral sphincter, and a low pressure, relaxed, and compliant bladder [735], data described earlier demonstrated that even those with "unfavourable" urodynamic factors may have a good outcome after AUS placement [58].

2. Atrophy of the urethra

Urethral atrophy may occur at the cuff site secondary to long-term mechanical compression of the periurethral and urethral tissues. However, some authors do not mention it as a possible cause of AUS failure [336,738,739]. About 4 months following implantation, cuff efficiency diminishes, presumably because pressure atrophy occurs in every patient to some extent 740. The incidence of urethral atrophy leading to revision varies from 3% to 9.3% [253,259,262,423,736,741-743]. Atrophy can be lessened with nocturnal deactivation of the cuff [744].

b) Mechanical failure

The causes include perforation: of one of the components with loss of fluid from the system, air bubbles or organic debris within the system causing inadequate function of the pump, disconnection of one of the tubes, or kinking of a tube. Introduction of "kink-free" tubing has virtually eliminated this last complication. The incidence of these complications varies widely and ranges from 0% [741] to 52.5% [269] with the longest follow-up. In this latter study, the cuff seemed to be the most vulnerable part of the system (22 cuff failures in 18 patients, most of them occurring during the first 2 to 3 years following implantation), followed by pump failure (6 times in 4 patients). Blockage is an exceptional event, occurring only once in 61 patients followed from 10 to 15 years [269]. In a publication from Baylor [262], chronicling a 13-year experience with the AUS, mechanical failure occurred at an average of 68.1 months postoperatively. An unusual mechanical complication has been reported. The locking tab became displaced distally into the cycling portion of the cuff preventing the fluid from flowing into the cuff surrounding the urethra.[745]

c) Erosion and/or infection

Erosion and infection are two major complications that almost invariably necessitate removal of the prosthesis. Their incidence may be reported separately, or more commonly together as a single complication. The incidence of these complications varies from 0% to 24.6% [253,336,423,729,735,736,741-743,746,747]. Most recent large series report an incidence of infection and erosion generally less than 8% [56,261,262,274,738,739,748,749]. As would be expected, the highest incidence has been reported with the longest follow-up (10-15 years) [253]. Lai and colleagues [262] from Baylor reported that erosion occurred at an average of 19.8 months postoperatively rather than in the peri-operative period. Previous surgery [750] at the site of cuff placement increases the risk of erosion. This, however, may be decreased by delayed cuff activation [751]. A recent study by Lai et al. [752] noted that patients undergoing a "secondary" implant (after a prior explant for erosion or infection) had a four-fold higher erosion rate compared to "virgin" cases. Some authors, however, did not find an increased incidence of complications when a new cuff was implanted at the site where several months before, a cuff has been removed for infection or erosion [753]. Other risk factors include urethral catheterization and urethral endoscopic manipulations with an activated sphincter in place [754]. This point is important and it is crucial that patients with an AUS understand that if they are to have a catheter placed they should ask their physician to have a urologist deactivate the AUS first.

A likely etiology of early erosion is intra-operative laceration of the urethra when dissecting it from the corpora cavernosa, where a difficult anatomical plane exists. Intraoperative recognition of urethral injury can be facilitated by retrograde perfusion sphincterometry using a flexible cystoscope35. While recognition of a urethral injury may alert the surgeon to the necessary termination of the procedure, urethral erosion may still occur without a known urethral laceration [755].

As mentioned above, while the majority of authors consider previous radiotherapy a risk factor for increased infection and erosion, it is not a contraindication to implantation of an AUS in the male patient with PPI [252,254,276,332,713,739,756]. Overall patient satisfaction is similar in those who have been irradiated, compared to those who have not been [252,263,713]. Furthermore, the degree of satisfaction does not diminish with an increased number of surgical revisions [267,757].

d) Rare complications

Several unusual and rare complications have been reported in the literature, such as the intravesical migration of the reservoir with secondary stone formation in the bladder [758], or a giant urethral diverticulum at the site of a previously removed cuff because of erosion and urinary extravasation [759].

5. DURABILITY OF AUS COMPONENTS

When defining durability of one of the components or the AUS as a whole, one should distinguish

between explantation of the device due to device malfunction (e.g. leak in one of the components) or complications caused by an otherwise properly functioning sphincter unit (e.g. cuff erosion, infection at the site of implantation, etc.). This distinction is rarely made in the literature. Durability of a device is defined as time elapsed during which no mechanical problem alters the normal function of the device. This should exclude the second group from further analysis.

There are very few references in the literature pertaining to the length of time a device functioned normally before its removal due to mechanical failure. In a multicenter trial, for neurogenic bladders, conducted in France [736], the authors mention that the "mean operational life" of the sphincter was 56 months (range 3-118 months). Haab et al [259] analyzed 68 patients and noted that the mechanical failure rate dropped from 44.4% to 12.4% since modifications were made to the device, mainly the cuff component. Survival time of these components was not provided. Similar conclusions can be drawn from a series from the Mayo Clinic [265] where the modification of the cuff design (narrower back) resulted in a substantial drop of the reoperation rate at 5 years. In the "narrow back" group 17% (31/184) required reoperation. In that cohort, non-mechanical failure decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff [265]. Mean time to reoperation was 26.2 months (mean 2-68 months). Using Kaplan-Meier statistical analysis for this group of patients, the overall 5-year expected product survival was 75%. In Lai's report regarding Baylor's 13-year experience with the AUS, only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years [262]. In a review, Venn et al. [336] analysed the outcome of 100 patients in whom an artificial urinary sphincter was implanted for more than 10 years. Thirty-six percent of them still had the original sphincter and were continent at a median follow-up of 11 years. The bulbar cuff, as compared to the bladder neck cuff provided a slightly better continence rate at 10 years, 92% and 84%, respectively. The lowest erosion rate occurred with the bulbar cuff. Device survival rate at 10 years was 66% in this series.

In a series of 30 boys with spina bifida Spiess et al. [760] found that the mean lifetime of all AUS was 4.7 years, with no statistically significant difference in sphincter survival of those inserted at the bladder neck or the bulbous urethra (4.6 and 4.9 years, respectively). A sharp drop was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point. In a series of 35 adolescents with neurogenic voiding dysfunction implanted with a bladder neck cuff over an 11-year period, with an average follow-up of 5.5 years, Lopez Pereira and colleagues [761] reported a 20% mechanical failure rate, with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, who thereby required augmentation cystoplasty. However, continence was achieved in 91.4% of individuals.

In other series, the global long-term (2 to 7.7 years) revision rate, for any of the above mentioned reasons varies between 16% and 50% [261,262,266,267,424,757,761-763]. In Webster's report [757] of 554 implantations over a 10 year period, (i.e. performed since the 1987 device modification), he noted a mechanical failure rate of only 31/554 (5.5%). Non-mechanical failure was 88/554 (15.9%), with 63/554 (11.3%) due to urethral atrophy and 21/554 (3.8%) due to cuff erosion. Of the total cohort, 21.4% required at least one revision surgery, while 78.6% did not. Of those 119 patients who required reoperation, 76.5% required no further treatment (similar to the non-reoperation rate of the initial cohort), while 23.5% required re-operation for either mechanical or non-mechanical failure. Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence status was comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day urinary control. Patients with neurological deficits seem to have a higher risk of non-mechanical failure and the overall continence rate may be lower compared to non-neurologic patients [32].

6. DIAGNOSTIC PROCEDURES RELATED TO ARTIFICIAL SPHINCTER FAILURE

The diagnostic evaluation of urinary incontinence after the placement of the AUS is critical for the management of these patients and represents a challenging problem for the urologist. Several diagnostic and management algorithms have been proposed, some relatively simple, others more complex [32, 33, 276, 282, 737, 764-766]. **Figure 11** shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

Physical examination should exclude infection at the site of the cuff or the scrotal/labial pump. Difficulty compressing the pump suggests tube kinking, fluid loss or an obstructed system. Loss of fluid from the system may be suggested by the inability of the pump to appropriately refill after just one or two pumps.

Plain X-rays of the abdomen or pelvis may show fluid loss, if the system is filled with radioopaque solution [767, 768] (**Figure 1**). Alternatively, sonography of the pressure-regulating balloon may show volume loss. One should obtain a baseline plain film after the primary implantation when the reservoir is filled with contrast for subsequent comparison as radio-

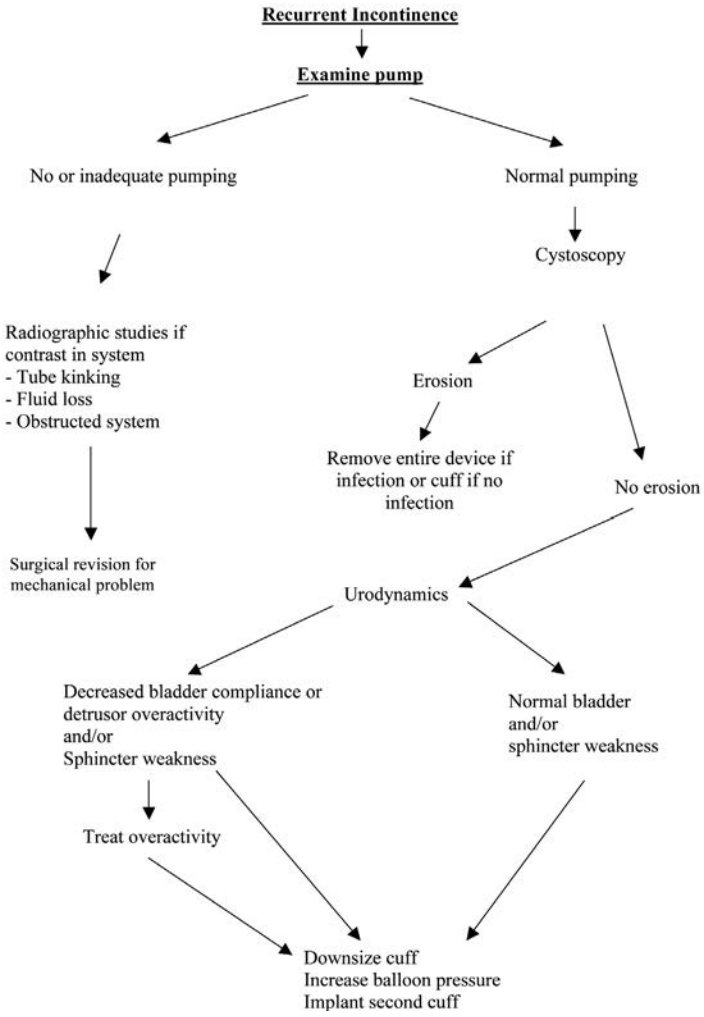


Figure 11. Algorithm for managing incontinence after AUS placement.

Figure 12. Endoscopic view of AUS cuff erosion into the bulbar urethra. The patient had undergone radiation after radical prostatectomy.

graphic imaging of the balloon does not detect changes until at least 50% of its volume has been lost [15]. Cystometrogram or complete urodynamic study will demonstrate changes in bladder behavior following insertion of the AUS as described above. Cystourethrography could eventually demonstrate a urethral diverticulum at the site of previous cuff erosion (**Figure 2**). Endoscopy will disclose any urethral erosion by the cuff (**Figure 12**).

Retrograde perfusion sphincterometry has been reported to diagnose the loss of compressive pressure in the urethral cuff [32]. It is done by infusing fluid from the meatus in a retrograde fashion. If the AUS cuff is functional and the urethral is intact there should be no flow when the pressure equals the AUS balloon pressure. This technique can also be used intraoperatively to detect urethral perforation or to adjust the pressure in the cuff [35]. This seems to be more useful than urethral pressure profile (UPP) [733].

Intraoperative electrical testing, using an ohmmeter [747,765] has been described to determine the site of fluid leakage from the system. This test can be helpful to avoid the need to change the whole system, and allow replacement of the leaking part only.

7. TREATMENT OF COMPLICATIONS

As outlined above, complications directly related to the presence of an artificial sphincter can be divided into categories: de novo OAB (which is typically treated as OAB), urethral atrophy, and/or mechanical failure, and infection/erosion. The treatment of these complications deserves comment, as no detailed reference can be found in the literature dealing exclusively with the treatment of these complications.

a) Atrophy of the urethra

Several therapeutic options exist to increase cuff pressure around the atrophied urethral wall: changing the balloon reservoir for one generating a higher pressure, downsizing the cuff diameter [15, 254, 769], or increasing the amount of fluid in the system. The most common approach is downsizing of the cuff. Another approach consists of placing the cuff inside the corporal tunica albuginea on the dorsal aspect of the urethra (transcorporal). This allows a safer mobilization of the urethra and adds some supplementary bulk of tissue to the circumference of the urethra, possibly decreasing the risk of erosion [272]. It should be mentioned, however, that there is a risk of reduced erectile function with this technique. The vast majority of such patients, however, already suffer from erectile dysfunction secondary to the prostate cancer surgery.

The implantation of a double-cuff AMS 800 had a recent period of increased popularity, as a primary procedure in the totally or severely incontinent patient [273,770], or as a salvage procedure, by adding a second cuff, following a failed previous single cuff [270,271,770]. Dimarco's group [271] and others showed excellent results with the addition of a second urethral cuff, placed 1.5–2.0 cm distal to the primary cuff. Alternatively, a circumurethral wrap of an organic bulking agent can be fitted, with subsequent placement of the AUS cuff over the biologic external urethral bulking agent [771]. Early reports of primary double cuff placement did not demonstrate any significant increase in morbidity with the double-cuff as compared with the single cuff system [273], and patient satisfaction also seemed to be higher [274] at an average of 21-41 months follow-up. However, O'Connor et al. [275] recently described their experience with 28 men who underwent double cuff placement and in contrast to an earlier report of theirs found that with longer follow-up there was no difference in continence between those men and 28 who underwent single cuff placement. In addition those who had the double cuff placement had a higher rate of additional surgery due to complications.

b) Mechanical failure

As with any device, mechanical failure can be expected with the AMS 800 AUS. The treatment involves surgical replacement of the failed component and reconnecting the system.

c) Infection

With overt infection the accepted treatment option is removal of the entire device and appropriate antibiotics. A second system can be subsequently implanted with equally good results [751]. It has been demonstrated, however, that immediate reimplantation of a new AUS after the removal of an infected, but not eroded, prosthesis can be a valid option with an overall success rate of 87% [772]. In 2007, AMS introduced the InhibiZone-coated artificial urinary sphincter (rifampin and minocycline hydrochloride coating) [773].

d) Erosion

In cases of urethral cuff erosion, the "offending" cuff must be removed. No clear guidelines exist whether removal of the whole system is superior to removal of the cuff alone but it must be assessed for infection and if present the whole device should be removed. When in doubt remove the entire system. Reservoir erosion into the bladder has been described following the removal of an eroded cuff [758]. Furthermore, it is not known whether it is nec-

essary to allow the urethra to heal over a catheter versus surgical repair. Most though would leave a catheter to allow for spontaneous healing and wait at least 4-6 months before placing another cuff. When a new cuff is placed it should be positioned away from the erosion site. In case of the erosion of one of the cuffs of a double system removal of the eroded cuff can successfully convert a double-cuff system into a single cuff system [774]. It is logical that intra-operative urethral injury may precipitate cuff erosion if unrecognized.

8. CONSENSUS PROTOCOL FOR FOLLOW-UP OF PATIENTS WITH AUS

As complications continue to be seen for years after implantation [775], it is helpful to have a structured follow-up plan. However, no standardized recommendations are available in the literature.

The consensus upon which the members of this subcommittee agreed and which is based on expert opinion are as follows:

1. Perioperative antibiotics are required. Gram-negative enteric bacteria and Staphylococcus epidermidis are the most frequently encountered microorganisms in infected prostheses [754].

2. Hospital stay should be kept to a minimum.

3. Urethral catheters, if inserted, should be withdrawn within 24-48 hours of surgery and the preoperative continence management continued.

4. The sphincter device should not be activated immediately postoperatively. In the initial period scrotal edema and pain prevent patients from manipulating the pump adequately. When this subsides after 6 to 8 weeks the device can be activated. Earlier activation may also be acceptable. Irradiated patients may benefit from a longer initial period of deactivation, up to 12 weeks [254]. Nocturnal deactivation should be considered in high-risk patients [253].

5. Patients are reviewed at 3 months after activation to ensure the device is working adequately, and to assess the continence status.

6. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time, alteration in bladder function may jeopardize renal function in the neurogenic patients. Periodic ultrasound evaluation of the upper urinary tract and monitoring of renal function is essential. If changes occur, urodynamic studies should be done to rule out detrusor overactivity. In non-neurogenic patients, periodic ultrasound may not be necessary.

7. When changes in the continence status occur diagnostic procedures depicted in **Figure 11** should be considered.

(Level of evidence 3; Grade of recommendation B-C)

XII. SUMMARY AND RECOMMENDATIONS

1. EVALUATION OF MALE INCONTINENT PATIENTS

Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (**Level of evidence 1-2: grade of recommendation A**).

- A voiding diary is helpful to assess functional capacity and total urine output (**Level of evidence 1-2: grade of recommendation B**).
- Pad tests may be useful in certain circumstances (**Level of evidence 1-2: grade of recommendation B**).
- Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria or poor urinary concentrating ability (in the absence of diuretics) is documented.
- Additional testing with cystoscopy and appropriate imaging of the urinary tract may be helpful in guiding therapy **(Level of evidence 2-3: grade of recommendation B).**
- The committee felt that multichannel urodynamics may be useful prior to invasive treatment for incontinence. **(Level of evidence 3: grade of recommendation C)**

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

After a period of conservative management, which may also be from 6 to 12 months **(Level of evidence 3-4; grade of recommendation C):**

- The artificial sphincter is the preferred treatment for properly selected men who have stress incontinence after radical prostatectomy with the longest record of safety and efficacy. The AUS has been reported extensively for men with moderate to severe incontinence. **(Level of evidence 2-3; grade of recommendation B)**
- Male slings are an alternative approach with intermediate data supporting their safety and efficacy in men with more moderate degrees of PPI. Long-term data are beginning to accumulate. However,

the literature contains results on many different kinds of slings. **(Level of evidence 3; grade of recommendation C)**

- Injectable agents are an inferior option. **(Level of evidence 3-4; grade of recommendation C)**
- Adjustable balloons have also been reported. **(Level of evidence 3; grade of recommendation D (no recommendation possible))**

3. INCONTINENCE FOLLOWING OTHER TREATMENTS FOR PROSTATE CANCER

- The artificial sphincter is most widely used but ra§diation may be a risk factor for an increase in complications. **(Level of evidence 3; grade of recommendation B)**
- Slings have variable results after radiation. **(Level of evidence 3; grade of recommendation C)**
- Injectable agents **(Level of evidence 3-4; grade of recommendation C)**
- Adjustable balloons have not been successful in this setting. **(Level of evidence 3; grade of recommendation D (not recommended))**

4. INCONTINENCE FOLLOWING PELVIC TRAUMA (Level of evidence 3; grade of recommendation C)

- The artificial sphincter is most widely reported.
- Lower urinary tract reconstruction has also been reported on a limited basis.

5. INCONTINENCE IN ADULT EPISPADIAS-EXSTROPHY COMPLEX (level of evidence 3; grade of recommendation C)

- Patients should be treated in centres of excellence.
- A patient-directed approach should be taken.
- The choices include further bladder neck reconstructive surgery, bladder neck closure, bladder reconstruction or diversion with bowel.
- The data are insufficient for a specific recommendation.
- Transition is important between the pediatric and adult urologist.
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications

6. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

- Botulinum toxin-A bladder injection is a minimally invasive treatment with efficacy **(Level of evidence 1-2; grade of recommendation B).**
- Neuromodulation is a treatment option with success reported in a limited number of male patients. **(Level of evidence 3; grade of recommendation C)**
- Detrusor myectomy has also been reported to be successful in a small number of male patients. **(Level of evidence 3; grade of recommendation C)**
- Augmentation cystoplasty is potentially successful in controlling symptoms but may be associated with unacceptable side effects**. (Level of evidence 3; grade of recommendation C)**
- Urinary diversion is a final option. **(Level of evidence 3; grade of recommendation C)**

7. REDUCED CAPACITY BLADDER

- Augmentation cystoplasty has been successful in most etiologies. **(Level of evidence 3; grade of recommendation C)**

8. URETHROCUTANEOUS FISTULA AND RECTOURETHRAL FISTULA (Level of evidence 3; grade of recommendation C)

- Etiologic factors causing acquired urethrocutaneous fistulae are demonstrated by clinical, endoscopic and imaging studies.
- Similar diagnostic maneuvers are applied to rectourethral fistulae.
- Surgical reconstruction is applied as required.
- In those that do not close with or without temporary urinary and fecal diversion, surgical reconstruction may be carried out.
- Most repairs are now carried out after prior fecal diversion.
- Various techniques are available for closure and can be done in collaboration with colorectal surgeons.

9. MANAGEMENT OF AUS COMPLICATIONS (Level of evidence 3; grade of recommendation C)

- Incontinence may result from alteration in bladder function, urethral atrophy, or mechanical malfunction.
- Infection and/or erosion of components demand surgical removal of all or part of the prosthesis.
- A treatment algorithm is presented to aid in management and in follow-up of patients.

10. NEW TECHNOLOGIES (Level of evidence C; grade of recommendation D)

- Tissue engineering has not been widely reported in males apart from isolated reports of preliminary studies. [776, 777]
- A new one-piece adjustable artificial sphincter has been reported with social continence (0-1 pads/day) in 28/36 men at 6 months after device activation. [778] The removal rate was 11% for erosion/infection.

FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices should continue to be evaluated
- Accuracy in reporting of early research results is mandatory
- Mechanisms of post-prostatectomy incontinence and device effects need further research

CLINICAL TRIAL RECOMMENDATIONS

- Randomized trials (AUS and slings)
- Standardized workup and outcome measures including QoL
- Evaluation of the role of urodynamics in the workup
- Complete reporting of complications and outcomes especially those of slings
- Standardised definitions of cure/improved/unchanged/worse
- Reporting of procedures to salvage failures
- Long-term results (>2 years)
- Standardized reporting of durability

A. Introduction

This chapter is intended to present a further assessment of surgical interventions for urinary incontinence in women. The intent of this chapter is to build upon data that were previously collated for the ICUD Report of 2009. This chapter updates the current status of surgical interventions for stress urinary incontinence and includes additional data that have been forthcoming regarding new interventions (such as transobturator tapes and single incision slings).

The further enhancement on sections related to clinical research and specific outcomes reporting on clinical trial design has been updated with experience from recently reported multi-institutional trials which assess surgical interventions for incontinence.

SEARCH STRATEGY

Material collected for this chapter was based on electronic searches of Medline, EMBASE, Cinhai, Cochrane Database of Systematic Reviews and the NICE website (www.nice.org.uk). Review papers were separately searched for additional references not identified by initial database search. Individual papers where then selected from April, 2008 to present in European, UK and North American journals of Urology, Gynecology, and Urogynaecology. Additionally, conference preceedings from 2008 were also reviewed inclusive of ICS, IUGA, AUA, AUGS. Hence, some more recent abstracts are included in the following reviews based upon time to press and non-identification of associated publications with those abstracts. Approximately 454 articles were identified for inclusion in addition to the original 762 which were included in the 2009 chapter. Search terms included; Urinary incontinence: stress, mixed, urge. Surgical procedures; minimally invasive, urogenital, gynaecologic, urologic, urinary tract, urethra, vagina, bladder, ligaments; colposuspension, vesicosuspension, urethrosuspension; vesicourethral or urethrovesical; colpourethrosuspension; colpofixation; Burch; Marshalls, Marchetti, Krantz; paravaginal, pubococcygeal, obturator; bladder, neck needle; ligament fixation; colporraphy; anterior or vagina; Surgical mesh; sling, bladder, surgical or synthetic, or biological or autologous; tape; urethra, suburethra, midurethra, transurethra, pubovesical; retropubic, suprapubic; pubovaginal, implant: Bologna, Ingelman, Sundberg; Prostheses: injections; bulking agents, Contigen; collagen; Macroplastique, silicones; microparticulate; hyaluronic acid; carbon particles; polytetrafluoroethylene; biocompatible materials; urinary sphincter, artificial.

Since the last review more high quality evidence is available based upon randomised controlled trials at multi-institutional programs. Level I, Level II and Level III evidence are included in the current publication. Additionally, systematic reviews where appropriate have also been included to update those referenced in the 2009 chapter. Additionally, national and international guidelines such as the National Institute for Health and Clinical Excellence (NICE) in the UK were also included where appropriate for complete summation of current status of interventions for stress urinary incontinence in women. It is to be noted that transobturator tape data are now of sufficient maturity to be included at length in addition to other midurethral data, both regarding standard retropubic as well as single incision approaches.

I. SURGERY FOR STRESS INCONTINENCE (INCLUDING COMPLICATIONS)

1. URETHRAL BULKING AGENTS

Since the last International Consultation, bovine collagen (Contigen®) has become obsolete due to manufacturing cessation. Currently available agents include; calcium hydroxyl apatite (Coaptite®), carbon coated Zirconium (Durasphere®), polydimethylsiloxane elastomer (Macroplastique®) and polyacrylamide hydrogel (Bulkamid®) . Additionally limited data has been published regarding non-animal stabilized hyaluronic acid/dextranomer NASHA-dx (Zuidex®). Recent experience has also been reported with adult stem cells for the indication of stress urinary incontinence.

Urethral bulking agents may be injected either transurethrally or periurethrally in a retrograde manner, using either ultrasonographic, direct cystoscopic or implacer-guided device implantation. Device implantation optimally occurs in the proximal urethra, either single or multiple injections with strategic planning for reinjection at some point after initial injection. Clinical trials have defined specific injection schedules (usually three injections) as part of trial therapeutic algorithms. Optimal injection technique has yet to be standardized, although it does appear that urethral mucosa visualization at procedure completion is not predictive of final outcome. Prior systematic reviews have formed the basis of NICE guidance [National Collaborative Center for Women's and Children's Health, 2006, National institute for Health and Clinical Excellence, 2006b]. Methodologic problems with most non-regulatory trials limit the ability to generalize the results of those trials to clinical experience.

Ghoniem, *et al* [2009][1] reported a randomized controlled trial of polydimethylsiloxane elastomer versus Contigen in 247 women. Repeat injection was allowed at three months after initial delivery for persistent incontinence. Efficacy was determined at one year post last injection using Stamey Grade scoring, pad weight change and quality of life assessment. 122 patients received polydimethylsiloxane elastomer. Additionally, 125 patients received Contigen. At one year post treatment, 61.5% of patients who received polydimethylsiloxane elastomer had improved by one Stamey Grade as compared to 48% of controls. The cure rate at one year was 36.9% of the Macroplastique group and 24.8% in the Contigen group, which was statistically significant. Pad weight changes (one hour pad weight) were 25.4 mL from baseline in the polydimethylsiloxane elastomer group and 28 mL in the Contigen group. Both groups had improvement in quality of life assessments (28.7% and 26.4% respectively).

Ghoniem, *et al* recently reviewed clinical outcomes associated with the use of polydimethylsiloxane elastomer as a bulking agent for stress incontinence. They identified a total of 958 patients in 23 cohorts in their review. Overall, short term (defined as less than six months) improvement rates were 75% with 64% improvement rates long-term (greater than 18 months). Cure rates were 43% at less than six months and 36% at greater than 18 months using a variety of definitions including pad weight, number of pads used and subjective reporting. The authors noted that as re-injection rates increased, there was improvement in long-term stress incontinence outcomes. Safety events associated with injection included retention, irritative voiding symptoms, dysuria, and urinary tract infection. [Ghoniem, 2012] [2]

The same study population was assessed at 24 months from last injection in subsequent publication. At that time, 67 patients in the polydimethylsiloxane elastomer arm were available for follow-up of whom 45 or 67% were continent. Of those patients who were dry at 12 months [38], 33 remained cured at 12 months. Additionally, 12 of 29 patients improved at 12 months, progressed to urinary continence at 24 months. Global quality of life scores and subscales all were statistically improved from baseline. Pad weight changes decreased from 24 grams at baseline to 4 grams at 12 and 24 months. There was no long-term complication noted in this population. [Ghoniem, 2010].[3]

Polyacrylamide hydrogel has also been reported as a potential agent for bulking. Lose, et al [2010],[4] reported on the use of polyacrylamide hydrogel in 135 women with urinary incontinence (either stress or mixed) who were followed-up for 12 months after injection. Of that group, 47 (35%) required repeat injection. At one year, overall subjective response rate was 66%. Incontinence episodes per 24 hours decreased from baseline of 3 to 0.7 at one year. Additionally, overall urine leakage by pad gram weight decreased from 29 grams at baseline to 4 grams at end of trial. Overall ICIQ demonstrated improvement in quality of life. The most frequent adverse event in this trial was urinary tract infection (10 patients).

Toozs-Hobson, et al, [2011][5] reported a two year follow-up of polyacrylamide hydrogel in 135 women. At twenty four months, 64% of patients remained responders (as compared to 67% at twelve months). Responder was defined as subjective improvement. Overall decreases in urinary incontinence episodes and volume of urine incontinence (pad weight) were stable as compared to twelve months evaluation, as were other objective outcomes and quality of life data.

Gopinath [2011][6] reported a periurethral abscess associated with the use of this agent which required surgical drainage.

Non-animal stabilized hyaluronic acid/dextranomer has been compared to bovine collagen by Lightner, et al [2009].[7] This trial utilized an implacing device for non-animal stabilized hyaluronic acid/dextranomer injection. Bovine collagen was delivered endoscopically under direct vision. This trial failed to demonstrate equivalence of non-animal stabilized hyaluronic acid/dextranomer to direct vision injected bovine collagen in all primary and secondary outcome variables. 84% of women who were injected with bovine collagen experienced a 50% reduction in urinary incontinence in provocative testing versus 65% in the non-animal stabilized hyaluronic acid/dextranomer group. Of note, non-animal stabilized hyaluronic acid/dextranomer was associated with injection site sterile abscesses in 8.4% of patients, injection site mass in 4.4% of patients and pseudo cyst formation in 2.2% of patients. Irritative voiding

symptoms and injection site pain were more common with non-animal stabilized hyaluronic acid/dextranomer than with bovine collagen.

Lightner, et al [2010][8] reported a single institutional review of 56 patients who underwent implantation with non-animal stabilized hyaluronic acid/ dextranomer. This trial included 35 women and 6 men. Of the women, 4 developed pseudo abscess formation requiring multiple operative interventions also associated with a high rate of failure amongst all women with ISD.

Mohr, et al [2012][9] reported a large series of 514 women treated with bulking therapy with either collagen, hyaluronic acid, ethylene vinyl alcohol (no longer marketed,) or polyacrylamide hydrogel. Outcomes were reported using standardized pad tests, visual analogue score for severity of incontinence and Kings Health Questionnaire. 61 patients in the entire study were lost to follow-up. Overall pad testing was negative in 73.2% of women after bulking therapy with statistical improvement in both pad weight and visual analogue score changes for each of the agents used at one year post implantation. Re-injection was permitted six weeks after initial injection in this study.

The role of bulking agents as salvage therapy for women who undergone prior mid-urethral sling procedures and were no satisfied with postoperative results was assessed by Lee, et al [2009].[10] The authors reported 23 women who had undergone mid-urethral slings who then received therapy with polydimethylsiloxane elastomer or carbon coated zirconium beads. They noted a cure rate of 34.8% at a median follow-up of ten months and improvement in secondary outcomes. Overall, 92% of patients reported benefit from therapy and the authors reported no complications.

Isolated reports of bladder masses or urethral outlet obstruction continue to emerge in the literature. Crites, et al [2010][11] reported a single case of bladder mass post bovine collagen injection which required transurethral resection for improvement of symptoms. Kumar, et al [2011][12] reported a pseudo-diverticulum of the urethra due to an encysted collagen implant.

Recently an update to the Cochrane Analysis of Urethral injection therapy has been published [Kirchin, 2012]. [13] This analysis identified 14 further trials for non-injectable agents. The Cochrane Analysis concluded there was no difference in manner of delivery (peri- versus trans-urethral injection) method, although there was a trend towards higher early complications with peri-urethral injection. Additionally, weak evidence supports mid-urethral injection resulting in improved patient satisfaction compared to bladder neck injection. The Cochrane analysis also concluded that all bulking agents appeared to provide similar overall improvements as compared to bovine collagen. Non-animal stabilized hyaluronic acid/ dextranomer appeared to be associated with higher rates of injection site complications (16% with non-animal stabilized hyaluronic acid/ dextranomer as compared to none with bovine collagen). In the few trials that have compared injection therapy with surgical management, better overall objective cure was obtained in surgical as compared to the injection groups.

The overall conclusion of the Cochrane analysis was that the evidence base remained insufficient to guide practice, specifically regarding optimal choice regarding bulking device, mechanism delivery, or identification of the optimal patient for bulking.

Research in autologous stem cell based urethral bulking continues. To date, no large scale randomized trials have been published, although, abstracts have been presented at various meetings. Durability and length of follow-up will be critical to assess the contribution of this possible bulking option. [Du,2012][14]

Recommendation

Bulking agents provide an option in the management of women with stress incontinence. Optimization of results is dependent upon repeat injections to achieve and sustain efficacy. Additionally, efficacy with at least some bulking agents appears to diminish with time and may be inferior to surgical interventions. Overall complication rates associated with bulking agents appear to be relatively low (Grade B). Continued development of new materials for injection should be under strict regulatory guidance and evaluation using RCT design construct and long-term follow-up (at least 12 months after last injection) (**Grade D**) (**Evidence level II/III**).

2. RETROPUBIC MID-URETHRAL SLINGS (MUS)

The tension-free vaginal tape (TVT) procedure for treatment of female stress urinary incontinence was first introduced by Ulmsten et al. in 1996. [15] The development of the TVT operation was an attempt to support the middle portion of the urethra, instead of restoring anatomy and correcting urethral hypermobility at the bladder neck. The idea of supporting the “mid-urethra” has been derived from the results of several research projects conducted during the last thirty years. The work of Zaccharin in 1968 and DeLancey in 1994 had already shown that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was closer to the middle portion of the urethra than the bladder neck. [16, 17] In 1978, Owman et al. found that the most densely innervated portion of the urethra was the middle part and Huisman in 1983 showed in histological studies that the mid-urethra had the most abundant vascularisation. [18] Additionally, Westby et al. in 1982 showed in radiographic studies how the urine stream was interrupted at the mid-urethra

on holding in continent women and Asmussen et al. in 1983 showed that the maximal urethral closure pressure was situated at the midurethra.[19, 20] It quickly became apparent that focusing on the mid-urethra might bring improvement in the performance of incontinence surgery.

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90 % in primary cases of SUI [Ulmsten et al., 1996; Ulmsten et al., 1998; Nilsson, 1998; Ulmsten et al., 1999; Nilsson et al., 2001], [15, 21-24] in recurrent cases [Rezapour and Ulmsten, 2001; Kuuva and Nilsson, 2003],[25, 26] in mixed incontinence cases [Rezapour and Ulmsten, 2001], [25] and in an unselected group of women including primary, recurrent and mixed incontinence as well as women with intrinsic sphincter deficiency [Nilsson and Kuuva, 2001]. [24] Since those initial reports of success, several groups have reported long-term outcomes exceeding 5 years [Ankardal et al., 2006; Doo et al., 2006; Deffieux et al., 2007; Chene et al., 2007; Song et al., 2009] and 10 years after the TVT procedure [Nilsson et al., 2008; Olsson et al., 2010][27] [28] A variety of follow-up regimens and definitions of success reveal that the effects of the TVT on resolution of SUI are durable over the long-term.

Since the last ICI review was conducted, the literature regarding the TVT and other retropubic MUS procedures has expanded at an almost exponential pace. As an example, only 12 RCTs comparing MUS to other procedures were available for review and most of these were small (<50 patients in each arm) and underpowered. The number of RCTs and large cohort studies available today significantly exceeds the previous review, and, unless otherwise mentioned, only fully-published studies have been included herein.

a) Retropubic MUS vs. no treatment (*table 1*)

A multicentre, prospective RCT performed by Campeau et al. enrolled 69 elderly who initially consented to be randomised to either undergo immediate TVT surgery or to wait for 6 months before submitting to the same surgery (control group). [29] The main outcomes measured at every visit (pre-randomisation, 8-12 weeks and 6 months) consisted of the Incontinence-Quality of Life (I-QOL) Questionnaire, the Patient Satisfaction Questionnaire and the Urinary Problems Self-assessment Questionnaire. The analysis included 31 patients in the immediate surgery group and 27 subjects in the control group. Perioperative complications in the immediate surgery group were bladder perforation (22.6%), urinary retention (12.9%), urinary tract infection (3.2%) and *de novo* urgency (3.2%). At 6 months, the mean scores on each questionnaire were significantly in favour of the TVT group. [EL=1/2]

b) Retropubic MUS vs. open colposuspension (*table 1*)

Since the ICI-4 review, only 3 additional studies have published comparing TVT and open colposuspension [McCracken et al., 2007; Tellez Martinez-Fornes et al., 2009; Wu et al., 2010]. [30-32] In a nonrandomised trial with significant failed-to-complete-follow-up, McCracken et al. found no difference in subjective success rates via questionnaire between colposuspension and TVT at 5 to 10 years. [30] In an RCT randomising 49 women to TVT or colposuspension, Tellez Martinez-Fornes found no significant difference in subjective success rates (cured/improved) between the 2 procedures at follow-up periods of 6, 12, and 36 months. [31] In a retrospective, nonrandomised trial comparing 105 women who underwent TVT with 81 women who underwent MMK, the authors found that while the short-term success rate of the MMK was 89%, the rate fell to 68.2% at 5 years and 32% at 10 years. [32] In comparison, the short-term success rate of the TVT was statistically similar to the MMK (90%) but decreased only to 84.3% at 5 years. Women who underwent TVT also experienced shorter operative time, less blood loss, and shorter hospital stay. [EL=3/4]

Four of the studies from ICI-4 comparing TVT with open colposuspension used objective outcome measures for defining cure: 1 hour pad test [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Ward et al., 2004; Ward et al., 2008], [33-37]cystometry [Ward et al., 2002], [33] and a cough-stress test [Ward et al., 2002; Ward et al., 2004; Bai et al., 2005].[33, 36, 38] One study only used subjective outcome measures [El-Barky et al., 2005]. [39] None of these studies found any statistical differences in objective cure rates between the two operations. The cure rate ranged between 63 and 87 % in the TVT groups and between 51% and 90 % in the open colposuspension groups. The time period of follow-up was between 3 and 24 months in all five trials except the 5-year extension of the U.K. & Ireland TVT Trial Group [Ward et al., 2008]. [37] These 5-year outcome data are hampered by a significant lost to follow-up rate (58% in the TVT group and 67 % in the colposuspension group). The criteria of subjective cure were for the most part poorly defined and validated QOL questionnaires were only used in the 2002 study.[33] There was no difference in subjective cure between the TVT and the colposuspension groups. [EL=1/2]

As in the study by Tellez Martinez-Fornes, operative time, hospital stay and time for resuming normal activity was significantly shorter in the TVT groups [Ward et al., 2002; Liapis et al., 2002; El Barky et al., 2005].[33, 34, 39] Ward et al. [2002] found that the percentage of intraoperative bladder perforations was significantly greater in the TVT group (9%) than in the colposuspension group (3%), while El Barky et al.

**: Included in ICI-4*
^: Included in Systematic Review (Novara, 2010)
†: Included in Cochrane Review (Ogah, 2011)

Key: RP MUS=retropubic midurethral sling; F/U=follow-up (months); LE=level of evidence; TVT=tension-free vaginal tape; o=objective; s=subjective; N/A=not available; OC=open colposuspension; LC=laparoscopic colposuspension; ITT=intention to treat

reported no perforations in the colposuspension group and two in the TVT group ($p< 0.05$). [33, 37] Wound infections were more common in the colposuspension group ($p<0.05$). Significantly more patients experienced delayed voiding in the colposuspension group in the Ward et al. [2002] study and in the 2 years follow-up report of the same study there were significantly more patients in the colposuspension group needing intermittent self catheterisation ($p<0.0045$) and surgery for pelvic organ prolapse ($p<0.0042$). [33, 36] [EL=1/2]

The Cochrane review comparing the outcomes of minimally-invasive suburethral sling operations with open colposuspension included 9 trials, and included 5 of the trials mentioned above [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Bai et al., 2005; El Barky et al., 2005].[40] The remainder of the studies were either in abstract form or provided a comparison between transobturator MUS and colposuspension. A total of 729 women studied within the first 12 months after surgery showed subjective cure rates of 79% with MUS and 82% after open colposuspension. This difference was not statistically significant (RR 096, 95% CI 0.90 to 1.03). In 2 trials [including Ward et al., 2004] follow-up at 2 years also failed to show a statistically significant difference (RR 1.11, 95% CI 0.91 to 1.34). In the 3 trials evaluating objective cure rates [including Liapis et al., 2002, and Wang et al., 2003], there was no significant difference at 12 months (RR 1.04, 95% CI 0.94 to 1.14), after 2 years (RR 1.01, 95% CI 0.92 to 1.11) and after 5 years (RR 0.90, 95% CI 0.77 to 1.04). [EL=1/2]

A limitation to the conclusions that can be drawn from the aforementioned study results is the fact that most of the trials include fewer than 50 patients in each arm and lacked any mention of power calculations. The trials by Ward et al. enrolled a greater number of patients and included power calculations, but did not reach the required number of patients. [33, 36, 37]

*c) Retropubic MUS vs. laparoscopic colposuspension (***table 1***)*

Four of the 12 RCTs in ICI-4 comparing retropubic MUS with traditional incontinence procedures compare TVT with laparoscopic colposuspension [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41] [40] [39] [38] [37] [36] [35] [34] [33] [32] [31] [30] [29] [28] [27] [26] [42, 43] Two additional trials have been published since that review [Foote et al., 2006; Tong et al., 2008] as well as an update of the Paraiso et al. study [Jelovsek et al., 2008]. [44-46] The Cochrane review included 5 fully-published manuscripts [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004; Foote et al., 2006] along with 2 abstracts. [40]

In the studies comparing TVT or Supra Pubic Arc Sling (SPARC; a monofilament polypropylene MUS placed through a top-down approach) with laparoscopic colposuspension objective cure was assessed by a pad test in 2 of the 6 studies [Persson et al., 2000; Valpas et al., 2004], [43, 47] and by a cough-stress test in 3 of the studies [Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41, 42, 47] The criteria for cure or improvement were unclear in the study by Foote et al. [44]. The trial by Valpas et al. with the greatest number of patients enrolled showed a significantly higher objective and subjective cure rate in the TVT group than in the laparoscopic colposuspension group ($p<0.0001$), [47] while the other studies showed similar cure rates for both procedures ranging between 72.9% and 96.8% in the TVT groups and between 58.8% and 87% in the laparoscopic colposuspension groups. It was thought that the Valpas et al. trial may have shown a significant difference in outcomes in favour of TVT due to a difference in laparoscopic technique (using mesh rather than sutures to perform colposuspension). [40] In their trial, Paraiso et al. performed postoperative multichannel urodynamic studies in 32 laparoscopic Burch colposuspension and 31 TVT patients showed a higher rate of urodynamic stress incontinence at 1 year in the laparoscopic Burch colposuspension group, 18.8% versus 3.2% ($p=0.056$).[41] There was a significant improvement in the number of incontinent episodes per week and in UDI and IIQ scores in both groups at 1 and 2 years after surgery ($p<0.001$). However, postoperative subjective symptoms of incontinence (stress, urge, and any urinary incontinence) were reported significantly more often in the laparoscopic Burch colposuspension group than in the TVT group ($p<0.04$ for each category). At long-term follow-up of the previous study, Jelovsek et al. confirmed that the TVT has similar efficacy to the laparoscopic Burch for the treatment of SUI. [100] While not always bothersome, the authors cited a substantial number of women in either group who had some degree of incontinence 4 to 8 years after surgery. Although laparoscopically-performed colposuspension is regarded as a less-invasive operation than the open colposuspension the MUS procedures had significantly shorter operating time, hospital stay, and time for resuming normal activity than the laparoscopic colposuspension. [40] [EL=2]

As with the studies comparing open colposuspension with MUS, the conclusions of studies comparing MUS with laparoscopic colposuspension may be limited due to underpowering. Dean et al. performed a systematic review of laparoscopic colposuspension (n=264) and TVT (n=290) which included 7 trials. [101] There was no statistically significant difference in the reported subjective cure rate between laparoscopic colposuspension and TVT within 18 months (RR 1.12, 95% CI 0.98 to 1.29). However, within the same time period, the overall objective cure rate was statistically significantly higher for TVT (RR 1.16, 95% CI 1.07 to 1.25). There were no significant differences be-

tween the two procedures with regards to perioperative complications, *de novo* detrusor overactivity, voiding dysfunction, procedural costs and QoL scores. The authors confirmed that the TVT procedure was quicker to perform and was associated with a shorter hospital stay. [EL=1/2]

A systematic review by Novara et al. evaluated open and laparoscopic colposuspensions together with retropubic MUS. [48] Women receiving MUS had significantly higher overall (OR 0.61; 95% CI 0.46 to 0.82, p=0.00009) and objective (OR 0.38; 95% CI 0.25 to 0.57, p<0.0001) cure rates than those receiving colposuspension. A clinical and economic subanalysis of the Valpas et al. study suggested that over a follow-up period of 1 year the TVT is more cost-effective than laparoscopic mesh colposuspension as a primary treatment for female SUI. [103] [49][EL=1/2]

d) Retropubic MUS vs. traditional sling

This comparison will be addressed in the section on traditional pubovaginal slings.

e) Retropubic MUS vs. retropubic MUS (*table1*)

The favorable results obtained with the TVT operation have resulted in several modifications of the procedure and the use of different tape materials. These retropubic modifications have been poorly clinically evaluated and only 6 randomised studies comparing these with the TVT have been published. The meta-analysis by Novara et al. did not evaluate the comparison between different types of retropubic MUS procedures. [48] In ICI-4, 3 RCTs compare the TVT with the SPARC [Andonian et al., 2005; Tseng et al., 2005; Lord et al., 2006]. [50-52] The study by Lord et al. included 147 TVT and 154 SPARC cases and showed no statistical difference in estimated blood loss of >100 mL (TVT, 21.8% vs. SPARC, 18.2%), *de novo* urgency (TVT, 40.5% vs. SPARC, 42.4%), objective cure (TVT, 97.3% vs. SPARC, 97.4%) or vaginal mesh extrusion (TVT, 4.8% vs. SPARC, 10.5%). [51] Acute urinary retention (TVT, 0% vs. SPARC 6.5%; OR ∞, 95% CI 2.2-∞; p=0.002) and subjective cure (TVT 87.1% vs. SPARC 76.5%; OR 2.07, 95% CI 1.13-3.81; p=0.03) were statistically significantly different. Tseng et al. reported a 12.9 % of bladder perforation in the SPARC group with none in the TVT group. [52] While the difference did not reach statistical significance in this small study (31 patients in each group), the authors felt it to be clinically significant. [EL=1/2]

Four additional non-randomised studies compared TVT with SPARC [Dietz et al., 2004; Gandhi et al., 2006; Kim et al., 2006; Paick et al., 2008].[53-56] In the Dietz et al. study, there were no significant differences for subjective cure/improvement, patient satisfaction, or symptoms of incontinence. [56] The cough-stress test was positive in 8 of 37 women who underwent SPARC compared to 4 of 69 TVT patients (p=0.019). The TVT had a more negative effect (p=0.001) on postoperative voiding. In the Gandhi et al. study, 107 of 122 women returned for objective postoperative evaluation after surgery. [55] The TVT procedure was associated with higher subjective (86% vs. 60%, p=0.001) and objective (95% vs. 70%, p<0.001) SUI cure rates, while there was no difference between the TVT and SPARC groups in the resolution of subjective and objective UUI. Kim et al. found no difference in objective cure rates at 1 year of follow-up and complication rates were similarly low. [54] Paick et al. found no significant difference in cure of SUI or cure of all incontinence between TVT and SPARC at 6 months. [53] [EL=3/4]

In ICI-4, 3 RCTs compared TVT with the intravaginal slingplasty (IVS) procedure, which utilises a multifilament, miniporous polypropylene tape material [Rechberger et al., 2003; Lim et al., 2005; Meschia et al., 2006]. [57-59] Only the study by Lim et al. was included in the Cochrane analysis. [40] In the study by Meschia et al. that included 95 patients in each group, the objective cure rate was 85% for the TVT and 72% for the IVS and the subjective cure rate was 87% and 78%, respectively, with no difference between groups. [58] There was a 9% vaginal extrusion rate during the 2 years of follow-up in the IVS group, and 0% extrusion in the TVT group. Rechberger et al. found no significant difference in cure rates between the groups at a mean of 13 months of follow-up.[57] Lim et al. compared TVT with both IVS and SPARC, with 65 patients in each group. [58] The subjective cure rates between 6 and 12 weeks of follow-up were 87.9% in the TVT group, 81.5% in the IVS group and 72.4% in the SPARC group, the differences not being significant. Interestingly, the authors found a significantly greater rate of tape extrusion in the SPARC group compared to both TVT and IVS (p<0.04). An additional retrospective study found a significant difference in favour of TVT in objective SUI cure rate at 3, 12, and 60 months compared with IVS, while the subjective cure rates did not differ significantly at any of those time intervals (Prien-Larsen & Hemmingsen, 2009]. [60] Vaginal extrusions were found in 11.8% of the women in the IVS group compared with 0% in the TVT group. [EL=1/2]

Most concerning is the report by Balakrishnan et al. in which they followed the subgroup of IVS patients of the Lim et al. study for up to 30 months and found that 13% had sling extrusions requiring sling removal. [61] Additionally, of the 29 patients (47%) of the initial IVS group who were seen 12 to 34 months post-operatively, 24% experienced sling erosion with sinus formation requiring sling removal. Further infectious complications, like retropubic abscess and pyogenic granuloma associated with

vaginal extrusion, indicate that the IVS may behave clinically like microporous synthetic materials rather than other polypropylene slings.[62, 63] [EL=3/4]

Two additional studies compared TVT against other retropubic midurethral MUS procedures. Agarwala found no difference in subjective (94% vs. 92%) and objective (96% vs. 94%) cure rates in 96 women consecutively assigned to TVT or to Lynx mid-urethral sling (Boston Scientific; monofilament polypropylene), respectively. [64] Yoon et al. compared TVT to the IRIS (innovative replacement of incontinence surgery) with a follow-up of 3 years. [65] The instrument of the IRIS system is comprised of a nondisposable metal handle to which two metal needles can be attached. The needles have an outer diameter of 5-6 mm and the non-absorbable polypropylene tape, which is 11 mm wide and 450 mm long with a plastic sheath cover, is fixed to the needles. The tape of the IRIS system is polypropylene monofilament mesh (Trelex; Meadox Medicals, Oakland, NJ/Boston Scientific, NJ, U.S.A.), and the diameter of the pore size is greater than 75 µm such as the tape of TVT. Success rate encompassing both objective and subjective criteria were not statistically different between the 2 procedures at 12 and 36 months. Likewise, the incidence of perioperative complications and postoperative voiding dysfunction was not statistically different. [EL=3]

The Cochrane review encompassing 4 aforementioned RCTs [Andonian et al., 2005; Lim et al., 2005; Tseng et al., 2005; Lord et al., 2006] and an abstract, found that, in 492 women studied within the first 12 months after surgery, women were significantly more often subjectively dry with the TVT than SPARC (85% vs. 77%; RR 1.10, 95% CI 1.01 to 1.20). [40] In a total of 636 participants, women were statistically significantly more likely to be objectively cured with the TVT than SPARC or IVS (92% vs. 87%; RR 1.06, 95% CI 1.01 to 1.11). There were significantly fewer women experiencing bladder punctures during trocar passage after TVT compared with SPARC (4.7% vs. 8.5%; RR 0.55, 95% CI 0.31 to 0.98), as well as fewer vaginal extrusions (RR 0.27, 95% CI 0.08 to 0.95). No statistically significant difference was seen in overall perioperative complications, but the confidence interval was wide (RR 0.98, 95% CI 0.53 to 1.84). There were no statistically significant differences between the 2 groups with respect to postoperative *de novo* urgency symptoms and UUI, as well as urodynamic detrusor overactivity. Finally, there were no statistical differences in QoL indices between the 2 procedure groups. [EL=1/2]

The Cochrane review also evaluated 3 of the aforementioned RCTs [Rechberger et al., 2003; Lim et al., 2005; Meschia et al., 2006] that compared TVT to IVS.[40] At 12 months, the higher subjective cure rates seen with TVT did not reach statistical significance (83% vs. 77%; RR 1.08, 95% CI 0.98 to 1.19). Objective cure for the TVT was significantly higher than for the IVS (83% vs. 72%; RR 1.15, 95% CI 1.02 to 1.30). There were few perioperative complications and the combined results from 2 small trials did not show a statistically significant difference (RR 1.16, 95% CI 0.36 to 3.69). However, the confidence intervals were wide. There were no statistically significant differences in the rates of *de novo* urgency symptoms and UUI, detrusor overactivity, and postoperative voiding dysfunction. [EL=1/2]

***f) Retropubic MUS vs. transobturator mus* (table 2)**

A unique complication of the retropubic MUS procedures has been inadvertent puncture of retropubic and, on occasion, intra-abdominal viscera or neurovascular structures. The most common organ punctured is the bladder and the rates of puncture have varied between 0.8% and 21 % in different reports [Wang et al., 2004; Andonian et al., 2005]. [50, 66] Two systematic registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide and one from Austria including 2795 operations [Kuuva and Nilsson, 2002; Tamussino et al., 2001]. [26, 67] The rates of bladder perforation were 3.8% and 2.7%, respectively. In an effort to minimise the incidence and morbidity of bladder injuries, Delorme in 2001 introduced a modified tape procedure in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramina on both sides.[68] De Leval further modified the outside-in transobturator tape procedure (TOT) procedure to be an inside-out procedure, now called the tension-free vaginal tape-obturator (TVT-O). [69]

The comparison between the retropubic and transobturator MUS procedure has become the most-documented topic in sling surgery over the last 5 years. ICI-4 reported on a total of 9 RCTs comparing RP with TO midurethral slings. TVT was compared with the inside-out TVT-O in 6 randomized trials [Liapis et al., 2006; Laurikainen et al., 2007; Meschia et al., 2007; Zullo et al., 2007; Araco et al., 2008; Rinne et al., 2008], [70-75] and with the outside-in TOT in 2 trials [Andonian et al., 2007; Porena et al., 2007]. [76, 77] Wang et al. compared the TOT with SPARC and found no difference in cure rate or rates of complications between the group of 31 TOT patients and 29 SPARC patients.[78]

The studies evaluated in ICI-4 were quite heterogeneous. Five of the studies comparing TVT with TVT-O included power calculations either for detection of differences in cure rates and complication rates [Meschia et al., 2006; Laurikainen et al., 2007; Rinne et al., 2008], [70, 71, 75] or only for detection of differences in complications [73]. The study by Liapis et al. reported no power calculations. [70] No differences in the overall objective or subjective cure rates were seen between the TVT and the TVT-O procedures

Key: RP=retropubic; MUS=midurethral sling; F/U=follow-up; LE=level of evidence; TVT=tension-free vaginal tape; TOT=transobturator tape; m=months; s=subjective; o=objective; TVT-O=tension-free vaginal tape obturator; ITT=intention to treat; RCT=randomized controlled trial; SUI=stress urinary incontinence; ISD=intrinsic sphincter deficiency; IVS=intravaginal slingplasty; DO=detrusor overactivity; OR=odds ratio; CI=confidence interval; NS=not significant.

during follow-up periods of 6 to 12 months. The only statistically significant difference in objective cure rate was seen in the Araco et al. report where stratification between mild and severe stress incontinence had been made.[74] They found a significantly higher cure rate in the TVT patients with severe SUI than in the TVT-O patients with the same condition: 100% versus 66 % cure respectively (p<0.001). [EL=1/2]

The trials presented contradictory results concerning postoperative complications. The reports by Meschia et al. [71] and Laurikainen et al., [70] including 3-4 times more patients than the reports by Zullo et al. [73] and Liapis et al. [79] show either no differences in the overall number of complications or a significantly higher rate of overall complications in the TVT-O group (Laurikainen et al.). It is not clear from the Zullo et al. study, which showed a higher complication rate for the TVT, how the overall complication rate was calculated. The two trials comparing TVT with TOT [Andonian et al., 2007; Porena et al., 2007] found no difference in cure rates between the procedures. [76, 77] There were no differences in complication rates between the procedures in the Porena et al. study, while Andonian et al. reported significantly greater rates of complications in the TOT than in the TVT group. [EL=1/2]

As an example of the continued and exponentially-increasing interest in these procedures, the Cochrane systematic review evaluated 16 fully-published RCTs and 7 additional meeting abstracts. [40] The published studies included the following: Enzelsberger et al., 2005; Kim et al., 2005; Wang A et al., 2006; Liapis et al., 2006; Andonian et al., 2007; Darai et al., 2007; Lee et al., 2007; Meschia et al., 2007; Porena et al., 2007; Zhu et al., 2007; Zullo et al., 2007; Araco et al., 2008; Barber et al., 2008; Barry et al, 2008; Rinne et al., 2008; Schierlitz et al., 2008. [71, 73-87]. Three of the abstracts included in the Cochrane review have since been published as full manuscripts [Rechberger et al., 2009; Deffieux et al., 2010; Teo et al., 2011],[88-90] while the population in the study by Rinne et al. has recently been updated with long-term outcomes. [91]

The Cochrane review reported subjective cure within 12 months in 10 trials with a total of 1281 participants. [43] Assessment of cure was self-reported by participants and by responses to symptom based questionnaires. The combined results from the 10 trials showed no statistically significant difference in the subjective cure rates between the RP and TO routes (RR 1.00, 95% CI 0.96 to 1.05). Subjective cure rate in each group was approximately 83%. In this instance, the confidence interval is narrow and may not include a clinically significant difference. The confidence interval is compatible with the cure rate for the transobturator route being 6% better, or being 3% better for the retropubic route. [EL=1/2]

Objective cure was assessed by 17 studies with 2434 participants using a variety of measures such as urodynamic assessment, negative cough-stress test, 1-hour pad test of ≤ 2 g, 1-hour pad test of ≤ 1 g, and 24-hour pad test of ≤ 5 g. [40] The cure rate using the obturator route was significantly lower at 84% versus 88% for the retropubic route (RR 0.96, 95% CI 0.93 to 0.99). However, the confidence interval was narrow and the difference between the groups (4%) may not represent a clinically significant difference in the short term. There was no significant difference in women whose improvement and cure rates were demonstrated objectively (RR 0.96, 95% CI 0.91 to 1.02). [EL=1/2]

In 14 trials, there were no statistically significant differences in the rates of tape erosions (RR 1.58, 95% CI 0.83 to 3.00) or, in 5 trials, the need for repeat incontinence surgery (RR 1.52, 95% CI 0.90 to 2.59). [40] However, once again, the confidence intervals in both cases could include a clinically significant difference favouring the RP approach. There was significantly higher occurrence of groin pain (12%) in women with a TO approach compared with suprapubic pain in women with a retropubic sling (1.7%, RR 6, 95% CI 3 to 11). There was no statistically significant difference between the groups in terms of detrusor overactivity (RR 1.22, 95% CI 0.56 to 2.63) in 3 trials, or *de novo* urgency and urgency incontinence (7% with the TO route versus 6% via the RP route (RR 1.08, 95% CI 0.75 to 1.56) in 14 trials, but the confidence intervals were wide because these were relatively rare events and clinically significant differences could not be ruled out. However, postoperative voiding dysfunction occurred significantly less frequently in the TO route group (4% versus 7%, RR 0.63, 95% CI 0.44 to 0.89). [EL=1/2]

The systematic review by Novara et al. included 13 RCTs that compared classic TVT with inside-out TOT: TVT-O in 10 studies [71-75, 84, 89, 90, 92-96] and a less invasive free tape in a single study [Naumann et al., 2006 (abstract only)].[48] Nine studies compared TVT to outside-in TOT: ObTape in 3 studies, [76, 77, 80] Monarc in 4 studies, [86, 87, 97], Freeman et al., 2008 (abstract only)] Iris-TOT in a single study, [Kim et al., 2004 (abstract only)] and Obtryx in a single study. [98] The implanted devices were not specified in a single study.[99] A single trial compared TVT to both TVT-O and Monarc, [Scheiner et al., 2009 (abstract only)] a single trial compared retropubic IVS to outside-in IVS, [142], and 2 trials compared SPARC sling to Monarc.[78, 81]

Overall (OR: 1.02; 95% CI OR: 0.78 to 1.33; p = 0.90), and subjective (OR: 0.97; 95% CI OR: 0.75 to 1.24; p = 0.80) continence rates were overlapping in the two procedures. [48] Among the studies providing subjective outcomes using validated questionnaires, postoperative UDI-6 (WMD: 0.07; 95% CI: -0.39 to 0.53; p = 0.76) and IIQ-7 (WMD: 0.01; 95% CI: -0.22 to 0.24; p = 0.95) scores were

similar. Notably, retropubic MUS were followed by significantly higher objective continence rates (OR: 0.80; 95% CI OR: 0.65 to 0.99; p = 0.04). Moreover, a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI OR: 0.52 to 0.96; p = 0.03), whereas no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI OR: 0.66to 1.22; p = 0.51). Sensitivity analyses limited to studies of higher methodological quality showed only a nonstatistically significant trend in favour of TVT with regard to objective cure rate (OR: 0.74; 95% CI OR: 0.54 to 1.01; p = 0.05). No differences in subjective and overall continence rates were found in the other sensitivity analyses. [EL=1/2]

With regard to complications, bladder or vaginal perforations (OR: 2.5; 95% CI OR: 1.75 to 3.57; p < 0.0001) were significantly more common following retropubic MUS, without any significant difference between inside-out and outside-in TOT.[48] Again, as expected, the prevalence of postoperative haematoma was significantly more common following placement of retropubic MUS (OR: 2.62; 95% CI OR: 1.35to 5.08; p = 0.005). In fact, the rates of vaginal extrusion were slightly higher following TOT (OR: 0.64; 95% CI OR: 0.41to 0.97; p = 0.04), due to the studies using ObTape, a device removed from the market due to a high risk of erosion and extrusion. Finally, the risk of urinary tract infections (OR: 0.95; 95% CI OR: 0.69 to 1.31; p = 0.74), the need for clean intermittent catheterisation or re-catheterization (OR: 1.16; 95% CI OR: 0.84 to 1.59; p = 0.37), and the reoperation rate (OR: 1.1; 95% CI OR: 0.75 to 1.59; p = 0.62) were not significantly different between retropubic and transobturator MUS. Interestingly, the prevalence of storage LUTS was significantly higher in those patients randomised to RT (OR: 1.35; 95% CI OR: 1.05to 1.72; p = 0.02), without any significant difference between inside-out and outside-in TOT. A nonstatistically significant difference in favour of TOT was found for voiding LUTS (OR: 1.56; 95% CI OR: 0.97 to 2.5; p = 0.07). In sensitivity analyses limited to studies of higher methodological quality, only a nonstatistically significant trend in favour of TOT was found for storage LUTS (OR: 1.44; 95% CI OR: 0.99 to 2.09; p = 0.06) and voiding LUTS (OR: 1.59; 95% CI OR: 0.85 to 2.97; p = 0.15). Similarly, with regard to the risk of all the other complications and reoperation, no differences were identified in the other sensitivity analyses. [EL=1/2]

The largest RCT to date comparing retropubic and transobturator MUS was recently published by Richter et al.[37] This was a multicentre, randomised equivalence trial with the primary outcome being objective (a negative stress test, a negative pad test, and no retreatment) and subjective (self-reported absence of symptoms, no leakage episodes recorded, and no retreatment) success at 12 months. The predetermined equivalence margin was ±12% points. A total of 597 women were randomly assigned to a study group and 565 (94.6%) completed the 12-month assessment. The rates of objectively assessed treatment success were 80.8% in the RP group and 77.7% in the TO group (3.0%-point difference; 95% CI: −3.6 to 9.6). The rates of subjectively assessed success were 62.2% and 55.8%, respectively (6.4%-point difference; 95% CI, −1.6 to 14.3). The rates of voiding dysfunction requiring surgery were 2.7% in the RP group and 0% in the TO group (P = 0.004), and the respective rates of neurological symptoms were 4.0% and 9.4% (P = 0.01). There were no significant differences between groups in postoperative urgency incontinence, satisfaction with the results of the procedure, or quality of life. Thus, the success rates met the predetermined criteria for equivalence of the 2 procedures. [EL=1]

There have been numerous additional, non-randomised trials published in peer-reviewed literature. [100-118] The majority of these concluded that there is no statistically significant difference in subjective or objective outcome measures between retropubic and transobturator MUS procedures. As concluded in the RCTs, postoperative complications are more common in the retropubic MUS group. [EL=3/4]

g) Other studies

Two additional topics deserve mention. Pelvic floor muscle training (PFMT) with or without biofeedback is a recognised and effective treatment for various pelvic floor conditions, including SUI, UUI, and pelvic pain. While a trial comparing MUS procedures and PFMT has not been published, there is a design for a prospective RCT in place to address this question [Labrie et al., 2009]. [58] This multi-centre RCT will be include women between 35 - 80 years old with moderate to severe, predominantly SUI, who have not received specialised PFMT or previous anti-incontinence surgery. Women will be assigned to either PFMT for a standard of 9-18 sessions in a 6-month period or TVT-O surgery. The main endpoint of the study is the subjective improvement of urinary incontinence. Objective cure, a secondary outcome, will be assessed from history and clinical parameters. Subjective improvement in QoL will be measured by generic (EQ-5D) and disease-specific (UDI & IIQ) QoL instruments. The economical endpoint is short term (1 year) incremental cost-effectiveness in terms of costs per additional year free of urinary incontinence and costs per Quality Adjusted Life Years gained. Finally, treatment strategy and patient characteristics will be combined in a prediction model, to allow for individual treatment decisions in future patients. Four hundred female patients will be recruited from over 30 hospitals in the Netherlands.

Finally, single-incision mini-slings (SIMS) have emerged as an additional option for the woman

with SUI. These procedures theoretically require minimal anesthesia and may be performed entirely under local anesthestic. While most outcomes and comparisons between SIMS and traditional MUS procedures have not yet reached medium-term follow-up, a recent abstract at the 2011 International Continence Society Annual Meeting presented a systematic review and meta-analysis of SIMS and MUS procedures [Abdel-Fattah et al., 2011].[59] Nine studies were included, comparing TVT-Secur (6 studies; n=548), Mini-arc (2 studies; n=160) and Ophira (one study; n=50) to traditional MUS. A total of 758 women were included and 60 women were lost to follow-up (MUS n=23, vs. SIMS n=37). The meta-analyses showed a significantly lower patient-reported cure rate with SIMS when compared to MUS, specifically TVT-O (RR 0.84, 95% CI 0.71 to 0.99), however a non-significant difference in favour of TVT was seen (RR 0.79, 95% CI 0.37 to 1.67). These results were supported on sensitivity analysis when studies of unclear quality were excluded. SIMS were associated with significantly lower objective cure rates when compared to MUS, specifically TVT-O (RR 0.88, 95% CI 0.77 to 0.99). In addition there was a significant difference in favour of TVT when compared to SIMS. This was also confirmed on sensitivity analysis when studies of unclear quality were excluded. A shorter operation time was associated with SIMS (WMD -8.67 minutes, 95% CI -17.32 to -0.02), and this was due to the significant difference in operation time in the single TVT comparison. There were significantly lower day-one pain scores in the SIMS group (WMD -1.74, 95% CI -2.58 to -0.09). Repeat continence surgery was significantly higher in the SIMS group (RR 6.72, 95% CI 2.39 to 18.89). Tape erosion and de-novo urgency incontinence were significantly higher in the SIMS group (RR 3.86, 95% CI 1.45 to 10.28 and RR 2.08, 95% CI 1.01 to 4.28, respectively). There were non-significant differences between both groups in respect to post-operative voiding difficulties (RR 1.47, 95% CI 0.78 to 2.74) and other minor (postoperative wound infection, haematoma, UTI, and haematuria) post-operative complications (RR 1.59, 95% CI 0.74 to 3.45). There was no significant difference in the QoL scores between the groups (WMD -33.46, 95% CI -87.55 to 20.62). Statistical heterogeneity was found throughout the analysis and was highest in patient reported cure rate, QoL scores, and operative time. [EL=1/2]

h) CONCLUSIONS / RECOMMENDATIONS

There is evidence that the retropubic TVT is more effective than colposuspension and is equally effective as traditional autologous fascial sling operations. **[EL=1/2]** Operation time, hospital stay, and time to resume normal daily activity is shorter with the TVT than with colposuspension. Post-operative voiding problems and need for urogenital prolapse surgery are more commonly associated with colposuspension, while bladder perforation is more commonly associated with TVT. **[EL=1/2]** TVT is more effective than the IVS and the SPARC procedure; however, the studies are heterogeneous. Inadvertent bladder puncture during SPARC (top-down) placement is more common than bladder puncture during TVT (bottom-up). **[EL=1/2]** Overall, retropubic and transobturator MUS procedures perform equally at a short term follow-up of 6 to 12 months. (Level 1/2) The rate of complications, including bladder puncture, vaginal extrusion, and hematoma formation are higher for the retropubic MUS. **[EL=1/2]**

Retropubic MUS is recommended as an effective treatment for stress urinary incontinence, which has longevity. **[Grade A]** Outcomes using subjective and objective criteria indicate that the retropubic MUS is at least equivalent, and usually superior, to other anti-incontinence procedures. **[Grade B]**

3. TRANSOBTURATOR MID-URETHRAL SLINGS

a) Evolution of the TOT including proposed advantages

The introduction of the tension-free vaginal tape (TVT) in 1995 [171] as well as the[172] development of other retropubic mid urethral slings, changed the way stress urinary incontinence (SUI) is treated. These procedures, although effective, were not without complications. Beyond voiding phase dysfunction, complications including bladder perforation, bowel perforation and vascular injury were described. [26, 173, 174] [175]The majority of serious complications reported from these procedures were thought to be related to penetration of the retropubic space. [176]

In 2001, Delorme first described placement of a synthetic sling avoiding the retropubic space by placing the sling through the obturator foramina.[68] Thus the first alternative to the retropubic tapes, the transobturator tape (TOT) was born. By avoiding the retropubic space, the major complications associated with retropubic passage of trocars were theoretically avoided. Another potential advantage of the transobturator method was the potential elimination of intraoperative cystoscopy. This point is still debated today.[177] Delorme's original description of the TOT required passage of the trocar from "outside-in". In 2003, de Leval aimed to further reduce the chance of bladder and urethral injury and described placing the trocar of the vaginal tape from "inside-out".[69] These two methods remain the major division of transobturator slings and are both still widely used today.

Further efforts have been recently made to modify the inside-out method. In an attempt to minimise post-surgical leg pain, the length of mesh used has been shortened and surgeons have tried to minimise the number of punctures to the obturator membrane [172, 178] Initial results have shown improvement in leg pain in the immediate post-operative

period, without sacrificing efficacy (at 1 year). Further confirmatory studies are needed to strengthen these findings.

b) Initial prospective cohort trials

The original TOT procedure was performed in 40 women, 16 of whom had isolated SUI. The authors reported 15/16 were "totally continent" and the remaining patients improved with short term follow up (3-12 months). [68]There were no intraoperative complications. Post-operatively, the only complication was 1 episode of sepsis. Following this study, Delorme et al. published a series of 32 patients treated with the transobturator tape with at least one year follow-up (UraTape® Mentor-Porge`s, a non-woven, non-knitted thermally-bonded polypropylene) [179, 180] With a mean follow-up of 17 months, and a rigorous definition of cure (defined by patients reporting no protection and no SUI, along with a negative cough test with a full bladder) 22/29 patients (90.6%) were cured and 3/32 (9.4%) were improved. Preoperatively, 43.7% (14 patients) had pure SUI, and 56.3% (18 patients) had mixed incontinence. Of note, 4 patients had prior anti-incontinence procedures (3 TVT, 1 Burch and 1 with multiple procedures) and 5/32 had preoperative urethral closure pressures of <20cm H20. Again, no intraoperative complications were recorded. There was one patient who required self-catheterisation but retention resolved in this patient by 4 weeks. There were 5 patients with voiding disorders suggestive of bladder outflow obstruction. Two patients developed de novo urgency incontinence and one had worsening of her preoperative urgency.

Short term safety and efficacy data are also available from a prospective multicentre cohort study. [176] In this study, 183 women received the UraTape (outside-in TOT) and follow up data were obtained at a mean of 7 months (1-21 months). All women had SUI associated with hypermobility, 26 had mixed incontinence and 26 had concomitant (POP) surgery performed at the time of their TOT. Intraoperatively, there was a complication rate of 2.2% including 1 bladder perforation, 2 urethral perforations and 1 lateral vaginal sulcus perforation. Seventeen patients were not cured of stress incontinence including 5 patients that had the sling removed for vaginal extrusion (3) and urethral erosion (2). 4 patients reported post-operative de novo urgency, 2 of which also complained of urinary leakage. At 6 months 83% (of 130 patients) were cured and 5.4% were improved.

Based on data from the prospective series from Costa et al. and other case reports, extrusions and infections were linked to the silicon part of the UraTape and the tape was modified to the Obtape®. [176, 181, 182] This modification was introduced in 2003. This newer tape was made of monofilament strands of nonwoven polypropylene fibre with interlacing monofilaments forming pores of 50 mcg (smaller than the 75 mcg needed to allow for the migration of macrophages and leukocytes). The materials used for transobturator slings have continued to be modified to decrease risk of erosion, extrusion and infection. Today, all commercially available synthetic transobturator slings (as well as retropubic slings) are made of Amid type I polypropylene mesh and have an extrusion and erosion rate well below 5%. This is much lower when compared to the transobturator Obtape® with vaginal erosion rates as high as 13%.[183] [184]

The first description of the "inside-out" modification by de Leval also included feasibility/safety data from 107 patients.[69] Of these, 74 suffered from isolated SUI, and the remaining 33 women had POP, 15 had associated SUI, and the remaining 18 had prophylactic slings for occult SUI. There were no intraoperative complications or perioperative complications reported. At one month, one patient had a minor vaginal erosion and 2.8% of patients had urinary retention (2 of the 3 had concomitant prolapse surgery). 15.9% of patients complained that they had moderate pain or discomfort in the thigh fold. All pain had resolved by one month.

After the original inside-out cohort was described, patients from the same institution were then offered participation in a prospective observational study (TVT-obturator or TVT-O, Ethicon, Sommerville NJ, USA). [185]102 patients out of 253 consecutive patients fulfilled the inclusion criteria and agreed to participate in the trial. 4.9% (5/102) of this group did not complain of SUI but had occult SUI. There were no urethral or bladder perforations and one patient had a vaginal sulcus laceration noted intra-operatively. No patients presented with vaginal or urethral erosion at follow-up. After catheter removal, 2 patients had an "important PVR" of >400ml. This voiding dysfunction resolved (after CIC in one and SPT What's SPT in the other) by the last reported follow-up. There were 99 women with least 12 month follow-up (mean follow-up of 14.9 months) and the complete cure rate was 91% while SUI symptoms improved in 5% of patients. Worsening or de novo urgency symptoms or urgency urinary incontinence (UUI) were reported by less than 10% of the patients. Approximately 75% of those with preoperative urgency and/or UUI experienced disappearance or improvement of these symptoms postoperatively. Voiding difficulties developed in 7% of the patients.

This same group of 102 women, who underwent a transobturator inside-out sling, were followed for a minimum of 3 years (median 40 months) and complete data were available for 91 (89.2%). [185] Issues of erosion or persistent pain were not found with this medium term follow-up. Four patients required tape release or tape incision, all within the first year. Disappearance and im-

provement of SUI were observed in 88.4% and 9.3% of the patients respectively. These cure rates were similar to those obtained 1 year after the operation. [185] Cure of SUI was defined as the disappearance of subjective SUI, as assessed by a SUI symptom scale score equal to zero. One patient developed a vesicovaginal fistula 2 years after sling placement. The authors did not believe that this was secondary to the TVT-obturator, but rather was due to a prior history of pelvic radiation. An additional 2 patients developed symptomatic POP between the first and second year and each went on to have an uncomplicated laparoscopic repair.

There are several large, multicentre European studies that examined the safety of the original TVT. [67, 186, 187] Similarly, a study was performed to address the safety of the inside-out transobturator approach. [188] This study compiled a registry of 984 women from 86 centers in France. There was an overall perioperative complication rate of 2.2%, with vaginal wall perforation (1.3%) and hematoma (0.7%) being the most common. The post-operative complication rate was 5.2%, with residual leg pain being the most common complication (2.7%). Reintervention, urinary retention, vaginal erosion, and paravesicle hematoma were all reported with percentages of less than 1 (0.9%, 0.8%, 0.6% and 0.1% respectively). Although the design of this study was aimed at safety, the paper does report efficacy at 4-12 weeks. Surgeons assessed 90% of patients as completely cured and 8.7% as improved, with only 1.2% of patients being similar to their preoperative status. Of those 303 patients with preoperative overactive bladder (OAB), cure was reported in 54.5%, improvement in 40.25%, and 5.3% noting no change. Other large single institution studies have also looked at safety of the inside-out transobturator sling. [189]

c) Transobturator Outside-in versus Inside-out

It was suggested by Delorme et al. that there is a greater risk of nerve injury (dorsal nerve of the clitoris) with the inside-out passage of the trocar. [180] A cadaveric study suggested that the inside-out technique required the trocar to pass closer to the obturator canal and was more likely to injure the obturator nerve (or vessels) that travel in this space. [190]

The association between inside-out obturator slings and an increased risk of complications compared to outside-in obturator slings has not been supported in clinical studies. Latthe et al. used a meta-analysis with direct and indirect comparisons of randomised trials to assess the effectiveness and complications for the inside-out (TVT-O) and outside-in (TOT) transobturator slings.[191] The conclusion was that there was equivalent short-term effectiveness between the two methods. By indirect comparison, fewer bladder injuries and voiding difficulties were seen in the inside-out tapes.

In 2009, a Cochrane Review of minimally invasive synthetic sub-urethral sling operations for SUI contained an analysis of the inside-out outside-in approaches (comparison #5) and concluded that there were no statistically significant differences in any of the outcomes measured.[40] However, the review acknowledged that the four trials randomised trials that this conclusion was based on were all small in size. [192-195]

Houwert et al. presented medium term follow up from their prospective comparative randomised trial.[196] They did not find any statistical significant difference, but it is not clear that the study was powered appropriately to show a difference. Abdel-fattah et al. published a study that was powered to show a 10% difference in success rates between the two methods of obturator sling placements. [197] They enrolled 107 inside-out and 171 outside-in patients. This prospective single blinded study did not show any differences in objective cure rates (87.6% inside-out vs. 83.2% outside-in, $p = 0.2$) or patient reported success rates as reported by Patient Global Impression of Improvement (83% inside-out vs. 77% outside-in, respectively, $p = 0.138$) at 6 months follow-up.[197] There were statistically more vaginal angle perforations with the outside-in approach compared the inside-out method (17 vs. 3, respectively, $p=0.001$). Women in the inside-out group more commonly reported severe post-operative thigh pain, but this was not statistically significant (6.7% vs. 3.5%, $p=0.19$).

d) Comparator Trials: Transobturator versus Retropubic MUS in the Index Patient

Once cohort studies had confirmed the feasibility of transobturator mid-urethral slings, a number of small RCTs and quasi-RCTs were performed comparing transobturator to the then gold standard, retropubic mid-urethral sling. A Cochrane review [40] and two recently updated meta-analyses [48, 191] use the pooled data of these RCTs to compare the outcomes of retropubic and transobturator MUSS.

In a Cochrane Review, Ogah et al. found 24 trials comparing outcomes between retropubic and transobturator MUSS.[40] Subjective cure or improvement rates were reported in 10 of these trials and meta-analysis revealed no statistically significant difference between approaches (83% subjective cure in each group, RR 1.00, 95% CI: 0.96-1.05). Objective cure was measured by urodynamic evaluation, cough-stress test, one hour pad test of ≤ 2 g, one hour pad test of ≤ 1 g, or 24 hour pad test of ≤ 5 g various means in 17 studies. The transobturator route was found to have a significantly lower cure rate than the retropubic route (84% vs. 88%, RR 0.96, 95% CI 0.93-0.99). The clinical significance of this 4% difference in objective cure versus no difference in subjective cure has been questioned.

In a recent systematic review and meta-analysis, Latthe et al. found 12 RCTs that compared TOT with TVT, and 15 that compared TVT-O with TVT.[191] When compared at 1–44 months, the subjective (OR 1.16; 95% CI 0.83–1.6) and objective (OR 0.94; 95% CI 0.66–1.32) cure of TOT was similar to TVT. For TVT-O, the subjective (OR 1.06, 95% CI 0.85–1.33) and objective cure (OR 1.03, 95% 0.77–1.39) was also similar to TVT.

Novara et al examined 11 RCTs comparing TVT with inside-out TOT and 9 RCTs comparing TVT with outside-in TOT.[48] Meta analysis revealed that continence rate according to any definition of cure (OR: 1.02; 95% CI: 0.78–1.33; p = 0.90), and subjective continence rates (OR: 0.97; 95% CI: 0.75–1.24; p = 0.80) were similar between the two procedures. Overall, retropubic tapes had significantly higher objective continence rates when compared to the transobturator tape group (OR: 0.80; 95% CI: 0.65–0.99; p = 0.04). Interesting, a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI: 0.52–0.96; p = 0.03) but no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI: 0.66–1.22; p = 0.51). However, when studies of lower methodological quality were excluded only a non-statistically significant trend in favour of TVT was found. (OR: 0.74; 95% CI: 0.54– 1.01; p = 0.05).

The majority of RCTs used in the aforementioned Cochrane review and meta-analyses were small, had short- to medium term follow-up and were designed only to detect superiority. This has precluded robust conclusions regarding long-term success and equivalence efficacy with this data.

Angioli et al. provide long-term data regarding the success rates of TVT and TVT-O in a multicentre RCT. [198] At 5 years follow-up, objective cure, defined as a negative cough stress test, was similar between TVT and TVT-O (71.4% vs. 72.9%; p=1). After 5 years, patients in this trial were asked to describe their overall satisfaction. 60% and 62% of women reported that they were satisfied or very satisfied with the results of their TVT and TVT-O respectively (p=1).

TOMUS (Trial of Mid-Urethral Slings) is a large multicentre, equivalence RCT designed to compare the efficacy and safety of retropubic and transobturator mid-urethral slings. [170] The 12-month outcomes of 565 women were recently reported. The criteria required for objective treatment success were a negative provocative stress test, a negative 24-hour pad test, and no retreatment (behavioural, pharmacological, or surgical) for SUI. The unadjusted rates of objective treatment success met the predefined criteria for equivalence, less than a 12 percentage-point difference. (80.8% in the retropubic sling group and 77.7% in the transobturator sling group; 3.0 percentage-point difference; 95% CI: 3.5to 9.6). The subjective treatment success criteria were the absence of self-reported SUI symptoms as assessed with the use of the Medical, Epidemiological and Social Aspects of Aging questionnaire, no leakage recorded in a 3-day voiding diary, and no retreatment for SUI. The unadjusted rates of subjective treatment success did not significantly differ between groups but the predetermined criteria for equivalence was not met (62.2% in the retropubic sling group and 55.8% in the transobturator group, 6.4 percentage point difference; 95% CI, −1.6 to 14.3).

e) Comparator Trials: Transobturator versus Retropubic MUS in patients with Intrinsic Sphincter Deficiency (ISD)

The diagnosis of ISD in the literature has traditionally been based on the urodynamic finding of a Valsalva leak-point pressure (VLPP) < 60 cmH20 or a mean urethral closure pressure (MUCP) < 20 cm H20. A retrospective study of 300 women with SUI and ISD found an overall cure rate for TVT to be significantly higher than TOT (78.3% vs. 52.5%; p<0.0001). [111] Jeon et al. retrospectively compared 253 patients with ISD and found that after 2 years cure rates were 86.94% and 34.89% for TVT and TOT respectfully (p<0.0001). [156] Schielitz et al. [87] randomised 184 women with urodynamic evidence of SUI and ISD to receive TVT or TOT. At 6 months, urodynamic SUI was present in 21% in the TVT group compared to 45% in the TOT group. [87] Similarly, in a large RCT, a VLPP < 60 cmH20 was a predictor of poor outcome in the transobturator sling group but not in the retropubic sling group.[88] In these studies ISD was defined by a low VLPP or MUCP, but there is no mention of urethral mobility. Contradictory to these findings, Rapp et al. retrospectively reviewed their results and found no significant differences in continence rates across different preoperative VLPPs. [113] In a large observational study, women with SUI were stratified according to preoperative MUCP and VLPP and followed for 5 years after TOT. The objective overall cure rates were similar across all strata indicating that MUCP and VLPP may not be predictive of outcome in TOT. [199] In the TOMUS trial, there was no material change in the rates of treatment success according to objective or subjective criteria when the analyses were adjusted for VLPP and MUCP. [170]

The data comparing retropubic and transobturator MUSS outcomes in patients with ISD appears equivocal. Recent studies suggest that evaluation of urethral mobility in ISD patients can be more informative. A cohort of 107 women with SUI had their urethral mobility measured prior TOT and at 10 months subjective cure was assessed. Women with preoperative urethral mobility < 45 degrees were at least 4 times more likely to report postoperative incontinence compared to women with preoperative urethral mobility > or = 45 degrees (29.4% vs 6.9%, RR 4.29, 95% CI 1.59-11.60, p=0.005).[200] Haliloglu et al. divided 65 women with SUI into three groups prior to receiving TOT: I) patients with ISD with a VLPP < or = 60 cm

H2O and a Q-tip test > 30 degrees (ISD and hypermobile urethra), II) patients with ISD who have VLPP < or = 60 cm H2O and Q-tip test < or = 30 degrees (ISD without hypermobile urethra), and III) patients without ISD who had VLPP > 60 cm H2O and Q-tip test > 30 degrees (hypermobile urethra without ISD). [201] All cure and improvement rates were statistically lower in group II at 6, 12, and 24 months leading authors to conclude that lack of urethral hypermobility may be an important risk factor for TOT failure in patients with ISD.

f) Complications of Obturator Slings

Complications of MUS are categorised as intraoperative complications (bladder, urethral, visceral and vessel injury), immediate postoperative complications (voiding dysfunction, groin pain, infection) and chronic problems (de novo urgency, sling erosion/extrusion). Placement through the obturator foramen avoids the space of Retzius, decreasing more serious intraoperative trocar complications. In 2008 Novara et al. conducted a systematic review and meta-analysis of complication rates in mid-urethral slings. [202] When comparing retropubic vs. transobturator approach, bladder perforations (OR 2.33; 95% CI: 1.26–4.32; p = 0.007), pelvic hematoma (OR 4.83; 95% CI: 1.22–19.15; p = 0.03) and storage lower urinary tract symptoms (OR 1.81; 95% CI: 1.13–2.91; p = 0.01) were less frequent in women who had undergone a transobturator sling. Rates of vaginal erosions, urinary tract infections and reoperation rates were similar amongst groups. The 2009 Cochrane review by Ogah et al. on mid-urethral slings found that the transobturator approach was associated with a shorter operating time, less blood loss, less postoperative voiding dysfunction, and fewer bladder perforations, but more groin pain (12% vs. 1.7%, RR 6, 95% CI: 3–11) than the retropubic route.[40] In 2010 Latthe et al. updated their systematic review which assessed the effectiveness and complications of transobturator slings.[191] Adverse events such as bladder injuries (TOT, OR 0.11, 95% CI 0.05–0.25; TVTO, OR 0.15, 95% CI 0.06–0.35) and hematomas (OR 0.06, 95% CI 0.01–0.30) were less in the TOT than TVT. Voiding difficulties (TOT, OR 0.61, 95% CI 0.35–1.07); TVTO, OR 0.81, 95% CI 0.48–1.31) were slightly lower in TOT but this was not statistically significant. Groin/thigh pain (TVT-O, OR 8.05, 95% CI 3.78–17.16) and vaginal injuries (TOT, OR 5.82, 95% CI 1.85–18.3; TVTO, OR 1.69, 95% CI 0.73–3.91) were more common in the transobturator tapes. Mesh erosion in TVT-O (OR 0.77, 95% CI 0.22–2.72) and TOT (OR 1.11, 95% CI 0.54–2.28) was similar to TVT.

A recent publication by Brubaker et al. reported on 2 year adverse events in patients enrolled in the TOMUS trial who were undergoing retropubic or transobturator midurethral slings. [203] UTIs were the most common adverse events in both groups with a higher incidence in the retropubic group (16.7% vs. 9.1%, p =.02). Patients in the retropubic group had higher rates of bladder perforation (5% vs. 0%, p <.0001), voiding dysfunction requiring surgery or catheter use (3% vs. 0%, p =.002) and postoperative bleeding (2% vs. 0%, p =.02). Neurological symptoms, defined as new paresthesias or alterations in motor function in the first 6 weeks after surgery, were more frequent in the transobturator group than in the retropubic group (9.7% vs. 5.4%, p =.04). Mesh complications were reported in 3-5 % of women and these rates were similar in both groups.

But and Fagenelj randomised 120 patients to Monarc (inside-out transobturator sling) or to TVT-O (outside-in). [193] There was a higher incidence of vaginal wall perforations and lacerations in the Monarc (0% vs. 15%), and the TVT-O was more painful than the Monarc (p =.00015). Liapis et al. evaluated 114 patients randomised to TVT-O and Monarc, finding no statistically significant differences between the two procedures. [195] In patients that have undergone the Obtape, there have been reports of higher rates of vaginal erosion, ischiorectal abscesses, adductor myositis with symptoms of leg pain, difficulty ambulating and cellulitis. The newer polypropylene slings have been associated with a lower incidence of complications. However, the true incidence of major complications is probably limited by the heterogeneity of the outcome measures and the short-term follow-up of most of the studies. Future studies with validated outcomes and long-term follow-up are needed.

g) Transobturator Slings in Special Populations

1. Mixed Urinary Incontinence

Mixed urinary incontinence (MUI) is defined as the complaint of involuntary leakage from the urethra, associated with urgency, and also with exertion, effort, sneezing or coughing. How mid-urethral slings affect patients with MUI is less apparent. Many studies have demonstrated an improvement or cure in OAB symptoms and UUI in those patients undergoing sling procedures for the stress component of MUI with cure rates ranging from 50-74%. [204] Other studies have reported a decrease in subjective and objective cure rates but still quality of life improvement after treatment in women with MUI [53, 205]. Two studies by Paick et al reported on patients with MUI.[53, 205] The first, which reported on 73/274 with MUI who underwent TVT with more than six months follow-up, showed that the mixed UI group had the same cure rate for stress urinary incontinence (SUI) as the SUI-only group. They also found that 16.4% of the mixed UI group had persistent UUI, so that the overall UI cure rate was lower for the mixed UI than the SUI group, but still quite favourable (78.1% vs. 95.5%). In their second study, they evaluated 144 women with mixed UI who had undergone TVT, Sparc or TOT slings. There were no significant differences in the three groups in terms of the cure rate for SUI (SUI; TVT, 95.8%; SPARC, 90.0%; TOT, 94.0%; p = 0.625) and for total cure (TVT, 81.9%; SPARC, 86.4%; TOT, 82.0%; p = 0.965). There were no risk factors for cure of SUI, except detru-

sor overactivity (DO) on urodynamic studies. There was one difference between groups preoperatively; the TOT patients had less severe UUI than those patients who underwent the SPARC or TVT.

In 2008 Gamble et al. evaluated 305 women with MUI and found 31.5% of women had postoperative resolution of detrusor overactivity (DO). [204] Sling type was strongly related to persistence of DO with a 53% persistence of DO in the transobturator tape group, followed by retropubic (64% after TVT, 66% after SPARC), and 86% after bladder neck slings ($p < .001$). Botros et al. evaluated 276 patients with MUI who underwent retropubic slings (TVT, N = 99; SPARC, N = 52) or transobturator slings (Monarc, N = 125).[206] Patients who underwent transobturator sling placement (8%) had significantly less de novo subjective UUI compared to the patients who had TVT (33%) and SPARC (17%) ($p = 0.04$). In patients with preoperative UUI, 14-16% who underwent TVT or SPARC had worsening of their UUI symptoms while only 6% of the transobturator sling group did ($p = 0.02$). There was no difference in rates of resolution of DO or de novo DO among the three groups. Ballert et al. evaluated 83 women who underwent TVT [203] and TOT-O ? TVT-O? [87]using pre- and post-operative AUASI (American Urologic Association Symptom Index) scores to evaluate lower urinary tract symptoms.[207] Patients with SUI had lower postoperative AUASI scores than patients with MUI. There were no differences between patients who underwent TVT or TVT-O in any category. In 2011 Lee et al. performed an observational cohort study evaluating risk factors for persistence of urgency or UUI after midurethral slings. [208] Out of 1112 women who completed the questionnaire, 754 patients had preoperative urgency or urgency urinary incontinence. 955 patients underwent retropubic slings and 270 patients underwent transobturator slings. The overall subjective rate for persistent urgency and UUI was 40.3% and 32.3% respectively. Age (OR 1.03, 95% CI: 1.02-1.04), baseline symptoms severity (OR 1.41, 95% CI: 1.10-1.78) and coexistent DO (OR 2.04, 95% CI: 1.39-3.01), were risk factors for persistent urgency while concomitant prolapse surgery (OR 0.54, 95% CI: 0.38-0.75) and transobturator sling surgery (OR 0.61, 95% CI: 0.39-0.94) decreased the risk. There was no difference in type of sling surgery and persistence of UUI. These studies are consistent with results published by Novara et al. who performed a meta- analysis of randomised controlled trials comparing transobturator vs. retropubic MUSS.(33) Results showed a higher prevalence of storage lower urinary tract symptoms in patients randomized to retropubic slings than in patients randomized to transobturator slings (OR 1.35; 95% CI OR: 1.05–1.72; $p = 0.02$).

In conclusion, women with mixed urinary incontinence benefit from sling surgery. It appears that placement of a transobturator sling provides the greatest improvement in OAB and UUI symptoms and seems to have the lowest rates of de novo urgency and UUI; it also appears to have the greatest resolution of DO. However, women with mixed urinary incontinence should be carefully counseled preoperatively as persistence or worsening of symptoms may have a negative impact on quality of life and may lead to poor overall satisfaction after surgery.

2. Recurrent Sui

There have been multiple studies reporting on outcomes after repeat anti-incontinence surgery, however the appropriate choice of a secondary continence procedure for women with recurrent SUI is poorly studied and the available studies are limited by their small numbers. Two studies of repeated mid-urethral slings report cure rates of 74–76% at 18 months, which is lower than cure rates for primary surgery.[209, 210] Lee et al. performed a retrospective study on repeat midurethral slings.[209] 13 patients underwent retropubic and 16 patients underwent transobturator slings. Overall cure was 75.9% and overall improvement was 6.9%. Cure rates were 92.3% for the retropubic approach and 62.5% for the transobturator approach, however this was not statistically significant ($p = 0.089$). Stav et al. evaluated 1,225 women with SUI, among these 77 patients had repeat mid-urethral slings.[211] The subjective stress incontinence rate was 62% in the repeat group compared to 86% in the primary group ($p <0.001$). A repeat retropubic approach was significantly more successful than a repeat transobturator approach (71% vs. 48%, $p= 0.04$). These results could be due to a higher incidence of intrinsic sphincter deficiency or lack of urethral mobility in patients undergoing a repeat mid-urethral sling (31% vs. 13%, $p <0.001$). A recently published study by Abdel-Fattah et al. reported on outcomes on a total of 46 women with recurrent SUI after previous failed continence surgery.[212] 18 patients underwent “outside-in” and 28 underwent “inside-out” procedure. Overall subjective and objective success rates in this group were 70% and 77% but it should be noted that these numbers included 10 women with failed colposuspension. Higher success rates were seen in women who underwent the inside-out TVT-O compared to the ‘outside-in’ TOT but this study was not adequately powered to make this comparison. Biggs et al. evaluated 27 patients who underwent TVT-O after a previous anti-incontinence procedure.[213] There was an 80% success rate assessed by PGI-I (“very much better” or “much better) at a mean follow-up of 25.7 months.

A repeat synthetic mid-urethral sling procedure has significantly lower cure rates than a primary sling procedure. Although the data are limited, it seems that in patients who failed a primary anti-incontinence surgery, a repeat retropubic approach has a higher success rate than the repeat transobturator approach especially in cases with intrinsic sphincter deficiency.

3. Elderly

Thirty-seven million people are aged > 65 years (12% of the total US population) and 5.3 million of these are aged > 85 years. With the national life span

increasing, it is estimated that by 2030, 1 in 5 people in the United States will be aged > 65 years, and 1 in 4 elderly individuals will be aged > 85 years. Advanced age is related to increased prevalence of urinary incontinence and there is evidence of a higher rate of DO and ISD in the elderly population. Surgical intervention is considered the most efficient and durable approach to treat SUI and mid urethral slings have become the treatment of choice in the majority of patients. The effect of age on outcomes of mid urethral slings is still scarce and the definition of elderly varies across studies. There are some studies that evaluate the efficacy of retropubic slings in the older population but there are limited data assessing safety and efficacy of the transobturator slings in elderly vs. younger patients. Sevestre et al. analysed a series of 76 patients with a mean age of 76 years who underwent TVT.[214] There were no major postoperative complications, however, 13.7% of the patients had postoperative persistent SUI and 18.4% had urgency incontinence. De novo urgency without incontinence was detected in 21% of the patients. In another study, pre- and postoperative quality of life parameters were compared in a small series of 21 elderly and 46 younger stress-incontinent patients that underwent TVTs.[215] At postoperative follow-up of 3-24 months, SUI was improved in 91% of the younger and 80% of the elderly patients and all quality of life parameters were significantly improved in all age groups. Perioperative morbidity and complications are also a consideration in older patients. In the study of Gordon et al. the incidence of early postoperative morbidity was similar in both age groups who underwent TVTs. [216] However, several cases of significant age-related morbidity were noted among elderly patients: two cases of pulmonary embolism, two cases of cardiac arrhythmia, one case of severe pneumonia, and one case of deep vein thrombosis. All major complications occurred in elderly patients who were undergoing concomitant prolapse surgery. The risk of de novo urgency was 18% at one year in older vs. 4% in the younger patients. Barber et al. identified predictors of recurrent urinary incontinence one year after treatment with retropubic and transobturator slings. [85] They found that increasing age was the only identified variable that was independently associated with recurrent SUI (adjusted OR 1.7; 95% CI: 1.1-2.6 per decade). Chen et al. found that surgical failure after inside-out transobturator sling was significantly greater in women aged 60 years old or older, compared with those younger than 60 years (adjusted OR 11.7, 95% CI: 1.8-76) in a small series of 54 women. [217] Groutz et al. evaluated patients aged 70 or older (n=97) and compared them to patients younger than 70 (n=256) who underwent TVT-O.[218] The mean follow up was 30 months ± 17 months. The incidence of persistent, urodynamically confirmed, SUI was similar in both age groups (5%). However, asymptomatic urodynamic SUI was significantly more common among elderly patients (19% vs. 3.7%, p <0.05). The incidence of persistent OAB was similar in elderly and younger patients (68% and 62%, respectively), while de novo OAB was significantly more common in elderly patients (11.9% vs. 4.7%, p <0.05). Postoperative morbidity was similar in both groups except the elderly group had a higher incidence of recurrent UTI's (13.7% vs. 6.2). Even though there are limited data and further studies are needed, it appears that transobturator slings are both safe and efficient in elderly patients and women should not be excluded from mid-urethral slings based on their age.

4. Concomitant Prolapse Surgery

Approximately 40% of women with pelvic organ prolapse (POP) also report SUI.[219] Asymptomatic women who undergo prolapse surgery have a 11-20% risk of developing de novo stress incontinence. [220] Patients who leak during preoperative testing after reduction of their prolapse have a risk of up to 80% of developing de novo SUI.[221] The role of concomitant slings in patients undergoing POP repair has been debated, with some studies showing differences in cure rates or complications and others finding no differences. In a prospective observational study, Liang et al. evaluated 49 patients with stage 3 or 4 prolapse and occult stress incontinence.[222] In 32 (65.3%) patients a concomitant TVT procedure was performed and the remaining 17 (34.7%) patients had a prolapse repair only. The rate of postoperative SUI was significantly lower in those who had a TVT placed (9% vs. 65%) and the rate of detrusor overactivity was lower in patients who had prolapse repair alone after surgery (6% vs. 16%). Casiano et al. compared outcomes after retropubic mid-urethral slings with and without concomitant prolapse repair. [223] After 2.7 years survival free of "any" incontinence (Incontinence Severity Index score, >0) was similar in both groups (adjusted hazard ratio, 1.07; p=0.77). Women with concomitant repair for advanced prolapse tended to be more bothered by frequent urination (adjusted OR 1.78; p=0.08) and more likely to require urethrolysis (OR 6.11; p=0.04) than those without prolapse repair. There is only one study that reports on transobturator slings and prolapse surgery. Wang et al evaluated 140 women who underwent TVT (n = 70) and TOT (n = 70) with SUI with or without POP.[224] In the TVT group 30 patients and in the TOT group 22 patients had concomitant prolapse surgery. Surgical results were similar in both groups and concomitant pelvic reconstructive procedures had no effect on surgical results. At 1-year follow-up, the objective cure rates for patients with isolated SUI were 95% in the TVT group and 93.75% in the TOT group. For patients with concomitant POP, the cure rates were 90% in the TVT group and 86.36% in the TOT group. There are no randomised trials in patients undergoing pelvic organ prolapse surgery and obturator slings but with the currently available literature, it would appear that it is beneficial to treat concomitant SUI and prolapse. There are no current studies on the role of transobturator slings in occult SUI.

5. Obesity

Obesity is gradually increasing worldwide and epidemiological studies have found a link between obesity and urinary incontinence with odds ratio for the presence of urinary incontinence as high as 1.6 to 5 with each unit increase in body mass index (BMI). [225, 226]The role of mid-urethral slings in obese women has been debated due to concerns for higher failures and a potential increase in intraoperative and postoperative complications. Numerous studies have been carried out evaluating obesity as an independent predictor in patients that have undergone TVTs. [227, 228] [229] [230] [231-234]

Hellberg et al. reported a decrease in cure of 52.1% in patients with a BMI higher than 35 compared to 81.2% in those with a BMI less than 25. Six other studies have shown overall cure rates that approach 90% with no difference in the obese vs. the non obese patient.[231] However Greer et al. in their meta-analysis included these seven studies and did find a significant difference in cure rates between the two groups with cure rates being 81% and 85%, respectively (p= 0.001; OR 0.576, 95% CI: 0.426–0.779).[227] There are very limited data evaluating outcomes for transobturator slings in obese women. Liu et al did a retrospective review evaluating the TVT-O procedure in overweight and obese and women. [235]They retrospectively evaluated 129 patients who had undergone TVT-O and they were stratified according to their BMI, normal weight (n=29), overweight (n = 58), and obese (n = 32) groups. The median follow up was 24 months and there were no statistically significant differences in between groups comparing objective or subjective surgical outcomes, in the incidence of de novo DO, in quality of life scores or postoperative complications. Another study undertaken by Rechberger et al. found no significant association between BMI and surgical outcome at 18 months of follow-up among normal weight (n = 43), overweight (n = 81), and obese (n = 73) women who underwent transobturator slings.[88] However, they did notice a trend towards worse outcomes in overweight patients. Haverkorn et al. conducted a retrospective study evaluating patients that had undergone a transobturator sling (Monarc) in women with a BMI higher than 30 (n = 117) and BMI less than 30 (n = 161) with a minimum follow up of 12 months. [236] The percentage of women achieving global cure and SUI cure was significantly higher in non-obese women (83.9% and 91.9%) than in obese women (70.9% and 81.2%) (p < 0.001). Obese women achieved improvement in quality of life similar to those of non-obese women. Although the results from these studies are conflicting, it seems that regardless of BMI, transobturator slings may be an acceptable method of treatment for SUI in obese patients. Follow up in these studies is limited and larger studies are needed to confirm these findings and to evaluate the long terms effects of the procedure.

h) Conclusion and recommendation

Sufficient **Level I /II** evidence exists which evaluate mid-urethral tapes (retropubic). Current series include retrospective cohort studies and high level RCTs . There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. **Quality of evidence is A / B**.

4. SINGLE INCISION MINI SLINGS (SIS) (TABLE 3)

The single incision mini slings have been developed in an attempt to further reduce the morbidity associated with continence surgery and to provide an outpatient or office procedure to treat stress urinary incontinence. The blind passage of needles, during TVT and TOT procedures, through the retropubic space or the obturator foramen respectively is associated with a small risk of vascular , nerve or visceral injury [202]. The shorter SIMS will theoretically minimise this risk.

The concept of the single incision sling is not novel. Smith presented a small series of SIMS in 1987[237], however this was a porcine dermis sling which in vivo probably degrades and hence long term cure rates were poor.

The first commercially available mid-urethral single incision sling , TVT-Secur (Gynaecare), was launched in 2006 with no published human trial data. The last 6 years have seen a increase in the number of commercially available single incision slings. There are currently 9 different products available. All are made of type I polypropylene mesh however the length & anchoring mechanisms are variable. (**Figure 1**)

The method of insertion is either U shaped, inserted in the same manner as the TVT or the H “hammock” insertion of the TOT. There is currently very little good quality RCT data to support the use of these slings.

Ten trials have been published including 1072 women. 6 of the RCTs published compared TVT- Secur to MUS, 2 compared MiniArc to MUS, 1 compared TVT-Secur to MiniArc and to MUS, and one compared Contasure to TVT-O. The numbers in each trial are relatively small (60- 194).

Five of the seven trials of TVT-secur found it to be inferior to TVT or TVT-O. Several different outcome measures were report in these 7 trials , making it difficult to compare the trials directly. Two of these trials were stopped prematurely following an interim analysis which demonstrated TVT-secur results to be significantly less effective than the comparator MUS. Hamer et al [245] also reported concerns about the morbidity associated with TVT-secur. They reported three significant complications in 67 cases, one hemorrhage 1000ml, one urethral perforation and one perforation of the bladder.

Three trials compared MiniArc to MUS , two found no significant difference between MiniArc and obturator tapes however the third trial by Basu et al[240] reported a considerably worse outcome for MiniArc compared to TVT, 9 out of the 37 patients who underwent the MiniArc subsequently had a TVT. **Table 3** summarises the data currently available.

Figure 1. Variation in anchorage of SIS

In 2011 Abdel-Fattah et al[247] published a meta-analysis of RCT comparing SIMS to standard MUS, the review included both full text publications and conference abstracts. A total of 758 women in nine RCTs with a mean follow-up of 9.5 months were included. SIMS were associated with significantly lower patient-reported and objective cure rates compared with MUS (risk ratio [RR]: 0.83; 95% confidence interval [CI], 0.70–0.99, and RR: 0.85; 95% CI, 0.74–0.97, respectively).

One of the reasons for the development of SIMS is to reduce the morbidity of continence surgery. Hence trial design should include an assessment of morbidity, including perforation, hemorrhage, chronic pain and voiding difficulty. The meta-analysis demonstrated that there was no significant difference in the perforation rate between SIMS and MUS, the confidence intervals (CI) for these parameters were however extremely wide. There was also a trend toward more voiding difficulties following SIS but again the CI were very wide.

Proponents of SIMS have speculated that the initial poor results reflect an incorrect insertion technique used in early trials. SIMS were initially inserted in the tension free manner by which TVT are inserted, however SIMS insertion has evolved and the current insertion technique is in closer proximity to the urethra and with greater tension than TVT.

Jeffery et al[248] have published the protocol Cochrane review of SIMS which will enable ongoing assessment of data.

Due to the considerable variation in the anchoring mechanism of each type of SIMS, data from one device cannot be extrapolated to another. There is a need for further RCT. Currently the recommendation is that SIMS should only be performed in the context of research.

All reports are Level I - III in terms of evidence and there continues to be a lack of durable outcomes reporting for this technique. Current series suggest that some efficacy may be inherent to these interventions, however, comparable efficacy to either retropubic or mid-urethral tapes has yet to be proven. Grade of recommendation is –B/ C.

5. TRADITIONAL SLING PROCEDURES

As in the previous ICI4 review, the term ‘traditional’ sling procedure is used here, in line with the terminology used in the latest Cochrane review. [249] This is done mainly to distinguish open sling procedures typically placed at the region of the bladder neck from the newer, minimally-invasive mid-urethral sling (MUS) procedures.

Sling procedures came into prominence in the beginning of the twentieth century. In 1907, Giordano transplanted gracilis muscle and wrapped it around the urethra. [250] Soon thereafter, other autologous tissues were transplanted under the urethra to provide additional support: pyramidalis [251], levator ani [252], rectus fascia [253], gracili [254], and bulbocavernosus muscle and fat [255]. While it was

hypothesised that the transplanted muscle would retain its contractility and act as a neo-sphincter to prevent SUI, these procedures compressed the urethra and created a partial obstruction. Complications such as recurrent cystitis, urethral sloughing, and fistula formation were common.

The modern autologous bladder neck sling exists mainly due to the work of Aldridge in the 1940's and McGuire and Blaivas in the latter part of the twentieth century. [256-258] The majority of sling procedures have involved a combined abdominovaginal approach, although procedures performed entirely through an abdominal approach have been described. Suspended, or 'sling on a string,' methods have been developed in order to reduce the invasiveness of the procedure and to shorten the length of sling material. These shorter slings can also vary in length, from a "mid-length" sling (7-10 cm) to a "patch" sling (2-4 cm). As with needle suspension procedures, bone anchoring has been used as an alternative form of sling suspension, although the benefit of this additional step has not been adequately studied.

Sling materials may vary widely and individual materials may have only a modest effect on initial sling efficacy. However, these materials may considerably affect the long-term outcomes of sling procedures and the associated morbidity. Materials may be synthetic or biological. The latter include autografts (rectus fascia, fascia lata, round ligament, dermis, vaginal skin, and gracilis, levator, and rectus muscles), cadaveric allografts (fascia, dermis, and dura mater) and xenografts (porcine dermis and small intestinal submucosa, bovine dermis and pericardium). Case series of autologous rectus fascial (ARF) sling were reviewed within the systematic review underlying the NICE guidance on urinary incontinence. [259] Ten series including a total of 1280 women were considered. Studies had a mean or median duration of follow-up between 2 and 6 years, while in three studies, maximum follow-up of 15–18 years was reported. Subjective cure rates ranged from 26% to 97% (median 81%); and cure rates that included subjective and objective elements ranged from 73% to 95%. Satisfaction rates of 86% and 92% were reported in two studies.

Synthetic sling materials have included nylon, polyethylene, polytetrafluoroethylene (PTFE), and polypropylene. On occasion, these polymers have been 'enhanced' with synthetic or biologic coatings in an attempt to improve their biocompatibility profiles. Many additional variations in the technique have been described, although it is unclear which of these materially influence the outcome. Several case series have published outcomes for polyethylene and PTFE slings with short-term cure rates typically in the 80-90% range, depending on the definition [EL=3]. Vaginal extrusion, erosion, and sinus formation have been common with these materials. Since the last ICI review, there have been no additional studies published and the number of these procedures performed appears to have waned significantly in favour of polypropylene midurethral slings.

Both biological and synthetic sling materials are analysed together in the Cochrane review [Rehman et al., 2011], although these were considered separately in the systematic review underlying the NICE guidance on urinary incontinence. [249, 259] NICE has also published a non-systematic review of biological sling procedures under its Interventional Procedures Programme. [260]The most recent Cochrane review included 26 RCTs (or quasi-randomised trials) describing a total of 2284 women of whom 1287 were treated with suburethral traditional slings. Sample sizes ranged from 20 to 655 participants. Several of these trials are available only in abstract form and remain unpublished as full peer-reviewed papers. Owing to the significant number of recent meeting abstracts about surgical procedures for SUI, only full publications have been included in this section. Additional studies have been included, but the majority of these are case-control studies and have a relatively low level of evidence.

There have been no trials identified that compared traditional suburethral sling operation vs. no treatment, sham operation, conservative management (e.g. pelvic floor muscle training, electrical stimulation, cones, biofeedback), anterior repair, laparoscopic retropubic suspension, or artificial urinary sphincter [Rehman et al., 2011]. [249] One trial studied patients with MUI treated with oxybutynin or surgery [Osman, 2003]. [261] The type of surgery was selected according to Valsalva leak point pressure (VLPP): those women with VLPP ?> 90 cm H2O underwent an ARF sling and those with VLPP ?> 90cm H2O underwent Burch colposuspension. The results for the total surgically managed group were similar to those for the subgroup having slings. The study suggested that slings are significantly better for treating MUI than oxybutynin. Results were analysed in terms of patient reported incontinence within one year (RR 0.18; 95% CI 0.08 to 0.43). Fewer women had persistent UUI after the sling surgery (RR 0.29; 95% CI 0.09 to 0.94).

a) Traditional sling vs. bulking agent (*table 4E*)

One RCT compared ARF sling with periurethral silicone injection in women with SUI secondary to ISD in whom conservative treatment had failed [Maher et al., 2005]. [165] At 6 months, no significant differences were seen between groups in subjective cure (1-hour pad test) or satisfaction, QOL (UDI-6, IIQ). Significantly more women undergoing sling surgery were objectively cured on the basis of urodynamic assessment (81% vs. 9%; p=0.0001), but duration

Key: RP MUS=retropubic midurethral sling; F/U=follow-up (months); LE=level of evidence; TVT=tension-free vaginal tape; o=objective; s=subjective; N/A=not available; OC=open colposuspension; LC=laparoscopic colposuspension; ITT=intention to treat

of the procedure, catheterisation, inpatient stay, and time to return to normal activities were significantly longer in the sling group. A survey of two-thirds of the women at 5 years found no statistically significant differences between groups in urinary symptoms or in satisfaction with surgery, although fewer women in the silicone bulking group were satisfied (29% vs. 69%) (n=45). [EL=2] .

Open continence surgery (a suspension procedure in 46% and ARF sling in 54%) was compared with periurethral collagen in women with SUI or MUI in an additional RCT [Corcos et al., 2005]. [164] As in the previous study, there were no significant differences in patient satisfaction or QOL (SF-36, IIQ) between groups at 1 year. Using ITT analysis, there was no significant difference in continence rates at 1 year (52% collagen, 55% surgery). If only the 89% of women who underwent the randomised intervention were considered, the continence rate with surgery was significantly higher (72% vs. 53%; *p*=0.01). The incidence of adverse effects was significantly higher in the surgery group: urinary retention 13% vs. 2%, transient voiding difficulty 36% vs. 17%, UTI 6% vs. 0% (n = 133). [EL=2]

b) Traditional sling vs. colposuspension (*Table 4A*)

Nine randomised or quasi-randomised trials were identified from the literature. Six of the trials compared suburethral slings with open abdominal retropubic suspension [Henriksson & Ulmsten, 1978, Enzelsberger et al., 1996, Sand et al., 2000, Demirci & Yucel, 2001, Bai et al., 2005, Albo et al., 2007] while one trial reported the long-term outcomes [Culligan et al., 2003] and another reported the complications [Chai et al., 2009] of aforementioned trials. [38, 119, 121-126] One additional trial compared sub urethral slings with the Stamey transvaginal needle suspension [Hilton, 1989]. [120] The Cochrane review systematically evaluated the six trials comparing suburethral slings with open retropubic suspension and an additional trial that was only published in abstract form [Rehman et al., 2011]. [249]

One RCT compared dura mater sling with open colposuspension in 72 women with recurrent SUI after hysterectomy [Enzelsberger et al., 1996]. [121] At a minimum follow-up of 32 months, the combined objective and subjective cure rates were 92% after dura mater sling compared with 86% after colposuspension. While both were common, significantly more women in the sling group developed postoperative voiding difficulty or urinary retention. More women in the colposuspension group developed a postoperative rectocele. Bladder perforation and de novo urgency were common in both groups. The time to spontaneous voiding was significantly longer in the sling group (n = 72). [EL=1/2].

Three trials compared ARF sling with open colposuspension. In a small trial alternating ?17 women each to ARF and colposuspension, ARF was superior to colposuspension at 12 months follow up by objective measures (94% vs. 88%) [Demirci & Yucel, 2001]. [124] In a second trial randomising women to ARF, colposuspension, and TVT, ARF was significantly superior to colposuspension at 12 months (92.8% vs. 87.8%) using a subjective and objective definition of cure [Bai et al., 2005]. [38] The significant difference in the two procedures was not evident at 6 months follow-up (92.8% vs. 90.9%). Finally, a large RCT performed by the Urinary Incontinence Treatment Network revealed that ARF was significantly superior to colposuspension both in its cure of SUI (47% vs. 38%) and overall incontinence cure (66% vs. 49%) at 24 months [Albo et al., 2007]. [125] Fifty percent of the women underwent concomitant surgery for pelvic organ prolapse (POP) and 79% (265:255) were available for the 24-month outcome assessment. Women undergoing ARF sling had a higher percentage of postoperative UTIs within the first six weeks of follow-up, voiding and storage urinary symptoms [Chai et al., 2009]. [126][EL=1]

Two small RCTs evaluated an expanded polytetrafluoroethylene patch sling (PTFE; Gore-Tex®) and open colposuspension, with the second trial providing long-term subjective and objective outcomes [Sand et al., 2000; Culligan et al., 2003]. [122] [123] Although the groups were different at baseline in terms of the proportion with detrusor overactivity (DO) (95% colposuspension vs. 41% sling), cure rates with PTFE were not significantly different from open colposuspension at 3 months (objective 100% vs. 90%) and 2.5 years (objective 100% vs. 85%; subjective 84% vs. 93%) (n = 36). No significant differences were found between groups in hospital stay or time to catheter removal. [EL=2]

In the Cochrane review, trials comparing rectus fascia with other materials heavily weighted the comparison of different types of sling [Rehman et al., 2011]. [249] Furthermore, the results of the most recent, and by far the largest and most rigorous RCT of colposuspension and ARF sling heavily weighted the results of the analysis [Albo et al., 2007]. [125]This trial randomised 655 women of whom 520 were assessed at 24 months, while the next largest trial randomised 72 women [Enzelsberger et al., 1996]. [121] The summary statistic, combining urodynamic and symptom only diagnosis, showed a lower incontinence rate with sling procedures (RR 0.75; 95% CI 0.62 to 0.90). The data from the trials where women all had urodynamic SUI showed no significant difference in urinary incontinence after one year (RR 0.72, 95% CI 0.31 to 1.67). Data beyond five years were provided by only one trial [Sand et al., 2000], and there was no statistically significant difference between the groups, but with very wide confidence intervals (RR 2.31; 95% CI 0.24 to 22.62). [122] Adverse events in general (47% vs.63% (*p*<0.001)

and voiding difficulty in particular (14% vs. 2%, $p<0.001$) were more common in sling group [Chai et al., 2009]. [126][EL=1].

Only one small trial is available to allow comparison between sling (porcine dermis) and needle suspension (Stamey) in a group of women unsuitable for abdominal colposuspension because of vaginal narrowing secondary to either previous interventions or atrophic change [Hilton, 1989]. [120]. Although there were no differences in objective cure rates at 3 or 24 months, perioperative complications (RR 4.50; 95% CI 1.28 to 15.81) and length of hospital stay (RR 13.00; 95% CI 5.00 to 21.00) favored the needle suspension procedure (n=20). [EL=2]

c) Traditional sling vs. traditional sling (*Table 4B*)

Our review identified 3 RCTs and 2 quasi-RCT comparing one type of traditional sling with another [Barbalias et al., 1997; Lucas et al, 2000; Viseshsindh et al., 2003; Choe et al., 2000; Kuo, 2001], with an additional RCT providing long-term outcomes of one of the aforementioned studies [Guerrero et al., 2007]. [128, 132-135, 139] The remainder were cohort and case control studies.

ARF and vaginal wall slings were compared in one RCT and two non-randomised retrospective studies [Viseshsindh et al., 2003; Kaplan et al., 1996; Rodrigues et al., 2004]. [127, 139, 141]All of these trials were considered to be of poor quality. The RCT reported high subjective cure, and satisfaction rates (80–100%) for both procedures, with median follow-up of 7 months and minimum follow-up of only 3 months (n = 26) [Viseshsindh et al., 2003] [139][EL=2]. The non-randomised studies reported similar 'success' rates with both interventions, ranging from 80% to 97%, with follow-up of 21 months, and 70 months versus 45 months (n = 232, n = 79) [Kaplan et al., 1996; Rodrigues et al., 2004]. [EL=2/3]. Other than the proportions of patients requiring intermittent catheterisation after surgery (2% in the ARF group and 0% in the vaginal wall group), no additional differences were noted in rates of other postoperative complications (e.g. voiding and storage dysfunction, wound infection and seroma formation, and bladder or urethral injury).

One RCT compared two techniques of fascial sling in 168 women with urodynamic SUI 89% of whom had had prior continence surgery [Lucas et al., 2000]. [133] Women underwent a standard fascial sling procedure or a 'sling on a string' (a shorter sling mounted on each end with a nylon thread). At 1 year, subjective cure rates were 84% using both techniques. Satisfaction and changes in IIQ scores were also similar in both groups, whereas improvements in UDI scores were greater with the standard approach (adjusted for differences in baseline UDI data). A further evaluation of women in this study was reported at 5 to 7 years of follow-up [Guerrero et al., 2007]. [134] There were no significant differences in symptoms of SUI or UUI between groups, with 40%-53% vs. 36%-51% reporting SUI in sensitivity analysis. [EL=1]

Eight non-randomised studies compared the outcomes of autologous and allograft slings in a total of 859 women with SUI [Wright et al., 1998, Brown & Govier, 2000, Soergel et al., 2001, Flynn & Yap, 2002, O'Reilly & Govier, 2002, Almeida et al., 2004, McBride et al., 2005, Onur et al., 2008], while one additional study also compared both interventions with a xenograft material (porcine dermis) [Simsiman et al., 2005]. [129-131, 137, 138, 140, 142, 143, 146]All were retrospective reviews, each with differences in duration of follow-up for the interventions evaluated (between 1 month and 3 years), with dropout rates of 4% to 34%. Additionally, between 16% and 82% in different studies underwent other concomitant surgeries, and all of these studies were considered to be of poor quality. [EL=3]

Four of these studies compared autologous with allograft (cadaveric) fascia lata. Three reported similar results for all outcomes (subjective cure, satisfaction, and UDI-6, IIQ-7 and SEAPI scores) [Wright et al., 1998, Brown & Govier, 2000, McBride et al., 2005], while the fourth study reported significantly higher cure rates in the autologous group [Almeida et al., 2004]. [129, 130, 140, 142] [EL=3] In three studies that compared autologous rectus fascia or fascia lata with allograft fascia lata, two found a significantly higher cure rate in the autologous group [Soergel et al., 2001, Simsiman et al., 2005]; [137, 143]the other found no significant differences in cure rate, although satisfaction rates were higher in the autologous group after 2 years follow-up [Flynn & Yap, 2002]. [36] In the study with a xenograft arm, cure rates were significantly higher with autograft material [Simsiman et al., 2005]. [143]The study comparing ARF to cadaveric dermis found no significant difference in subjective cure rates at a mean follow-up of 18 months and 13 months, respectively [Onur et al., 2008]. [146] [EL=3].

One RCT compared the porcine dermis sling vs. ARF and tension-free vaginal tape (TVT), a retropubic MUS [Guerrero et al., 2010]. [160]It should be noted that the ARF and porcine dermis slings were placed at the midurethra rather than the bladder neck, but suspended above the rectus fascia like traditional slings. The primary outcome was patient-reported improvement rates at 6 months and 1 year. At 6 months, the porcine dermis arm had significantly poorer improvement rates (73%) than TVT (92%) and ARF (95%), and, at 1 year, only 61% of the porcine dermis slings remained as improved, vs. 93% and 90% of the TVT and ARF arms, respectively. At 1 year, women undergoing porcine dermis slings had significantly lower dry rates (22%) as compared to TVT (55%) and ARF

slings (48%), respectively. Subsequently, the porcine dermis arm was suspended following interim analysis. There was no difference in success rates between the TVT and ARF arms. [EL=1/2].

One non-randomised trial compared porcine dermis sling vs. ARF [Giri et al., 2006], a second compared porcine dermis sling vs. both ARF and TVT [Morgan et al., 2007], and a third trial mentioned earlier compared porcine dermis vs. both ARF and allograft slings [Simsiman et al., 2005]. [143-145] At a follow-up of 36 months, the subjective success rate (cure and improved) after ARF sling was significantly higher than porcine dermis sling (80.4% vs. 54%) [Giri et al., 2006]. [144] Women undergoing porcine dermis slings were found to have significantly higher postoperative symptom severity than women undergoing either ARF sling or TVT [Morgan et al., 2007]. [145]Objective cure rates after ARF were significantly higher (87%) than either porcine dermis sling (54%) or cadavercis fascia lata (64%) [Simsiman et al., 2005]. [143][EL=2/3]

A quasi-RCT compared an ARF sling with a self-fashioned polypropylene mesh sling placed at the bladder neck [Kuo, 2001]. [135, 148] At a median follow-up of approximately 24 months, cure and satisfaction rates were similar but operating time and hospital stay were significantly shorter in the prolene sling group. Delayed voiding occurred in more women in the ARF sling group. No other significant differences were seen between groups in complications (e.g. haematoma, dysuria, de novo urgency or UUI) (n=50). [EL=2] A second, retrospective, non-randomised trial found no significant difference in subjective cure rate (81% vs. 88.9%) in women undergoing ARF and polypropylene mesh (Marlex) slings [Winckler et al., 2010]. [45] It should be noted that both slings in this study were placed at the midurethral but tied without tension above the rectus fascia as in the traditional bladder neck sling. Interestingly, vaginal extrusion rates and rates of surgical intervention for extrusion were not significantly different between ARF and Marlex slings. [EL=3]

One RCT compared ARF and PTFE slings in women with SUI, 92% of whom had had previous continence surgery [Barbalias et al., 1997]. [128] Combined objective and subjective cure rates at 6 months follow-up were 81% and 88%, respectively. No complications were reported in the ARF sling group; however, urethral erosion, recurrent UTI and *de novo* DO were very common with PTFE (n = 48). [EL = 1] A quasi-randomised comparison of MycroMesh patch sling (PTFE mesh impregnated with silver diacetate and chlorhexidine) with vaginal wall sling gave no statistical analysis, but found combined subjective and objective cure in 95% vs. 75% at mean follow-up of 22 months [Choe et al., 2000]. [132][EL=2] Again, the need for sling removal was common, reported in up to 31% (median 8%) in a review of case series within the systematic review underlying the NICE guidance on UI [National Collaborating Centre for Women's & Children's Health, 2006, National Institute for Health & Clinical Excellence]. [259][EL=3].

A retrospective cohort study compared an ARF sling with one reinforced with polyglactin mesh in women with urodynamic SUI, one-third of whom also had UUI (n=51) [Maher et al., 2001]. [136]Follow-up differed between groups and, overall, no clear difference was seen between groups in success rates. As with most studies, results depended on the definition of success used. No significant differences were noted between groups in terms of complications (e.g. wound infection, incisional hernia, voiding dysfunction, and de novo DO). [EL=3]

A small, non-randomised trial compared ARF to bovine dermis sling (n=85) [Wilson et al., 2008]. [147] Patients were allocated to material by institution and all had ISD, advanced age, and/or recurrent SUI after previous anti-incontinence surgery. At 12 months follow-up, the SUI-specific cure rates (consisting of subjective stress SEAPI domain and negative cough stress test) and global cure rates (consisting of SEAPI composite score and visual analog score) were not significantly different between the two slings. QOL indices (UDI-6, IIQ-7) were significantly improved in both groups. There were significant differences in several preoperative demographic variables between the groups.

The Cochrane review included 4 published trials in their statistical comparison [Barbalias et al., 1997; Lucas et al., 2000; Viseshsindh et al., 2003; Guerrero et al., 2008], as well as 2 trials in abstract form [Rehman et al., 2011]. [249]A total of 379 women studied after 12 months showed no statistically significant difference in incontinence rates (RR 0.89; 95% CI 0.72 to 1.10). However, results reported improvement after one year in favour of the traditional ARF sling (RR 0.33; 95% CI 0.17 to 0.64). The incontinence rate after five years was reported in only one trial [Lucas et al., 2000] and showed no statistically significant difference between different lengths of the autologous material used (RR 1.17; 95% CI 0.86 to 1.59). There was significant heterogeneity in the incidence of perioperative complications between groups in two trials, which was attributed more to complications with the use of Gore-Tex in one trial (RR 0.05; 95% CI 0.00 to 0.80, Barbalias et al., 1997). In the other trial, there was no statistically significant difference between two biological slings (RR1.14, 95% CI 0.78 to 1.66, Lucas et al., 2000). No statistically significant difference was found in assessment of the following adverse events, reported in only one trial [Lucas et al., 2000]: bladder perforation (RR 0.69; 95% CI 0.12 to 4.03), UTI (RR 1.73; 95% CI 0.66 to 4.54), de novo DO or urge symptoms (RR 3.11; 95% CI 0.65 to 14.97), and voiding dysfunction (RR 1.16; 95% CI 0.65 to 2.07).

d) Traditional sling vs. midurethral sling (Table 4C and D)

Our review identified 17 trials that addressed the comparison between traditional sling operations and MUS operations. Eight RCTs compared traditional slings placed at the bladder neck with the retropubic MUS [Arunkalaivanan & Barrington, 2003; Lucas et al., 2004; Bai et al., 2005; Wadie et al., 2005; Kondo el al., 2006; Basok et al., 2008; Sharifiaghdas & Mortazavi, 2008; Amaro et al., 2009;] and 3 additional RCTs provided long-term outcomes of aforementioned studies [Abdel-Fattah et al., 2004; Guerrero et al., 2010; Wadie et al., 2010]. [38, 149, 150, 152, 154, 155, 158, 160, 161, 262] One of the trials [Lucas et al., 2004] was only available as an abstract and 3 studies were non-randomised case control or cohort studies (Hung et al., 2004; Morgan et al., 2007; Trabuco et al., 2009). [145, 151, 153] [159] Two RCTs compared a traditional ARF sling to a transobturator (TO) MUS (Safyre-t) (Silva-Filho et al., 2006; Tcherniakovsky et al., 2009). [162, 163] Finally, a non-randomised trial compared pubovaginal slings (material not stated) with TVT and TOT (Jeon et al., 2008). [156]

Five RCTs compared ARF sling with TVT and reported on a total of 403 patients (Lucas et al., 2004, Bai et al., 2005, Wadie et al., 2005; Sharifiaghdas & Mortazavi, 2008; Amaro et al., 2009). [38, 152, 158, 161, 262]Two of the studies were recently updated at a longer-term follow-up (Guerrero et al., 2010; Wadie et al., 2010). [153, 160]Cure rates at 12-36 months (subjective +/- objective) varied widely depending on definition and were 55%-95% for both ARF and TVT. Although a statistical difference was not observed at 6 months, one trial (Bai et al., 2005) showed a significant difference in subjective + objective cure rate at 12 months favoring TVT (92.8% vs. 87%).[38] This trial also had a colposuspension arm, which had a 12 month cure rate of 88%. Another trial had a porcine dermis sling arm with a cure rate of only 53% (Lucas et al., 2004; Guerrero et al., 2010). [160, 161] The remainder of the RCTs did not reveal a statistical difference in cure rates between ARF and TVT. [EL=1/2]. One RCT found no statistical difference in objective and subjective cure rates at 12 months after cadaveric fascia lata slings and the intravaginal slingplasty (IVS), a multifilament, polypropylene MUS (Basok et al., 2008). [155]

One non-randomized trial that also included a porcine dermis arm found no statistical difference between ARF slings and TVT (Morgan et al., 2007). [145] Symptom severity, as assessed by validated questionnaire, was not significantly different between the ARF sling and TVT groups. As mentioned in the previous section, symptom severity was significantly higher in the porcine dermis group than in the other 2 groups. [EL=2/3] A second retrospective study compared traditional sling (material not stated), TVT, and the transobturator tape (TOT) (Jeon et al., 2008). [156]Overall complication rates were not significantly different between the sling groups. At 2 years postoperatively, the cumulative cure rates of the traditional sling, TVT, and TOT groups were significantly different (87.3% vs. 86.7% vs. 34.9%, respectively; $p<0.0001$). The risk of treatment failure in women who received TOT was 4.6 times higher than in women who underwent traditional sling. The 7-year cumulative cure rates of traditional sling and TVT groups were 59.1% and 55.1%, respectively. [EL=2/3] One trial each found no statistical difference in outcomes between traditional polypropylene sling and TVT (Hung et al., 2004) and ARF sling and Uretex, a monofilament polypropylene sling (Trabuco et al., 2009). [151, 159][EL=2/3]

One RCT comparing porcine dermis sling with TVT found no significant differences operating time, hospital stay, complication rates, or subjective cure at 1 year (85% vs. 89%) (Arunkalaivanan & Barrington, 2003), nor in cure (88% vs. 82%) or satisfaction at 3 years, assessed by mailed questionnaire (77% vs. 80%) (Abdel-Fattah et al., 2004). [48, 55] [EL=1]. It is not clear why this study found comparable results between porcine dermis and TVT, whereas the 3-arm trial cited above found such significantly poorer results after porcine dermis to require the premature curtailment of recruitment (Lucas et al., 2004; Guerrero et al., 2010). [160, 161]

Two small RCTs compared ARF sling to Safyre-t transobturator MUS (Silva-Filho et al., 2006; Tcherniakovsky et al., 2009). [59, 60] At a follow-up of 12 months, subjective + objective cure rates were not statistically different (95% vs. 90.5%) in one trial (Tcherniakovsky et al., 2009), while higher pad weight at 6 months was observed for the ARF group in another trial (39g vs. 8.4g) (Silva-Filho et al., 2006). [162, 163] [EL=2]

The Cochrane database identified 12 trials that addressed the comparison between traditional sling procedures and minimally invasive, MUS operations. [249]Ten of these studies have been summarised in our assessment and 2 studies were only in abstract form. [38, 149, 152, 154-156, 158, 160, 163, 262]Data on incontinence after the first year were available from four RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Guerrero et al., 2010). [38, 149, 154, 160]Incontinence was reported by 31.6% of those women in the traditional sling and 25.3% of those in the MUS groups. This was not statistically significant (RR 1.23; 95% CI 0.91 to 1.66). This translates to 311 per 1000 women being incontinent after a traditional sling compared with 253 per 1000 after a MUS. Improvement after a year was addressed by two trials (Arunkalaivanan & Barrington, 2003; Guerrero et al., 2010) and there was no statistically significant difference between the two types of sling (RR 1.30; 95% CI 0.57 to 2.94). [149, 160]

Pooled data from 3 trials (Arunkalaivanan & Barrington, 2003; Kondo et al., 2006; Tcherniakovsky et al, 2009) showed a statistically significant higher risk of perioperative complications after traditional sling operations (RR 1.59; 95% CI 1.03 to 2.44). [149, 154, 163]Seven RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Sharifiaghdas & Mortazavi, 2008; Song et al., 2004 (abstract only); Tcherniakovsky et al., 2009; Wadie et al., 2005) reported bladder perforation. [38, 149, 152, 154, 163, 262]There were more perforations after MUS procedures, but this did not reach statistical significance (RR 0.62; 95% CI 0.34 to 1.11) and the confidence interval was wide. The combined results from 3 trials showed less *de novo* urgency symptoms after MUS (RR 3.13; 95% CI 0.96 to 10.24) but this did not reach statistical significance and the confidence interval was wide. However, 3 trials showed that development of *de novo* DO was significantly less after MUS operations (RR 3.21; 95% CI 1.29 to 8.03). This was principally due to the higher weighting given to the largest trial (Basok et al., 2008). [155] The combined results from 5 trials showed that more women had postoperative voiding dysfunction after traditional slings than after MUS (RR 1.60; 95% CI 0.94 to 2.71) but this did not quite reach statistical significance and the confidence interval was wide. More women in the traditional sling group required release of sling (9% versus 2%), reported in two trials (RR 3.67; 95% CI 0.95 to 14.22) but again this was not statistically significant. There was no statistically significant difference in urinary retention up to 6 weeks (RR 5.51; 95% CI 0.68 to 44.63) from one trial and vaginal erosion (RR 0.35; 95% CI 0.02 to 8.10) based on one trial.

e) CONCLUSIONS / RECOMMENDATIONS

The conclusion of the Cochrane review was that data on traditional sling operations remain too few to adequately address the effects of this type of surgical treatment. They highlight the fact that many studies fail to address appropriate outcome measures to address the broader effects of the surgery, such as general health status and health economics. They also emphasise that reliable evidence on which to judge whether or not traditional slings are better or worse than other surgical or conservative management is currently not available.

From the available evidence, ARF sling is the most widely evaluated biological sling and is an effective and durable treatment for SUI. **[EL=1]** Limited data suggest that pubovaginal sling using porcine dermis is also effective, **[EL=1]** although data relating to other biological slings are few, and generally of poor quality. The inclusion of the large trial on traditional slings (Albo et al., 2007) strengthened the trend towards a better performance of the traditional slings in terms of patient reported incontinence rates, but higher early post-operative voiding dysfunction rates compared to open colposuspension. **[EL=1]** The limited data available suggest that the overall rates of late surgical complications are similar after sling and colposuspension; however, the pattern of complications may vary.

Meta-analysis showed a significantly greater patient-reported improvement of symptoms, using autologous materials, both within and after 1 year. There is no high level evidence of a difference in efficacy between biological and synthetic sling materials, although adverse events may be more common following the use of synthetic materials for 'traditional' sling procedures **[EL=3]**. Some synthetic slings, such as Gore-Tex, may have a higher incidence of erosion, infections and urgency symptoms. There is no high level evidence of a difference in efficacy between different biological sling materials, although those studies that find a difference all favour autologous materials **[EL=2]** However trials were few in number, with short follow-up and small populations. More evidence is needed to compare slings made of autologous materials with synthetic or exogenous biological materials.

Minimally invasive MUS operations appeared to be as effective as traditional suburethral slings in the short term (RR 0.97; 95% CI 0.78 to 1.20), although the confidence interval was compatible with minimally invasive slings being 20% better or 12% worse. **[EL=1]** The operating time and length of stay were also significantly shorter with minimally invasive synthetic MUS operations, and women had less perioperative complications and DO. The main perioperative complication of minimally invasive sling procedures is bladder puncture, although this does not appear to have longer term implications.

Autologous fascial sling is recommended as an effective treatment for stress urinary incontinence, which has longevity. **[Grade A]** Further high quality research is required to clarify the place of 'traditional' sling procedures in relation to other procedures, and to establish the optimum sling materials. **[Grade D]**

6. LAPAROSCOPIC COLPOSUSPENSION (TABLE 5)

a) Laparoscopic versus open colposuspension

The Cochrane review of laparoscopic colposuspension includes details of 22 RCTs that include laparoscopic colposuspension [263], 14 more than their initial review [264]. Of these 22 trials, ten compared laparoscopic colposuspension with open colposuspension [265-274].

Eight of the ten studies comparing laparoscopic colposuspension with open colposuspension were included along with eight retrospective cohort studies in a recently published meta-analysis [275].

We identified two further RCTs on laparoscopic colposuspension [276, 277]; in addition one study

Table 5. Published level 1 & 2 evidence relating to laparoscopic colposuspension for the treatment of stress urinary incontinence

	Study references	Type	Comparator	N/N (n1:n2)	FU	Cure (obj or subj)/ effect size	EL	Comments
1	[288]	RCT	Transperitoneal vs. extraperitoneal	22 (?:?)	1-12m	92% (s+o)	2	Mixture of suturing/stapling techniques; outcomes not separately evaluable.
2	[286]	RCT	Sutures vs. mesh/staples	69/69 (35:34)	1y	91% vs. 94%; RR 0.97; 95% CI 0.85, 1.11	2	
3	[271]	RCT	Open colpo	92/92 (46:46)	6m	80% vs. 96%; p=0.044 (o)	2	Part preference, part randomised; sample size calculation req'd 152.
4	[285]	RCT	2 single bite vs. 1 double bite sutures	161/? (83:78)	1y	83% vs. 58%; p<0.001	2	Enrolment curtailed early after interim analysis
5	[276] [287] [300] [301]	RCT	Sutures vs. mesh/staples	53/60 (27:26)	1 & 3y	89% vs. 75% (o - at 1y) 70% vs. 42%(o - at 2y) 58% vs. 38% (o – at 3y); p<0.05	2	Only completers analysed in 2001 paper; ITT used in 3 year follow-up.
6	[269]	RCT	Open colpo	74/74 (34:40)	18m	88% vs. 85%; p=ns (o+s)	2	No ss calculation.
7	[282]	RCT	TVT	68/79 (31:37)	1y	87% vs. 89% RR 0.98; 95% CI 0.82, 1.16	2	270 approached; 79 randomised. Study designed to examine costs.
8	[268]	RCT	Open colpo	90/90 (47:43)	1y	85% vs. 86%; p=ns (o)	2	15% vs. 37% underwent concomitant hysterectomy
9	[166]	RCT	TVT	46/46 (23:23)	3-24m	83% vs. 83%; RR1.00; 95% CI 0.77, 1.30 (s+o)	2	No information on randomisation; no allowance for variation in FU
10	[302] [283] [279]	RCT	TVT	121/128 (51:70)	1y	57% vs. 86% (95% CI for diff. 12.7, 43.9); p=0.000 (o)	2	Lap. colpo with mesh. SS calculation required 176.
11	[281] [46]	RCT	TVT	71/72 (35:36)	12-43m 12-88m	97% vs 81% (o – at median 18m) 43% vs. 52% (s – at median 65m)	2	SS 130; recruitment stopped early because of slow recruitment. 63 (88%) FU at 1y; 33 (46%) at 2y
12	[266]	RCT	Open colpo Lap colpo (mesh)	184/211 (49:63:72)	1y	90% vs. 92% vs. 63% (o) p<0.05 open vs. mesh	2	Unclear randomisation; all pts randomised to Burch or lap colpo (mesh) also included in separate multicentre study [265]. Only completers analysed.
13	[277]	RCT	Open colpo	52/52 (26:26)	3-24m	81% vs. 81%; p=ns	2	Many concurrent procedures - varied between groups
14	[270] [289]	RCT	Open colpo	242/291 (144:147)	2y	80% vs. 70% (o)	1	5 had no op., & 12 changed op. after randomis'n. Objective data on 83%.
15	[267]	RCT	Open colpo	164/200 (76:88)	3-5y	72% vs. 78%; p=0.22 (o at 6m) 69% vs. 80%; p=0.38 (s at 2y)	2	Telephone interview at 3-5y; results 'similar' to 24m

Notes: patient numbers are given as – total no. followed up or analysed /total no. recruited (no. in index group: no. in comparator group)
SS = sample size; ITT = intention to treat

previously only in abstract form has recently been published [267], and two have further publications with longer-term follow-up [278] or cost-effectiveness data [279].

Studies included in the Cochrane review had different lengths of follow-up, although eight studies had follow-up in the region 6 to 18 months. In comparison with open colposuspension they found subjective cure rates to range from 58% to 96% in the open and 62% to 100% in the laparoscopic group within the 18 months follow up, with a non-significant 5% lower relative subjective cure rate for laparoscopic colposuspension (RR 0.95, 95% CI 0.90 to 1.00) [263] [EL=1]. The two studies with follow-up at five years or beyond unfortunately remain unpublished and available in abstract form only. Both these studies were relatively small, and their results are inconsistent, one finding better subjective outcome from the laparoscopic procedure [273], and one favouring the open procedure [272]; the methodology of this latter study in particular has been questioned [EL=2].

Overall, the objective cure rate as judged by cough stress testing or pad test within 18 months was statistically significantly lower following laparoscopic colposuspension (RR 0.91, 95%CI 0.86 to 0.96) [EL=1]. Between 18 months and five years there was no significant difference (RR 1.01, 95% CI 0.88 to 1.16); again however, there was heterogeneity with one small trial greatly favouring open procedure [272] and the other favouring laparoscopic [273] [EL=2]. When objective cure was judged by urodynamic investigations there was a significantly higher success rate following open colposuspension (RR 0.91, 95%CI 0.85 to 0.99).

b) Laparoscopic colposuspension versus other techniques

Eight trials have compared laparoscopic colposuspension with minimally invasive mid-urethral slings [166, 280-284].

In comparison with minimally invasive mid-urethral slings there was no statistically significant difference in subjective cure rates within 18 months (RR 0.91, 95% CI 0.80 to 1.02) [EL=1]. The definition of objective cure varied widely between studies, although overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95% CI 0.85 to 0.99) [EL=1].

Although laparoscopic colposuspension is regarded as a less invasive operation than the open colposuspension the mid-urethra tape procedures had significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01 -0.001) than the laparoscopic colposuspension.

c) Different techniques of laparoscopic colposuspension

Different aspects of the laparoscopic technique (one vs. two sutures [285], sutures vs. Mesh [266, 286, 287] and transperitoneal vs. extraperitoneal approach to laparoscopy [288].

Two sutures either side of the bladder neck resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95% CI 1.14 to 1.77) cure rate than one [285] [EL=2].

When comparing sutures and mesh to secure paraurethral support, sutures resulted in higher subjective (RR 1.28, 95% CI 1.11 to 1.47) and objective (RR 1.20, 95%CI 1.07 to 1.35) cure rate than mesh [266, 276, 286, 287] [EL=1].

The transperitoneal versus extraperitoneal study reported above employed different techniques (sutures vs mesh) and therefore gives little insight into the value of either approach given the superior results obtained with sutures.

The use of glue or fibrin sealants has not been reported outside small case series.

d) Cost effectiveness of laparoscopic colposuspension

Cost effectiveness was assessed in only one trial [270, 289]. This study showed that whilst laparoscopic surgery produced greater quality adjusted life years (QALYs), there was an additional cost when compared to open surgery. The differential mean cost was GB £372 (95% credibility interval [CrI]: 274–471), and at 6 months QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CrI: –0.012 to 0.023). The cost of each additional QALY in the laparoscopic group or incremental cost-effectiveness ratio (ICER) was £74,400 at 6 months, but reduced to £9,300 by 24 months, in view of a further increase in QALYs, but no additional costs (assumed) [289] [EL=1].

Earlier studies have shown TVT™ to be dominant in cost effectiveness terms over both open [290] and laparoscopic colposuspension (albeit using a mesh technique) [279] [EL=1].

e) Complications of laparoscopic colposuspension

Bladder, ureteric and vascular injuries are recognised complications of colposuspension. The Cochrane review reported 21 bladder injuries among 521 laparoscopic procedures (compared with 10 among 507 open procedures) and two studies reported obturator vein lacerations. However, when compared with the traditional open colposuspension, the laparoscopic group was found to have significantly fewer postoperative complications (RR 0.74, 95% CI 0.58–0.96) with lower estimated blood losses and shorter duration of catheterisation.

Longer operating times are a significant disadvantage of the laparoscopic approach; however, women have reported significantly less pain, (Carey et al 2000, Burton 1999)[272, 291] shorter hospital admissions, faster recoveries and quicker return to normal activities. (Cheon et al 2003, Fatthy et al 2001, Kitchener et al 2006 and Su et al 1997)[292-295].

f) Longevity of laparoscopic colposuspension

A long-term review of women who had undergone laparoscopic colposuspension more than 10 years previously (Barr et al 2009)[296] compared the results with a group of women who had open colposuspension. Subjective cure rates deteriorated over time from 71% and 67% at 6 months to 52% and 36% at 10 years for the laparoscopic and open procedures, respectively.

The conclusion from the Cochrane review was that the available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension two years postoperatively [263]. The systematic review specific to laparoscopic colposuspension and TVT™ concluded that the evidence so far appears to favour the latter as the minimal-access technique of choice for USI [297]. In both cases however the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long-term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalisable to the urogynecological/urological community at large. The NICE guidance includes amongst its recommendations that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of UI [298, 299]; this same point is emphasised in the meta-analysis from Tan and colleagues [275] [EL=4].

g) Summary:

Laparoscopic colposuspension shows comparable subjective and objective outcome to open colposuspension in the short to medium term; longer term outcomes are unknown **[EL=2]**.

Limited evidence suggests that whilst the subjective outcome from laparoscopic colposuspension is similar to the TVT™ the objective outcome is poorer. **(EL=2)**

Laparoscopic colposuspension may not be good value for money when compared with open colposuspension in the short term (i.e. first 6 months following surgery), but it could be a cost-effective alternative over 24 months **[EL=1]**; other comparisons however suggest that minimally invasive mid-urethral tape procedures may be dominant in health economic terms.

h) Recommendations:

Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise. **(Grade D)**

Women should be advised about the limited evidence available about the longevity of laparoscopic colposuspension. **(Grade D)**

Laparoscopic colposuspension might be considered for the treatment of SUI in women who also require concurrent laparoscopic surgery for other reasons. **[Grade D]**

II. STRESS INCONTINENCE AND PELVIC ORGAN PROLAPSE

Women who present with urinary incontinence as their primary symptom may often have symptomatic or asymptomatic pelvic organ prolapse (POP). In a patient with POP, SUI may be evident and overt or POP may be protective of, or mask, obvious urinary incontinence via urethral kinking. This is termed “occult” SUI and is elicited only during maneuvers to reduce the POP. SUI and POP are intimately related. Coexistent symptoms of SUI may be present in over 60% of women with POP, [38] and occult SUI may occur in up to 80% of clinically continent women with severe POP. [303-306] Postmenopausal women may have up to twice the risk of developing occult SUI. Furthermore, women with both SUI and POP have more lower urinary tract symptoms and more functional impairment than women with POP only. [307]

There is some evidence from Medicare claims data that addressing POP at the time of SUI surgery may avoid an early repeat operation for either POP or SUI; however, the rates of postoperative outlet obstruction are higher. [308] As such, the decision to treat POP surgically at the same operation as the SUI should be determined by the symptoms and bother the POP produces to the patient and the influence that the POP surgery may have on the outcome of the surgery for SUI. In instances where the prolapse is symptomatic, it will be a matter of subjective opinion whether the incontinence or the prolapse is more significant and bothersome (rather than a pathological diagnosis). If the treatment selection is based on subjective assessment, it follows that the outcome from treatment must also be based on subjective rather than objective measures. As with most issues in pelvic floor reconstruction, the decision to perform an anti-incontinence procedure

and the choice of the procedure itself is a source of great debate. The literature evaluating the following clinical scenarios will be evaluated: (a) overt SUI with POP; (b) occult SUI with POP reduction; (c) high grade POP in the absence of occult or overt SUI; and, (d) the status of preoperative urgency urinary incontinence (UUI) and overactive bladder symptoms (OAB) after POP repair.

1. OVERT SUI WITH POP

Women who present with SUI commonly have deficient support of the anterior vaginal wall. Significant POP is generally defined anatomically as the presenting part of the prolapse reaching to within a centimetre of the hymenal remnant. The presence of preoperative POP may have an impact on the efficacy of anti-incontinence surgery, and the outcomes of any surgery to correct SUI should be evaluated along with the incidence of *de novo* or worsened postoperative obstructive and storage urinary symptoms.

Milani et al noted that the presence of preoperative POP led to a lower cure rate of SUI after either the Burch colposuspension or the MMK procedure, with greater degrees of POP associated with lower SUI cure rates. [309] (Level 3) Additionally, Colombo et al performed a RCT to compare Burch colposuspension with anterior colporrhaphy in women with SUI and Grade 2-3 anterior vaginal wall prolapse. [310] Level 1/2) The authors found that the Burch colposuspension was better in controlling SUI but that cystocele recurred in 34% of patients. The cure rate for cystocele with anterior colporrhaphy was high (97%) but cure rate of SUI was very low. The authors concluded that neither operation was recommended for combined SUI and advanced cystocele.

In a recent RCT, Costantini *et al* revealed that Burch colposuspension does not provide a significant cure of SUI in incontinent women undergoing sacrocolpopexy. [10] (Level 1/2) Out of 47 women with POP and SUI, 24 underwent sacrocolpopexy and Burch and 23 underwent sacrocolpopexy alone. The primary outcome measures were anatomical outcome and changes in incontinence status as indicated by a bladder diary, daily pad use, and CST, while secondary end points were changes in subjective symptoms and quality of life as measured by the UDI and IIQ. In the Burch group, 13 of 24 patients (54.2%) were still incontinent after surgery compared with 9 of 23 (39.1%) in the non-Burch group. Two women in the Burch group (8.3%) and one in the non-Burch group (4.3%) complained of *de novo* urinary storage symptoms. There was no significant intergroup difference (p=0.459). No significant intergroup difference emerged in anatomical outcome and UDI and IIQ scores improved in both groups (p = 0.0001) and the intergroup difference was not significant in either questionnaire (p = 0.769 and p = 0.327, respectively).

Moon *et al* compared the Burch colposuspension (n=49) and TOT (n=60) in consecutive women undergoing sacrocolpopexy for POP ≥ Grade III and SUI. [311] (Level 2) Mean hospital stay was longer in the Burch group (11.3 days vs. 7.8 days, p<0.001), as were the rates of postoperative urinary retention (53.1% vs. 11.7%, p<0.001), *de novo* urgency (18.4% vs. 3.3%, p=0.01), and recurrent SUI (18.4% vs. 1.7%, p=0.003). The SUI cure rate was significantly higher in the TOT group than in the Burch group (98.3% vs. 69.7%, p <0.001).

Gordon *et al* prospectively followed 30 patients short-term who underwent TVT at the same time as surgery for severe POP. [312] (Level III) No patients had postoperative symptoms of SUI despite three patients (10%) having positive postoperative stress tests. *De novo* detrusor overactivity occurred in 13% of subjects. Yip and Pang recruited 302 patients, 250 (82.8%) of when completed 1-year follow-up. [313] (Level II/III) There were 157 (62.8%) patients who had a TVT alone, and 93 (37.2%) had TVT and concomitant POP surgery. All patients had urodynamic studies before and one year following surgery. The objective cure rate for SUI was 87.3% for patients with TVT alone and 80.6% for TVT with concomitant procedures (p>0.05). The subjective SUI cure rates for TVT alone and TVT plus concomitant procedures were 89.2% and 86.0% at 4 months, and 93.0% and 94.6% at 1 year, respectively (p>0.05). The most common complications were postoperative urinary retention (15.2%), *de novo* detrusor overactivity at one year (10%), and intraoperative bladder puncture (8%). In an additional prospective cohort study and a case series, the TVT combined with vaginal reconstruction resulted in 85% to 95% cure rates for urodynamic SUI. [314, 315] (Level III) The rates of postoperative urinary urgency and voiding dysfunction were 10% and 11%, respectively. Voiding difficulties and post void residuals of > 100 mL were treated with urethral dilatation and the authors did not report any cases of long-term urinary retention.

Transobturator midurethral slings may also be effective in the setting of overt SUI and POP. The addition of TVT-O to anterior colporrhaphy in 50 women with SUI and high grade anterior POP resulted in 1-year objective cure rates for SUI and POP of 92% and 91%, respectively. [316] (Level 3) Overall early postoperative complication rate was 16%, although all were minor. At 12-month follow-up, tape extrusion requiring surgical removal developed in only one patient. The ICIQ-UI SF questionnaire scores were 13.4 +/- 6.8 and 3.5 +/- 3.2 (p <0.01) between preoperative and 12-month follow-up, respectively.

In data from the National Hospital Discharge Survey, the addition of an anti-incontinence procedure did not significantly increase the immediate morbidity in women who underwent POP surgery. [317] Of the 1931 women who underwent POP procedures, concomitant anti-incontinence procedures

were performed in 26.6% and complications were reported in 14.9%. Complications were associated with medical comorbidity (OR 11.2) and concomitant hysterectomy (OR 1.5), while concomitant procedure for SUI was not.

2. OCCULT SUI WITH POP

Overall, the level of evidence supporting a specific anti-incontinence procedure in women with POP and occult SUI is low. Chaikin *et al* discovered occult SUI after reduction of prolapse with a pessary in 14 of 24 women (58%). [304] (Level III) Ten women with no urodynamic evidence of sphincteric incontinence underwent anterior colporrhaphy and no additional anti-incontinence procedure was performed. Mean follow-up was 44 months (range 12 to 96). None had postoperative SUI but one (10%) had a recurrent grade 2 cystocele. The 14 remaining women with urodynamic stress incontinence after POP reduction underwent anterior colporrhaphy with a bladder neck pubovaginal sling procedure. Mean follow-up in these cases was 47 months (range 12 to 108). In two patients (14%) SUI developed postoperatively and one (7%) had a recurrent grade 3 cystocele. The incidence of UUI did not appear to be significantly influenced by either surgical intervention. Overall 12 patients had preoperative UUI, of whom 9 (75%) had persistent UUI postoperatively. *De novo* UUI developed in another woman. The authors' findings suggest that patients without occult SUI may be effectively treated with POP repair alone, while women with occult SUI on urodynamics should be offered anti-incontinence surgery.

Barnes *et al* reported on 34 women with grade 3-4 POP and occult SUI who underwent a bladder neck pubovaginal sling as the anti-incontinence procedure. [318] (Level III) Sling materials included autologous rectus fascia, cadaveric fascia lata, or a free vaginal wall graft. Mean follow-up was 15 months (range 6 to 39). The mean time required before spontaneous voiding resumed without the need for catheterisation was 11.8 days (range 2 to 46) and no patient developed permanent urinary retention. Two (9.5%) of 21 women without preoperative UUI developed *de novo* UUI; however, preexisting UUI resolved in 45%. SUI occurred in two women (7%) at four and 19 months postoperatively, while clinically significant uterine prolapse developed in one woman two years after surgery.

Groutz *et al* reported on 100 women with occult SUI undergoing concomitant transvaginal POP surgery and TVT.[319] (Level 3) The mean follow-up period was 27 months (range: 12-52 months). Two patients had postoperative urinary retention necessitating catheterisation for more than seven days, but neither required any surgical intervention. Vaginal extrusion was diagnosed in three patients, all of whom were successfully treated by partial TVT excision. Two (2%) patients developed urodynamically-confirmed SUI within one year postoperatively; however, postoperative urodynamics revealed asymptomatic urodynamic stress incontinence in 15% of other patients. Thirteen (72%) of 18 patients with preoperative UUI had postoperative persistent UUI, while *de novo* UUI developed postoperatively in 8 (8%) of patients.

A RCT compared concomitant endopelvic fascia plication at the urethrovesical junction vs. TVT in 50 women with severe POP and occult SUI. [320] (Level 1/2). The addition of a TVT resulted in a higher 2-year objective continence rate than endopelvic fascia plication (92% vs. 56%, respectively; $p<0.01$). The subjective cure rates were 96% for TVT compared to 64% for plication ($p=0.01$). Time for resumption of spontaneous voiding, rates of urinary retention, *de novo* UUI, and perioperative complications did not differ between the groups. Despite negative cystometrograms, *de novo* UUI symptoms were reported in 12% of the TVT group compared to 4% of the suburethral plication group ($p=0.66$).

Karateke *et al* reported on the outcomes of TOT in the treatment of women with occult SUI and POP. [321] (Level 3) Urodynamic evaluation revealed occult SUI in 25 of 79 patients with POP. Post-operative OAB, SUI, and MUI were found in three (12%), two (8%), and one (4%) patients in the occult SUI group, respectively. The corresponding numbers were six (11%), five (9%), and three (6%) in the preoperatively continent group. No significant difference was found between the groups in terms of post-operative OAB symptoms, SUI, and MUI. Groutz *et al* also reported on the outcomes of TVT-O in the management of occult SUI in women with significant POP. [322] (Level 3) Of the 117 patients, 6 (5.1%) had immediate postoperative voiding difficulties necessitating catheterisation for more than two days. Late postoperative morbidity was assessed in 110 patients with ≥3 months of follow-up (mean 27.2 ± 17.7). Of these 110 patients, 7 (6.4%) had protracted postoperative thigh pain with spontaneous resolution within 1-3 months and 7 (6.4%) had developed recurrent UTIs. There were no cases of vaginal extrusion. The functional outcome analysis was restricted to 92 patients with ≥12 months follow-up. Of these, 13 (14%) were found to have urodynamic stress incontinence; however, only two patients (2.2%) were symptomatic, amounting to a subjective and objective cure rate of 97.8% and 86%, respectively. Of the 34 patients who had had urinary storage symptoms preoperatively, 22 (64.7%) had persistent symptoms postoperatively. An additional four patients (6.9%) had developed *de novo* urinary storage symptoms, and one patient developed bladder outlet obstruction.

3. NO OVERT OR OCCULT SUI AND POP

There has been a tremendous amount of debate on how to treat women with significant POP who have no complaints of SUI and occult SUI cannot be demonstrated on either cough-stress test or urodynamic evaluation after prolapse reduction. The case for a concomitant anti-incontinence procedure is to

potentially prevent a second surgical intervention in a cohort at high risk for developing SUI. The case against performing anti-incontinence surgery in the same time hinges on the potential for developing *de novo* or worsened urinary storage and voiding symptoms in a population with minimal to no preoperative symptoms. The literature appears divided on the topic. As mentioned previously, Chaikin *et al* found that the majority of women with significant POP who do not have overt or occult SUI will not develop overt SUI after transvaginal POP repair alone. [304] (Level III)

The decision to perform a concomitant colposuspension at the time of sacrocolpopexy has been passionately debated. In a well-publicised study by Brubaker *et al* as part of the Colpopexy and Urinary Reduction Efforts (CARE) trial, stress-continent women undergoing sacrocolpopexy were randomised to receive or not to receive a concomitant Burch colposuspension. [323] (Level I) At two years, 302 of 322 randomised participants were available for analysis. Two years after surgery, 32.0% and 45.2% of women in the Burch and control groups, respectively, met the SUI endpoint (presence of SUI symptoms, positive CST, or interval treatment for SUI, p=0.026). The apex was well supported in 95% of women, and this was not affected by concomitant Burch. There was a trend toward fewer urgency symptoms in the Burch group (32.0% vs. 44.5% no Burch, p=0.085). In a subanalysis of the CARE trial, Visco *et al* confirmed that women who demonstrated preoperative occult SUI were more likely to report postoperative SUI, regardless of concomitant Burch colposuspension (controls 58% vs. 38%, p=0.04; Burch 32% vs. 21%, p=0.19). [324] The authors also concluded that occult SUI detection rates varied widely based on the method of prolapse reduction. Interestingly enough, while only 23% of the 1134 members of the American Urogynecological Society (AUGS) responded to a survey about their practice patterns regarding high-grade POP, 57% of the respondents stated that they would not perform a prophylactic Burch colposuspension at the time of sacrocolpopexy in a woman without symptoms of SUI. [325]

Conversely, Costantini *et al* found that the Burch procedure did not confer a significant benefit in terms of SUI cure to women undergoing surgical prolapse repair.[326] (Level I/II) A total of 66 continent women with POP were randomly assigned to abdominal sacrocolpopexy and concomitant Burch in 34 (group 1) or sacrocolpopexy alone in 32 (group 2). Median follow-up was 97 months (range 72 to 134). Nine of 31 group 1 patients (29%) were incontinent compared with 5 of 31 (16%) in group 2 (p=0.553). In group 1, all except one patient were successfully treated for voiding dysfunction. Storage symptoms had disappeared in one patient and *de novo* storage symptoms had developed in two since the previous follow-up. *De novo* incontinence developed in two group 2 patients after midterm outcomes were reported. Median UDI-6 and IIQ-7 scores were improved in all groups at last follow-up (p<0.0001).

Ballert *et al* suggested a protocol to determine if MUS should be placed at the time of transvaginal POP repair. [327] (Level 3) A total of 50 women reported clinical (symptomatic) SUI preoperatively, while 55 did not. Regardless of clinical presentation, patients with urodynamic or occult SUI underwent simultaneous MUS, while those without urodynamic or occult SUI did not. The risk of intervention due to obstruction after receiving MUS was 8.5%, while the risk of intervention for *de novo* SUI in patients with no clinical, urodynamic, or occult SUI who did not undergo MUS was 8.3%. The risk of intervention for SUI in patients with clinical SUI but no urodynamic or occult SUI and no MUI was 30%. These data suggest that a prophylactic sling in women without clinical, urodynamic, or occult SUI may be as likely to cause postoperative urinary retention requiring reoperation as it is to prevent postoperative de novo SUI requiring surgery. The evidence also suggests that MUS should be considered for women with clinical SUI (regardless of the presence or absence of urodynamic or occult SUI), as there is a much higher possibility for further intervention for SUI in this population. While this report lacks a control group, the findings of this study underscore the importance of a detailed informed consent discussion between the patient and surgeon.

A study by Liang *et al* further supported the suggestion that urodynamic evidence be used to guide possible treatment of SUI during POP surgery. [222] (Level III) Among the 79 patients evaluated for severe POP without symptoms of SUI, 32 patients had a positive pessary test and underwent vaginal hysterectomy, anterior and posterior colporrhaphy, and TVT (Group 1). In group 2, 47 patients (17 of whom had positive pessary tests and 30 of whom had negative pessary tests) underwent vaginal hysterectomy and anterior and posterior colporrhaphy alone. Eleven (64.7%) of 17 patients with positive pessary tests who did not undergo TVT had urine leakage after their hysterectomies. Conversely, none of the 30 patients who had negative pessary tests developed symptomatic SUI after vaginal hysterectomy. Among the 32 patients with positive pessary tests who had TVT with their hysterectomies, three developed urine leakage later for a cure rate of 90.6%. Had all patients with high-grade POP undergone TVT, 35% would have undergone an unnecessary anti-incontinence procedure. This study supports the notion that women without symptoms of overt or occult SUI are not likely to leak after undergoing POP surgery alone. Additionally, the Cochrane database recently evaluated the value of anti-incontinence surgery at the time of prolapse repair in continent women and concluded that this practice did not reduce the rate of postoperative SUI (RR 1.39, 95% CI 0.53 to 3.70). [328]

Thus, the value of adding an anti-incontinence procedure to a POP repair in women who are dry before operation remains to be adequately assessed; however, available evidence suggests that the majority of women without occult or overt SUI may remain continent after POP repair alone. While the addition of a Burch colposuspension to a sacrocolpopexy may not add a significant amount of additional morbidity, it may not confer a benefit in terms of preventing the development of overt SUI. Furthermore, the potential benefit of Burch colposuspension cannot necessarily be extrapolated to other prophylactic anti-incontinence procedures. An urodynamic approach to decision making appears to be a prudent one. Adequately powered RCTs are urgently needed to answer these questions and high level evidence may be on the horizon. The details of multicentre, prospective RCTs comparing POP and anti-incontinence surgery in women with overt SUI and those with occult SUI (CUPIDO) have recently been described and recruitment is under way. [329] A second, multicentre RCT is in preparation to determine whether the prevalence of postoperative urinary incontinence differs between stress continent women receiving vaginal prolapse repair with concomitant TVT and those with only sham incisions at 3 months after surgery. [330] A second objective of the OPUS trial is to determine whether it is more cost-effective to place a TVT prophylactically than to treat the SUI symptoms postoperatively as they occur over a 12-month period after the index surgery.

4. UUI AND POP

Symptoms of OAB such as urinary urgency, frequency, and UUI are often seen in women with POP and community-based, hospital-based, and cross-sectional studies have shown that the prevalence of OAB is higher in women with POP vs. those without POP. [331, 332] The prevalence of any OAB symptom approached 50% and increases with advancing age. [332]Symptoms of POP may be an independent risk factor for symptomatic OAB.[332] As such, the impact of POP repair on OAB symptoms and UUI is of great value in preoperative counseling of women with high-grade POP.

The impact of anterior vaginal wall prolapse repair on bladder function has been much debated. Digesu *et al* reported on a 12-month prospective cohort study of 93 women who had a standard anterior colporrhaphy for cystocele. [333] (Level 3) Post-operatively, urinary frequency resolved in 60%, urgency resolved in 70%, and UUI resolved in 82%, illustrating that anterior repair may lead to resolution of the majority of OAB symptoms. Similar findings were reported in a prospective cohort study of prolapse repair in elderly women by Foster et al. [334] (Level 3) The authors also noted that vaginal reconstructive or obliterative surgery produced a similar improvement in urinary symptoms at 12 months after surgery. Nguyen and Bhatia noted that UUI resolved in 24 of 38 women (63%) and persisted in 14 (37%) after surgical repair of uterine and/or vaginal vault POP. [335] (Level 3) The authors included both transvaginal and transabdominal POP repairs in their analysis. Uninhibited bladder contractions < 25 cm H2O during cystometry (p=0.01) and bladder trabeculation (p=0.03) were each an independent predictor of UUI resolution after POP repair. In a review of MEDLINE and Embase literature, de Boer et al found no evidence for a distinct relationship between the compartment or stage of the POP and the presence of OAB symptoms. [331] The authors also concluded that all treatments for POP, including surgery and pessary management, resulted in an improvement of OAB symptoms. There is no consensus regarding the predictors for OAB symptom resolution and individual OAB symptoms had different predictors. [331] When there is concomitant DO and POP, DO resolves in a proportion of the patients and bladder outlet obstruction appears to be the primary mechanism by which POP induces OAB symptoms and urodyanmics DO.

5. CONCLUSIONS

There is **Level II/III** evidence to support a concomitant anti-incontinence procedure at the same time as repair of POP in a woman with overt SUI. There is **Level II/III** evidence supporting pubovaginal sling, retropubic MUS, and transobturator MUS as effective anti-incontinence options in a woman with overt SUI and POP. Anterior colporrhaphy alone and pubocervical fascia plication are not effective options for overt SUI in women undergoing POP repair. **(Level I/II)** Burch colposuspension may not be more effective than no additional surgery in curing overt SUI in women undergoing sacrocolpopexy. **(Level I/II)** There is Level III evidence that bladder neck pubovaginal sling, retropubic MUS, and transobturator MUS are effective in resolving occult SUI during POP repair. There is controversy whether prophylactic Burch colposuspension is effective in improving the chances of developing overt SUI after sacrocolpopexy. **(Level I)** There is Level 3 evidence to support not performing a concomitant anti-incontinence procedure in a continent woman at time of POP repair. There is **Level III** evidence that treatment of prolapse by reconstructive or obliterative surgery improves overactive bladder symptoms.

III. NEUROMODULATION

1. SACRAL NEUROMODULATION

a) Recent Cochrane review

A recent Cochrane review [336] examined, systematically the evidence of the effects of implantable stimulation devices in the treatment of urgency urinary incontinence, urgency or frequency, and urinary retention.

Eight RCTs were considered eligible and were included in the analysis.

At 6 months follow up SNM was found to be superior to no treatment for all indications as there were highly significant changes in all the outcomes measured (leakage episodes, number of voids, rating of urgency, having no leakages, reduction in number of voids, pad usage, volume at first contraction, and bladder capacity). Both the SF-36 mental and physical scales favoured the immediate implant group but the results were not statistically significantly different between the treatment and no treatment groups

The quality of the studies included was rated poor. There were no studies comparing SNM with other treatment methods.

The review concluded that SNM can be of benefit in selected patients with overactive bladder symptoms, retention without organic obstruction, and in those for whom other methods of treatment have failed.

b) Long term results

1. Refractory Uui

The long term results of SNM have been addressed by several case studies. There are 4 studies reporting median or mean follow up of >5 years. Two of the studies are presented in the last ICI report and these are the largest ones. Most of the long-term studies do not report the complete continence rates.

2. Long Term Results – Efficacy Over Time

De Groen et al [337] evaluated the long-term results of neuromodulation in 60 patients with refractory idiopathic urgency urinary incontinence. All subjects recruited from a single institution and were assessed prospectively at regular intervals for at least 5 years after implantation. The success rate gradually decreased from 52 patients (87%) at 1 month to 37 (62%) at 5 years. Complete continence persisted in 15% of patients. The analysis was extended to the 41 patients who passed the 10-year follow-up. At least 25 of these women (61%) were still on active SNS. The 10-year success rates did not appear to be different from the 5-year results suggesting that a deterioration of the results is observed during the first 5 years which stabilised thereafter. A total of 57 adverse events occurred in 32 (53%) patients the majority of those being related to hardware failure and pain or discomfort at various sites. Pain was managed conservatively. A total of 23 reoperations, including the 2 explantations, were done in 15 patients (25%). **(Level 3 evidence)**

3. Urgency And Frequency

There are no new studies examining the long term results of SNM in patients with urgency frequency. The largest study so far (van Kerrebroeck) has been presented in the last ICI report.

A more recent small case series [338]examined the long term efficacy of sacral neuromodulation in patients with IC/PBS not responding to medical treatment. Overall 22 patients had a permanent generator implantation. Success with the device was defined as greater than 50% improvement in the chief complaint of urinary pain, urgency and frequency or urgency incontinence. For an average follow up of 59.9 months 17 of 22 patients (77%) reported long-term cure or more than 50% improvement in those symptoms. However 50% of patients underwent explantation due to technical reasons, infection, battery depletion, or pain at the implantation site **(Level 3 evidence).**

Zabihi et al [339]evaluated the efficacy of bilateral caudal epidural sacral neuromodulation for the treatment of refractory chronic pelvic pain (CPP), painful bladder syndrome, and interstitial cystitis (IC). Thirty consecutive patients (21 female, 9 male) with severe refractory symptoms underwent bilateral S2–S4 sacral neuromodulation for CPP/IC. Patients were evaluated with the O'Leary IC symptom and problem index (ICSI, ICPI), the short form of the Urogenital Distress Inventory (UDI-6), and the RAND 36-item health survey (SF-36) preoperatively and 6 months postoperatively. The mean and minimum follow-up were 15 and 6 months, respectively. Of the 30 patients, 23 (77%) had a successful trial stimulation and were permanently implanted. Among these patients, the ICSI and ICPI scores improved by 35 (p = 0.005) and 38% (p = 0.007), respectively. The pain score improved by 40% (p = 0.04) and the UDI-6 score by 26% (p = 0.05). On average, patients reported a 42% improvement in their symptoms. SF-36 scores did not improve significantly. **(Level 3 evidence)**

4. Non Obstructive Urinary Retention (Table 6)

The effectiveness of SNM in women with urinary retention has been confirmed by previous RCT (Jonas 2001) and hs been presented in the last ICI report.

The long term efficacy of SNM for women with urinary retention particularly those with urethral hyperactivity (Fowler's syndrome) has been presented by Datta et al [340].

Thirty (50%) had a one stage and the rest a two stage procedure. Overall, 43 of 60 (72%) women were voiding spontaneously, with a mean postvoid residual volume of 100 mL; 30 (50%) no longer needed to use CISC. The efficacy of the 2 stage compared to the one stage procedure was similar (73% vs 70%). Women with a normal urethral sphincter electromyogram had worse outcomes than women with an abnormal test (43% vs 76%). There were 99 adverse events (AEs) and 63 surgical revisions for the women during a total of 2878

months of SNS experience. In all, 73% of the women had an AE during their treatment with SNS **(Level 3 evidence).**

A recent retrospective single centre study [341] examined the long-term efficacy and durability of sacral nerve stimulation (SNS) for the treatment of refractory, non-obstructive urinary retention. Forty patients were included (29 with complete retention requiring CISC) and 11 with incomplete retention (high post -micturition residuals). Of the 40 patients 28 (70%) responded successfully to the test stimulation and underwent a placement of an IPG. At a mean follow-up of 40.03 +/- 19.61 months, 24 (85.7%) of 28 patients demonstrated sustained improvement of greater than 50% with significantly reduced number and volumes of catheterisations/day and improvement of post-micturition residuals. The Interstim device was removed in 4 patients (14.3%) and required revision in further 6 (21.4%) **(Level 3 evidence).**

5. Effect Of SNM On Sexual Function

The effect of SNM on the female sexual function was investigated by a small pilot prospective single centre study[342]. Overall 36 women with severe frequency, urgency, retention, and chronic pelvic pain refractory to medical and other treatments were enrolled and were assessed by the Female Sexual Function Index (FSFI) questionnaire preoperatively and 6 months postoperatively. Twenty-one patients had some form of pelvic pain component to their symptoms, and 15 had voiding dysfunction without pain. The overall score on the FSFI improved by 52% (p = 0.05). Results were better in patients who underwent the treatment for voiding dysfunction (n = 15) compared to those who had pain as their primary complaint. In this group, the overall score improved by 157% (p = 0.004). Those who underwent the procedure for the indication of IC/CPP (n = 21) did not show a statistically significant change in their scores.

Another small study [342] showed that in sexually active women who had a permanent sacral neuromodulator implanted there was no difference in the sexual function before and 6 months after implantation as assessed by the FSFI.

6. Patient Satisfaction

Long-term clinical efficacy of SNM has been assessed and confirmed by many studies. However it is quite unclear how this can be translated to patient satisfaction and improvement of quality of life bearing in mind that there are technical problems and adverse effects needing constant medical attention in a significant proportion of these patients.

The long term QOL data were assessed in 2 previous reports. [343] [344]

Leong et al [345] examined the longterm satisfaction of patients with an implanted SNM for various medical indications such as overactive bladder syndrome, non-obstructive urinary retention, combined overactive bladder and retention, and pelvic pain. Overall 275 patients received a postal questionnaire regarding satisfaction and experiences with the system, such as side effects, complications, burden, impact on sexuality and defecation changes. The response rate was 75% (207 patients) with a median post-implantation period 77 months (range 12 to 214). The patient satisfaction rate was high at 90% and significantly related to the perceived clinical effect and 85% if all explanted cases (13 patients) were considered as failures. Satisfaction had no direct relationship with patient age, gender, duration of therapy or type of complaint for which SNM was offered, but was significantly lower in patients with more than 1 pelvic floor comorbidity. The patient's attitude towards

Table 6 : Summarises the follow-up data for patients with non obstructive urinary retention who were treated with SNM (from 1. Bosch JL. An update on sacral neuromodulation: Where do we stand with this in the management of lower urinary tract dysfunction in 2010? BJU Int 2010, Nov;106(10):1432-42.)

Reference	Patients, *n*	Follow-up duration, months	% with >50% decrease no. of CISC/day	% without need for CISC
Jonas *et al.* [70]	24	At 18	NR	58
Aboseif *et al.* [71]	20	Mean 24	NR	90
van Kerrebroeck *et al.* [56]	31	At 60	58	NR
De Ridder *et al.* [75]	62	Mean 43	NR	55

NR, not reported.

yearly follow-up and the ability to use the patients programmer was positively related to the degree of satisfaction. Overall 40% reported having some limitations or concerns with SNM such as exclusion from MRI and passing through metal detectors after an INS was implanted, possible changes in future reimbursement. Most patients perceived regular pain (56%) and discomfort (40%) at the INS site. **(Level 3 evidence)**

7. Neurogenic Lower Urinary Tract Dysfunction (LUTD)

The efficacy and safety of the use of SNM for the treatment of neurogenic lower urinary tract dysfunction was examined in a recent meta-analysis [346]. This included overall 357 patients from 26 independent studies (prospective and retrospective cohort studies and case reports) with level of evidence ranging from 2b to 4. There was no RCT available for analysis. The pooled success rate was 68% and 92% for the testing and the permanent phase of SNM respectively for a mean follow up of 26 months. With regards to adverse events the pooled rate was 0% during the first stage to 24% for the chronic phase of the treatment. The most frequent adverse events were lead migration and pain at the site of permanent neuromodulator further surgery was performed in 45 of 224 patients. The available evidence from this meta-analysis suggest that SNM may be effective and safe for the treatment of patients with neurogenic LUTD (level of evidence 2) but further well designed adequately powered studies are needed before SNM is routinely recommended for the treatment of neurogenic LUTD.

The use of SNM in patients with neurogenic LUTD is limited by the fact that quite often they need to be investigated by magnetic resonance imaging studies.

The progressive nature of the neurologic disease in some patients could be a limiting factor in the effectiveness of the SNM.

8. Selection Of Patients

• Testing procedure

The application of the two-stage procedure using the permanent tined lead appears to be superior to the percutaneous PNE technique

A study by Bannowsky et al.[347], in a retrospective case control study examined urodynamic and clinical outcomes of the two different testing techniques and found that permanent quadripolar electrodes led to significant differences in the overall response rate (81.8% versus 47.6%) and urodynamic parameters (max detrusor pressure, bladder capacity) compared to the PNE.

This has to be balanced against the cost implications: the permanent electrodes are several times the cost of the cheaper PNE wires.

In a recent study [348] 41 of 76 (54%) who failed to respond to PNE were subsequently tested with tined lead procedure permanent stimulators. Of those 18(44%) were implanted with a neurostimulator after a successful response suggesting that the tined lead procedure is more sensitive screening tool. At 53-month follow-up 12 of these patients (67%) had a successful outcome, which was not statistically different from the success rate in patients with a positive response to an initial PNE or TLP test.

The response rate to PNE as compared to the 1st stage tined-lead placement test ((FSTLP) were directly compared in a prospective single centre study[349].

One hundred patients with refractory idiopathic overactive bladder syndrome (OAB) or non-obstructive urinary retention, screened with both PNE and FSTLP. The positive response rate on PNE was 47%. FSTLP showed a 69% positive response rate, which was negatively related to age. The 22% gain in positive response was statistically significant ($p < 0.001$) and positively associated with female gender and younger age. This study also suggests that the FSTLP may be a more sensitive screening method than PNE. (Level of evidence 2)

• Unilateral versus Bilateral lead placement at screening phase

A retrospective study by Pham et al. [350] compared the success of the bilateral to unilateral neuromodulator lead placement in 124 patients undergoing screening for permanent placement of sacral neuromodulation. Fifty-five (44%) patients underwent unilateral stage I lead placement and 69 (56%) received bilateral S3 leads. Successful stage I trials were reported in 32/55 (58%) and 53/69 (76%) of unilateral and bilateral cohorts, respectively (P = 0.03). There was no difference in wound infection or other complications. **(Level of evidence 3)**

• Pre-treatment psychological problems

Psychiatric comorbidity has previously been proposed as a negative predictor by some authors.

In a recent single centre prospective study the relationship between psychiatric history and the outcome of chronic SNM treatment was assessed. Fifty four patients with symptoms of OAB or chronic non-obstructive problems completed the Amsterdam Biographic Questionnaire (ABQ), which measures the personality traits of the patient, and the Symptom Check-List-90-Revised (SCL-90-R), which is a screening instrument for

neuroticism, and for current level of complaints. Of those 15(28%) reported a history of psychiatric disorder in their medical history. The authors found that a history of psychiatric disease was not related to the outcome of test stimulation, but was shown to be a positive predictor for the occurrence of AEs with permanent SNM treatment.**(Level of evidence 4)**

• Urodynamics

A recent study [351] examined urodynamic diagnosis as a predictor of outcome. 111 patients undergoing permanent SNM after a successful PNE test were divided into those with DO (67) on urodynamics and those without DO (44). Both groups showed a statistically significant improvement in bladder volumes at first sensation of filling (FSF) and at maximum fill volume (MFV) before voiding for both UI subgroups, compared with baseline. Resolution of DO post treatment occurred in 51% of patients, however the success in those patients was not significantly different from those with persistent DO. Interestingly patients with UI and no DO had a higher rate of clinical success (73%) than those with UI and DO (61%) although this did not reach to statistical significance. (Level of evidence 3)

• Comparison to the botulinum toxin-A (BTX-A)

The efficacy rates reported for both SNM and BTX-A in patients with refractory OAB appear to be similar.

The use of BTX-A has recently been approved by the FDA for use in patients with OAB due to neurological conditions such as spinal cord injury and multiple sclerosis. SNM is more invasive but offers long term efficacy whereas treatment with BTX-A injections is less invasive but needs to be repeated on a less-than a year basis in order to provide sustained efficacy. In addition it has been reported that 20% of patients treated with BTX-A injections need to enhance treatment efficacy with anticholinergics and a small proportion report reversible voiding difficulties and need to self catheterisation.

At present there is no RCT published to compare the efficacy and safety of the two methods.

However there are published studies examining the cost-effectiveness of these 2 methods.

Siddiqui et al [352] suggested that BTX-A would be a cost-effective therapeutic option for refractory urgency incontinence in the first 2 years of therapy. Costs were analysed from the societal perspective and in relation to effectiveness. All direct costs related to the treatment modalities as well as the costs of incontinence were calculated but not the indirect costs (lost productivity secondary to incontinence) due to the limited data available. Two years is a short duration for a chronic condition. The prolonged effect of SNS and the cost and time needed for repeat BTX-A injections might change significantly the comparison of cost effectiveness for a longer duration of treatment.

In another study Leong et al [353] by comparing the costs and effects value of the two methods in patients with refractory OAB concluded that starting with SNM, treatment is cost-effective after 5 years compared to BTX. However, when different scenarios were examined, such as the use of local anaesthesia for BTX treatment and SNM peripheral nerve evaluation or bilateral test, SNM was not cost-effective.

It is also acknowledged that the costs for surgery and for the devices may vary significantly between countries and even between hospitals within one country.

c) Conclusion and Recommendations

Sufficient **Level II /III** evidence exists evaluating implantable neuromodulation. Current series include retrospective cohort studies and no high level RCTs. There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. **Grade of recommendation is A / B**

2. PERCUTANEOUS TIBIAL NERVE STIMULATION (PTNS)

a) Efficacy

Several case series have shown a reduction of frequency, urgency, urgency urinary incontinence in 60-80% of patients with no serious adverse events. Recent research provides level I evidence that PTNS is efficacious in the treatment of refractory OAB.

b) PTNS vs Placebo (sham device)

A multicentre, double-blind, RCT (SUmiT) [354] compared the efficacy of PTNS to sham through 12 weeks of therapy. A total of 220 adults with overactive bladder symptoms were randomised 1:1 to 12 weeks of treatment with weekly percutaneous tibial nerve stimulation or sham therapy. In the sham group a Streitberger placebo needle was used to simulate the location and sensation of PTNS needle electrode insertion without actually puncturing the skin. In addition two active TENS surface electrodes were placed, one under the little toe and one on the top of the foot. Sham stimulation parameters were determined based on subject first sensory level of localised stimulation through a TENS unit.

Patients were evaluated by overactive bladder and quality of life questionnaires as well as 3-day voiding diaries before treatment and at week 13.

At 13 weeks follow-up there was moderate or marked improvement in overall bladder symptoms in 54.5%(60/110) and 20.9% (23/110) of subjects respectively (p<0.001). All individual symptoms such as frequency, nighttime voids, voids with moderate to severe urgency and uregency urinary incontinence episodes demonstrated statistically significant improvement from baseline to 13 weeks for the PTNS group compared to the sham group (**Table 7**). This was also confirmed on voiding diaries.

There were no serious adverse effects with 4% (5/110) reporting bleeding and discomfort at the needle site and one case of ankle bruising and a further one with leg tingling.

In a further RCT[355], 35 patients not responding to anticholinergics were randomised to PTNS or control group. The control group (17 patients) received an original placebo treatment using a 34 gauge needle placed in the medial part of the gastrocnemius muscle. Patients were considered to be responders if they had a reduction in urgency incontinence episodes greater than 50%. After 12 weeks of weekly treatments 71% (12/17) in the PTNS group and 0% (0/12) in the placebo group were considered responders (p < 0.001). **(Level of evidence I - II)** ?

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of response to this intervention

c) PTNS vs tolterodine ER

Another multicentre RCT showed comparable efficacy of PTNS to medical treatment (OrBIT trial)[356].

A total of 100 adults with urinary frequency (> 8 times/day) were randomised 1:1 to 12 weeks of treatment with weekly PTNS or to 4 mg daily extended-release tolterodine. Voiding diaries and an overactive bladder questionnaire were completed at baseline and at the end of therapy. Global response assessments were completed by subjects and investigators after 12 weeks of therapy. The two groups were comparable for baseline characteristics and OAB symptoms.

At 12 weeks 79.5%(35/44) of the PTNS and 54.8% (23/42) of the tolterodine patients considered themselves to be cured or improved (p = 0.01).

Urinary frequency, urgency urinary incontinence episodes, urgency severity and nighttime voids, voided volume and QoL improved significantly in both groups but there was no difference between the PTNS and the tolterodine patients. **(Level of evidence I)**

d) Long term data

A long-term follow-up of the OrBIT Trial evaluated the durability of PTNS benefits[357].

Patients who were randomised to weekly PTNS in the OrBIT trial were offered an additional 9 months of treatment with assessments at 6 and 12 months from baseline. Outcome measures included voiding diary data, overactive bladder questionnaires, global response assessments and safety assessments. A total of 33 percutaneous tibial nerve stimulation responders continued therapy with 32 and 25 subjects completing 6 and 12 months of therapy, respectively. Subjects received a mean of 12.1 treatments at various intervals during an average of 263 days, with a mean of 21 days (median 17) between treatments.

Sustained improvement was shown with 94% (30/32) of patients continuing periodic treatment considering themselves to be cured or improved at 6 months and 96% (24/25) at 12 months follow-up. Overactive bladder questionnaire symptom severity was significantly improved from 12 weeks to 12 months (p <0.01) as well as from 6 to 12 months (p <0.01). No serious adverse events were reported.

Table 7: PTNS: Improvement of global response assessment at 13 weeks compared to baseline (Level of evidence I)

Overall bladder symptoms (intent to treat)	60/110 (54.5)	23/110 (20.9)	<0.001
Overall bladder symptoms	60/103 (58.3)	23/105 (21.9)	<0.001
Urinary urgency	44/103 (42.7)	24/105 (22.9)	0.003
Urinary frequency	49/103 (47.6)	23/105 (21.9)	<0.001
Urinary urge incontinence	39/103 (37.9)	23/104 (22.1)	0.02

e) Mode of action

The exact mechanism of PTNS on bladder function is unclear but it is thought that this is mediated through the retrograde stimulation of the sacral nerve plexus. The posterior tibial nerve is a peripheral nerve with mixed sensory and motor fibres. It originates from spinal roots L4 through S3, which also contribute directly to sensory and motor control of the urinary bladder and pelvic floor. A recent study suggests that a plastic reorganisation of cortical network triggered by peripheral neuromodulation could be a mechanism of action of PTNS[358].

f) Neurogenic DO

The efficacy and safety of PTNS was evaluated by a prospective multicentre study in 16 women with MS and LUTS unresponsive to anticholinergics.[359] Patients were offered 12 sessions of PTNS. Assessment of LUTS was by validated, self-administered chart and questionnaires, testing the subjective and objective relevance of LUTS for patients and their impact on QoL before and after treatment. There was a significant reduction in daytime frequency, nocturia and the mean post-micturition residual and there was an increase of the mean voided volume. Eighty-nine percent of patients reported treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King's Health Questionnaire. No adverse events were reported. **(Level of evidence III)**

Kabay et al.[360] suggested that PTNS can be acutely effective to suppress detrusor overactivity in patients with neurogenic detrusor overactivity due to Multiple Sclerosis. The researchers performed urodynamics before and during PTNS treatment and found that there was a significant improvement of mean volume of first involuntary detrusor contraction from 145.2 ml, to 244.7 ml and of the maximum cystometric capacity from 204.8 ml, to 301.2 ml during the stimulation period. The results have been criticised as the PTNS was applied after a 2nd filling of the bladder and this repeat cystometry during the stimulation could have affected the urodynamic parameters. **(Level of evidence III)**

In a further study [361] the same group of researcher found similar results of an acute effect of PTNS on detrusor contraction in patients with neurogenic DO due to Parkinson's Disease. **(Level of evidence III)**

g) CONCLUSION AND RECOMMENDATIONS

Reports are **Level I - III** in terms of evidence and there are few comparative reports assessing different techniques. Most current series are retrospective in nature however recent prospective randomised (against sham) assessment of management of these patients has improved the overall quality of reporting. **Current recommendations range from A – C.**

IV. ENTEROCYSTOPLASTY

Vesical enlargement, or augmentation cystoplasty (AC), has been used for many years with varying degrees of success for refractory detrusor overactivity (DO) and related incontinence. Other than idiopathic detrusor overactivity (IDO), indications for enterocystoplasty include small capacity bladders due to fibrosis, tuberculosis, radiation, or chronic infection, neurogenic detrusor overactivity (NDO), poor bladder compliance, as well as others [362-365] AC typically involves a segment of the bowel that is removed from continuity with the fecal stream, detubularised, and patched into the bisected bladder. This method increases bladder capacity and decreases bladder pressure caused by uninhibited detrusor contractions. Additionally, incorporation of bowel into the bladder results in decreased bladder contractility and an increased interval in the volume to first involuntary bladder contraction during cystometric evaluation.

Virtually any portion of the GI tract can be utilised for enterocystoplasty, and each segment has its own unique favourable properties as well as inherent complications [365, 366] There is no ideal segment for all cases. Technically, the surgeon must be aware that the selected bowel segment should contain a suitable length of mesentery to reach into the deep pelvis for a tension free anastomosis between bowel and bladder. There has been no general agreement on whether it is more favourable to bivalve the bladder sagittally or transversely during enterocystoplasty; however, it is considered ideal to create the broadest possible opening in the bladder and thereby create the widest possible anastomosis between bladder and bowel resulting in the most spherical configuration possible. The bowel is divided and detubularised on its antimesenteric side prior to anastomosis to maximally reduce peristaltic contractions. Again, the goal of enterocystoplasty is to create a high capacity, low-pressure reservoir during the filling/storage phase of the micturition cycle. When successful, and properly combined with other concomitant reconstructive procedures (i.e. ureteroneocystostomy, slings, artificial urinary sphincters, continent catheterisable channels, etc.), enterocystoplasty can protect the upper urinary tract from pressure-related injury, infection, and vesicoureteric reflux while ideally providing complete urinary continence.

Apart from the inherent risks of open abdominal surgery associated with bowel and bladder anastomoses, AC carries several distinct long-term risks. The risks of this surgery include kidney or bladder infections, new-onset recurrent UTIs, metabolic derangements, mucus production, and,

in rare cases, bladder tumours. As a segment of bowel is used for AC, the available absorptive surface area of the bowel is reduced, and the incorporation of bowel segments into the urinary tract may have metabolic consequences [367]. Hyperchloraemic metabolic acidosis can occur if ileal and/or colon segments are used, as well as malabsorption of vitamin B12 and bile acid after the use of ileal segments. Blackburn et al demonstrated a reduction in serum B12 level with time following ileocystoplasty in 44% of their patients at 7-year follow-up and recommended that these patients should have their B12 levels measured in the long term [368].

There has been concern about the incidence of secondary malignancies that may develop as a long-term consequence of bladder augmentation. Using colonic segments, tumours are most likely to occur at the ureteral implantation site. To prevent metabolic complications, careful patient selection and meticulous and lifelong follow up, as well as prophylactic treatment, are mandatory. Endoscopy for early detection has been recommended, starting 10 years postoperatively for patients who underwent surgery for a benign condition. Of interest, Higuchi et al retrospectively review their registry of 153 patients with an ileal/colonic AC and a matched control population and found that AC does not appear to increase the risk of bladder malignancy over the inherent cancer risk associated with the patient's underlying congenital abnormality [369]. Immunosuppression irrespective of bladder treatment was an independent risk factor for malignancy in their patient population.

Conclusion and Recommendtions

Level I Evidence:

There have been no randomised controlled trials, double blind or sham-controlled trials or cohort studies which have examined the effects of enterocystoplasty for the treatment of NDO or directly compared it to another therapy for the same indication, **(Recommendation grade C)**. Also the role of enterocystoplasty is not defined in subjects with idiopathic detrusor overactivity. **(Recommendation grade D)**

Other Evidence:

The conclusions of several recent reviews on the role of AC indicate that the overwhelming predominance of literature is dedicated to AC in patients with a neurogenic bladder [370, 371]. By some estimates, approximately 10% of reports in the literature have examined the results of AC in adults with IDO. These include only case series **(LOE=4)**. Since the publication of the 4th International Consultation on Incontinence, there have been few additions to the AC literature for IDO (See Table). The studies differ in several ways. Most include both males and females, and some include a varying number of patients with NDO. Additionally, length of follow-up differs widely and the criteria for success may be considerably different and inconsistently reported [372]. Outcome measures have included mostly non-validated questionnaires and subjective patient assessments. Furthermore, continence rates must also be considered with caution, as many AC procedures are combined with bladder outlet procedures [364]. Overall, there does not appear to be a consensus whether patients with IDO or NDO achieve better outcomes [364, 373, 374] The reasons for the inconsistencies in patient satisfaction in neuropathic patients and non-neuropathic patients remain unclear.

Several variations on the standard AC have been recently described. Novel bowel options include urothelium lined seromuscular colocystoplasty and an appendicular-based caecal flap [375-377]. The recent incorporation of robotic-assisted laparoscopic surgery (RALS) and laparoendoscopic single site (LESS) procedures has further added to the surgical options for AC [34-40]. While the initial results are encouraging, long-term outcomes are uniformly absent. Overall, due to its invasive nature and potential for long-term adverse effects, AC is considered to be one of the last choices of treatment in refractory IDO cases [378].

V. AUTO AUGMENTATION

Initially described by Cartwright and Snow, auto augmentation of the bladder was described as an alternative option to AC, especially in children with neuropathic bladder [379, 380]. Auto augmentation may be performed by incision (detrusor myotomy) or excision (detrusor myectomy) of a portion of the detrusor muscle. Either technique aims to create an iatrogenic bladder mucosal "bulge" or pseudodiverticulum and an increase in the storage capacity of the bladder with a concomitant decrease in storage pressures. The reported advantages of detrusor auto augmentation over enterocystoplasty is the avoidance of complications related to the use of bowel in the urinary tract including malignancy, mucous formation, stones, surgical morbidity related to opening and reanastomosis of the GI tract, and metabolic acidosis [364, 381, 382].

Level I Evidence:

There have been no randomised controlled trials, double blind trials or cohort studies which have examined the effects of auto-augmentation as a treatment for non-neurogenic detrusor overactivity incontinence. **(Recommendation grade D)**

Other evidence:

There are few studies on auto-augmentation in the adult non-neurogenic population and there

have been no additions to the literature since the publication of the 4th International Consultation on Incontinence (See **Table 8**). One small study of 5 patients with urgency incontinence showed promising results in all patients at the initial postoperative visit, but clinical deterioration and failure occurred in 4 of the 5 patients at three months follow-up [383]. **(LOE=4)** Mean bladder capacity increased but mean volume to first involuntary bladder contraction decreased. Four of the 5 patients continued to have involuntary bladder contractions on cystometry. One additional retrospective study including 61 patients with NDO and IDO compared detrusor myectomy to AC [384]. Comparable clinical success was reported for the two procedures; however, there was a 22% incidence of serious complications in the 27 patients undergoing AC, compared to only 3% of the 33 patients undergoing detrusor myectomy.

Long term follow-up of auto augmentation i**n children** with neurogenic bladder have for the most part demonstrated disappointing results, which have been attributed to eventual fibrosis of the pseudodiverticulum [382, 385, 386]. Recently, Chrzan et al reported promising results on 49 detrusorectomies performed for neuropathic bladder at a mean follow-up approaching 10 years [387]. Bladder behaviour was assessed as good, fair or poor depending on the volume and intravesical pressure. In 24 patients, good bladder compliance and capacity were seen before detrusorectomy. Good and fair outcomes were observed in 35 (71%) patients at 1 year and in 39 (79%) patients 6 years after detrusorectomy. In 30 (60%) patients, there was hardly any difference between the first and second follow-up. In 9 (18%) patients, formal AC was necessary. Seven patients improved during follow-up, 5 of them after resuming oxybutynin. In 11 patients, oxybutynin could be stopped, and in 2 the dosage could be reduced to once daily.

In an attempt to improve long-term outcomes with this procedure and create a biological "backing" and blood supply for the pseudodiverticulum, a number of variations of this procedure have been described. These variations have included the use of demucosalised bowel segments, stomach, peritoneum and rectus abdominis muscle [382, 388-392]. Additionally, the use of an inflatable balloon placed in the bladder for 2 weeks after auto-augmentation improved long-term capacity and compliance [393]. Long-term follow-up demonstrating favourable clinical results with these variations is lacking. This technique is no longer considered as an option for surgical management of detrusor overactiivty. **(Recommendation grade F).**

VI. URETHRAL DIVERTICULUM

1. PREOPERATIVE STAGING

Since the last consultation, relatively insignificant data have emerged on the treatment and surgical management urethral diverticula. No new data have been published regarding classification systems and many are now characterised on the basis of MRI, presentation and size. A variety of imaging techniques need to be investigated for urethral diverticula. The MRI is widely used for evaluation. Dwarkasing, et al., in 2011 [408] reported a study of 60 women undergoing evaluation of urethral diverticula. They emphasized the importance of T2-weighted sequences and the use of endoluminal coil placement in the vagina to produce best overall results. Using a combination of techniques, they had 100% sensitivity and specificity for diagnostic tests. Some groups, however, have found MRI to be nonconsistent with findings at surgery. Chung, et al., [409] [2010] assessed a case series of 76 women who underwent diverticulectomy (41 actually ? had pre-operative MRI scanning. In ten of those patients the discrepancy between MRI imaging and surgical findings was noted. MRI mis-diagnosed one diverticulum as a Bartholin's cyst. In another case a sterile abscess was diagnosed as urethral diverticulum. In two cases MRI was not sensitive enough to determine a malignancy within the diverticulum. Porten et al., [2011] [410] assessed MRI evaluation and other imaging modalities including VCUG and CT scan. MRI was felt by these authors to be a useful adjunct for determining the extent of surgical dissection and any other complicating factors related to the diverticulum size or presentation. Han, et al., [411] [2007] analysed 30 women undergoing diverticulectomy with pre-operative MRI. They found the MRI useful for surgical planning especially in cases of large, complicated or circumferential diverticula.

Foster et al., [412] [2007]) also identified the utility of MRI imaging in diagnosis and surgical planning in women. In a study of 27 women, 15% of the patients had altered surgical management based upon preoperative staging with MRI scanning.

Additional staging studies continue to be utilised including VCUG. Double blend retrograde urethrography is not considered of historic interest only. Recent data regarding transvaginal ultrasonographic evaluation also demonstrated the utility of this technqiue Wu,et al., [413] (2009) reported the utility of transvaginal ultrasound for determination of size, content and location of the diverticulum and had good correlation with operative findings.

2. TREATMENT

Since the last report, various management options have been reported. Ljungqvist, et al., [414]

Table 8: Outcomes of AC for non-neurogenic detrusor overactivity

Author	Yr	Dx	No. Pts	Pop	Mean F/U (m)	Type of Augment	% Complete Continence	>50% Continence	% Subjective Success

Key: Dx: diagnosis; N: neurogenic; I: idiopathic; O: other; C+I: cured and improved.

(2007) reported a long follow-up series of 68 women who underwent standard urethral diverticulectomy. They noticed over a 26 year follow-up, that 11 of the 68 women experienced diverticula recurrence and urinary incontinence of varying degrees. Dyspareunia was also noted in these patients with recurrence. Despite this, 92% of the patients would recommend surgery, in their study. One small fistula was also identified over long-term follow-up in their patients. Recent analysis of surgical procedures performed in the United States of America over a twenty year period, (Burrows, et al, 2005) [415] assessed frequency of interventions for diverticulectomy in the United States at 6.7 per 1 million women per year. Rates of intervention were three-fold higher for African American as opposed to Caucasian women. Overall frequency of surgical intervention for diverticula has decreased over time.

Several authors have described standard resection techniques and these appear to be the most commonly and now currently reported (open diverticulectomy, transvaginal resection with periurethral dissection and layered closure being the most common technique). This technique now is the most commonly performed, (Rovner, et al, 2007) [416]. Lee et al (2009) [417] reported the use of SIS graft and noted good response in a single patient where this was utilized. Additionally, bovine pericardium has also been used for this purpose (Tolosa Eizaguirre, et al, 2012) [418]. Native tissue appears to be best for this purpose. Additionally, pericardium has recently been described as another type of interpositional graft with good results in a single case study (Gunasekaran et al, 2011) [419] Recent urologic guidelines, Dmochowski et al., [420] stressed the importance of not placing synthetic materials over a fresh urethrotomy at the time of diverticular repair due to concerns regarding erosion.

Recently, increased reports of diverticula formation related to midurethral tape formation have been identified. The first report in the English literature occurred in 2007 (Hammad) [421], since then Mahdy, et al, 2008, [422] and Athanasopoulos, 2008 [423] have both described diverticula occurring after implantation of transvaginal tape presumably due to excess tension placed on the midurethral tape.

The importance of differential diagnosis continues to be critical as women with chronic pelvic pain are sometimes found to have a urethral diverticulum (Fletcher, et al 2009) [424]. Foley et al,2011,[425] identified the importance of critical evaluation in differential diagnosis and accurate assessment of these individuals. Another important aspect in consideration of surgical management of urethral diverticula is potential risk of malignant chane within these. Thomas et al. 2008 [426], Ninety women going through diverticulectomy at a single institution. Neoplastic changes were identified in five patients of whom all were glandular carcinomas. The potential for metaplasia occurring in these lesions is needs to be stressed. Reoperation for diverticulum has recently been assessed. (Ockrim, et al 2009)[427] evaluated a group of women who had undergone previous intervention for diverticulum requiring repeat resection. The resection was secondary either to incomplete resection and/or recurrence of the diverticulum. The authors found that a standard approach utilising a sling or Martius fat pad labial graft interposition provided the best results in their complicated series.

3. RECOMMENDATIONS

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of urethral diverticulae. **(Grade of recommendation B/C)**

VII. ARTIFICIAL URINARY SPHINCTER IN WOMEN

The artificial urinary sphincter continues to be used as a surgical option for sphincter dysfunction in women solely a salvage procedure (after multiple failed previous procedures or special circumstances). There is limited but now some long term experience with the sphincter as a primary intervention.

Since the last publication, there have been several longer term follow-up studieswhich will be referenced below. The device may be placed either transvaginally, trans-abdominally or recently described as being placed laparoscopically. Success (cure or improvement of stress incontinence) rates overall range between 76 and 89 per cent.

More recent results have been reported in small groups (Hoda,et al) [428] reported experience with two women who underwent open implantation of a sphincter(endoscopic extraperitoneal approach, laparoscopic) . The overall operating time for these cases was 120 minutes. Both women were reported as being continent after the device implantation A slightly larger experience with laparoscopic insertion of artificial urinary sphincter reported has been reported by Roupret et al [429] . Twelve women underwent laparoscopic insertion of a sphincter over a two year period, eleven of whom had undergone previous procedures. After a variable period of activation ranging from four to fourteen weeks, with a mean follow-up of 12.1 month (range 5.2 to 27) incontinence was cured in 88% of the women. Com-

plications included the need for open conversion in two patients, two bladder injuries, two vaginal injuries with an overall complication rate of 25%.

Mandron, et al, [430] contemporaneously reported their experience with 25 patients undergoing laparoscopic AUS implantation over a four year timeframe. No cases required open conversion and the authors reported only an intraoperative complication, Of vaginal perforation. Five of the patients developed urinary retention which required re-catheterisation for a short period (no longer than four weeks). At a mean follow-up of 26.1 months, two patients failed due to vaginal erosion and required removal of the AUS, however, 23 patients reported continence, either total [19] or social (minimal pad use) [4].

Longer term follow-up has been reported by several groups recently. Chung et al [431] reported twenty-five year a single institution experience with sphincter implantation in 47 consecutive women, of whom 35 had failed previous anti-incontinence surgery. Two wound infections were identified after insertion. Of the 47 patients 83% still retained a functional sphincter at follow-up. Eight (17%) required removal due to erosion or infection. Additionally 20 revisions were required; the majority due to mechanical complications. Kaplan–Meier analysis revealed slightly over 80% of devices still working after 100 months. Continence rate (no pad use) at the time of follow-up was 59%.

Vayleux, et al., [432] reported an analysis of 215 women undergoing sphincter implantation over a 22 year period. 88% of women had undergone previous treatment for incontinence. 73.5% of the patients were considered continent (0 to 1 pad use) at follow-up. 170 (or 79%) were satisfied. The revision rate in this group was 15.3% after a mean interval of 8.47 years. 15 explantations (7% of total) were performed. The major risk factor for intraoperative complications was a history of smoking (10.7%). Multivariate analysis revealed age to be the major risk factor for failure (odds ratio 2.46), which occurred in 23.7% of the subjects. In addition, pelvic radiotherapy was also associated with failure (4.37 odds ratio). The largest long term analysis was recently published by Costa, et al., [433] . Over a 20 year period, 376 devices were implanted in 344 women. At mean follow-up of 9.6 years, 85.6% of patients were fully continent (no incontinence), 8.8 were socially incontinent (occasional incontinence epsiode) and 5.6% were incontinent (defined as one pad or more incontinence). Three, five and ten year device survival rates by Kaplan-Meier analysis were 92%, 88.6% and 69.2%. Mean mechanical survival time was 176 months (14.7 years). The authors identified three factors for AUS survival including number of previous incontinent procedures, presence of associated neurogenic disease, and simultaneous augmentation procedure. Recent Cochrane Database Review (Lipp,et al), [434] failed to identify any subsequent new data regarding the experience of artificial urinary sphincters.

Two trials have also assessed role of the sphincter in women as a salvage procedure. Chung et al., [435] reviewed 29 patients in whom AUS was implanted after failed anti-incontinence procedures. 5 (17%) of those patients required explantation of the device either due to erosion or infection. In addition, 13 revisions were performed with device malfunction accounting for 95% of those cases. Overall survival analysis revealed 90% malfunction of the device at less than 100 months from the time of implant. There was a significant decrease in pad use noted in the trials and overall continence rates (no pad use) were 70% in this study.

Other additional device modifications have included the use of a larger implanted cuff (greater than 8cm). Revaux, et al., [436] reported 50 women who underwent implantation with a large cuff device over a 23 year period, of whom 86% had undergone previous incontinence procedures.

At a mean follow-up of eight years, 34 women had complete resolution of their incontinence (68%). Factors that were associated with device survivability included less than two pregnancies, urethral closure pressure higher than 19cm of H2O and a cuff size equivalent to 8 cm.

Several consensus statements regarding use of the artificial urinary sphincter have recently been published. Chartier-Kastler, et al., [437] noted a higher risk of erosion and revision rates in women after multiple previous procedures. The authors concluded that the theAUS should be implanted at high volume specialist centres with appropriate knowledge and experience in the management of complex cases of incontinence.

Richard, et al., [438] reported the recommendations of the committee in Women's Urology and pelviperineology of the French Association of Urology. This guideline recommended avoidance of patients who had not had multiple prior procedures and where a well standardised technique performed by surgeons with regular experience and sufficiently long deactivation after implantation, long term monitoring as key aspects for device success.

Lovatsis et al., [439] summarised the guidelines for the evaluation of treatment of urinary incontinence for the Society of Obstetricians and Gynaecologists of Canada. The authors concluded that the AUS was an option in patients with significantly decreased dexterity and mobility (recommendation of III-C).

Modifications of the sphincter have been reported and evolution of the device types continues.

Garcia-Montes, et al., [440] reported a new type of sphincter known as the FlowSecure device. Feasibility of implantation was assessed and noted to be reasonable. The authors concluded that further research and development of the device should continue.

Conclusion and Recommendations

All reports are **Level III/IV** in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. **(Evidence Level III/IV).** Evidence is available to support the use of the artificial sphincter for the indications of recurrent and primary incontinence **(Grade of recommendation is B/C)**.

VIII. CONFOUNDING VARIABLES

1. INTRODUCTION

Surgery remains the main stay in the management of women with stress urinary incontinence and there are many different operations and procedures reported. Success rates are often found to vary significantly; this may be due to many confounding factors some of which may be modifiable and some which are not.

The purpose of this review is to update the previous report on confounding variables published in the 4th consensus with the more recently reported evidence. A Medline search was performed from 2008 onwards and, for convenience; the confounding variables are subdivided as in the previous report. For the purposes of this update only new studies will be included.

2. AGE

There have been several recent papers investigating the effect of age on continence surgery since the last report and a large Australian epidemiological study has demonstrated that the number of procedures, particularly in the elderly is increasing. [441] Data from Medicare Australia from 1994 -2009 were analysed and showed that there was almost a doubling of procedures for stress urinary incontinence over a three year period following the introduction of mid-urethral tapes. Over the 15 year period there was an 87% increase in women over 55 years old as compared to a 1% increase in younger women. Mid urethral slings were the most commonly performed procedure and accounted for 85.5% of all operations for stress urinary incontinence performed in 2009 (14 mid urethral slings for every one colposuspension).

Although now less commonly performed both colposuspension and pubovaginal sling remain efficacious procedures for stress urinary incontinence. The Stress Incontinence Surgical Treatment Efficacy Trial investigated the effect of age on both perioperative and postoperative outcome with both procedures in 659 women. [442] The older group (mean age 69.7 years) were compared with a younger group (mean age 49.4 years). Overall older women had slightly longer return to normal activities (50 days vs 42 days; p=0.05) although there were no differences in the return to normal voiding (14 days vs 11 days; p=0.42). In addition older women were more likely to have a positive stress test at follow up (OR 3.7; 95%CI: 1.70-7.97; p=0.001), less subjective improvement in both stress and urgency symptoms and were also more likely to require redo surgery (OR 3.9; 95%CI: 1.30-11.48).

The safety and efficacy of mid urethral sling surgery has been investigated in a large Australian series of 1225 women (955 retropubic and 270 transobturator) which compared outcomes in the elderly (96 women ≥ 80 years) to those in younger women (1016 women < 80 years). [443] Overall there was no significant difference in subjective cure between the two groups (elderly 81% vs younger 85%; p=0.32). Whilst there were no differences in bladder perforation rates the hospital stay was longer in the elderly group (1.6 ± 1.7 days vs 0.7 ± 1.1 days; p<0.001). In addition there was a higher incidence of short term voiding difficulties in the elderly with 37% failing their initial trial of void as compared to 9% in the younger group (p<0.001). However there were no differences in long term voiding problems (elderly 8% vs younger 6%; p=0.21) and de novo urge symptoms occurred in 7% of both groups.

These findings are supported by a further study investigating the safety and efficacy of TVTO in a consecutive series of 97 older women aged over 70 years (mean 75 years) and 256 younger women (mean 55 years). [218] Mean follow up was 30 ±17 months and post operative morbidity was similar in both groups although there were significantly more recurrent urinary tract infections in the elderly (13.7% vs 6.2%). Post operative asymptomatic urodynamic stress incontinence (USI) was found more commonly in the elderly group (19% vs 3.7%; p<0.05) although the rate of overt USI was 5% in both. Whilst the incidence of persistent overactive bladder (OAB) was similar in both elderly and younger women (68% and 62% respectively) de novo OAB was higher in the elderly group (11.9% vs 4.7%; p<0.05).

A smaller prospective questionnaire survey of 100 women undergoing tension Free Vaginal Tape (TVT) has also investigated the effect of age on outcome of surgery. Those women with more severe symptoms preoperatively were found to have a greater improvement in the symptom of stress incontinence and Quality of Life (QoL) and age did not appear to have an effect on outcome [444] although these findings are contradicted by a larger study of 537 women undergoing a retropubic or transobturator mid urethral

sling which found a significant detrimental effect of age and menopausal status.[445]

Patient reported outcomes have become increasingly important in the evaluation of women following surgery and a small retrospective cohort study has been reported in 122 younger women (<65 years) and 70 older women (≥ 65 years) who had combined surgery for SUI and urogenital prolapse. [446] At mean follow up of 10 ± 1.2 months both groups reported significant subjective improvement in symptoms and QoL although the older group had an increased risk of SUI treatment failure (OR 1.10; 95% CI: 1.05-2.5) but not prolapse treatment failure (OR 0.90; 95%CI: 0.29-2.8). A further study investigated preoperative and postoperative factors which correlated with surgical satisfaction in 371 women following fascial or mid urethral sling surgery. [447] Overall increasing age (OR 0.8; p=0.002), body mass index (BMI) (OR 0.8; p=0.003) and autologous fascial sling (OR 0.5; p=0.003) were associated with decreased odds of satisfaction.

3. RACE

There have been four papers evaluating the effect of race on the outcome of continence surgery since the last report. A large epidemiological study examining 129 778 women who underwent continence surgery in the United States in 2003 found the overall rate of 12 surgical procedures per 10 000 women. This figure was 10 per 10 000 (95% CI: 7-12) in white women and dropped to 3 per 10 000 (95% CI: 0-9) and 6 per 10 000 (95% CI: 0-13) in women of other ethnicity. [448] This is further supported by Medicare data from the United States which showed higher operation rates for SUI in white and Hispanic women when compared to black or Asian women (p<0.01). [449]

A further analysis of the Stress Incontinence Surgical Treatment Efficacy Trial examined the effect of racial group in 654 women (11% Hispanic, 73% non – Hispanic white, 6.7% non- Hispanic black and 8.9% were of other ethnicity) following colposuspension or pubovaginal sling. Overall there were no differences seen between groups in any of the urinary incontinence measures investigated. [450]

The function of the continence mechanism has also been compared in a cross sectional population based study of 335 black and white women aged 35-64 years classified as continent (n=137), stress incontinent (n=102) and urge incontinent (n=96). [451] When comparing black women to white women the maximum urethral closure pressure (MUCP) was 22% higher (68.0 vs 55.8 cmH20; p<0.0001). In addition white and black women complaining of stress incontinence were found to have an MUCP 19% and 23% respectively lower than controls. The MUCP in white women with urgency incontinence was as low as those white women with stress incontinence although black women with urgency incontinence had normal urethral function.

4. OBESITY

Whilst there are now considerable data linking severity of incontinence with obesity the evidence regarding the effect on continence surgery is less robust. Evidence from a large series of mid urethral tape procedures has shown no effect of BMI in terms of outcome. [445] This is supported by a further study of 195 women who were followed up for one year following TVT which showed no difference in outcome in different BMI cohorts. [452] The risk of perioperative morbidity however is higher with an increased risk of pain following transobturator sling placement (OR 2.51; 95% CI: 1.01-6.22) and of hip and thigh pain (OR 1.99; 95%: 0.79-4.99) in obese women. [453] This however is contradicted by a retrospective review of 129 women with BMI < 30 kg/m2 and 69 with BMI ≥ 30 kg/m2. Overall the bladder injury rate was significantly higher in those patients with lower BMI (14.0% vs 4.3%; p=0.04). After controlling for confounding factors BMI < 30 kg/m2 remained a risk factor for bladder injury (OR 4.63; 95% CI: 1.20 -17.86) as did previous continence surgery (OR 3.55; 95% CI: 1.01-12.50). [454]

5. PSYCHIATRIC ILLNESS

There have been no new relevant publications since the last report.

6. ACTIVITY

There have been no new relevant publications since the last report.

7. PREVIOUS CONTINENCE SURGERY

Surgical success rates often tend to be lower in those women having redo continence surgery and there have been several studies examining this since the last consensus statement. The efficacy of redo colposuspension has been reported in a case series of 52 women from one centre with an objective cure rate of 78% and a subjective cure rate of 80%. [455] The role of redo laparoscopic colposuspension following a failed mid urethral tape has also been assessed in a smaller retrospective case series of 16 women. At a median follow up of 24.5 months objective and subjective cure rates were 54.5% and 92.9% respectively. [456]

There is now also a considerable amount of data examining the efficacy of mid-urethral tape procedures following failed previous surgery. The efficacy of TVT following failed previous continence surgery has been reported in a prospective follow up study of 130 women in Finland. Of these 60 women had recurrent and 70 primary incontinence. Overall there were no differences between the groups in terms of transient voiding difficulties and complications. At three year follow up satisfaction rates were 86% and 91% in the recurrent and primary groups respectively and the subjective cure rate was 93%

in both. At follow up 20% of those having recurrent surgery complained of de novo urge symptoms as compared to 5.7% in the primary group. [457] A small series of 24 women with recurrent urinary incontinence and intrinsic sphincter deficiency following Burch colposuspension has also reported an objective success rate of 70.8% following TVT. [458]

In addition to studies investigating the use of the retropubic approach there are also several studies investigating the efficacy of the transobturator approach in recurrent stress incontinence. A secondary analysis in a large Scottish study comparing inside-out TOT with outside-in TOT in 341 women assessed outcome in a subgroup of 46 women with recurrent incontinence at one year. [212] Overall the subjective and objective success rates were 69.9% and 76.5% respectively and there were no differences between the two routes. Once again in this study a low MUCP (<30 cmH2O) was the only independent risk factor for failure (OR: 4.52; 95%CI: 1.51-56.1; p=0.016). A smaller series of 29 women with recurrent stress incontinence following a previous colposuspension has also been reported in 29 women who had a TVT or TOT with cure rates of 62.1% after one previous procedure and 57.1% after two. [459]

There is now also increasing evidence to support the use of a redo mid-urethral sling in those women who have previously had a failed mid-urethral sling. In a large series of 1 225 women reported from Australia 1 112 were a primary procedure and 77 were secondary procedures. [460] All redo slings were placed without removal of the first. Those women having a redo procedure were more likely to have intrinsic sphincter deficiency (31% vs 13%; p<0.001) and cure rates were 86% and 62% in the primary and secondary procedures respectively. A repeat retropubic approach was significantly more successful that a repeat transobturator approach (71% vs 48%; p=0.04). Whilst complications were similar in both groups de novo urgency (30% vs 14%; p<0.001) and urgency incontinence (22% vs 5%; p<0.001) were more common with redo surgery. A further study has reported on 31 patients who had a TVT after a failed mid urethral tape with an 18 month follow up. Overall objective cure assessed using a pad test was 74% with a 6% improvement rate and 19.5% failure rate whilst objective cure assessed with urodynamics was 77.4%. The subjective cure rate was 71%. [210] (also, see section on mid-urethral slings).

8. CONCOMITANT HYSTERECTOMY

There have been no new relevant publications since the last report.

9. SEVERITY AND DURATION OF SYMPTOMS

There have been no new relevant publications since the last report.

10. DETRUSOR OVERACTIVITY AND STRESS INCONTINENCE

There have been four papers assessing the effect of detrusor overactivity as a confounding variable in stress incontinence surgery since the last report.

A large Australian cohort study has reported on 754 consecutive women with stress urinary incontinence and urgency (SUI) and 514 women with stress urinary incontinence and urgency urinary incontinence (UUI) who had a mid urethral sling and were followed up for a mean of 50 months. [208] Overall persistent urgency was commonly reported in both groups (SUI 40% and UUI 32%). In the SUI group coexistent detrusor overactivity (OR 2.04; 95%CI: 1.39-3.01), baseline symptom severity (OR 1.41; 95% CI: 1.10-1.78) and age (OR 1.03; 95%CI: 1.02-1.04) increased the risk of persistent urgency. Conversely transobturator sling (OR 0.61; 95%CI: 0.39-0.94) and concomitant prolapse surgery (OR 0.54; 95% CI: 0.38-0.75) decreased the risk. In the UUI group coexistent detrusor overactivity (OR 1.86; 95% CI: 1.18-2.93) baseline symptom severity (OR 1.88; 95% CI: 1.38-2.56), previous continence surgery (OR 2.18; 95% CI: 1.28-3.70) increased the risk of persistent urgency whilst apical prolapse surgery (OR 0.33; 95% CI: 0.15-0.70) decreased the risk.

A further study of 121 women has investigated the risk factors affecting outcome after TVT and TOT. Multivariate analysis revealed that preoperative detrusor overactivity was an independent risk factor affecting cure after TVT (OR 113.1; 95%CI: 1.84-6592.77; p=0.02) or TOT (OR 23.7; 95%CI: 1.63-344.53; p=0.02) and MUCP <40 cmH2O (OR 8.34; 95%CI: 1.52-45.65; p=0.01) was a risk factor in the TOT group. [167]

A case control study in 34 women with mixed incontinence matched for age and type of procedure has shown a significantly higher rate of failure in the TOT group (29.4%) compared to the TVT group (0%). In addition women were significantly more likely to require repeat surgery following TOT (OR 10.1: 95% CI: 2.6-38.2). [116]

11. URETHRAL OCCLUSIVE FORCES

Since the last report there have been several papers investigating the role of the urethra on outcome following continence surgery.

The role of urethral mobility and intrinsic deficiency on outcome following mid urethral tape has been assessed in two studies. The first of these investigated 134 women following transobturator tape insertion. Overall 86% reported subjective cure and 14% complained of persistent symptoms. Median preoperative urethral mobility was significantly lower amongst treatment failures compared to those women who were cured (40 (10-60) degrees vs 50 (10-90) degrees ; p=0.0049). In addition women with

preoperative mobility <45 degrees were at least four time more likely to report incontinence when compared to those with ≥45 degrees mobility (29.4% vs 6.9%; RR 4.29; 95% CI: 1.59-11.60; *p*=0.005). [200]

A prospective 2 year study of 65 women has also found that intrinsic sphincter deficiency with a fixed urethra is associated with a poorer objective outcome at 24 months following TOT when compared to intrinsic sphincter deficiency and urethral hypermobilty and hypermobility alone (66.7% vs 87.5% and 96.6% respectively). [201]

Two studies have also examined the role of urethral retro-resistance pressure (URP) and surgical outcome. The first of these reported on 100 women and found no relationship between URP and severity of incontinence assessed by a 24 hour pad test. In addition there was no correlation between URP and incontinence severity. Following mid urethral tape insertion the objective cure rate was 84.9% although there were no significant differences in pre and post operative URP values (62.7±19.4 cm H2O vs 61.2 ± 20.4 cm H2O; *p*=0.57). [461] A further study of 69 women has shown that URP is not predictive of outcome following TVT. [462]

12. SURGEON'S EXPERIENCE

All surgical procedures and surgeons are subjected to the effect of a 'learning curve' and this has recently been assessed in two studies evaluating the outcome of mid urethral tapes. The learning curves of TVT and TOT have been compared in a study of 83 women and overall found TVT procedures were longer (*p*=0.025) although the duration was reduced after the surgeon had performed 15 procedures. [463] The effect on outcome was not assessed.

The impact of surgical experience and the effect of the learning curve has also been investigated in the use of Single Incision Mini Slings (SIMS) in a prospective study of 131 patients who had TVT Secur. Overall the study clearly demonstrated improved surgical outcome in those patients who had their procedures performed by more experienced surgeons. In addition whilst surgical time and intraoperative complications were not associated with surgical experience, the length of postoperative catheter use and hospital stay decreased with increasing experience. [464]

13. ADJUVANT OESTROGEN THERAPY

The role of oestrogens and lower urinary tract dysfunction remains controversial although there is evidence to suggest that vaginal oestrogen therapy may be useful in women with symptoms suggestive of OAB Since the last report two studies have investigated the role of adjuvant oestrogen therapy in women having continence surgery.

The role of adjuvant vaginal oestrogen therapy has been assessed in a prospective study of 59 post-menopausal women having a TVT procedure. [465] Patients were randomised to surgery with and without vaginal oestrogen therapy and followed up over 6 months. Overall the incidence of OAB symptoms at baseline was 7% and this rose to 32% at 6 months. Urinary urgency was significantly higher in those women not receiving vaginal oestrogen therapy (28% vs 4%; *p*=0.01) although decreases in frequency and nocturia were not significantly different.

More recently the role of adjuvant vaginal oestradiol (Vagifem, Novo Nordisk) 25mcg has been assessed in a prospective randomised study of 190 postmenopausal women who had a TVTO procedure with 6 month follow-up. Overall there was no statistically significant difference between those women who received oestradiol and those who did not in terms of peri operative complications and hospital stay. However in the post-operative period those women treated with vaginal oestradiol showed a statistically significant decrease in the symptoms of urgency and frequency although not nocturia and urgency incontinence. Equally there were no difference in efficacy rates between the two groups. [466]

IX. CLINICAL TRIAL OUTCOMES USED IN STRESS URINARY INCONTINENCE RESEARCH

The last decade has seen a massive expansion in the field of stress urinary incontinence (SUI) research. While initially criticised for poor quality research, significant advances have been made especially in the area of clinical trials. Indeed, in the United States, the National Institute of Health has helped foster this improvement with development of clinical trials networks such as the UITN and the PFDN. In addition, we have seen a maturation in the field of SUI research including improvements in the quality of trials and the instruments utilised. Use of validated outcome measures and properly conducted prospective trials are now the standard with emphasis being placed on comparative efficacy trials.

The increase and improvements seen in SUI research has also brought to light the problems that investigators typically encounter when assessing SUI outcomes. Strohbehn reported "there are as many shades of dry as there are shades of gray" in his editorial response to the UITN's SISTER trial which reported a wide range between different SUI outcome measures [467]. In this prospective randomised clinical trial comparing the Fascial Sling and Burch procedures, success for overall incontinence was 47% vs 38%, respectively compared to SUI specific success which was 66% vs 49% respectively. [125] Indeed, it is difficult to think one can clearly report SUI surgery outcomes when investigators have trouble defining the population before treatment is initiated. Brubaker reported variations in the categorisation of a cohort of wom-

en enrolled in a clinical trial who were planning to undergo SUI surgery. While all women were reported to have pure or predominant SUI for study inclusion, the range of women with mixed incontinence was 8.3% to 93.3% depending on what definition was used. If such variations exist in the defining of subjects enrolled in SUI trials from the onset, it is natural to expect wide variations in how outcomes are reported post operatively. [468] Rapp reported such wide variations when looking at different definitions of success after SUI surgery. In the same cohort of women, successful outcomes ranged from 33% to 87% depending on the definition used for success. [469]

Outcome assessments can be broken down into objective and subjective measures. [470] Objective parameters typically include: physical exam, pad tests, voiding diaries, urodynamic studies. Subjective assessments typically include patient reported measures such as validated instruments that measure symptoms , patient bother, satisfaction and HRQOL. However, these outcome tools are usually limited to a specific area and improvement in one area may not mean improvement in other areas or could even be at the detriment of another area. In addition, the degree of improvement experienced by one patient might be considered a "success" in that patient however the same improvement may be perceived differently by another patient. Furthermore, outcome measures limited to specific domains may not take other symptomology into account. For example, resolution of SUI might be considered a success by itself however if it were to occur in conjunction with urinary retention or worsening irritative voiding symptoms and urgency incontinence, the patient might not agree. Indeed, the majority of SUI outcome assessments rarely take complications into account. It is clear that focusing on a single measure is often inadequate and necessitates the need for measuring multiple outcomes which imposes greater burden on patients. [471] (SUNG). Lastly, no single instrument is universally accepted by all investigators although significant headway has been seen in the adoption of instruments advocated by professional organisations such as the International Continence Society and the International Consultation on Incontinence.

In response to the shortcomings seen with traditional SUI research outcomes, investigators have increasingly relied on greater use of composite outcomes as well as patient reported outcomes that especially assess global response. The use of composite outcomes have increased especially with the advent of clinical trial networks. While providing more comprehensive assessments, composite outcome often create a stricter definition of success especially if all of the components of the composite must be satisfied. Many of the large scale trials often include multiple outcomes measures as primary or secondary outcomes which allows them to be more comprehensive. However, a vast number of outcome measures have been utilised in the field of SUI research. While more comprehensive listings of SUI clinical trials can be found in the respective sections of this chapter, examples of trials utilising different outcome parameters that have been published since the last ICI report are listed in the following tables. **Table 9** provides a sampling of composite outcomes used in SUI trials. **Table 10** provides a sampling of patient reported outcomes measures used in SUI trials.

Table 9: Examples of Composite Outcomes

Author	SUI Surgery	Composite Outcome	Results
Albo[125]	Facial Sling vs Burch 655 women 24 months	*Negative pad test and *Negative (no UI) on 3 day diary and *#Negative cough test and *#No Self reported SUI on MESA and *#No retreatment for SUI *Required for overall success # required for SUI specific success	Overall Success: Sling =47% vs. Burch= 38%, P = 0.01) SUI specific success: Sling=66% vs. Burch=49%, P<0.001).
Richter[170]	Retropubic vs transobuturator midurethral sling 597 women 12 months	Objective Negative stress test and Negative pad test and No SUI retreatment and Subjective No Self reported SUI symptoms and No leakage reported on 3 day diary and No report of SUI retreatment and	Objective success: retropubic =80.8% vs transobturator =77.7% (equivalent) Subjective Success: retropubic=62.2% vs transobturator=55.8% (equivalent)
Barber[97]	TVT vs TOT 170 women 12 months	Abnormal bladder function defined by composite presence of any of the following: incontinence symptoms of any type positive cough stress test retreatment for stress incontinence postoperative urinary retention	Abnormal bladder function was: TVT: 46.6% TOT: 42.7% Conclusion: TOT was not inferior based on noninferiority test

While many of the self-reported measures can be considered “patient reported”, the concept of true Patient Reported Outcomes (PRO) is one that is more complex and encompasses a more global assessment. The use of PRO’s has gained acceptance as noted by the fact that most research funding sponsors, industry and regulatory agencies now require inclusion of outcome measures that include the patient’s perspective. The NIH recently established the Patient Reported Outcomes Measurement Information System (PROMIS) for women with urinary incontinence [471] (Sung). True PRO’s measure patient impressions in a more global context by encompassing 4 domains: 1) Symptoms, 2) Functioning, 3) General Health Perception and 4) HRQOL. The International Consultation on Incontinence has adopted the use of PRO’s and established the ICI Modular Questionnaire (ICIQ) Project that includes the assessment of a wide spectrum of urinary, bowel and vaginal symptoms along with their impact on HRQOL (Coyne)[477].

Another outcome measure that has recently gained popularity is the patient global impression of severity (PGIS) and the patient global impression of improvement (PGII). Initially validated by Yalcin, use of such global assessment instruments provides a single response which is easier for the patient and clinican to understand [478] (Yalcin). Furthermore, the measurement is all encompassing since the subject takes success and complications into account when responding. Indeed, the UITN recently adopted the use of the PGIS and PGII for use as a major eligibility criterion and as the primary outcome in the VALUE trial which will look at the impact of urodynamic studies on SUI Surgery outcomes. [479]

Table 10: Example of Patient Reported Outcomes

Author	Study Details	Outcome Measure	Results
Freeman [472]	N=183 Monarc TVT=100 Gynecare TVT=93	ICI Modular Questionnaire-Female LUTS	TVT: 65.6% TOT: 63.4% Conclusion: TOT not inferior to TVT
Brubaker [473]	655 randomised to Burch or Sling 450 Sexually active	POP/Urinary Incontinence Sexual Questionnaire (PISQ)	PISQ improved after SUI surgery Fewer felt restriction of sexual activity due to fear of incontinence Successful SUI surgery associated with greater improvement in PISQ
Filocamo [474]	157 women who underwent Mid-urethral sling Included women who were not sexually active	Female Sexual Function Index (FSFI)	Female sexual function improved after MUS 40% of women previously not sexually active later became sexually active after MUS
Tennstedt [475]	655 Randomised to Burch or Sling	Incontinence Impact Questionnaire (QOL)	QOL improved (scores decreased) more in women with successful SUI surgery
Miles	N=329 randomised to TVT or TVT-O	UDI-6 IIQ-7 PISQ	Similar improvements in UDI-6, IIQ-7 and PSIQ between both procedures TVT-O appears as effective as TVT
Lier [476]	194 women randomised to TOT or TVT	Cost Utility Analysis 15D questionnaire Quality Adjusted Life-years (QALYS) Cost estimates	Statistically non-significant cost savings with TOT of $1133 per patient despite no difference in health outcome between TVT and TOT
Biggs [213]	TOT in 27 who failed previous SUI surgery	PGII	Success: 80%

I. INTRODUCTION

Pelvic organ prolapse (POP) is a common problem affecting up to 50% of parous women and 6.3% of women will have undergone a surgical correction for pelvic organ prolapse by the age of 80. Prolapse surgery is an increasingly important aspect of gynaecological practice due to our ageing population, the decreasing rate of hysterectomy due to alternative treatments of menorrhagia and finally decreasing rates of cervical interventions for cervical dysplasia following introduction of vaccinations for Human Papilloma Virus. Already prolapse surgery is performed at least as frequently as continence surgery and, the operating and admission times are at least three times greater than for continence surgery. Given the increasing time and resources that will be required for POP surgery in the future it is paramount that we perform effective, durable, cost effective interventions with minimal morbidity. This chapter serves to outline and summarise the information relating to POP surgery reported in the English-language scientific literature after searching PubMed, Medline, Cochrane library and Cochrane database of systematic reviews, published up to January 2012, with Level 1 evidence. Level 2 or 3 evidence have been included if Level 1 data were lacking.

II. PREVALENCE AND INCIDENCE OF POP

There is a lack of epidemiological studies of the natural history, incidence and prevalence of POP.

It is widely accepted that 50 percent of women will develop prolapse but only 10 to 20 percent of those seek evaluation for their condition [Phillips 2006]. In the current literature, the overall prevalence of POP varies significantly depending upon the definition utilised, ranging from 3-50 percent (**Table 1**). Where POP is defined and graded on symptoms the prevalence is 3-6 percent as compared to 41-50 percent when based on examination, because mild prolapse on examination is common and frequently asymptomatic (Phillips 2006, Samuellson 1999, Nygaard 2004, Swift 2003). On examination anterior compartment prolapse is the most frequently reported site of prolapse and is detected twice as often as posterior compartment defects and three times more commonly than apical prolapse [Hendrix 2002, Handa 2004]. Following hysterectomy 6 to 12 percent of women will develop vaginal vault prolapse [Marchionni 1999, Aigmueller 2009] and in two-thirds of these cases multi-compartment prolapse is present [Morley 1988].

There is little knowledge about the natural history of POP. The reported incidence for cystocele is around 9 per 100 women-years, 6 per 100 women-years for rectocele and 1.5 per 100 women-years for uterine prolapse [Handa 2004]. Some data show that there is a 1-year incidence of POP of 26 percent and a 3-years incidence of 40 percent with regression rates of 21 percent and 19 percent, respectively. In general, older parous women are more likely to develop new or progressive POP than to show regression. Over a three year period 11 per cent of the women aged over 65 had prolapse progression of more than 2 cm whilst only 2.7 percent had a regression by the same amount [Bradley 2007].

Luber has shown in a large demographic study that the peak incidence of symptoms attributed to prolapse is between ages of 70 to79 whilst POP symptoms are still relatively common in women of younger age (**Figure 1**) [Luber 2001].

Demographic changes including an ageing population have significant implications for the future planning of women's health services. Wu et al [Wu 2009] have predicted that by 2050 the number of women suffering from symptomatic POP in the United States will increase at minimum by 46 percent (from 3.3 up to 4.9 million women and in a "worst-case scenario" up to 200 percent or 9.2 million women with POP. These figures were based upon population growth statistics in the United States however models that evaluate the impact of decreasing parity and increasing elective caesarean section rates are required to more accurately predict future rates of POP.

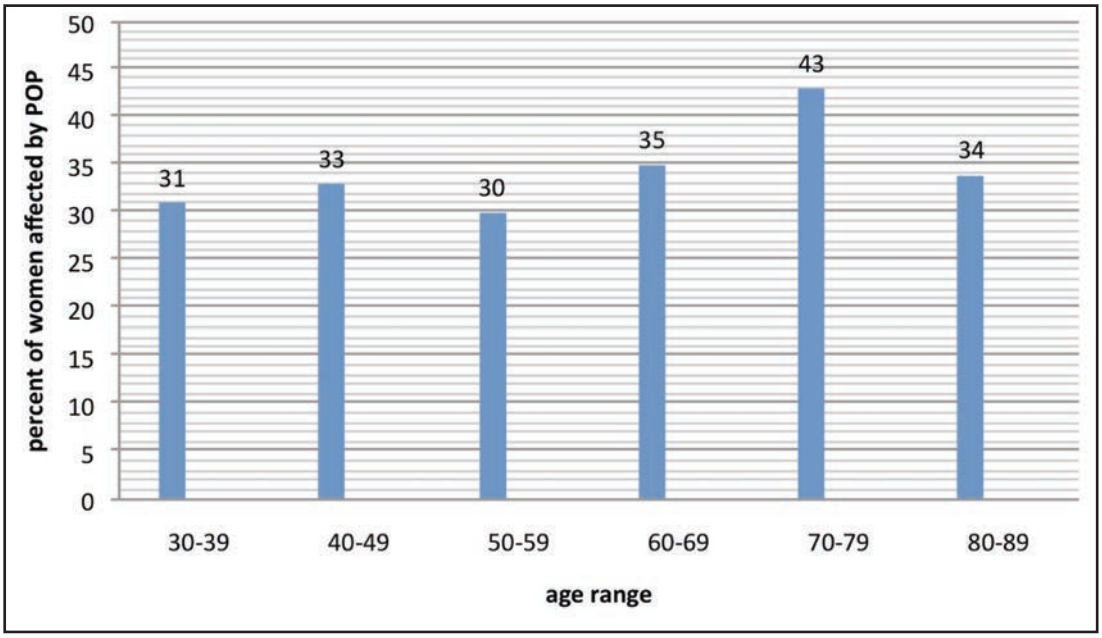

Figure 1. Shows the distribution of POP among women seeking care, US 2000 (Modified Luber 2001)

Table 1. Prevalence and Incidence POP

Study	Definition	Prevalence	Incidence	Country
Rorveit 2007	Symptom-based	5.7%		US
Nygaard 2008	Symptom-based	2.9%		US
Hendrix 2002	WHI-Study, Examination	Any prolapse: 41.1% Cystocele: 34.3% Rectocele: 18.6% Uterine: 14.2%		US
Swift 2003	Examination	6.4% stage 0 43.3% stage 1 47.7% stage 2 2.6% stage 3		US
Handa 2004	WHI-Study, Examination	Cystocele: 24.6% Rectocele: 12.9% Uterine: 3.8%	Cystocele: 9.3/100 Rectocele: 5.7/100 Uterine: 1.5/100	US
Nygaard 2004	Examination	2.3% stage 0 33% stage 1 63% stage 2 1.9% stage 3		US
Bradley 2007	Examination	23.5 - 49.9%	26%/1 year 40%/3 year	US
Maccharoni 1999	Examination	Vault-prolapse: 12%		Italy
Aigmueller 2009	Examination	Vault-prolapse: 6-8%		Austria

Incidence and Prevalence of Prolapse Surgery

Both incidence and prevalence for prolapse surgery increase with age. Women older than 80 years are currently the fastest growing segment of the population. The estimated lifetime risk of an American woman undergoing at least one surgical intervention by the age of 80 is 6.3 percent with 30% requiring subsequent surgery [Olsen 1997]. However, a more recent, prospective study showed a significantly lower reoperation rate of only 13 percent which may be explained by improved surgical procedures [Clark 2003]. The longevity and durability of POP surgery are important variables for planning and require ongoing evaluation .

The annual incidence for POP surgery is stated to be between 1.5 [Boyles 2003]and 1.8 [Shah 2007]cases per 1000 women-years with the incidence peaking in women between 60-69 years. Shah et al also demonstrated a peak incidence in 70 year old women however surprisingly high numbers of younger women were also undergoing surgical treatments reflecting a similarity in the prolapse symptoms reported in younger women by Luber 2001 (**Figure 2**) [Shah 2007]. In a more recent study Smith et al [Smith et al 2010] reported a lifetime risk of undergoing prolapse surgery as high as 19% in Western Australia. This figure is three times higher than the 6.3% lifetime risk for POP surgery reported by Olsen and requires further evaluation of local factors and definitions that may have contributed.

In the US, POP is thought to be the leading cause for more than 300.000 surgical procedures per year [22.7 per 10.000 women] with 25% undergoing reoperations at a total annual cost of more than 1 billion dollars [Brown 2002, Boyles 2003,Silva 2006, Shah 2007]. Also of note during a nine year period [1996 – 2005] the ambulatory costs related to pelvic floor disorder increased by 40% and if these figures are extrapolated to POP surgery the total annual cost would be over 1.4 billion dollars.

The incidence of prolapse which required surgical correction following a hysterectomy is 3.6 per 1000 women-years according to Mant et al from his large cohort study in the UK. The cumulative risk rises to 5 percent 15 years after hysterectomy [Mant 1997].

Further more detailed modelling of factors that will impact on future rates of POP in the community are required so that services can be provided to match the future demands of POP surgical interventions.

III. OUTCOME ASSESSMENT

Pelvic organ prolapse, like all pelvic floor disorders, is a multidimensional phenomenon and “success” of treatment is often difficult to define. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life [Barber 2009], yet until recently these areas have largely been ignored. Fortunately, over the last 15 years, measures to evaluate POP have

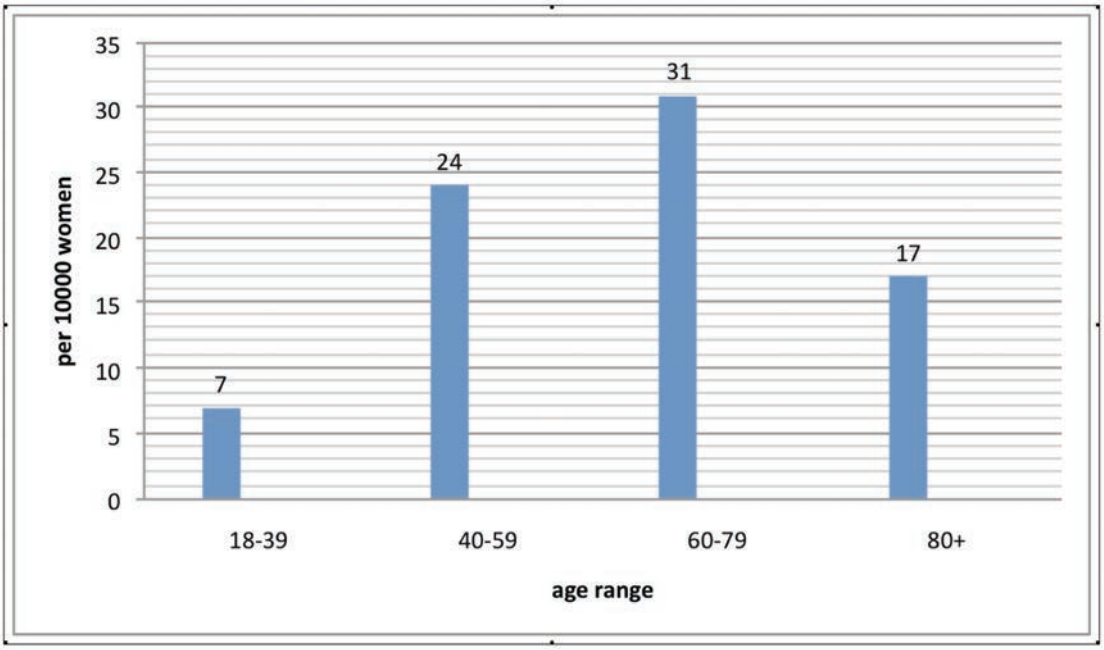

Figure 2. Shows the surgical treatment for POP/ rate per 10000 women (2003)

improved; there is now an internationally-accepted and reliable assessment of the anatomic support of the uterus and vagina [POPQ] and a number of valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments.[Bump 1996; Barber 2001; Barber 2005; Digesu 2005; Price 2006; Baessler 2010]. A recent joint report from the International Continence Society [ICS] and International Urogynecological Association [IUGA] recommended that the following outcomes be reported in studies of POP surgery: Objective (e.g. POPQ), Patient reported outcomes (particularly the presence or absence of vaginal bulge symptoms), Satisfaction, Quality of Life, and Perioperative data (e.g. operative time, hospital stay, etc) (Toozs-Hobson, 2012). A careful report of short- and long-term complications are also essential to properly weigh the risk-benefit ratio of each procedure.

1. OUTCOME ASSESSMENT: ANATOMY

The Pelvic Organ Prolapse Quantification system (POPQ), introduced in 1996, is the international standard for describing female pelvic organ support. [Bump 1996] The POPQ allows a reproducible and reliable description of the support of the anterior, posterior and apical vaginal segments using precise measurements to a fixed reference point, the hymen, and established criteria for “staging” the various levels of pelvic organ support from good support [POPQ stage 0 or I] to almost complete lack of support [POPQ stage IV].[Bump, 1996] The POPQ system has proved a valuable measurement tool that over the last 15 years has improved our understanding of POP and allowed a reliable assessment of the anatomical success of POP surgeries. However, there remain several critical challenges in the anatomical assessment of POP surgery.

First, it is difficult to establish dichotomous anatomical outcome criteria for success and failure, especially in the absence of symptoms. Traditionally researchers have defined surgical success using the NIH satisfactory anatomic outcome [POPQ stage 0 -1] and defined surgical failure as POPQ stage 2 or greater. More recently it is suggested that these anatomic definitions are too strict as over 75% of women presenting for annual gynaecological examinations without symptoms of pelvic organ prolapse would not meet the definition of “optimal anatomic outcome” and almost 40% would not meet the definition of “satisfactory anatomic outcome.”[Samuelsson 1999; Swift 2005] Thus, a substantial number of women considered “surgical failures” by these definitions would be within the normal distribution of vaginal support for parous women. The hymen maybe a more clinically relevant anatomic threshold for surgical success and some researchers have begun defining anatomic failure after surgery as POP that extends beyond the hymen.[Culligan 2005; Barber 2009; Zyczynski 2010; Chmielewski 2011; Sayer 2011].

Second, the five-level staging system of the current POP-Q (Stages 0-IV) may be insufficient to discriminate among clinically important groups of women with POP, placing virtually all such women into Stage II or III. While the staging may facilitate comparisons, it may not describe sufficient detail as the individual POP-Q measurements provide. A third area of uncertainty is whether or not apical prolapse should be considered by the same anatomic standards as prolapse of the anterior or posterior vaginal wall.

Controversy also surrounds the impact that the observer recording the anatomical outcomes has upon reported success rates. Traditionally in the retrospective assessment of anterior compartment trials the reported success rates ranged from 80-100%[Macer 1978; Stanton 1982; Walter 1982; Porges RF 1994]. However, prospective assessment of similar surgical interventions utilising similar definitions of success under the auspices of randomised controlled trials report significantly lower success rate ranging from 37-64%[Sand 2001; Weber 2001]. Further variation is also reported in prospective evaluations of prolapse staging depending upon whether the assessor is blinded to the surgical intervention. Antosh et al[Antosh 2011] demonstrated that the recurrence rate in a RCT comparing native tissue and transvaginal mesh repairs was significantly higher when performed by a blinded versus unblinded assessor at the 3 months (68 versus 53%) and at 1 year (57 versus 43%). Finally, there is an increasingly common trend for authors with financial conflict of interest related to the commercial products being evaluated reporting the outcomes of surgical interventions, which further increases the risk of reporting bias.

2. OUTCOME ASSESSMENT: SYMPTOMS

Women seeking care for POP often have concurrent pelvic symptoms. Ellkermann et al found that in 237 women evaluated for POP 73% reported urinary incontinence, 86% reported urinary urgency and/or frequency, 34-62% reported voiding dysfunction and 31% complained of faecal incontinence.[Ellerkmann 2001] The evaluation of a patient with vaginal prolapse requires a comprehensive review of the full spectrum of pelvic floor symptoms and an assessment of how these symptoms affect their quality of life. The most valid way of measuring the presence, severity, and impact of pelvic floor symptoms on a patient’s activities and well-being is through the use of psychometrically robust self-administered questionnaires [Bump 1996; Barber 2001; Barber 2005; Digesu 2005; Price 2006; Baessler 2010]

We have gained an improved understanding of the relationship between pelvic organ support and the development of symptoms. Most symptoms often attributed to POP have at best weak to moderate correlations with worsening pelvic organ support, however, the one symptom that is almost consis-

tently acknowledged by patients with advanced POP is the presence of a vaginal bulge that can be seen or felt.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Tan 2005] The absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient's assessment of overall improvement and improvement in quality of life after surgery, while anatomic success alone does not.[Barber 2009] The hymen seems to be an important "cut off point" for symptom development. Women with prolapse beyond the hymen have more pelvic floor symptoms and are more likely to report a vaginal bulge than women with prolapse at or above the hymen.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Swift 2005; Tan 2005]

3. OUTCOME EVALUATION: QUALITY OF LIFE

Health-related quality of life [HRQOL] refers to a person's total sense of well-being and considers multiple dimensions including (but not limited to) their social, physical, and emotional health. Measures of HRQOL can be classified into two types: generic and condition-specific. Generic HQOL instruments are used to assess quality of life in a broad range of illness or populations while condition-specific measures are designed to measure the impact of a specific disease on HRQOL. Women with advanced POP (stage 3-4) have decreased generic and condition-specific HRQOL compared to women with normal vaginal support.[Jelovsek 2006] It is recommended that investigators describe the impact of POP surgical treatment on HRQOL. Most studies that have assessed condition-specific HRQOL after POP surgery have demonstrated a significant improvement postoperatively. Improvements in generic HRQOL after POP surgery have been seen in some studies but not others. Maher et al reported significant improvements in condition-specific and generic QOL after SSLF, similar to that after abdominal sacrocolpopexy.[Maher 2004] The CARE trial reported significant improvements in condition-specific quality of life following sacrocolpopexy at three months and two years. [Brubaker 2006; Brubaker 2008] Barber et al demonstrated significant improvements in generic and condition-specific HRQOL in a prospective cohort of elderly women receiving vaginal surgery for POP and demonstrated similar improvements in women undergoing reconstructive surgery and those receiving colpocleisis.[Barber 2007] While some of these condition specific HRQOL incorporate assessment of sexual function [Baessler 2010] specific validated questionnaires on sexual function are available and provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire [PISQ][Rogers 2001] and the Female Sexual Function Index[FSFI][Rosen 2000] are two questionnaires frequently used. The joint ICS/IUGA paper on reporting outcomes after prolapse surgery has also recommended authors report the sexual function status of all individual participants pre and post intervention as seen in **Figure 3** (Toozs-Hobson, 2012).

4. OUTCOME ASSESSMENT: REOPERATION

Reoperation after POP surgery for recurrence is an important measure of procedure efficacy. It is important to realise that reoperation rates are likely to represent the "tip of the iceberg" in terms of unsuccessful surgical outcomes as many women with recurrence of symptomatic prolapse may not elect another operation, nonetheless the repeat surgery for recurrent POP is an undesirable outcome that should, in most cases, be considered a surgical failure. The rates of reoperation after POP surgery vary widely in the literature, in large part because of varying definitions and timeframes. Olsen et al using administrative data from a large U.S. healthcare system reported a lifetime reoperation rate of 29.2%.[Olsen 1997] Importantly, this study included both POP and stress incontinence surgery and did not distinguish between reoperation for incontinence or POP in their report. Moreover, the authors did not distinguish between reoperation for POP in the same compartments originally operated versus the development of new POP in a new segment of the vagina ["de novo POP"]. More recently several investigators have looked specifically at the issue of site-specific recurrence with re-operation rates ranging from 3.4%-9.7%.[Miedel 2008; Kapoor 2010] In a meta-analysis of 258 studies evaluating reoperation rates after apical prolapse repairs, Diwadkar et al, reported a reoperation rate of 3.9% [95%CI 3.5-4.4%] for traditional vaginal vault suspensions (sacrospinous ligament suspension and uterosacral vault suspensions) after a mean of 32 months, 2.3% (95% CI 1.9-2.7%) for sacrocolpopexy with a mean follow-up of 26 months and 1.3% (95% CI 1.0-1.7%) after transvaginal mesh procedures at a mean follow-up of 17 months.[Diwadkar 2009] Notably, the total reoperation rate if one includes reoperations for recurrent POP and for complications was highest in the transvaginal mesh group (8.5%). [Diwadkar 2009]

In order to provide some clarity for future studies reporting reoperation rates after POP surgery, the joint ICS/IUGA report on reporting outcomes after prolapse surgery has proposed the following standardised terminology for POP surgery studies[Toozs-Hobson 2012]:

Primary surgery for POP is the first procedure required for the treatment of POP in any compartment

Further surgery This gives a global figure for the number of subsequent procedures the patient undergoes directly or indirectly relating to the primary surgery. This is subdivided into:

a. Primary prolapse surgery/different site. A prolapse procedure in a new site/compartment following previous surgery in a different compartment (e.g. anterior repair following previous posterior repair).

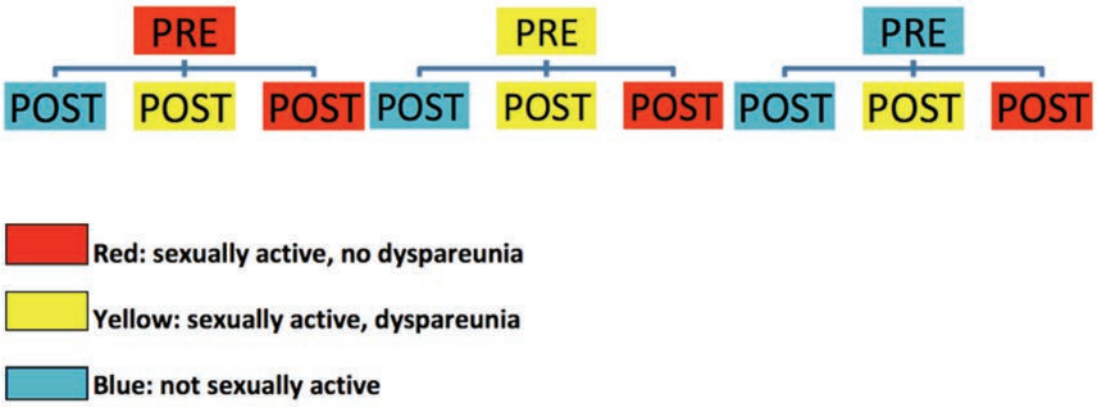

Figure 3. Describes color coordinated approach to systematically recording pre and post-intervention sexual function outcomes.

b. Repeat surgery: is a repeat operation for prolapse arising from the same site. Where combinations of procedures arise, e.g. new anterior repair plus further posterior repair these should be reported separately i.e. repeat posterior repair and primary anterior repair.

c. Surgery for Complications: e.g. mesh exposure or extrusion or pain or patient compromise e.g. haemorrhage (see complications section)

d. Surgery for non-prolapse related conditions: e.g. subsequent surgery for stress urinary incontinence or fecal incontinence.

5. DEFINING TREATMENT SUCCESS

The definition of success substantially affects treatment success rates following POP surgery.[Barber 2009] Since the publication of the NIH Workshop recommendations, considerable variability in defining treatment success still persists in studies evaluating surgery for prolapse. A number of trials define success as POPQ stage 0 or 1 consistent with the Workshop's "satisfactory anatomic outcome" definition with one reporting success rates as low as 30% using standard surgical techniques.[Weber 2001; Brubaker 2005] Some have used the Baden-Walker prolapse grading system rather than the POPQ system.[Maher 2004] Other studies have used a combination of anatomic criteria and the presence or absence of symptoms to define treatment success. [Paraiso 1996; Barber 2000; Brubaker 2005] Such variability makes it difficult to compare study results. Moreover, there are many unknowns, including clinical relevance of these definitions or how different outcome definitions might affect the comparison between treatment arms within a study.

A recent secondary analysis of the CARE trial described POP surgical success rates after sacrocolpopexy using 18 different definitions of treatment success with differing requirements for anatomic, symptomatic and/or retreatment outcomes.[Barber 2009] Treatment success varied widely depending upon definition used (19.2% to 97.2%). 71.4% considered their surgery "very successful" and 85.2% considered themselves "much better" than before surgery. Definitions of success requiring all anatomic support to be proximal to the hymen had the lowest treatment success (19.2% to 57.6%). 94.3% achieved surgical success when it was defined as the absence of prolapse beyond the hymen. Subjective cure (absence of bulge symptoms) occurred in 92.1% while absence of retreatment occurred in 97.2% of subjects. Subjective cure was associated with significant improvements in the patient's assessment of both treatment success and overall improvement, more so than any other definition considered [$p = .0002$ and $<.0001$ respectively]. Similarly, the greatest difference in symptom burden and HRQOL between treatment successes and failures was noted when success was defined as subjective cure (absence of vaginal bulge symptoms; $p<.0001$). These authors concluded that the absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient's assessment of overall improvement, while anatomic success alone does not. Based on this analysis along with the currently available literature on the distribution of pelvic support loss in the general population and on data on the relationship between pelvic organ support loss and symptom development, authors from the NIH Pelvic Floor Disorders Network have recommended that: 1) any definition of success after POP surgery should include the absence of bulge symptoms in addition to anatomic criteria and the absence of re-treatment and 2) using the hymen as a threshold for anatomic success seems a reasonable and defensible approach.[Barber 2009].

Conclusion

The committee concludes that authors when reporting outcomes on the surgical management of prolapse should include a variety of standardised anatomical and functional outcomes. It is expected such measures will improve the reporting of surgical outcomes and aid in meaningful meta-analysis of pelvic organ prolapse outcome data in the future.

- Anatomical outcomes reported should include all POP-Q points and staging utilising traditional definition of success and also with the hymen as the threshold for success. Assessment should be prospective and assessors blinded as to the surgical intervention performed if possible and without any conflict of interest related to the assessment undertaken. (**Grade C**)
- Subjective success postoperatively should be defined as absence of vaginal bulge (**Grade C**).
- Functional outcomes are best reported using valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments (**Grade C**).
- Sexual function is best reported utilising validated condition specific HRQOL that assess sexual function or validated sexual function questionnaires such as the Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ) or the Female Sexual Function Index(FSFI). The sexual activity status of all study participants should be reported pre and post-operatively under the following categories: sexually active without pain, sexually active with pain or not sexually active (**Grade C**).
- Prolapse surgery should be defined as primary surgery, and repeat surgery sub- classified as primary surgery different site, repeat surgery, complications related to surgery and surgery for non-prolapse related conditions. (**Grade C**)

IV. ANTERIOR COMPARTMENT SURGERY

Ahlfelt stated in 1909 that the only remaining problem in plastic gynaecology was the permanent cure of cystocele and now more than a century later this problem persist[White GR 1909]. Following high reported objective failure rates and reoperation rates after native tissue repairs and the success of mesh tapes in continence surgery and mesh utilised abdominally at sacral colpopexy the last decade has seen an unprecedented introduction of biological and permanent meshes in the management of anterior compartment prolapse.

1. NATIVE TISSUE REPAIRS

Historically anterior colporrhaphy was the standard procedure in the management of anterior compartment prolapse with objective success rates ranging from 80-100% in retrospective series[Macer 1978; Stanton 1982; Walter 1982; Porges RF 1994]. White [White GR 1912] as early as 1912 demonstrated the importance of paravaginal defects in anterior compartment prolapse. Richardson [Richardson AC 1976] in 1976 described a series of defects in the pubocervical fascia explaining why no single repair should be applied indiscriminately to all with anterior compartment defects. He also advocated the abdominal paravaginal repair which has a 75-97% success rate for cystoceles reported in case series (**Table 2**) [Richardson AC 1976; Richardson 1981; Shull 1989; Scotti 1998; Bruce 1999]. The surgical technique of the laparoscopic paravaginal repair is well described however little information is available on the efficacy of this approach. Shull [Shull 1994] also reported on the safety and efficacy of the vaginal paravaginal repair in 1994. Although the success rates of the vaginal paravaginal repair for cystoceles in case series vary from 67 –100%[White GR 1912; Shull 1994; Grody. M 1995; Elkins. T 2000; Mallipeddi 2001; Young 2001] significant complications have been reported recently. Mallipeddi [Mallipeddi 2001] reported on complications in a series of 45 including: 1 bilateral ureteric obstruction, 1 retropubic hematoma requiring surgery, 2 vaginal abscesses; 2 transfusions. In a series of 100 women Young [Young 2001] reported a 21 major complications and a 16% transfusion rate.

No randomised control studies have evaluated the abdominal or vaginal paravaginal repair in isolation. Benson et al [Benson 1996] and Maher et al [Maher 2004] have reported RCT's on upper vaginal prolapse comparing abdominal sacral colpopexy and vaginal sacrospinous colpopexy. Abdominal paravaginal repair was performed in the abdominal group if required and an anterior colporrhaphy without or without vaginal paravaginal laterally. Both authors reported the abdominal group to have a statistically lower rate of postoperative anterior vaginal prolapse than the vaginal group.

Raz et al [Raz 1989] popularised the needle suspension type procedure for cystoceles and reported success rates in case series may vary from 90-98% [Gardy 1991; Raz 1991; Benizri 1996]. The addition of polyglactin mesh to the repair appears to have little impact on the success [Safir. M 1999] [160]. Dmochowski et al [Dmochowski 1997] reported a lower success rate using a stricter outcome definition of success.

Goldberg et al [Goldberg 2001] reported results from a case control study of women with cystocele and stress urinary incontinence. He suggested that the addition of the pubovaginal sling to the anterior colporrhaphy significantly reduced the recurrence rate of cystocele from 42% in the control group to 19% in the anterior colporrhaphy and sling group [P<0.05].

APR Abdominal paravaginal repair AC Anterior colporrhaphy Definition varies between authors

In line with our surgical colleagues there has been a move towards the use of prosthesis to augment native tissue repair in reconstructive Gynecology. This movement took much of its impetus from two early papers. Firstly, Olsen et al [Olsen 1997] reported a reoperation of 29% following prolapse and or continence surgery and Weber [Weber 2001] reported a 70% failure rate of native tissue anterior compartment repair. Recent re-evaluation of the Olsen's same demographic 10 years later revealed a significantly lower re-operation rate of 17% [Denman M 2008] and the reader should be cautious in making conclusions even from this data as the surgical interventions performed in 1995 are not representative of interventions performed today. More importantly, Weber et al [Weber 2001] and Sand et al [Sand 2001] in randomised control trials reported the anterior col-

porrhaphy to be successful in the management of cystocele in only 30% and 57% respectively. Recent re-analysis of data from Weber's paper using the hymen as the threshold for objective success reported considerably better outcomes with only 10% of subjects developing anatomic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence and re-operations less than 1% at 23 months follow-up [Chmielewski 2011].

During the decade between these initial and subsequent publications surgeons have introduced a plethora of biological and mesh grafts to improve the outcomes of anterior compartment prolapse surger.

2. SYNTHETIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY

As seen in **Table 3** as early as 1996 Julian et al [Julian 1996] demonstrated in a prospective case control study that in women who had undergone at least 2 previous vaginal repairs, the overlaying of a Marlex (Bard) mesh to the anterior colporrhaphy reduced the recurrence rate of cystocele from 33% to 0%. The Marlex mesh was associated with a mesh erosion rate of 25%. Flood et al [Flood 1998] in a retrospective review of 142 women with Marlex mesh augmentation of anterior colporrhaphy demonstrated a 100 % success rate for cystoceles at 3.2 years and a mesh erosion rate of only 2%.

Absorbable meshes are an attractive option as an augmenting material as they offered the increased strength during the early healing phase without the long-term complications of permanent mesh and have been evaluated in 2 randomised controlled trials. Weber et al [Weber 2001] in a randomized control trial compared the anterior colporrhaphy [33], ultrawide anterior colporrhaphy [24] or anterior colporrhaphy with absorbable polyglactin (Vicryl) 910 mesh [26] in the management of cystocele. The study size was too small to detect small differences in efficacy or adverse events. However, at a mean follow-up of nearly 2 years the groups had similar proportions of women experiencing satisfactory or optimal anatomic results, 30%, 46% and 42% respectively.

Sand et al [Sand 2001] in a larger RCT allocated cystoceles to anterior colporraphy alone [n=70] and to anterior colporraphy plus polyglactin mesh underlay [n=73]. At I year the success rate in the mesh group was 75% and significantly greater than the 57% success rate in the anterior repair group alone [P=0.02]. Concurrent paravaginal defect were present in 11 women and concomitant paravaginal repair was significantly associated with a lower recurrence of cystocele overall [P=0.02].

A variety of permanent polypropylene mesh overlays have been evaluated in case series for the management of anterior wall prolapse. The anatomical success rate varies from 76 to 100% [Cervigni ; Julian 1996; Salvatore S 2002; O'Reilly BA 2003]. Salvatore et al reported worrying functional outcomes after a prolene mesh overlay including a mesh erosion rate of 13%, overactive bladder increasing from 28 to 56% and dyspareunia increasing from 18 to 38% postoperatively [Salvatore S 2002]. More recently, three year follow-up after the polypropylene mesh

overlay in the anterior compartment has been reported. Cervigni reported on 218 women and found a 76% objective success rate at three years. Mesh erosions were identified in 12.3% and vaginal stenosis in 7.7% [Cervigni 2007]. De Tayrac reported on 55 women at 3-year review with a 89% success rate, 9.1% mesh erosions, 5.5% mesh shrinkage and 16.7% dyspareunia [de Tayrac 2006]. He concluded that lower weight and coated meshes were required to limit the rate of complications and duly reported on 132 women, 12 months following low weight coated polypropylene mesh with a 92% success rate [de Tayrac 2007]. Unfortunately local problems remained with mesh erosions in 6.3% and de novo dyspareunia in 12.8%. Rane et al provided a 5 year review of 376 consecutive women with grade 3 anterior compartment prolapse after Perigee (AMS) and reported a 94% success rate, 11.1% mesh extrusion rate and deteriorating sexual function in 4% [Rane 2011].

Carey et al [Carey 2009] performed an RCT comparing anterior and posterior fascial plication and repair with self styled anterior and posterior polypropylene Gynemesh (Ethicon) overlay and reported no significant advantage to adding a mesh overlay at one year. The morbidity in the mesh group was lower than that reported above with a mesh erosion rate of 6.5% and no difference in dyspareunia and denovo dyspareunia rates between the groups.

Five randomised control trials have been published comparing armed or trans-obturator polypropylene mesh and traditional anterior colporrhaphy (**Table 3**). Nieminen et al [Nieminen 2010] compared 104 women undergoing anterior compartment prolapse repair with self-styled 6x11cm low weight monofilament 4 armed polypropylene mesh (Parietene light, Sofradim Co, Trevoux, France) with 97 undergoing traditional anterior colporrhaphy. Concomitant hysterectomy and posterior compartment prolapse surgery was allowed. At 3 years the objective success (stage 0 or 1 Aa and Ba) rate was 87% in the mesh group and 59% in no mesh group [P<.001]. Awarness of bulge was seen in 18% in the repair group as compared to 10% [p=0.07] in the mesh group. The mesh exposure rate was 19% with 66% requiring surgical correction. The reoperation rate for prolapse was 10% in the native tissue group with all but one of the recurrences in anterior compartment. In the mesh group the prolapse reoperation was 6% with all six recurrences occurring in the posterior or apical compartments.

Sivaslioglu et al reported on 43 undergoing low weight self styled polypropylene mesh as compared to 42 undergoing site-specific vicryl repair and at 12 months found the objective success rate was significantly higher at 91% in the mesh group as compared to 72% in the non-mesh group[Sivaslioglu 2007]. The mesh erosion rate was 6.9% and de novo dyspareunia was reported in 4.6% in the mesh group. Quality of life assessment demonstrated no difference in outcomes between the groups and no patient in either group underwent further surgery for anterior compartment prolapse.

Nguyen compared anterior polypropylene [Perigee, AMS] mesh [n=37] with anterior colporrhaphy [38]. At 1 year the objective success rate was higher in the mesh group (89% vs. 55%). Functional outcomes including quality of life, sexual activity and dyspareunia were similar in both groups with a 5% mesh erosion and 2% unilateral leg pain that settled at 8 weeks following the mesh surgery.[Nguyen 2008].

Altman and colleagues reported on behalf of the Nordic transvaginal mesh group a multicentre study (funded by Karalinska Institute and Ethicon unrestricted grants) comparing anterior colporrhaphy [n=182] to anterior transvaginal trocar mesh kit

(Prolift)[n=186] in women with symptomatic stage II or greater cystocele [Altman 2011]. Although the need for concomitant prolapse and continence surgery were exclusions an undetermined number of women with posterior and apical compartment prolapse well beyond the introitus were included. Reviewers were unblinded, surgeons were reviewers and conflict of interest statements are not available for authors or members of Nordic transvaginal mesh group. At one year, the success rate [composite Point Ba <-1 and absence of vaginal bulging] was significantly greater after the mesh repair 61% as compared to colporrhaphy group 35%. The subjective success rate was also significantly greater after the mesh repair (75% versus 62% p=0.008) as compared to the native tissue repair while no difference was detected on validated pelvic floor questionnaires (Urinary Distress Inventory) between the groups. The Prolift mesh procedure was associated with greater morbidity with a longer operating time, greater blood loss, higher rate of intra-operative cystotomy (3.5 versus 0.5%) , post- operative denovo stress urinary incontinence [12.3 versus 6.0%], and combined reoperation rate for USI, prolapse and mesh exposure (6% versus 0.5%). Denovo dyspareunia was seen in 7.3% after the mesh surgery as compared to 2% after anterior colporrhaphy [p=0.07] however no difference was detected between the groups utilising the Pelvic organ Prolapse Urinary Incontinence questionnaire [PISQ-12]. The mesh exposure rate was 11.5% [21/183].

Lastly, Vollebregt and colleagues reported a multicentre randomised control trial from the Netherlands with blinded reviewers comparing anterior colporrhaphy [n=58] with polypropylene trans-obturator mesh kit Avaulta [n=56] [Bard] for stage 2 primary anterior compartment prolapse [Vollebregt 2011]. Concomitant hysteropexy and posterior compartment surgery was allowed with hysterectomies being excluded. At one year the objective success rate was significantly greater in the mesh group as compared to anterior colporrhaphy group (91% versus 41%). Reoperation for anterior compartment prolapse was performed in 5% after the native tissue repair and in no patients in the mesh group [p>0.05]. No difference in awareness of prolapse or outcomes using validated questionnaires (Urogenital Distress Inventory and Incontinence Impact Questionnaire) were identified between the groups. The authors attributed the low mesh exposure rate of 4% to not performing hysterectomy and or collagen coating on the polypropylene mesh. Resolution of preoperative dyspareunia occurred in 80% in the repair group as compared to 20% in the mesh group. Denovo dyspareunia was reported in 15% following mesh and 9% after native tissue repair and denovo rectocele in 23% versus 10% respectively. The authors concluded that despite the significantly improved anatomical outcome in the mesh arm when using a functional outcome as a definition of success that there was not enough evidence to support the trans-obturator mesh in primary anterior compartment prolapse surgery.

The 2012 Cochrane meta-analysis of these RCT found that transobturator meshes had a lower rate of recurrence on examination [59/424, 14%] as compared to anterior colporrhaphy alone [200/410, 49%] RR 3.50, 95% CI 2.71 to 4.52. This finding was consistent for both the self styled (Nieminen 2010; Sivaslioglu 2008] [RR 3.41, 95% CI 2.04 to 5.67] and commercial transobturator polypropylene mesh kits [Altman 2011; Nguyen 2008; Vollebregt 2011] [RR 3.53, 95% CI 2.62 to 4.74]. Three trials demonstrated that anterior colporrhaphy [94/333, 28%] also had a higher subjective failure rate than the anterior transvaginal mesh repair [60/344, 17%] [RR1.62, 95% CI 1.22, 2.14] [Altman 2011; Nieminen, Vollebregt 2008]. Further prolapse surgery was not significantly more common after anterior colporrhaphy 14/459 (3%) as compared to 6/470 (1.3%) after trans-obturator polypropylene mesh [RR 2.18 95% CI 0.93 to 5.10]. No difference was detected in individual studies in validated prolapse specific questions and meta-analysis was not possible due to variations in questionnaires utilised. The operating time and blood loss were significantly greater in the mesh group and there was a tendency towards lower cystotomy rate [0.4% versus 2.7%, RR.0.19 95%CI 0.03,1.07] Altman 2011;Nieminen 2010], denovo dyspareunia [4% versus 8%, RR 0.51 95% CI 0.21 to 1.23] and denovo stress urinary incontinence [7.3% versus 11.4% RR, 0.65 95% CI 0.4 to 1.07,] [Altman 2011, Sivaslioglu 2008; Nieminen 2010] after anterior colporrhaphy. Further continence surgery was performed in 15/368 women following anterior colporrhaphy and 12/380 after polypropylene mesh procedure [RR 1.29, 95% CI 0.63 to 2.63]. This data need to be interpreted with caution as variations in concomitant surgeries existed. Mesh erosions were reported in 10.4% [41/393] of women who had an anterior compartment polypropylene mesh and surgical intervention to correct mesh erosion occurred in 6.3% [34/540].

Withagen in an observational study of 150 women undergoing Polypropylene mesh kit (Prolift) found that after an isolated anterior polypropylene repair there was a 46% incidence of stage 2 prolapse in the untreated compartment [Withagen 2010]. Altman et al, performed no concomitant surgery in the study and no difference in posterior compartment prolapse was identified between the groups or post-operatively within the mesh group when evaluating median Point Bp. However, meta-analysis of those studies [Nieminen 2010; Vollebregt 2011] that reported denovo prolapse in the apical or posterior compartment following anterior compartment mesh repair found at a lower rate after the anterior colporrhaphy [14/147, 9.5%] as compared to trans-obturator mesh [26/148 17.7%] [RR 0.49 95% CI 0.24 to 0.97] Both study protocols allowed concomitant posterior compartment

prolapse surgery. Although the reoperation rates for prolapse was similar in Nieminen et al between the 2 groups all the reoperations in AC group were anterior compartment failures and all in trans-obturator mesh group were in the posterior or apical compartment [Nieminen 2010]. This outcome is not surprising as we have seen previously when the vaginal axis is significantly altered compensatory prolapse can develop in other compartments. Compensatory prolapse is described in the posterior compartment after colposuspension [Ward 2008] or in the anterior compartment after sacrospinous colpopexy [Paraiso 1996; Maher 2001].

In the 8 trials that evaluated 553 patients that underwent some form of transvaginal mesh in the management of anterior compartment prolapse no patient underwent surgical intervention for vaginal pain or dyspareunia. This is in contrast to the Food and Drug Administration (FDA) transvaginal mesh alert were vaginal pain and dyspareunia accounted for 39% of adverse events and was marginally more frequent than mesh erosions at 38% of adverse events reports. While mesh exposures and their management remain well described vaginal pain and dyspareunia associated with anterior transobturator polypropylene mesh remain poorly characterised and will be fully evaluated in the complications and sexual function section of this chapter.

Given the relatively robust anatomic outcomes associated with transobturator mesh many clinicians were surprised that many mesh kit manufactures recently elected to introduce trocarless mesh kits and the majority have little or no data supporting their claims of superiority. Most recently, Moore et al [Moore 2012] described single incision anterior elevate [American Medical Systems, Minnetonka, MN, USA] using a lightweight polypropylene graft (24g/m2) and reported 92% objective success rate at 13 months in 60 patients with anterior and or apical prolapse. No mesh exposures were reported and the authors who reviewed the patients reported a financial relationship with the company manufacturing the product being evaluated.

Another new system involves polypropylene mesh [Prosima, Ethicon] overlay with arms extending but not secured to deeper structures. Patients use a Vaginal Support Device that is removed in the outpatient setting 3-4 weeks postoperatively, to splint the mesh while it is being incorporated into the paravaginal tissues. On prospective evaluation performed by surgeons all of whom have declared financial agreements with the manufacturing company, they reported a 77% objective success rate [<stage 2 POP-Q] at 1 year [Zyczynski 2010] and 69% at 2 years [Sayer 2011] with a mesh exposure rate of 9% in women with Stage 2 anterior and/or posterior compartment prolapse. Significant further prospective comparative trials with blinded independent reviewers are required for all mesh kits.

3. BIOLOGIC GRAFTS ANTERIOR COMPARTMENT SURGERY

Alternatively to synthetic prosthetic grafts autologous material may have a lower risk of host rejection or infection. Cosson [Cosson 2001] described an autologous 6-8cm long and 4 cm wide vaginal patch suspended from the tendinous arches of the pelvic fascia and tucked under the anterior repair. The success rate [<grade 1 POP] was 93% at a mean follow-up of 16 months.

Allografts from post-mortem tissue banks have been used for many years in orthopaedic surgery and decrease the risk associated with harvesting autologous rectus sheath or fascia lata. Cadaveric fascia lata with or without pubovaginal sling has been utilised to correct anterior compartment prolapse with a success rate varying from 81-100% with acceptable complication rates[Groutz 2001; Kobashi 2002; Powell 2004; Frederick 2005]. Gandhi et al have reported preliminary results of a randomised control trial comparing anterior colporrhaphy alone and augmented with fascia lata graft for cystoceles [Gandhi 2005]. At 1 year they were not able to demonstrate that the addition of the fascial lata graft improved outcomes with the success rate after anterior colporrhaphy alone being 71% as compared to 82% in those augmented with the fascia lata graft [P=0.07]. No complications were reported. Cadaveric dermis has been employed as a graft material in the anterior compartment with success rates varying from 42-84% at 2 years [Chung 2002; Clemons 2003; Behnia-Willison 2007; Ward 2007]. Concerns regarding prion transmission causing infectious diseases [Simonds RJ 1992] or residual antigenicity [Hathaway 2002] that may cause host graft reactions have encouraged the use of porcine or bovine xenografts as detailed in **Table 4**.

Leboeuf et al retrospectively reviewed 24 women with native tissue four corner defect repair (FDR) and 19 FDR with porcine dermis [Leboeuf L 2004]. At 15 months the success rate was 100% in the FDR group and reduced to 84% if porcine dermis overlay was utilised. Wheeler et al reported on 36 women who all underwent high uterosacral vault suspension with anterior repair augmented with porcine dermis and at 17 months found a 50% recurrence rate [Wheeler 2006]. The authors highlighted that despite the high objective failure rate greater that 90% of the women were satisfied or somewhat satisfied with the repair and 83% would undergo the surgery again. Handel et al retrospectively compared anterior colporrhaphy [n=18], porcine dermis [n=56] and polypropelene graft [n=24] in those with cystocele [Handel 2007]. The success rate at 13 months was 94%, 64% and 96% respectively with a 21% rate of vaginal extrusion of the porcine dermis graft. Alternatively to these relatively disappointing

results, a number of groups have reported satisfactory objective results utilising porcine dermis. [Gomelsky 2004] [Simsiman 2006].

Meschia et al in a multicentre randomised clinical trial compared the anterior colporrhaphy [n=103] and anterior colporrhaphy-augmented with 4x7cm piece of porcine dermis [Meschia 2007]. The success rate at 1 year was 93% in the anterior colporrhaphy with porcine graft overlay group as compared to 81% in anterior colporrhaphy alone group [P<0.001] with a 1% rate of graft erosion.

Hviid et al reported a smaller randomised controlled trial comparing polyglactin plication anterior colporrhaphy and porcine dermis 4x7cm graft at one year [Hviid 2010]. The objective failure rate [defined as point Ba ≥-1] was 2/28 in the porcine dermis group as compared to 4/26 in the anterior colporrhaphy and was not significant. Guerette et al compared the anterior colporrhaphy group [n=17]and anterior colporrhaphy with bovine pericardium collagen [n=27] matrix graft reinforcement and reported no difference on objective examination with success rate of 63% after the AC and 77% in the bovine pericardium collagen repair at 2 years(Guerette 2009]. The reoperation rate for prolapse was 37% in AC group and 23% in the bovine pericardium group. Denovo dyspareunia occurred in 5% follow-

Table 4. Biological Grafts in anterior compartment prolapse

Variable definitions of success used.

ing AC only. There was no difference in quality of life outcomes between the groups utilizing Urinary Distress Inventory and Pelvic organ prolapse and Incontinence sexual questionnaire.

Feldner et al compared anterior colporrhaphy with 7x10cm small intestine submucosa (SIS) graft in a randomised control trial and demonstrated reduced operating time in AC group (30 min versus 46) as compared to SIS [p=0.02][Feldner 2010]. The objective failure rate of 33% [9/27] was significantly higher after the AC versus 14% [4/29] in the SIS group. The dyspareunia rate was similar in both groups [AC 4/27 versus 5/20 SIS] and no reoperations were reported. Prolapse quality of life assessment [P-QOL] improved postoperatively in both groups with no significant difference between the groups. In another RCT, Natale et al compared polypropylene mesh (Gynemesh) with porcine dermis (Pelvicol). At two years, significantly fewer women had anterior vaginal wall recurrence in the mesh group 28% [27/96] versus to 44% [41/94] of the porcine graft group [RR 0.64, 95% CI 0.43 to 0.96]. Mesh erosion was seen in 6.3% following mesh surgery. Although similar numbers of women reported dyspareunia [10 versus 12], the authors reported superior sexuality outcomes in the porcine graft group as compared to polypropylene mesh [p = 0.03][Natale 2009].

Finally, Menefee et al in a randomised control trial compared three operations, anterior colporrhaphy, vaginal paravaginal repair using porcine dermis graft and vaginal paravaginal with self-styled polypropylene mesh and also reported a higher objective success rate after the polypropylene mesh 86% [25/29] as compared to 52% [12/23] in the porcine dermis arm [Menefee 2011] and 53% [10/19] in the AC arm. The subjective failure rate was not significantly different and was 3.4%,12% and 13% respectively. The graft erosion rate was 1/23 [4.3%] in the porcine dermis group and 4/29 [13.8%] in the mesh group.

The 2012 Cochrane meta-analysis concluded that when anterior colporrhaphy was compared to any biological graft the objective failure rate in anterior compartment was significantly higher in the anterior colporrhaphy group 56/222 [25%] as compared to the biological graft group 31/218 [14%]. Results from 3 trials [Gandhi 2005; Meschia 2007,Guerette 2009] demonstrated no difference in prolapse symptoms when native tissue repair was compared to biological graft repair [RR 1.03 0.61 to 1.75]. Differences in the methodology and the nature of the different biological grafts utilised in five trials [Feldner 2010, Gandhi 2005, Guerette 2009, Hviid 2010, Meschia 2007, Menefee 2011] were considered to be too dissimilar to combine with any other results in a meta-analysis except to highlight that 2 RCT's [Feldner 2010, Menefee 2011] demonstrated superior objective outcomes following polypropylene mesh as compared to Porcine graft overlay.

While many clinicians believe the primary role of polypropylene mesh may be in complex or high risk prolapse such as recurrent prolapse there is little evidence to support these proposals. Fayyad et al prospectively evaluated 36 women with recurrent anterior compartment prolapse and reported an objective success rate (less than stage 2 anterior compartment prolapse) of 47% with a mesh exposure rate of 19%[Fayyad 2011].

In a prospective multicentre Dutch RCT trial women who had undergone prior prolapse surgery were randomised between native tissue repairs and tension free Vaginal polypropylene mesh [Withagen 2011]. Allocation concealment was not confirmed and neither patient, surgeon or assessor were blinded. Surgeons performed the reviews and all authors declared a financial relationship with the company manufacturing the commercial mesh product. Unfortunately preoperatively the two groups were significantly different pointing to a systematic failure in the randomization process which discredits the remaining findings of the manuscript.

The reported failure rate in the native tissue group using an unorthodox outcome definition (no prolapse in the treated compartment or reoperation) was 45% AC versus 9% mesh group at 1 year. Utilising the definition any grade 2 prolapse or subsequent prolapse surgery the failure rate was 66% in the conventional surgery group as compared to 49% [p=0.03] in the mesh group. The mesh exposure rate was 16.7% with 6% undergoing surgical intervention. Utilising Patients global Impression of Improvement [PGII] and Urogenital Distress Inventory both groups had similar outcomes.

Conclusion for anterior vaginal compartment repairs:

The following conclusion can be made regarding surgical interventions for anterior vaginal compartment repairs:

- absorbable mesh augmentation of native tissue repair improves the anatomical outcome as compared to native tissue repair alone with no increased complication rate in meta-analysis of 2 RCTS (**Grade B**)
- Biological grafts in meta-analysis have improved anatomical outcomes with no change in subjective outcomes as compared to native tissue repairs (**Grade B**). Conflicting level one evidence supports porcine dermis graft (Meschia, Hviid, Menefee) and single RCT supports small intestine submucosa as graft agent in anterior compartment prolapse surgery (Feldner) (**Grade B**) .
- Consistent level one data supports a superior anatomical outcome for Polypropylene mesh as compared to biological graft (Pelvicol) in the anterior compartment (Feldner, Menefee). Mesh exposure rate was significantly higher in the polypropylene mesh group. (**Grade A**)

- Consistent level 1 evidence demonstrates improved anatomical and subjective outcomes for polypropylene mesh as compared to anterior colporrhaphy (**Grade A**). These outcomes did not translate into improved functional outcomes using validated questionnaires or a lower reoperation rate for prolapse. The mesh group was also associated with longer operating time, greater blood loss and a non significant tendency towards higher cystotomy, denovo dyspareunia and denovo stress urinary incontinence rate as compared to AC. Apical or posterior compartment prolapse was significantly more common following polypropylene mesh and mesh extrusion rate was 10.4% with 6.3% undergoing surgical correction. (**Grade B**)
- single Level 3 evidence does not support use of polypropylene mesh for recurrent anterior vaginal wall prolapse (**Grade C**)

V. UTERINE PRESERVATION DURING POP SURGERY

Traditionally, surgical correction of uterovaginal prolapse includes a hysterectomy despite the fact that the uterus is believed to be a passive structure in the disease process. More recently, women have opted for uterine preservation for a variety of reasons including: desire to maintain future fertility, belief that the uterus affects sexual function or sense of identity, and concern about risks of hysterectomy. While the overall number of hysteropexy studies have increased, most are retrospective or lack a control group. Comparisons between the different hysteropexy procedures are challenging due to the limited numbers of prospective controlled trials measuring a variety of outcomes.

1. PATIENT SELECTION

Careful patient selection is critical prior to considering uterine preserving prolapse surgery. **Table 5** list contraindications to uterine preservation. Most studies exclude subjects with menstrual disorders and abnormal uterine or cervical pathology such as large fibroids, endometrial hyperplasia, and cervical dysplasia. A recent study by Frick illustrates the need for hysterectomy in woman with postmenopausal bleeding even with a negative workup because of the high risk [13%] of unanticipated endometrial cancer or hyperplasia [Frick 2010]. Postmenopausal women without bleeding and premenopausal women with regular menses without abnormal uterine bleeding and a negative workup are at low risk for unanticipated pathology.

2. VAGINAL HYSTEROPEXY

The vaginal route can be divided into repairs with and without mesh. The non-mesh repairs include Manchester repair and sacrospinous hysteropexy.

a) The Manchester procedure

The Manchester procedure is one of the oldest prolapse repairs that involves amputation of the cervix and reattachment to the cardinal ligaments. Modified Manchester procedures include plication of the uterosacral ligaments posteriorly and cardinal ligaments anteriorly for improved apical support. Nevertheless, this is primarily a procedure for cervical elongation in premenopausal women that wish to maintain fertility or older women with medical comorbidity. There are high rates of cervical stenosis and menstrual disorders [7-35%] associated with cervical amputation and the use of Sturmdorf sutures [Williams 1966; Tipton 1970; Thomas 1995; Ayhan 2006]. All studies using this technique are retrospective and show relatively good anatomic and symptomatic improvement. One retrospective cohort comparing modified Manchester to total vaginal hysterectomy and uterosacral ligament suspension showed 100% cure of the apical compartment but a 40% success rate based on overall stage in the Manchester group. [DeBoer 2009] Three other retrospective cohorts comparing Manchester to vaginal hysterectomy showed no difference in anatomic or symptomatic outcomes with decreased operating time and blood loss in the Manchester group [Thys ; Thomas 1995; Kalogirou 1996]. Despite good success rates, Kalogirou concluded, “that the Manchester procedure has a limited place in modern gynecology…” Better surgical options exist for pre-menopausal women that wish to preserve fertility including sacrospinous hysteropexy, laparoscopic uterosacral hysteropexy or laparoscopic sacral hysteropexy. For post-menopausal women with medical comorbidity that require a minimally invasive approach, sacrospinous hysteropexy or LeFort colpocleisis would be preferable depending on their desire to preserve vaginal function.

Table 5. Contraindications to uterine preserving surgery

Uterine abnormalities
Fibroids, adenomyosis, endometrial pathology sampling
History of current or recent cervical dysplasia
Abnormal menstrual bleeding
Post menopausal bleeding
Familial cancer BRAC1&2 ↑risk ovarian cancer and theoretical risk fallopian tube and serous endometrial cancer
Hereditary Non-Polyposis Colonic Cancer 40-50% lifetime risk endometrial cancer
Tamoxifen therapy
Unable to comply with routine gynecology surveillance

b) Sacrospinous Hysteropexy

At sacrospinous hysteropexy the cervix or uterosacral ligaments are transfixed to the sacrospinous ligament using permanent or delayed absorbable suture. In a recent RCT comparing sacrospinous hysteropexy [n=37] to vaginal hysterectomy with uterosacral ligament suspension [n=34], Dietz et al reported a higher rate of apical recurrences in the hysteropexy group 21% versus 3% hysterectomy group p=0.03].[Dietz 2010] Three women had stage 4 uterine prolapse preoperatively that underwent hysteropexy and all developed recurrent uterine prolapse within one year. Subjective outcomes improved for both groups. Hysteropexy was associated with shorter hospitalisation, quicker recovery with more rapid return to work and the total vaginal length was longer 8.8cm versus 7.3cm in hysterectomy group [p<0.01]. Both groups had high rates of postoperative anterior vaginal wall prolapse [51% vs. 64%]. Another RCT unfortunately failed to report objective or subjective outcomes and revealed no difference in sexual function between sacrospinous hysteropexy and vaginal hysterectomy [Jeng 2005]. Sexual function domains of the Female Sexual Function Index-7 remained relatively unchanged in the majority of subjects with low rates of dyspareunia [5%]. Transient buttock pain occurred in 15% of subjects, similar to sacrospinous ligament fixation. Among the other studies in our review, buttock pain was present in up to 18% of patients and was usually self-limited [Hefni 2003; Jeng 2005; Hefni 2006; Dietz 2007; Dietz 2008].

Three cohort studies comparing sacrospinous hysteropexy to vaginal hysterectomy with or without sacrospinous fixation showed no difference in anatomical or symptomatic improvement with the exception of a three-fold increase in overactive bladder and urge incontinence symptoms in the vaginal hysterectomy group [Maher 2001; Hefni 2003; van Brummen 2003]. The sacrospinous hysteropexy group had shorter operating time, less blood loss, faster recovery, and fewer complications with similar recurrence and reoperation rates.

Lin and colleagues performed an interesting and unique prospective two-part study [Lin 2005]. The first phase identified cervical elongation [relative risk 10.9] and severe prolapse as risk factors for recurrent prolapse after sacrospinous hysteropexy. Among the first 33 patients, cure of uterine prolapse was 93% for those without risk factors compared to 71% for those with at least one risk factor. Next, they excluded patients with severe prolapse and performed a partial trachelectomy for those with cervical elongation resulting in a 96-100% cure rate with no recurrences in the 7 women undergoing partial trachelectomy.

The majority of studies have revealed relatively high success rates for the apical compartment with low complication rates for sacrospinous hysteropexy. Evaluation of available data from **Table 6** re-

Table 6. Compares outcomes sacrospinous hysteropexy and vaginal hysterectomy.

SSHP = sacrospinous hysteropexy; TVH = total vaginal hysterectomy; DVT = deep venous thrombosis
** variation in surgical techniques and definition success exist*

veals no difference in the mean objective success rate of 87% [373/428] sacrospinous hysteropexy versus 93% [244/262] in the hysterectomy group. While tha data on efficacy of sacrospinous hysteropexy are conflicting sacrospinous hysteropexy remains an alternative to vaginal hysterectomy in women who desire future fertility or uterine conservation. However, women with severe advanced prolapse desiring uterine conservation are at high risk of recurrence and should consider alternative approaches for hysteropexy [Lin 2005; Dietz 2010]. Those with cervical elongation should consider partial trachelectomy, which may affect future pregnancy outcomes.

c) Vaginal Mesh Hysteropexy

Several sacrospinous hysteropexy studies show high rates [11-51%] of recurrent anterior vaginal wall prolapse despite performance of a concomitant cystocele repair [Paraiso 1996; Maher 2001; Hefni 2003; Dietz 2007; Dietz 2008; Dietz 2010] and probably secondary to the posterior deflection of the vaginal axis with sacrospinous fixation. Level 1 evidence demonstrates improved anterior vaginal wall anatomical support with the addition of vaginally placed mesh. [Maher 2010] Intuitively, hysteropexy with anterior mesh placement seems ideal to improve anterior vaginal wall support and decrease recurrences in women desiring uterine conservation. Studies involving vaginal mesh repair with uterine conservation frequently include post-hysterectomy subjects and those undergoing concomitant hysterectomy making it difficult to identify outcomes specific to hysteropexy [Feiner 2010]. For the purposes of this section, we excluded anterior vaginal mesh repairs for uterovaginal prolapse that did not require an apical support procedure that would qualify as a hysteropexy.

Collinet et al reported 5-fold increased odds of mesh exposure with concomitant hysterectomy and 6-fold increased odds with an inverted T colpotomy incision [Collinet 2006]. Uterine preservation and minimising the size of the colpotomy were protective. These data support the role of hysteropexy for women with uterovaginal prolapse planning a vaginal mesh repair. However, there are no RCTs or prospective cohort studies comparing vaginal mesh hysteropexy to hysterectomy with prolapse repair. There are 3 retrospective cohort studies confirming the efficacy of vaginal mesh hysteropexy. McDermott et al reported similar high anatomic success, symptomatic improvement and perioperative outcomes with total Prolift hysteropexy and total Prolift colpopexy [McDermott 2011]. The mesh erosion rate was 13% in the hysteropexy group. Chu et al discovered excellent support and high satisfaction when hysteropexy and vaginal hysterectomy were performed in conjunction with Perigee and Apogee, apical arms placed through the sacrospinous ligaments (Chu). The hysteropexy group had shorter operating time, less blood loss, and lower rates of mesh erosions [4% vs. 13%, NS]. Neuman et al reported similar high success and satisfaction for posterior intravaginal slingplasty with hysteropexy and hysterectomy [Neuman 2007]. There was only 1 case of recurrent uterine prolapse despite the fact that cervical amputation was performed in 17% of hysteropexy subjects. Tape erosion rates were similar [11% vs. 14%, NS] and hospitalisation was shorter [1.5 vs. 4.2 days] in the hysteropexy group.

A prospective series of 100 anterior Prolift, sacrospinous hysteropexy and posterior colporrhaphy procedures revealed 75% objective success, 12% uterine recurrences and 11% mesh erosions [Feiner 2010]. Satisfaction was high [94%] because 84% had no prolapse symptoms and all recurrent uterine prolapse were mild, stage 2. Other retrospective and prospective hysteropexy series demonstrate higher cure rates with similar or lower mesh risk [Huang ; Nicita 2005; Inoue 2009]. Fatton et al demonstrated a high number of mesh related complications in a multicentre retrospective series of 110 Prolift procedures [Fatton 2007]. There was 1 bladder injury, 5 mesh exposures, 3 granulomas without mesh exposure, 18 cases of mesh shrinkage, and 1 vaginal synechia. Meta-analysis of the limited available data in **Table 7** demonstrates no difference in anatomic success rate of 86% [273/316] in the mesh hysteropexy versus 98% [81/83] in the mesh hysterectomy group [p=0.21]. Nor was there a significant reduction in the mesh exposure rate when mesh repairs were performed with hysteropexy 8.8% versus 13% with hysterectomy [p=0.22]. Newer trocarless kits using lower volume light weight mesh are being promoted for uterine conservation surgery without any supporting data in the peer reviewed literature to date.

3. ABDOMINAL HYSTEROPEXY

Abdominal hysteropexy has been performed for over a century. Early procedures transfixed the uterus to the anterior abdominal wall [Swain 1897; Giles 1930]. Other small series have successfully utilised ventral fixation to the pectineal ligaments with or without a graft [Nesbitt 1989; Joshi 1993]. However, abdominal sacral hysteropexy is generally the procedure of choice when performed through an open abdominal incision. Similar procedures can be performed laparoscopically or robotically including sacral hysteropexy and uterosacral ligament suspension. Other laparoscopic options have been described including round ligament suspension [O'Brien 1994] and anterior abdominal wall fixation [Chen 2010]. We present the data for the most common abdominal and laparoscopic techniques.

a) Abdominal Sacral Hysteropexy

Early studies performed in the 1950's either directly sutured the uterus to the anterior longitudinal ligament or used a thin strip of external abdominal oblique fascia tunneled retroperitoneally from the sacral promontory to the posterior cervix for support [Stoesser 1955; Arthure 1957]. More recently, a variety of grafts and techniques have been described. Frequently polypropylene mesh is secured posteriorly to the cervix/vagina or a second graft is passed through windows made in the broad ligament and secured to the anterior cervix/vagina. Addison and Van Lindert published a series of abdominal sacral colpopexy in 1993 containing subsets of women [11 total] undergoing successful abdominal sacral hysteropexy with synthetic mesh [Addison 1993; van Lindert 1993]. Over the past 15 years, there have been multiple small studies evaluating abdominal sacral hysteropexy [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Roovers 2002; Barranger 2003; Roovers 2004; Bai 2005; Costantini 2005; Demirci 2006; Jeon 2008] as listed in **Table 8**.

Roovers and colleagues performed the only RCT comparing abdominal sacral hysteropexy [n=41] and Burch to vaginal hysterectomy, uterosacral ligament suspension, anterior and posterior colporrhaphy, and needle suspension [n=41] [Roovers 2004]. Anatomic outcomes were similar with high success rates for the apical [95%] and posterior [85-95%] compartments. Anterior recurrences occurred in 61 and 64% of women. Urogenital distress inventory scores improved for all domains with the greatest improvement in prolapse symptoms. There were more doctor visits and reoperations performed or planned in the abdominal hysteropexy group. No differences existed for operating time, blood loss, length of hospitalisation, and number of complications. Constantini et al reported results of a prospective cohort study comparing abdominal sacral hysteropexy to total abdominal hysterectomy and sacral colpopexy [Costantini 2005]. There were no differences in anatomic success [91% vs. 92%], symptomatic improvement or satisfaction. Three women required vaginal revision due to mesh erosions [8%] in the hysterectomy group. Hysteropexy was associated with shorter operating time, less blood loss, and shorter hospitalisation.

There are 2 retrospective cohort studies that each included 3 arms. Jeon et al compared abdominal sacral hysteropexy to abdominal hysterectomy with sacral colpopexy or uterosacral suspension [Jeon 2008]. There were no recurrences in the hysteropexy group. Recurrences were 6.2 times more likely to occur in the uterosacral suspension group compared to the sacral colpopexy group when hysterectomy was performed. Bai et al compared smaller numbers of abdominal sacral hysteropexy to sacral colpopexy with or without hysterectomy [Bai 2005; Jeon 2008]. Success rates were high for all groups [95-100%]. There were 3[16%] mesh erosions in the hysterectomy group that did not require reoperation and no erosions in the other groups. Hysteropexy had shorter operating time and length of hospitalisation. All of the prospective observational trials and retrospective series revealed satisfactory anatomic success [87-100%] and symptomatic improvement [92-100%] [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Barranger 2003; Demirci 2006]. In 2 studies, cervical amputation was performed without subsequent problems for 7 women with cervical elongation.

b) Laparoscopic sacral hysteropexy

Laparoscopic sacral hysteropexy techniques are similar to those described with the abdominal sacral hysteropexy with an anatomic success rate

Table 7. Compares vaginal mesh hysteropexy and vaginal mesh hysterectomy outcomes.

Author	Study Type & Surgery	Review months	Success Rate Mesh hysteropexy	Success rate Mesh hysterectomy	Mesh exposure hysteropexy	Mesh exposure hysterectomy

Total			**273/316 (86%) 95% CI (82-90)**	**81/83 (98%) 95% CI (94-100)**	**28/318 (8.8%) 95% CI (5.7-11.9)**	**11/83 (13%) 95%CI 6-21**

**variety surgical techniques and definitions of success*

of 88-100% with equally high symptomatic improvement and satisfaction. Several of the studies include different combinations of patients including post hysterectomy prolapse undergoing laparoscopic sacral colpopexy, uterine prolapse undergoing both abdominal and vaginal hysterectomy or laparoscopic sacral hysteropexy making it difficult to determine specific results associated with laparoscopic sacral hysteropexy. **Table 8** describes the anatomic outcomes of sacral hysteropexy performed laparoscopically or open compared to hysterectomy and sacral colpopexy and demonstrates similar success rates in the two groups 91% [310/339] and 92% [84/91] respectively [p=.17]. The sacral hysteropexy was quicker to perform and also had a lower mesh exposure rate of 1.5% [5/339] versus 8.5% [11/129] versus sacral colpopexy with hysterectomy [p<0.05%].

c) Laparoscopic Uterosacral Hysteropexy

At surgery the plicated uterosacral ligaments are secured to the distal cervix or by plicating the ligaments in the midline with a McCall's technique. Some add a Moschcowitz culdoplasty at the time of uterosacral suspension. Rosen et al compared laparoscopic uterosacral hysteropexy to total laparoscopic hysterectomy with uterosacral suspension, both groups did reasonably well without noticeable differences in outcomes [Rosen 2008]. When laparoscopic uterosacral hysteropexy was compared to vaginal hysterectomy and colpopexy in 25 age matched pairs, anatomic and symptomatic improvement was slightly better for the laparoscopic group with less blood loss and shorter length of hospitalisation [Diwan 2006]. Other series show similar anatomic and symptomatic success [80-100%] with few complications in women undergoing laparoscopic uterosacral or McCall's hysteropexy. [Maher 2001; Krause 2006; Medina 2006]. Evaluation of available trials in **Table 9** demonstrates a mean objective success rate of 83% [148/176]after laparoscopic uterosacral hysteropexy as compared to 78% [21/27] after laparoscopic hysterectomy and 88% [22/25] after vaginal hysterectomy and uterosacral ligament suspension.

Laparoscopic round ligament suspension was not as successful with all women having a rapid re-

Table 8. Compares outcomes sacral hysteropexy (open or laparoscopic) and hysterectomy and sacral colpopexy outcomes.

currence of prolapse [O'Brien 1994]. Laparoscopic attachment to the anterior wall with mesh was highly successful in a group of 28 women [Chen 2010]. This technique could potentially increase the risk of posterior compartment recurrences due to vaginal axis deflection anteriorly, similar to a retropubic urethropexy.

d) Hysterectomy at time of sacral colpopexy

The evidence supporting sacral colpopexy is largely based on post-hysterectomy vault prolapse and it is not clear from the literature whether the excellent outcomes reported in the post- hysterectomy group will be reproduced in the uterine prolapse group. When considering sacral colpopexy for women with uterovaginal prolapse, the literature is relatively sparse. The choice of hysterectomy includes supracervical, abdominal, laparoscopic assisted vaginal and vaginal. Additionally, the mesh can be attached vaginally or laparoscopically following a vaginal hysterectomy. Placement of synthetic mesh over a healing sutured incision plus exposure to vaginal microbes theoretically increases the risk of graft erosion when hysterectomy is performed at the time of sacral colpopexy. While the evidence in the literature is conflicting meta-analysis of all available comparative studies in **Table 10** demonstrate that the risk of mesh erosion is approximately 4 times greater if a hysterectomy is performed at the time of sacral colpopexy 8.6% [51/592] as compared to 2.2% [25/1125] without a hysterectomy and 1.7% [1/58] if subtotal hysterectomy is performed. Introducing synthetic mesh transvaginally or laparoscopically after vaginal hysterectomy or through a posterior vaginal excision appears to significantly increase the risk of mesh erosion after sacrocolpopexy[Visco 2001; Tan-Kim 2011].

Therefore, based on the current literature, hysterectomy at time of sacral colpopexy should be selected with caution and patients should be counseled regarding increased risk of mesh exposure. For this reason supracervical hysterectomy and sacral hysteropexy seem to be gaining in popularity however, there is a very significant paucity of data supporting this approach. Clinicians and the patients planning sacral hysteropexy and supracervical hysterectomy should also consider the significant surgical challenge of removing a retained cervix or uterus that is encompassed in mesh.

4. PREGNANCY AND HYSTEROPEXY

For women with uterovaginal prolapse who have not completed their family, conservative management with a pessary should be offered as a first line treatment before surgical hysteropexy. Most believe that definitive surgical management should be deferred until childbearing is completed due to the potential impact of future pregnancy and delivery on pelvic support and surgical repair. In situations where a pessary cannot be fitted properly or for younger patients that refuse conservative therapy for a prolonged period of time, hysteropexy is a reasonable option. There are no documented pregnancies after laparoscopic sacral hysteropexy or vaginal mesh hysteropexy. There were 12 pregnancies after a Manchester procedure with mostly full term vaginal deliveries and only 1 documented recurrence of prolapse. There were 17 pregnan-

cies after sacrospinous hysteropexy with half vaginal and half cesarean deliveries at term followed by 2 recurrences. There were a few pregnancies after laparoscopic uterosacral hysteropexy that had mixed routes of delivery at term with 1 recurrence. Giles reported the majority of documented pregnancies that occurred after abdominal wall suture hysteropexy [Giles 1930]. There were 139 pregnancies and 110 full term deliveries that were mostly vaginal [75%] with only 1 recurrence. Ot, her abdominal hysteropexy studies revealed 9 pregnancies with mostly vaginal deliveries and no recurrences.[Stoesser 1955; Joshi 1993; Banu 1997; Barranger 2003]

Despite relatively good outcomes, limited information exists to aid in counseling patients that desire hysteropexy and plan to become pregnant in the future. Unfortunately, we do not know which type of hysteropexy is better for women that desire future pregnancy with respect to fertility, pregnancy and delivery, and postpartum support and durability? We also do not know the true impact of a future pregnancy on long-term success rates and whether a cesarean delivery prevents recurrent prolapse compared to vaginal delivery. Since relatively few women undergo hysteropexy and subsequent pregnancy, it would be difficult to design a feasible study to answer these questions

Summary

In summary a wide variety of surgical options remain for women presenting with uterine prolapse.

- Uterine preservation is a suitable option in women with uterine prolapse without contraindications to uterine preservation. However longterm data is limited and the need for subsequent hysterectomy unknown (**Grade C**).
- Sacrospinous hysteropexy is as effective as vaginal hysterectomy and repair in retrospective comparative studies and in a meta-analysis with reduced operating time, blood loss and recovery time. However in a single RCT there was a higher recurrence rate associated with sacrospinous hysteropexy as compared to vaginal hysterectomy (**Grade D**). Severe prolapse increases the risk of recurrent prolapse after sacrospinous hysteropexy.
- In consistent level 2 evidence sacrospinous hysteropexy with mesh augmentation of the anterior compartment was as effective as hysterectomy and mesh augmentation with no significant difference in the rate of mesh exposure between the groups. (**Grade B**)
- Level one evidence from a single RCT suggests vaginal hysterectomy and uterosacral suspension was superior to sacral hysteropexy based on reoperation rates despite similar anatomic and symptomatic improvement. (**Grade C**).

- Consistent level two and three evidence suggest sacral hysteropexy (open or laparoscopic) was as effective as sacral colpopexy and hysterectomy in anatomical outcomes however the sacral colpopexy and hysterectomy was associated with a five times higher rate of mesh exposure as compared to sacral hysteropexy (**Grade B**).
- At meta-analysis of hysterectomy at the time of sacral colpopexy as compared to sacral colpopexy without hysterectomy was associated with a four times higher risk of mesh exposure (**Grade B**).
- Abdominal sacral hysteropexy and hysterectomy with sacral colpopexy have better anatomic outcomes compared to abdominal hysterectomy with uterosacral suspension in a single retrospective comparison (**Grade C**).

VI. APICAL SUPPORT PROCEDURES

While anterior vaginal prolapse is most common, loss of apical support is usually present in women with prolapse that extends beyond the hymen [Swift 2000; Delancey 2002]. There is growing recognition that adequate support for the vaginal apex is an essential component of a durable surgical repair for women with advanced prolapse [Toozs-Hobson 1998; Shull 1999]. Because of the significant contribution of the apex to anterior vaginal support, the best surgical correction of the anterior and posterior walls may fail unless the apex is adequately supported [Rooney 2006; Hsu 2008]. While recognition of apical defects is one of the biggest challenges in the preoperative evaluation of pelvic support defects, surgical correction of the apex has several good options with relatively high success rates. Apical suspension procedures can broadly be separated into those performed transvaginally and those performed abdominally. Abdominal procedures can be performed via laparotomy or using conventional laparoscopic or robotically assisted-laparoscopic techniques. Although precise estimates are not available, most studies suggest that the vaginal approach is most common with 80-90% of procedures being performed through this route [Olsen 1997; Brown 2002; Boyles 2003; Brubaker 2005]. The individual woman's surgical history and goals, as well as her individual risks for surgical complications, prolapse recurrence and de novo symptoms affect surgical planning and choice of procedure for apical POP.

1. SACROSPINOUS LIGAMENT SUSPENSION (SSLS)

One of the most popular and widely reported transvaginal procedures for correcting apical prolapse is the SSLS. First described in 1958 [Sederl 1958], this procedure suspends the vaginal apex to the sacrospinous ligament either unilaterally or bilaterally, typically using an extraperitoneal approach. Observational series and clinical trials suggest that while apical recurrence after SSLS is uncommon [2.4% to 19%], recurrence of anterior vaginal prolapse is more problematic [6% to 28.5%] (**Table 11**). A meta-analysis by Morgan et al found an overall failure rate at any site of 28.8% [95% CI 18.4%-36.3%] with failure of the anterior segment seen in 21.3% [17-3-25.3%], apical segment of 7.2% [95% CI 4.0 – 10.4%] and posterior segment of 6.3% [95%CI 4.2-8.4%]. Whether the relatively high rate of anterior vaginal prolapse recurrence seen with SSLS is due to the posterior deflection of the vaginal axis, as many authors suggest,[Shull 1992; Benson 1996; Paraiso 1996; Colombo 1998] or simply represents a general predilection of anterior support to fail after pelvic reconstructive surgery remains unknown [Weber 2005]. Reoperation rates after SSLS range from 1.3% to 37%, with all but two series reporting rates less than 9% (**Table 11**).

Information on the functional or QOL outcomes of SSLS is limited. Maher et al demonstrated significant improvements in condition-specific and generic QOL after SSLS, similar to that after abdominal sacral colpopexy [Maher 2004]. A meta-analysis of randomised and observational studies found a pooled average for failure to provide relief of prolapse symptoms after SSLS of 10.3% [95% CI 4.4-16.2%] [Morgan 2007]. The pooled average for failure to provide patient satisfaction after SSLS in this analysis was 13% [95% CI 7.4%-18.6%] [Morgan 2007]. Although infrequent, serious complications associated with SSLS include buttock pain and sacral/ pudendal neurovascular injury. In a review of 22 studies that included 1229 SSLS procedures, 3 patients [0.2%] had life-threatening hemorrhage from sacral or pudendal vascular injury and the overall transfusion rate was 2% [Sze 1997]. Buttock pain occurred in 3% of subjects, the vast majority of which resolved by 6 weeks postoperatively [Sze 1997].

2. UTEROSACRAL LIGAMENT SUSPENSION (USLS)

The USLS was first described by Miller [Miller 1927] in 1927 and later popularised by Shull in the late 1990s. The USLS suspends the vaginal apex to the proximal remnants of the uterosacral ligaments using an intraperitoneal surgical approach. This procedure restores the vagina to its normal axis, avoiding the retroflexion associated with SSLS. The current evidence supporting the use of USLS is limited primarily to uncontrolled retrospective case-series and evaluation of these data confirm a mean objective success rate of 85% [range 48-96%] and mean reoperation rate for prolapse of 5.8% [range 0-12%] (**Table 12**). A meta-analysis performed by Margulies et al found

** Prospective and Retrospective cohorts with n >50 published since 1985 and SSLS arms of 3 RCTs comparing SSLS to Abdominal sacrocolpopexy (ASC) ;**POP staging systems, if used, are indicated as 'grade' for Baden-walker(Baden 1972) or 'stage' for POPQ(Bump 1996); # optimal and satisfactory outcomes combined*

pooled rates of anatomic success [POPQ Stage 0-1] of 81.2% [95%CI 67.5-94.5%] for the anterior segment, 98.3% [95% CI 95.7 -100%] for the apical segment and 87.4% (95% CI, 67.5%-94.5%) for the posterior segment [Margulies 2010]. Postoperative prolapse symptoms were reported in 5 of 11 studies in this review and were relieved in 82-100% of patients. These promising results are balanced by ureteral kinking/injury rate of 1%-11% with this procedure [Margulies 2010]. A review of 700 consecutive vaginal prolapse surgeries found intraoperative ureteral kinking/injury of 5.9% directly attributable to USLS. However, 87% were identified at cystoscopy before the completion of the index surgery and relieved by removing suspension sutures intraoperatively with no long-term consequence to the patient [Gustilo-Ashby 2006]. Only 3 of 355 ULS [0.9%] performed in this series required additional procedures to relieve or correct ureteral obstruction or injury. Margulies et al identified 10 studies including a total of 820 women that reported on perioperative complications of ULS [Margulies 2010]. The ureteral reimplantation rate in this series was only 0.6%. Blood transfusions were reported in 1.3%, cystotomy in 0.1%, and bowel injury in 0.2%. To date, no clinical trials comparing the ULS to sacrocolpopexy or to SSLS have been published. The Pelvic Floor Disorders Network has an ongoing RCT comparing USLS to SSLS that includes 440 subjects who will be followed for 2 years; results from this trial are expected in 2013. [Barber 2009]

While the USLS is traditionally performed using a intraperitoneal approach, Dwyer and Fatton have described an extraperitoneal variant of the USLS. [Dwyer 2008; Fatton 2009] In their series of 123 consecutive women undergoing an extraperitoneal ULS,

93 also received anterior and/or posterior synthetic mesh. The overall anatomic success (POPQ stage 0 – 1] at a mean follow-up of 2 years [range 6 mo – 5 years] was 85.5% with apical success of 95.4%. [Fatton 2009] The reoperation rate for recurrent prolapse was 7%. Ureteral injury occurred in only 1.7%, however the blood transfusion rate was 4.9% and the rate of mesh exposure was 19.3%.

Abdominal and laparoscopic USLS techniques have also been described. Lowenstein et al reported a retrospective review of 107 women who underwent prolapse surgery that included an abdominal USLS [Lowenstein 2009]. In the 75 patients who completed 1 year follow-up, 12% reported recurrent or persistent prolapse symptoms and 7% had an anatomic failure [POPQ Stage 2 or greater]. Complications were relatively few however erosion of the apical sutures [expanded PTFT, Gore-Tex] occurred in 9% at an average time of 56 months [range 3-75 mo] [Lowenstein 2009]. Rardin et al reported a retrospective comparison of 96 patients undergoing vaginal USLS to 22 undergoing a laparoscopic ULS procedure and found no significant differences perioperative morbidity or anatomic or subjective outcomes [Rardin 2009].

3. MAYO/MCCALL'S CULDOPLASTY

Like the USLS, the Mayo/McCall's culdoplasty uses the proximal uterosacral ligaments to suspend the vaginal apex. The major difference is that with the Mayo/McCall procedure the uterosacral ligaments are plicated in the mid-line to obliterate the posterior cul-de-sac. While commonly performed, data describing the outcomes for this procedure are limited. (**Table 13**) Colombo and Milani retrospectively compared the outcomes of a modified-McCall's culdoplasty to the SSLS [n = 62 in each group] [Colombo 1998]. Recurrence after the McCall's culdoplasty (Baden-Walker Grade >2] was 15% 4 to 9 years after surgery and not significantly different from the SSLS group. Recurrent anterior vaginal prolapse occurred less frequently in the McCall's group than the SSLS group (6% vs. 21%, p = .04; OR 4.1 [95% CI 1.3 to 14.2] [Colombo 1998]. A large retrospective series of 693 women from the Mayo clinic described an 82% satisfaction rate on subjective follow-up with few complications [Webb 1998]. The rate of subsequent prolapse repair in this population was 5.2%. A retrospective case series of 411 women undergoing Mayo culdoplasty found that a more dorsal "deep" placement of sutures through the uterosacral ligaments reduced the incidence of ureteral obstruction compared to other published series [Aronson 2005].

4. LEVATOR MYORRHAPHY

Francis and Jeffcoate described their retrospective series using levator myorrhaphy in which a wide midline plication of the levator ani muscles is performed to which the vaginal cuff is fixed in 1961.[Frances 1961] A large sponge pack in the rectum is used to avoid overplication and bowel dysfunction. Five of 35 women responding to the questionnaire had transient ureteral complications, one requiring re-operation. Seventeen women were quite satisfied, while six were dissatisfied. Natale et al compared the high levator myorrhaphy to the USLS in a randomised clinical trial of 229 women with Stage 2-4 prolapse. [Natale 2010] All women underwent a hysterectomy and all received placement of polypropylene mesh in the anterior vaginal segment. Anatomic success was not significantly different between groups. The mean total vaginal length was significantly shorter after levator myorrhaphy [7.9 cm vs. 8.9 cm, p = .04]. Urinary, bowel and sexual function did not differ between groups postoperatively. Intraoperative ureteral obstruction was less common in the levator myorrhaphy group [0% vs. 7.9%]; however all cases of ureteral obstruction in the ULS group were corrected intraoperatively with suture removal/replacement with no additional interventions required. [Natale 2010] Other complications including mesh erosion were similar between groups.

5. ILIOCOCCYGEUS FASCIA FIXATION

There are no randomised trials that support the use of this procedure. Several case series have provided

some information. Shull reported that apical support was optimal in 39/42 [83%] of patients, but eight others had apical or other defects. [Shull 1993] Meeks and colleagues reported a 96% objective cure in 110 women followed up to 13 years.[Meeks 1994] In a retrospective case-control study, Maher and colleagues reported similar subjective [91% v 94%] and objective [53% vs. 67%] cure rates with iliococcygeus fixation [n=50] compared to sacrospinous fixation [n=78].[Maher 2001].

6. TRANSVAGINAL MESH APICAL PROLAPSE

Two randomised control trials are available that evaluated transvaginal polypropylene meshes in apical prolapse. Sokol et al reported a multicentre double blinded RCT comparing uterosacral colpopexy and native tissue repair [n=33] and monofilament polypropylene mesh kit [Prolift n=32] for stage 2 or greater uterovaginal prolapse or vaginal prolapse [Sokol 2011].

At one year the conventional surgery group had no subsequent surgical interventions as compared to 15.6% in the mesh group [p=0.017] including 3 for prolapse surgery (2x sacral colpopexy and 1 iliococcygeous fixation) and 2 interventions for mesh exposure. The objective failure rate (any stage 2 or greater prolapse) was 70% in the conventional surgery group versus 63% in the mesh group [P>0.05]. The subjective failure rate was also similar in both groups, 9.1% in native tissue repairs versus 3.8% in the mesh group. One patient was transfused and 2 inadvertent cystotomies occurred in the mesh group with no perioperative complications reported in the native tissue group. No differences were seen between the groups utilising a wide variety of validated outcome tools. Unfortunately, due to reaching an ethics committee imposed stopping criterion of 15.6% mesh exposure rate the study did not recruit the appropriate sample size and is underpowered to detect a significant difference between the groups if they exist.

Maher et al recently reported results from a randomised trial comparing LSC [n=53] to a total vaginal mesh kit [TVM] [Prolift, Ethicon Women's Health and Urology] [n=55] [Maher 2011]. LSC was associated with longer operating time (mean difference +52 min [95% CI 41.5-62.6], decreased hospital stay [mean difference -0.5 days [95% CI -.93 to -.10] and quicker return to normal activities (mean difference -5.3 days [95% CI -8.4 to -2.3]. Two years after surgery, objective success [Overall POPQ Stage 0 or 1] was seen in 77% of the LSC group compared with only 43% of the TVM group, p <.001] [Maher 2011]. Also, reoperations were significantly higher in the TVM group [22%] than in the group that received LSC [5%, p =.006].

As seen in **Table 14** the success rate of transvaginal meshes for apical prolapse in level 3 evidence

Table 14. Mesh Kits used for apical repairs

Author	Year	Type	No.	Follow up weeks	Success rate	Complications
Abdel Fattah	2008	Apogee AMS	38	12	95%(36/38)	Blood loss>400mls1, erosion 4,
						Dyspareunia 1, rectal injury 1
Gaurder-Burmester	2007	Apogee AMS	48	52	100%	
Moore	2012	Anterior Elevate AMS	60	57	92%	No extrusions
Fatton	2007	Prolift, Ethicon	88	25	93%	2 haematoma
Belot F	2005	Prolift Ethicon	277	Not stated	Not stated	Erosion 34/277
Abdel Fattah	2008	Prolift ethicon	143	12	94%	1rectal injury, bladder injury
		Johnson & Johnson,				16 vag ersion, 1 bladder
Van Raalte	2009	Prolift, total, anterior post	97	72	87%	No mesh extrusions 6 reoperations prolapse
Milani	2009	Total vaginal mesh Prolift	46	52	91% (41/45)	15% mesh exposure 2 blood loss>500mls
McDermott	2011	Total vaginal mesh Prolift hysteropexy 24 Colpopexy 65	89	26 - 52	96%	10% mesh exposure 5% complications
Maher (RCT)	2011	Total vaginal mesh Prolift Ethicon	55	104	43%	9% mesh exposure 22% total reoperation
Biertho	2007	PIVS tyco	34	12	91%	1erosion 1 hemorrhage
Foote	2007	PIVS tyco	52	20	83%	Erosion 11/52
Matox	2006	PIVS	21	7	37%	1 proctotomy 1 hemotoma
Vardy	2006	PIVS	98	3	99%	2 erosion
Neuman [194]	2007	PIVS	140	120	99%	12 erosions
de Tayrac[238]	2007	PIVS	21	42	95%	2 hemotoma
Lee	2010	PIVS	32	52	100%	1 transfusion
Amrute [261]	2007	Polypropelene H shaped	76	123	95%	2 erosion, 2 dyspareunia

is significantly higher and ranges from 87-100% for monofilament polypropylene meshes with mesh erosion rates varying from 0-15%.

7. SACRAL COLPOPEXY

Since its introduction by Lane in 1962 [Lane 1962], sacrocolpopexy has proven to be an effective and durable technique for correcting apical prolapse. In 2010, approximately 34,000 sacrocolpopexies were performed in the U.S. representing 11% of all prolapse surgeries performed during that time period. Traditionally, sacrocolpopexy has been performed via a laparotomy (i.e. abdominal sacral colpopexy) but the use of laparoscopic and robotic approaches is increasing.

a) Abdominal Sacral Colpopexy (ASC)

Observational studies and clinical trials suggest that ASC is a highly effective procedure for apical prolapse. The success rate of ASC, when defined as lack of apical prolapse, ranges from 78-100% (**Table 15**). When success is defined as no recurrent prolapse in any segment the published success rates are 56% - 100%. A systematic review of ASC performed by Nygaard et al reported a median reoperation rate for recurrent prolapse of 4.4% [range 0 -18.2%] and for postoperative stress incontinence of 4.9% [range 1.2% to 30.9%] [Nygaard 2004]. Clinical trials demonstrate significant improvements in prolapse symptoms, urinary function and quality of life after ASC [Maher 2004; Maher 2004; Brubaker 2008]. There is level 1 evidence that ASC has superior anatomic outcomes when compared to SSLS but this is balanced by longer operating time, longer recovery and higher cost [Maher 2010]. There are no randomised trials comparing ASC to ULS or to transvaginal mesh procedures. Given the prolonged recovery and unique complications associated with laparotomy, many surgeons reserve sacrocolpopexy for patients with apical prolapse thought to be of high risk of failure from a vaginal approach, often considering such factors as age, comorbidities, history of previous prolapse surgery, and vaginal length. [Toozs-Hobson 1998; Shull 1999; Maher 2004; Brubaker 2005; Weber 2005] Unfortunately, there is little published data to allow an evidence-based decision about which patient with POP will be best served by an ASC relative to other techniques.

Some surgeons have attempted to decrease mesh complications of ASC by using biological materials instead of synthetic mesh. However, the current evidence suggests that biologic materials whether allograft or xenograft have inferior anatomic outcomes to synthetic mesh, particularly polypropylene, without decreased graft-related complications. Level 1 evidence supports the superiority of polypropylene mesh to fascia lata for objective anatomic support following ASC [Culligan 2005; Tate 2010]. A randomised trial of 106 women undergoing ASC compared polypropylene mesh to cadaveric fascia lata and found superior anatomic outcomes in those who received polypropylene at one year [success 91% vs. 68%, p = .007] and five years after surgery [93% vs. 62%, p =.02] [Culligan 2005; Tate 2010]. There were no differences in graft related complications overall between the two groups. Several retrospective case series support these data [FitzGerald 1999, Flynn 2005, Gregory 2005]. Similarly, Level 3 evidence suggests that use of xenografts such as porcine dermis and small intestinal submucosa also have inferior anatomic success rates compared with polypropylene mesh with similar rates of graft-related complications [Quiroz 2008; Deprest 2009; Claerhout 2010].

Beyond mesh erosion, reported complications of ASC are generally consistent with other major open pelvic surgeries. The systematic review by Nygaard et al reported that wound complications occurred in 4.6% [range 0.4% to 19.8%], hemorrhage or transfusion in 4.4% [.2% to 16.9%], cystotomy in 3.1% [0.4% to 15.8%], ureteral injury in 1.0% [0.8% to 1.9%] and bowel injury in 1.6% [0.4% to 2.5%] [Nygaard 2004]. One in 20 women in the CARE trial experienced significant gastrointestinal morbidity after sacrocolpopexy. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, 4 had reoperation for small bowel obstruction, 11 were readmitted for medical management, and 4 had a prolonged initial hospitalisation for gastrointestinal symptoms [Whitehead 2007].

b) Abdominal sacral colpopexy (ASC) versus sacrospinous ligament suspension (SSLS)

To date, there are three RCTs that directly compare ASC to SSLS.[Benson 1996; Lo 1998; Maher 2004] The Cochrane review on the surgical management of POP by Maher et al summarises these studies and concludes that these trials provide level 1 evidence that there were no statistically significant differences in objective failure at any site [any pelvic organ prolapse RR 0.77, 95% CI 0.39 to 1.53], subjective failure [RR 0.53, 95%CI 0.25 to 1.09], reoperation for POP [RR 1.46, 95% CI 0.19 to 1.11] or patient satisfaction [RR 0.82, 95% CI 0.32 to 2.06] [Maher 2010]. However, ASC was superior to SSLS for the following outcomes: Prolapse < Stage 2 [RR 0.29, 95% CI 0.09 to 0.97], recurrent vault prolapse [RR 0.23, 95% CI 0.07 to 0.77] post-operative stress urinary incontinence [RR 0.55, 95% CI 0.32 to 0.95] and less post-operative dyspareunia RR 0.39, 95% CI 0.18 to 0.86]. In contrast, ASC was associated with a longer operating time (Weighted Mean Difference [WMD] 21 minutes, 95% CI 12 to 30), longer time to recover [WMD 8.3 days, 95% CI 3.9 to 12.7] and was more expensive [WMD US $1334, 95% CI 1027 to 1641) than SSLS [Maher 2010].

c) Laparoscopic Sacral Colpopexy (LSC)

The laparoscopic approach of sacral colpopexy has been adopted by many surgeons over the last decade as an alternative to ASC with the hopes of

Table 15. Abdominal Sacral Colpopexy outcomes*

Author	Year	Number of patients, (number lost to follow-up, if known)	Follow –up (months)	Success rate (%)	Criteria for success#	Comments
Addison(Addison 1985)	1985	56 (2)	39	96	Good vaginal vault suspension in a normal axis	Fascia lata was graft material used for patient with early recurrence 1 patient unimproved as a presacral hemorrhage prevented successful completion of the procedure
Baker(Baker 1990)	1990	59 (6)	6	100	No complaint of protrusion from the vagin	51/59 patients had postoperative records available, at which time all patients had a well- supported vagina
Snyder(Snyder 1991)	1991	147 (15)	43	93 (108/116)	Lack of major long- term postoperative complications, restoration of functional vagina in the proper axis, and no recurrence of presenting symptoms with at least 6 months of follow-up	Graft attached to the entire length of the vagina in the rectovaginal septum
Imparato (Imparato 1992)	1992	71 (8)	NS	78	Excellent, well- suspended vault on exam	50 had direct attachment of the vaginal apex to the anterior sacrum
				16	Good vault suspension, but asymptomatic vaginal "relaxation"	
Timmons(Timmons 1992)	1992	163	33	99	Good vaginal vault support	The range of success is due to 4 different techniques which were compared
van Lindert(van Lindert 1993)]	1993	61	32	97	No recurrent vaginal prolapse	8 patients had preservation of the uterus
Grunberge(Grunberger 1994)[1]	1994	62 (14)	75.6	94	No moderate vaginal vault prolapse on exam	42 patients had direct attachment of the vagina to the sacral promontory 12 had permanent "suture bridges" 8 had lyodura loops
Lecuru(Lecuru 1994)**	1994	203	32.5	86.7-100	Anatomically good results	
				53.3-80.5	Functionally good results	
Brubaker(Brubaker 1995)	1995	65 (0)	3	71	No anterior or apical prolapse	63/65 patients had abdominal anterior compartment repair at the time of the sacrocolpopexy
de Vries(de Vries 1995)	1995	101 (29)	48	32	Fully cured (patient satisfaction based upon questionnaire)	Questionnaires sent to patients to evaluate pain, prolapse-related complaints and functional disorders. Patients indicated symptoms before surgery, >1 year after surgery, and >1 year after surgery
				39	Considerable improvement	
				29	No improvement	
Benson(Benson 1996)	1996	40	60	58 (another 26% of patients had"satisfactor y" outcomes)	Patient asymptomatic, vaginal apex supported above the levator plate, no protrusion beyond the hymen	All patients had sacrocolpopexy and paravaginal repair. Results are from a RCT comparing sacrocolpopexy to sacrospinous suspension.
Hardiman(Hardiman 1996)	1996	80	47	99	No recurrent vault prolapse	
Sullivan(Sullivan 2001)	2001	236 (31)	64	100	No recurrence of vaginal or rectal prolapse	Total pelvic mesh repair involved attachment mesh strip between the perineal body and the sacrum, and then attaching two additional strips laterally to the pubis to support the vagina and bladder
				34%	Very satisfied	
				38%	Satisfied	
Occelli(Occelli 1999)]**	1999	271 (54)	66	97.7	Cured for prolapse	
Patsner(Patsner 1999)	1999	175 (0)	≥ 12	97	No "mesh failures"	
Sze (Sze 1999)	1999	56 (9)	23	81	No recurrent prolapse to or beyond the hymen	All 9 patients with recurrent prolapse were Symptomatic
Lo(Lo 1998)	1998	52 (not clear)	25	94	No prolapse > Stage II	Results are from a RCT comparing sacrocolpopexy to sacrospinous ligament suspension.
Collopy(Collopy 2002)	2002	89 (0)	56.7	100	No recurrence of rectal or vaginal vault prolapse	All had concomitant culdoplasty
Culligan(Culligan 2002)	2002	245	61.2	85	Any POP-Q point ≥ 2	No apical failures observed
Lefranc(Lefranc 2002)	2002	85 (0)	126 (median)	90.6	No relapse of any prolapse	All patients without preoperative SUI had a prophylactic Burch procedure done
Lindeque(Lindeque 2002)	2002	262 (0)	≥ 16	99	No vaginal vault prolapse	1/3 failures due to graft detachment from vagina
Medina(Medina 2002)	2002	97 (1)	19	90	< Grade I prolapse	Etiology of 1 failure was graft detachment from the vagina (etiology of other 4 unknown)
Brizzolara(Brizzolara 2003)	2003	124	36		No recurrent vault prolapse	
Podratz(Podratz 1995)	1995	50(6)			Asymptomatic (including no incontinence) and durable repair by exam	
Hilger(Hilger 2003)	2003	69(31)			Subsequent POP operation or a positive response to question 5 on the PFDI***	
Maher(Maher 2004)	2004	47 (1)			Objective: No POP beyond halfway point Subjective: No symptoms of POP	Results are from a RCT comparing sacrocolpopexy to sacrospinous ligament suspension.
Higgs (Higgs 2005)	2005	148			No recurrent vault prolapse	24% required recurrent SUI surgery
					< Grade 1 prolapse	
					No prolapse symptoms	
Brubaker(Brubaker 2008)	2008	322 (302)			< Stage 2 prolape	CARE Trial 2 year follow-up; Reoperations for prolapse occurred in 6 (2%)
				98	≤ Stage 2 prolapse	
					POPQ point C within 2 cm of TVL	
Jeon(Jeon 2009)	2009	57			< Stage 2 prolapse	Major complication requring reoperation or intensive care developed in 12 (21%)
Huebner(Huebner 2009)	2009	78 (53)	NS		< Stage 2 prolapse	
Tate(Tate 2010)	2010	100 (58)			< Stage 2 prolapse	5 year follow-up of RCT comparing polypropylene to cadavaric fascia. Polypropylene demonstated supperior anatomic results (93% vs 62%, p =.02) but no difference in symptomatic outcomes
					Symptoms of prolapse or bulging	

**Prospective and Retrospective cohorts with n > 50 published since 1985, ASC arms of 3 RCTs comparing ASC to sacrospinous ligament suspension. #POP staging systems, if used, are indicated as 'grade' for Baden-walker{ or 'stage' for POPQ*

NS = not stated;SUI = stress urinary incontinence; RPU = retropubic urethropexy; RCT=randomised clinical trial

****Question 5 on the Pelvic Floor Distress Inventory – "Do you usually have a bulge or something falling out that you can see or feel in the vaginal area?"*

reproducing the high success rate of the ASC while decreasing the morbidity and delayed recovery associated with laparotomy. Multiple prospective and retrospective case series demonstrate good short to mid-term success rates with mean objective success rate of 90.5% [range 60 -100%, subjective success rates of 79-98%[Higgs 2005; Rivoire 2007; Sarlos 2008] and mean reoperation rate of 5.9% (**Table 16**). Recently, several prospective studies have been published that demonstrate significant improvements in pelvic symptoms and quality of life after LSC [Sergent ; Maher 2011; Paraiso 2011]. To date, no randomised trials have compared LSC to ASC, however three retrospective comparisons have been published [Paraiso 2005; Hsiao 2007; Klauschie 2009]. While results vary somewhat between studies, in general, LSC is associated with shorter hospital stay, less blood loss with conflicting data on operating time. Objective outcomes appear to be similar between the groups. Well designed high quality clinical trials are necessary to establish independently the effectiveness and safety of the LSC relative to ASC.

There is Level 1 evidence that LSC provides superior outcomes to total vaginal mesh procedure for women with symptomatic Stage 2-4 vaginal vault prolapse as described above. There are currently no comparative studies, randomised or not, evaluating the relative safety and efficacy of LSC and native tissue [non-mesh] vaginal POP repair.

A recent retrospective study assessed the complications rates in 402 LSC cases.[Stepanian 2008] This study compared patients who received concurrent laparoscopically-assisted vaginal hysterectomy with those that had previous hysterectomy. They showed no differences in intra- or perioperative complications and similar rates of mesh erosion between the two groups.[Stepanian 2008] Overall the complication rates for this cohort were 0.75% for hematoma, 2.2% for ileus or small bowel obstruction, 1.5% for bladder injury, 0.75% for bowel injury and 0.25% ureteric injury. At 1 year, the overall mesh erosion rate was 1.2%. In contrast, Tan-Kim et al reported on a retrospective series of 188 minimally invasive sacrocolpopexy and found a significantly higher mesh exposure rate in those who received concurrent total vaginal hysterectomy [TVH] [23%] compared with those who were post-hysterectomy (5%) or received a supracervical hysterectomy [5%].[Tan-Kim 2011] TVH was found to be an in independent risk factor for mesh erosion on multivariable regression analysis in this study [OR 5.67; 95% CI 2.88-17.10].

Despite the clinical advantages of a laparoscopic approach, adoption of LSC has been relatively limited probably because of the steep learning curve associated with attaining laparoscopic suturing and knot tying skills that are required to attach the mesh to the vagina and sacrum. Claerhout et al evaluated their learning curve in the first 206 cases performed by a single surgeon.[Claerhout 2009] Operating times declined rapidly during the first 30 procedures in this series and reached steady state (175 minutes) after 90 cases. Using a cumulative sum [CUSUM] approach to evaluate operative time and failures (laparotomy, complication or anatomic failures) they found that adequate learning occurred after 60 cases.[Claerhout 2009] Complication rates remained unchanged throughout this series. Akladios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases performed but that a turning point was observed after 18-24 cases.[Akladios 2010] Complication rates were also low throughout this series.

d) Robotic Sacral Colpopexy(RSC)

Because of the relatively long learning curve required for LSC, many surgeons have turned to robotic-assisted surgery in order to offer patients a minimally invasive approach to sacrocolpopexy. Robotic surgical systems have been developed with the goal of facilitating technically difficult procedures by improving the surgeon's vision, dexterity and ergonomics. No data has been published on the learning curve for RSC however expert opinion suggests that the learning curve is shorter for RSC compared to the laparoscopic approach.

The currently available data for RSC are relatively limited and consist primarily of uncontrolled cases series, but meta-analysis suggests anatomic outcomes similar to that of ASC and LSC with objective success rates reported at 60-100% [mean 93%], subjective success of 91-94% and mean mesh erosion rate 5%.(**Table 17**) To date, there are only two

published studies that provide comparative data for the RSC. Geller et al retrospectively compared 73 patients who received RSC to 105 who received ASC [Geller 2008]. RSC was associated with less blood loss, longer operative time, shorter length of stay and a higher incidence of fever [4.1% vs. 0%] Anatomic outcomes 6 weeks after surgery were similar between groups [Geller 2008].

In the only randomised comparison of RSC to date, Paraiso et al recently published a clinical trial that provides level 1 evidence that RSC results in longer operating time and increased pain and cost compared with LSC.[Paraiso 2011] This single-centre, blinded randomised trial compared RSC [n = 40] to LSC [n=38] in women with stage 2-4 post-hysterectomy vaginal prolapse. Total operative time was chosen as the primary outcome for this study serving as a proxy measure for surgical efficiency. Total operative time was significantly longer in the robotic group compared with the laparoscopic group (+67-minute difference; 95% confidence interval [CI] 43-89; P<.001).[Paraiso 2011] Anesthesia time, total time in the operating room, total sacral colpopexy time, and total suturing time were all significantly longer in the robotic group. Participants in the robotic group also had significantly higher pain at rest and with activity during weeks 3 through 5 after surgery and required longer use of nonsteroidal anti-inflammatory drugs (median, 20 compared with 11 days, P<.005). The robotic group incurred greater cost than the laparoscopic group (mean difference +$1,936; 95% CI $417-$3,454; P=.008).[Paraiso 2011] Both groups demonstrated significant improvement in vaginal support and functional outcomes 1 year after surgery with no differences between groups. It is worth noting that the surgeons in this study had considerable experience with LSC.

A meta-analysis of observational studies on robotic gynaecological surgery, found that the currently available evidence shows that for most gynaecological procedures studied robotic surgery achieved a shorter hospital stay and less blood loss than open surgery.[Reza 2010] However, no clinically significant improvements were noted when robotic surgery is compared with conventional laparoscopic surgery in benign gynaecological procedures.[Reza 2010] The current evidence, while limited, suggests that these conclusions are also applicable for RSC (**Table 18**). RSC probably has a shorter learning curve than LSC and thus may be more generalisable however published evidence for this is currently lacking. In surgeons with advanced laparoscopic skills, RSC offers no clinical benefit when compared to LSC and results in longer operating times, greater cost and greater postoperative pain.

8. OBLITERATIVE PROCEDURES: LEFORT COLPOCLEISIS, TOTAL COLPOCLEISIS

Obliterative surgery, such as total colpocleisis (also called colpectomy/colpocleisis) or the Le-Fort partial colpocleisis, corrects POP by reducing the pelvic viscera back into the pelvis and closing off the vaginal canal either in part or whole.[FitzGerald 2006] Obliterative procedures are less commonly performed in the Europe, Asia, and Australia compared to the United States, and are usually reserved for women who are elderly, medically compromised, and no longer sexually active.[Jelovsek 2007] The purported advantages of obliterative surgery in this population are decreased operative time, decreased perioperative morbidity, and an extremely low prolapse recurrence risk. The obvious disadvantage is the elimination of the potential for vaginal intercourse. Preoperative counseling is essential when choos-

ing between the obliterative and reconstructive options. A systematic review of colpocleisis published in 2006 noted colpocleisis appears to be nearly 100% effective for correcting pelvic organ prolapse, however until recently little was known about postoperative functional or quality of life outcomes.[FitzGerald 2006] In the last few years a number of reports evaluating symptom improvement and changes in quality of life after colpocleisis have been reported.[Barber 2007; Hullfish 2007; Fitzgerald 2008; Gutman 2009] Overall, these series have found high rates of patient satisfaction and significant functional improvement with low rates of regret for loss of sexual function.[Barber 2007; Hullfish 2007; Fitzgerald 2008] Barber et al reported results from a multicentre study of obliterative surgery using a prospective cohort design with a concurrent control group of age-matched women undergoing vaginal reconstructive surgery.[Barber 2007] Despite permanent alterations in sexual function, significant improvements in bladder, bowel and prolapse symptoms as well as body image were noted after surgery with no differences between those who received colpocleisis and those who underwent reconstructive surgery. Additionally, significant and clinically important improvements were noted in bodily pain, vitality, social functioning, role-emotional, and mental health summary scales of the SF-36.[Barber 2007] Similarly, a retrospective cohort of women over age 65 by Murphy et al comparing women who underwent colpocleisis [n=45] and similar group women who underwent reconstructive surgery with transvaginal mesh (Prolift, Ethicon Women's Health and Urology) found that improvements in condition-specific quality of life and postoperative patient satisfaction were comparable between the two treatment groups.[Murphy 2008].

The Pelvic Floor Disorders Network has reported on a large series of women undergoing colpocleisis [n=153] with one year follow-up.[Fitzgerald 2008]. All pelvic symptom scores and related bother significantly improved at 3 and 12 months, and 125 [95%] patients said they were either 'very satisfied' or 'satisfied' with the outcome of their surgery.[Fitzgerald 2008] Bothersome stress and urge incontinence were present before surgery in 54% and 41% of subjects respectively. Forty percent of subjects received a concurrent mid-urethral sling at the time of their colpocleisis and the rates of bothersome stress and urge incontinence one year after surgery was 14% and 15% respectively. Similarly, bothersome bowel symptoms were present in 77% of subjects at baseline. One year after surgery, the majority of bothersome bowel symptoms resolved, particularly obstructive and incontinence symptoms, and development of new bowel symptoms was uncommon [0-14%].[Gutman 2009].

While obliterative procedures are predominantly performed in elderly, frail women who often have multiple co-morbidities, the rate of serious adverse events after this procedure appears to be low. In general, major complications due to performance of surgery on the elderly (e.g. cardiac, pulmonary and cerebrovascular complications) occur at a rate of approximately 2%.[FitzGerald 2006] Major complications due to the surgery itself (e.g. pyelonephritis, blood transfusion) occur at a rate of approximately 4%.[FitzGerald 2006] A systematic review of published series of colpocleisis from 1966 to 2004 reported a surgical mortality rate of approximately 1 in 400 cases.[FitzGerald 2006] One complication that appears to be uniquely associated with obliterative surgery is development de novo rectal prolapse after surgery.[von Pechmann 2003; Collins 2007] Collins et al in a retrospective cohort of 916 women undergoing vaginal POP surgery at one institution and found that the incidence of postoperative full-thickness rectal prolapse in women who were > or = 65 years old who underwent obliterative surgery was 3 of 74 [4.1%; 95% CI, 1.4-11], with an estimated odds ratio of 22 [95% CI, 2.3-196; P < .002] compared with women who were > or = 65 years old who underwent reconstructive surgery.[Collins 2007].

Conclusions Apical prolapse

- Level 1 evidence suggest ASC has a higher success rate as compared to sacrospinous colpopexy with less SUI and post-operative dyspareunia. ASC had greater morbidity including operating time, inpatient stay, slower return to activities of daily living and higher cost. (**Grade A**)
- ASC has the lowest inpatient cost as compared to LSC and RSC. LSC has lower inpatient cost than RSC (**Grade B**)
- In single RCT's the RSC had longer operating time than both ASC and LSC (**Grade B**). In small trials objective outcomes appear similar although postoperative pain was greater in RSC.
- LSC as effective as ASC with reduced blood loss and admission time. (**Grade C**). The data relating to operating time are conlicting
- ASC performed with polypropylene mesh has superior outcomes to fascia lata (**Level I**) and porcine dermis and small intestine submucosa (**Level 3**) (**Grade B**)
- In a single RCT, LSC had a superior objective and subjective success rate and lower reoperation rate compared to polypropylene transvaginal mesh for vault prolapse (**Grade B**).
- Level three evidence suggest vaginal uterosacral ligament suspension, McCall culdoplasty, Iliococcygeus fixation and colpocleisis are relatively safe and effective interventions (**Grade C**)

VII. SURGERY FOR POSTERIOR VAGINAL WALL PROLAPSE

The prevalence of rectocele in women ranges from 12.9-18.6% and the average annual incidence is estimated to be 5.7 cases per 100 women years [Hendrix 2002; Handa 2004]. Approximately 225,000 operations are performed every year in the United States for pelvic organ prolapse and repair of posterior vaginal wall is performed in between 40-85% [Olsen 1997; Boyles 2003; Whiteside 2004].

Terms used to describe the supportive tissue utilised for posterior wall prolapse repair date back to a publication by Jeffcote in 1961 [Francis WJA 1961]. The concept of site-specific repair stems from observations by Richardson who felt that discrete defects in what he termed rectovaginal fascia should be addressed by a directed repair of the defect thus producing a more anatomical repair in his opinion [Richardson 1993]. In recent years there has been a clearer understanding of the anatomy of the posterior vaginal wall and its support however surgical studies in this area continue to utilise terms that are not anatomically based. The goal of this review will be to provide a brief overview regarding current understanding of the anatomy of the support of the posterior vaginal wall, discuss various anatomic defects that can clearly contribute to posterior vaginal wall prolapse, and finally update the previous ICI report by citing the various studies that have reported outcomes for the surgical correction of posterior vaginal wall prolapse.

1. ANATOMY OF THE POSTERIOR VAGINAL WALL

Historically pelvic organ support as it relates to the anterior and posterior vaginal wall compartments has been described in relation to supportive tissues termed endopelvic fascia. In the anterior segment this has been called pubocervicovesical fascia and in the posterior segment this has been called rectovaginal fascia. Histological studies have noted that what has previously been termed fascia is actually vaginal muscularis in both the anterior and posterior segments.[Farrell 2001] With respect to the rectovaginal fascia it is now well appreciated that there is no such layer between the posterior vaginal wall and the anterior wall of the rectum. At the level of the mid vagina histological assessment of the posterior vaginal wall from the lumen of the vagina to the lumen of the rectum notes the following layers; vaginal epithelium, the lamina propria of the vagina, fibro muscular wall of the vagina (smooth muscle cells, elastin, and type II collagen) adventitia, outer muscular wall of the rectum, inner muscular wall of the rectum, lamina propria of the rectum, and rectal mucosa.

Delancey et el performed cross-sections on nulliparous and multiparous cadavers and noted that the support of the posterior compartment was maintained by a complex interaction of connective tissue and levator ani muscle [DeLancey 1999]. He went on to note that the support of the posterior vaginal wall was best divided into 3 separate and distinct levels of support. Level III support being the most distal portion of the vagina is provided by the perineal membrane and the rectovaginal septum. This level of support has strong attachments to the levator ani complex and is thus less susceptible to pelvic pressure transmission that may cause prolapse. Level II or the mid vagina is supported by its attachments of the vaginal muscularis laterally to the fascia of the levator ani muscles. Level I support or the upper vagina is supported by the cardinal-uterosacral ligament complex.

This same group of investigator's recently discussed posterior vaginal wall anatomy in a review article and likened it to an open container. The front wall of the container would be formed by the posterior vaginal wall while the bottom of the container is made up of the perineal body and anal sphincters. The levator ani muscles form the lateral sides of the container and the levator plate where the muscles decussate behind the rectum to create the iliococcygeal raphe form the back wall of the container. The uppermost portion of the container would be that created by the attachment of the posterior vaginal wall to the uterosacral ligament which extend below the peritoneum All of these boundaries are subject to defects that can give rise to different structural failures.[Lewicky-Gaupp 2009]

2. ANATOMIC DEFECTS THAT MAY CONTRIBUTE TO PROLAPSE OF THE POSTERIOR VAGINAL WALL

The patient who presents with prolapse of the posterior vaginal wall either in isolation or in conjunction with prolapse of other segments of the pelvic floor could potentially have a posterior enterocele, a rectocele, or a sigmoidocele.[Fenner 1996] These 3 conditions can occur in isolation or in conjunction with each other and will commonly be accompanied by a perineal defect and or a widened genital hiatus. While it is beyond the scope of this article to discuss clinical and radiographic mechanisms that can be used to differentiate these various defects suffice it to say that they can all result in descent of the posterior vaginal wall in various degrees.

The published literature continues to classify posterior vaginal repairs into what has been termed a "traditional technique" which implies that the repair has been supplemented with a levator ani muscle plication in the midline or a "site specific technique" which implies that discreet defects in the rectovaginal fascia are identified and repaired and no levator plication is performed. To date we are unaware of any studies that have addressed how often a posterior enterocele and or sigmoidocele coexist with a rectocele and how the presence of these defects impacts on ultimate surgical out-

comes. Based on our current understanding of the anatomy of the posterior vaginal wall and perineum it is clear that the defect specific repairs involve plication of the fibromuscular layer of the posterior vaginal wall and based on the initial level of dissection this tissue may be found on the anterior wall of the rectum or may have to be mobilised off the vaginal epithelium to allow an appropriate tension free plication. In patients with advanced prolapse and a widened genital hiatus the only way to address the gaping vagina is to routinely perform a distal levatorplasty. In the authors opinion future surgical studies assessing outcomes of prolapse repair involving the posterior vaginal wall should take into consideration these points, and realise that these procedures are not mutually exclusive and a combination of the techniques, especially in cases of advanced prolapse is commonly required. Other type of repairs that have been reported include transanal repairs, transperineal mesh (biologic or synthetic) augmented repairs, and abdominal sacral colpopexy in which the mesh attachment is extended down to the distal portion of the posterior vaginal wall and or perineum. The authors have also observed that aggressive reattachment of the uppermost portion of the full thickness of the posterior vaginal wall (level III support) to the uterosacral ligament provides significant support to the posterior vaginal wall in patients with high rectoceles or rectoceles in conjuction with a posterior enterocele.

3. MIDLINE PLICATION OR TRADITIONAL POSTERIOR COLPORRAPHY

The mean reported anatomic success rates with this type of repair is 83% (range 76-96%) with mean post-operative dyspareunia rate of 18%(range 5-45%) and 26% using vaginal digitation to defecate. (**Table 19**)

4. SITE SPECIFIC DEFECT REPAIR

This technique is similar to traditional post repair in terms of dissection. The aim of the repair is for the surgeon to indentify and individually correct breaks in the rectovaginal septum. Tradition levatoroplasty is avoided. The mean anatomic success rate is 83% (range 56-100%) with 18% postoperatively needing vaginal digitation to defecate and 18% experiencing post-operative dyspareunia (**Table 20**).

Abramov et al retrospectively compared the midline fascial plication and discrete site specific repair for rectoceles [Abramov 2005]. They noted a significantly higher recurrence rate of rectoceles following the discrete site-specific repair (32%) as compared to 13% following the midline fascial plication [P=0.015]. The correction of the rectovaginal fascia defect that allows entrapment of feces on straining in significant rectoceles maybe to large to be repaired with the discrete approach [Kenton 1999] and appears to be corrected by the more robust midline fascial plication.

In a randomised control trial Paraiso et al compared three techniques for rectocele repair in a prospective randomized trial [Paraiso 2006]. Patients were randomized to receive either a traditional repair [N=37], a site specific repair [N=37] or a site-specific repair augmented with porcine small intestine mucosa [N=32]. All patients preoperatively had Stage II or greater posterior vaginal wall prolapse. The objective anatomic failure rate was highest in the graft augmented group [12 to 26] at 1 year which was statistically significantly worse then results in the site specific group [6 of 27] and traditional repair [4 of 28]. There was no significant difference in subjective symptoms (worsening prolapse or colorectal symptoms) or dyspareunia between the three groups.

Recently Sung et al reported on a double blind multicentre randomised control trial comparing native tissue repair [70] or native tissue porcine subintestine submucosal (SIS) graft [67] for symptomatic grade 2 rectocele [Sung 2012]. The native tissue repair involved either a midline plication or site specific repair with majority undergoing site-specific repair. In the graft group this repair was augmented with porcine SIS overlay. At one year there was no difference between the groups in objective and subjective success rates or in resolution of defecatory symptoms. Post operative dyspareunia rates were not significantly different at 7% in the native tissue group and 12.5% graft group.

In a single trial Vijaya (Abstract #52, ISC 2011 Glasgow) reported at 6 months follow up superior support of the posterior vaginal wall was attained after the fascial plication as compared to levator ani repair. Block randomisation was performed with 26 women randomised to each operation. Allocation concealment, power analysis, and status of reviewers was not reported. Anatomic outcomes were reported via Pop-Q point AP and a variety of quality of life assessments were performed without reporting the data.

5. TRANSANAL REPAIR OF RECTOCELE

Three trials have evaluated transanal vs transvaginal repairs of rectoceles [Kahn MA 1999; Nieminen 2004; Farid 2010]. Each trial had slightly different inclusion criteria. Kahn included women who had symptoms of prolapse or impaired rectal evacuation with incomplete emptying on isotope defaecography and normal compliance on anorectal manometry [Kahn MA 1999]. Nieminen's included women with symptomatic rectoceles not responding to conservative therapy. Importantly women with compromised anal sphincter function and other symptomatic genital prolapse were excluded. In both trials the vaginal repair was performed by gynaecologists and the transanal repair by colorectal surgeons. In Kahn's trial the posterior vaginal wall repair was performed using levator plication and in Nieminen's trial the rectovaginal fascia was plicated. Farid's inclusion criteria required women to have a rectocele

larger than 2 cm on defaecography with symptoms including digitation, incomplete evacuation, excessive straining and dyspareunia. Women with a compromised anal sphincter complex or recurrent prolapse, rectal prolapse, intussusception, or anismus were excluded. The surgery was performed within the surgery department and blinded examiners utilised defecography, anal manometry, and a modified obstructed defecation syndrome patient questionnaire to report outcomes.

Based on these three trials we can conclude that the results for transvaginal repair of rectocele are superior to transanal repair of rectocele, in terms of subjective and objective outcomes. In women with rectocele alone recurrent rectocele occurred in 2 out of 39 women in the vaginal group and 7 out of 48 following the transanal repair, a difference that did not reach statistical significance. Post-operative enterocele was however significantly less common following vaginal surgery as compared to the transanal group.

Farid [Farid 2010] reported on outcomes of three types of rectocele repair comparing transperineal repair to levatorplasty to transanal repair and noted conclusions similar to the two previously discussed trials. The size of the rectocele on defecography was significantly smaller in the transperineal group (with or without levatorplasty) as compared to the transanal repair. Also functional outcome based on a modified obstruction defecation syndrome patient questionnaire was better after transperineal repair compared to transanal repair.

Puigdollers et al reported results from a prospective cohort of women with rectocele and constipation who underwent surgery via either endorectal or a transperineal approach based on surgeon preference[Puigdollers 2007]. At the end of one year the overall subjective improvement in constipation was reported in 43% [p<0.001] and the need to splint decreased in 52% [p=0.001].

Thornton et al [Thornton 2005] reported in a single non-randomised study outcomes for a cohort of women with symptomatic rectocele who were treated laparoscopically [N=40] vs transanally [N=40]. Level 2B evidence from this study supports the superiority of the transanal approach for symptom relief (55% vs 28%, p<0.02) but lower post-operative dyspareunia rates (22% vs 36%) with the laparoscopic approach.

van Dam et al [van Dam 2000] performed a combined transvaginal and transanal repair in 89 women who were evaluated at a follow up of 52 months. The anatomic success rate was 71% (defined as no persistent or recurrent rectocele on defaecography at 6 months). However de novo dyspareunia was reported in 41% of women and there was a deterioration of fecal maintenance in 7 patients.

6. GRAFT AUGMENTED RECTOCELE

Sand et al [Sand 2001] compared posterior repair with and without mesh and noted rectocele recurrence appeared equal with and without polyglactin (vicryl) mesh augmentation [7 out of 67 vs 6 out of 65]. Neither Paraiso et al or Sung et al noted any benefit to augmenting a native tissue repair with a porcine subintestine submocosal graft overlay [Paraiso 2006; Sung 2012]. Mesh exposure was not reported in these trials. Altman et al reported on a prospective evaluation of insertion of a 7x4cm porcine dermis graft at three years and found a 40% recurrence rate on examination and while there was a significant decrease in rectal emptying difficulties as compared to preoperatively less than 50% reported cure of rectal emptying issues [Altman 2006]. There was no change in the rate of anal incontinence or dyspareunia post-intervention.

7. MODIFIED SACROCOLPOPEXY

The abdominal route has been employed in the correction of posterior vaginal wall prolapse when a co-existing apical defect requires surgery. The technique is a modification of sacrocolpopexy with extension of the posterior mesh down to the distal posterior vaginal wall and or the perineal body. The procedure has been reported completely abdominally or as a combined abdominal and vaginal approach. **Table 21** summarises a series of studies that have reported on extended posterior fixation of sacrocolpopexy mesh.

Summary

- Transvaginal Repair of Posterior Vaginal Wall prolapse continues to be reported as either a traditional repair with levatorplasty, midline fascial plication without levatorplasty or site-specific repair. Level one and two evidence suggest midline plication posterior repair without levatorplasty has superior objective outcomes as compared to site-specific posterior repair. (**Grade B**)
- Higher dyspareunia rate reported when levatorplasty is employed. (**Grade C**)
- Transvaginal approach is superior to the transanal approach for repair of posterior wall prolapse (**Level 1 Grade A**)
- To date no study has shown any benefit to mesh overlay or augmentation of a suture repair for posterior vaginal wall prolapse. (**Grade B**)
- While modified abdominal sacrocolpopexy results have been reported, data on how these results would compare to traditional transvaginal repair of posterior vaginal wall prolapse is lacking.

Table 21. Abdominal Repair (Posterior extension of Colpopexy Mesh)

Author	N	Follow Up	Success	Dyspareunia Pre-op	Post-op
Baessler K（Baessler 2001）	33	26 months	45%	39%	13%
Fox S. (Fox 2000)	29	14 months	90%	38%	17%
Su K (Su 2007)	122	12 months	90%	-	-
Lyons (Lyons 1997)	20	12 months	80%	-	-
Marinkovic (Marinkovic 2003)	12	39 months	91%	29%	None

VIII. PELVIC ORGAN PROLAPSE SURGERY AND BLADDER FUNCTION

In women with stage II POP about 55% have concurrent stress urinary incontinence (SUI). This prevalence decreases with increasing POP stages to 33% in women with stage IV POP [Slieker-ten Hove 2009]. However, if the prolapse is reduced digitally or with the help of a pessary, sponge holder or speculum, SUI might be demonstrated in a further 10% to 80%. [Haessler 2005; Reena 2007; Sinha 2007; Ellstrom Engh 2010] This type of SUI is termed occult, masked or latent SUI and is present when stress urinary incontinence is only demonstrable with the prolapse reduced in otherwise continent women. The importance of this finding remains ambiguous [Visco 2008]: the test itself is not optimal [Visco 2008] as it does not necessarily mimic prolapse surgery and may obstruct or put undue tension on the urethra. Although different techniques to reduce the prolapse have been described, a gold-standard has not been established. [Visco 2008; Ellstrom Engh 2010] Neither the speculum nor the pessary test to reduce the prolapse had acceptable positive predictive values to identify women in need of a concomitant continence procedure. The negative predictive values however were 92.5% [95%CI 90.3–1.00] and 91.1% [95%CI 88.5–99.7], respectively. Therefore, women with negative tests for occult SUI preoperatively are at low risk of developing SUI postoperatively. [Ellstrom Engh 2010; Chughtai 2011] Women with occult SUI are at risk of developing SUI after POP repair. Reducing the prolapse may also restore normal voiding function during urodynamics.[Romanzi 1999] These findings demonstrates the importance of testing bladder function in continent women with and without the prolapse reduced.

The Cochrane review on surgical management of POP found that new or denovo SUI symptoms were reported by 187 of 1280 women (15%) after prolapse surgery. [Maher 2010] The term de novo stress urinary incontinence is used to describe stress incontinence that develops following surgical correction of the prolapse, amongst women who were continent prior to surgery. De novo SUI might develop because POP surgery has unkinked the previously obstructed urethra.[Kenton 2005; Mueller 2007] De novo stress urinary incontinence is clearly disappointing to women and this outcome measure is considered in this review.

A third of women with stage II or more POP experience difficulties emptying the bladder.[Slieker-ten Hove 2009] Voiding difficulties might disappear postoperatively because the obstruction caused by the prolapse has been corrected.[Romanzi 1999] In contrast, they might develop because of kinking of the urethra due the surgical technique.

This section of the chapter assesses the effect of POP surgery on bladder function including stress urinary incontinence, overactive bladder and voiding dysfunction. In order to optimally evaluate pre and postoperative bladder symptoms, only studies with standardised or validated pre and postoperative outcome measures, more than 20 operated women and a follow up time of at least 12 months are included and summarised in Table 22. The follow up time of 12 months does not apply to studies assessing voiding dysfunction. We will evaluate the evidence surrounding common clinical scenarios.

1. CONTINENT WOMEN UNDERGOING POP SURGERY. WHAT IS THE RISK OF DE NOVO SUI AND IS CONTINENCE SURGERY REQUIRED?

For symptomatically and clinically dry women an anterior native tissue repair yields lower rates of de novo SUI than transobturator anterior mesh procedures. The overall cumulative de novo SUI rate after anterior repairs is 9% [44/481]. In five RCT´s [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011] de novo SUI was found in 31/377 (8%) women and in 13/104 (12%) women in two prospective studies [Hung 2004; Ellstrom Engh 2010]. After armed-mesh repairs the overall cumulative rate is significantly higher at 14% [134/951; p=0.017, chi-square] with a rate of 17% [101/584] in six RCT [Hiltunen 2007; Sivaslioglu 2008; Halaska 2010; Altman 2011; Sokol 2011; Withagen 2011] and 9% [33/367] in eight prospective trials [Sentilhes 2007; Ek 2010; Fayyad 2010; Feiner 2010; Sergent 2010; Takahashi 2010; Kuribayashi 2011; Liang 2011].

Five RCT´s directly compared anterior colporrhaphy and transobturator mesh procedures [mesh kits or self-fashioned] and reported 12-months results [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011]. Anterior native tissue repair significantly reduced the risk of de novo SUI (RR

0.64 95%CI 0.42, 0.97; **Figure 4**). Although all these trials employed quality of life and symptom questionnaires, different instruments were used and meta-analysis was not able to be performed.

In a longer term follow up of Hiltunen ´s trial [Hiltunen 2007], subsequently more women developed new SUI after anterior repair resulting in similar SUI rates after three years of 17% after both anterior repair [15/86] and transobturator mesh procedure [15/84]. [Nieminen 2010].

Similar rates of de novo SUI occurred if the anterior compartment prolapse was repaired using a polypropylene transobturator mesh 2% [2/96] or a porcine dermis graft 1% [1/94].[Natale 2009] In a single RCT de novo SUI was significantly more common after sacrospinous fixation and vaginal repairs compared with abdominal sacral colpopexy [8/24, 33% versus 2/22, 9% in a single RCT][Maher 2004], however, these data need to be reviewed cautiously as in the sacral colpopexy group continent women pre-operatively received paravaginal repairs which may be effective in limiting de novo SUI postoperatively.

In the large multicentre randomised controlled CARE trial (Colpopexy and urinary reduction efforts), preoperatively continent women were randomly allocated to undergo sacral colpopexy with [n=157] or without colposuspension [n=165]. Brubaker et al. demonstrated at 2 years that Burch colposuspension, performed concomitantly with an abdominal sacrocolpopexy significantly reduced the risk of de novo SUI. Subjective SUI was reported by 38/147 (26%) after additional Burch colposuspension and by 63/155 women (41%) after sacrocolpopexy alone. However, objective testing yielded similar findings in the two groups: 11/116 (9%) and 9/134 women (7%), respectively, demonstrated SUI. The study was terminated prematurely because of the high postoperative SUI rate in women who did not receive concomitant Burch colposuspension and as a result of early termination was underpowered. Unfortunately, irregularities in study design create uncertainty for the reader regarding the study findings. Firstly, different and complicated definitions were used to categorise stress continence prior to and after the interventions that made it more difficult to be classified as stress continent post intervention than prior to the intervention. Thirty-nine percent of women classified as stress continent prior to surgery would have been classified as stress incontinent using the post-intervention definition! Secondly, while surgery was standardised for colposuspension neither the paravaginal repair nor sacral colpopexy was standardised with significant variations in use of suture type and graft materials: in 17% biological grafts, in 43% Mersilene, in 39% polypropylene and in 6% Gore-tex was utilised.[Brubaker 2006; Brubaker 2008] which may have impacted on the continence results.

After a follow up of 8 years, Costantini et al. in another smaller RCT reported contrary results with 9/31 women (29%) developing SUI after additional Burch colposuspension compared to 5/31 (16%) after sacrocolpopexy alone.[Costantini 2007; Costantini 2010].

Figure 5 summarises these two RCT´s in a meta-analysis.[Brubaker 2008; Costantini 2010] Because of contrary outcomes resulting in significant heterogeneity, a random-effects model was used. According to this model, women do not benefit from Burch colposuspension in addition to abdominal sacral colpopexy. This is true for subjective de novo SUI [RR 0.96 95%CI 0.35, 2.62] and objective rates of de novo SUI [RR 1.56 95%CI 0.82, 2.95].

2. POP SURGERY AND STRESS URINARY INCONTINENT WOMEN

In women with SUI undergoing prolapse surgery, what kind of prolapse procedure and which continence surgery is required concomitantly in order to reduce postoperative SUI rates? The cumulative success rate for SUI after anterior colporrhaphy in two randomised trial arms was 48% [19/40][Colombo 2000; Hviid 2010]. Colombo et al.[Colombo 2000] compared to Burch colposuspension and anterior repair for the treatment of women with anterior vaginal wall prolapse and SUI. While women benefited more from Burch colposuspension with regards to SUI [cure of SUI 30/35, 86% versus 17/33, 52%], anterior repair better corrected the anterior prolapse [cure of cystocele 23/35 versus 32/33].[Colombo 2000].

Prospective POP surgery studies employing transobturator mesh without additional continence surgery show a cumulative SUI success rate of 61% [81/132]

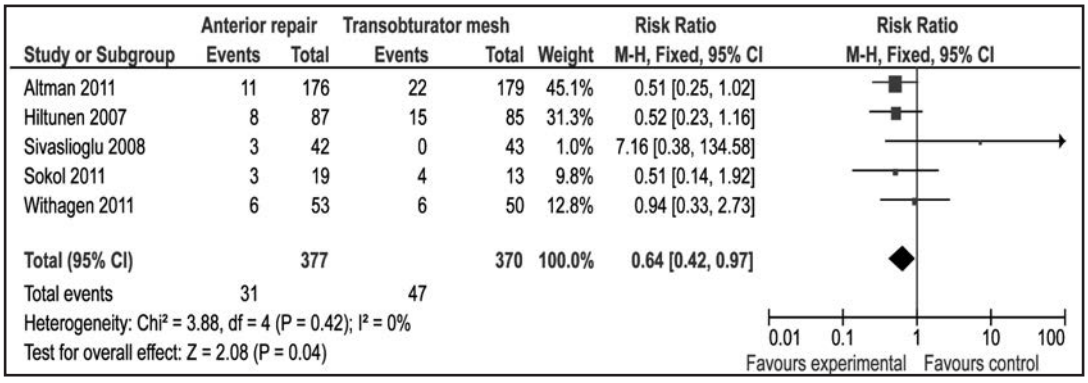

Figure 4. De novo SUI: Forrest plot of five RCT´s comparing anterior repair and transobturator mesh repairs.

[Sentilhes 2007; Sergent 2009; Sergent 2010]. Success rates improve considerably if a suburethral tape is performed concomitantly [cumulative rate 235/237, 99%]. [Hung 2004; Fayyad 2010; Feiner 2010; Takahashi 2010] Persisting or worsening SUI was described in 9/15 (60%) by Fayyad et al.[Fayyad 2010] who prospectively evaluated the role of transobturator polypropylene mesh without any concomitant surgery in the management of recurrent prolapse.

Whether a suburethral tape (TVT) is inserted concomitantly or after three months did not result in significantly different success rates based on an "on-treatment" analysis of Borstad et al. [83/87, 95% versus 47/53, 89% three months later].[Borstad 2010] Twenty-seven/94 (29%) women were cured of SUI after prolapse surgery alone and did not receive a TVT three months later.[Borstad 2010].

Costantini et al. 2008 compared abdominal sacrocolpopexy or sacrohysteropexy with and without concomitant Burch colposuspension in women with POP and SUI.[Costantini 2008] Similarly to their randomised trial in continent women, Burch colposuspension increased the postoperative SUI rate: 13/24 (54%) versus 9/23 (39%) were incontinent.[Costantini 2008].

3. SHOULD WOMEN UNDERGOING POP SURGERY WITH OCCULT SUI IDENTIFIED PREOPERATIVELY UNDERGO CONTINENCE SURGERY AT TIME OF POP SURGERY?

Three randomised trials addressed this issue [Meschia 2004; Schierlitz 2007; Wei 2011] and found that after the addition of TVT to vaginal prolapse repairs (mainly anterior and posterior colporrhaphy) significantly fewer women complained of SUI [21/116, 18% versus 64/125, 51%]. The meta-analysis of these three trials calculated that a concomitant TVT reduced the risk of postoperative SUI significantly [RR 0.54, 95%CI 0.41, 0.72; **Figure 6**]. In two trials, including women who tested positive for SUI after the POP was reduced (occult SUI) [Meschia 2004; Schierlitz 2007], whereas in Wei et al. study (OPUS trial) only 34% demonstrated occult incontinence. [Wei 2011] However, they reported data separately for women with a positive stress test after reduction of the prolapse: 41/57 women without and 16/54 with an additional TVT were stress incontinent at three months follow up (**Figure 6**).

In a retrospective trial of 60 women who tested negative for occult SUI on preoperative urodynamic studies, 15 (25%) developed SUI after vaginal mesh surgery.[Kasturi 2011] However, 12% [7/60] had preoperative symptomatic SUI.

4. OVERACTIVE BLADDER (OAB) SYMPTOMS

OAB symptoms may be associated with POP.[Slieker-ten Hove 2009] Therefore, prolapse surgery may cure or improve OAB but it may also result in new OAB symptoms. The current Cochrane review on the surgical management of POP [Maher 2010; Maher 2011] calculated that new overactive bladder symptoms developed in 103/854 [12%] women in nine trials with various prolapse surgery.[Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Meschia 2004; Brubaker 2006; de Tayrac 2008; Natale 2008; Natale 2009] Whether women have been treated with anticholinergics e.g. postoperatively is not at all clear and numbers might in fact be higher. The cumulative rate of de novo OAB in women who underwent transobturator anterior mesh procedure

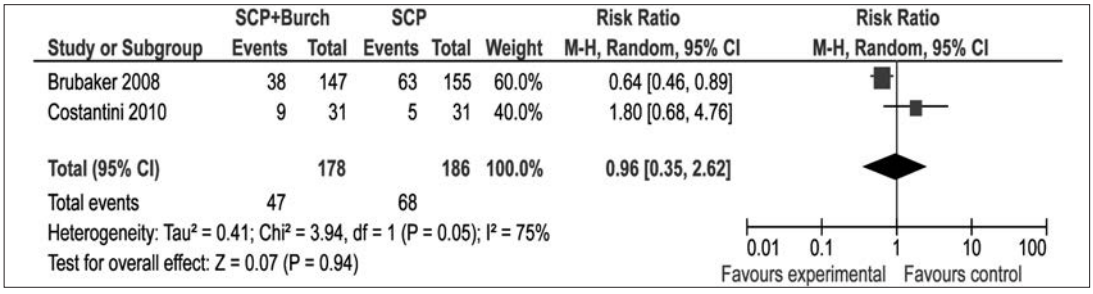

Figure 5. Meta-analysis of two RCT´s looking at the effect of Burch colposuspension in addition to sacrocolpopexy. Presented are subjective rates of de novo SUI

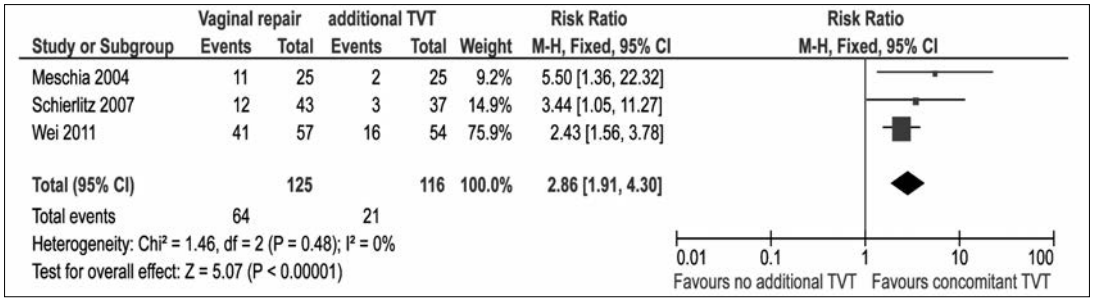

Figure 6. The addition of a suburethral sling to vaginal prolapse repairs in women without symptomatic SUI

is 7% [39/557], [Sentilhes 2007; Moore 2009; Fayyad 2010; Feiner 2010; Halaska 2010; Liang 2011] whereas it is 10% [7/71] in the few studies reporting data after anterior repair with or without suburethral tape.[Meschia 2004; Foster 2007] This difference is not statistically significant [p=0.4].

In a new RCT, Halaska et al. reported de novo overactive bladder in 7/97 [7%] after anterior Prolift, in 7/34 (21%) after anterior Prolift and sacrospinous fixation, in 8/84 (9%) after total Polypropylene mesh repair and in 1/98 (1%) after posterior Prolift only. [Halaska 2010] In another RCT, after vaginal sacrospinous fixation 6/29 women complained of OAB whereas after sacrocolpopexy 11/33 developed symptoms.[Maher 2004]. Sacrocolpopexy with or without Burch colposuspension resulted in similar rates of de novo OAB [3/34 versus 2/32][Costantini 2007]. Similarly, after vaginal POP surgery with or without TVT OAB rates were not different [3/25 versus 1/25].[Meschia 2004].

In 22/48 (46%) of women with several different prolapse operations urgency incontinence resolved, whereas it persisted in 26/48 (54%) and developed de novo in 3 (12%).[Foster 2007].

5. VOIDING PROBLEMS

The Cochrane review noted new voiding dysfunction in 56/476 (12%) women in six randomised trials with various prolapse surgeries with or without continence procedures [Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Natale 2007; de Tayrac 2008]. However, variation in defining and reporting voiding problems makes meta-analysis is unfeasible.

After anterior repair, voiding dysfunction ranges from 0% to 37%.[Colombo 2000; Meschia 2004; Gandhi 2005; Meschia 2007; Stekkinger 2011; Withagen 2011]

In their RCT Withagen et al. described significantly different temporary urinary retention rates in 5/97 (5%) compared with 15/93 (16%) after transobturator mesh repair [p=0.008]. Normal micturition was restored in all women within 14 days. [Withagen 2011] Anterior repair with or without concomitant vaginal POP surgery resulted in postvoid residuals exceeding 150 ml in 27/126 (21%) in an RCT comparing transurethral and suprapubic catheterisation.[Stekkinger 2011]

After anterior mesh repair, voiding difficulties occur between 5% and 42%.[Maher 2004; Feiner 2010; Steinberg 2010; Withagen 2010; Feiner 2011; Maher 2011; Withagen 2011] One study looked at postoperative urinary retention defined as the need to discharge the patient with an indwelling catheter because of a failed trial of void.[Steinberg 2010] Voiding dysfunction ranged from 34% [10/29] after isolated anterior mesh repair to 42% [30/71] cases after combined anterior and posterior repairs. After isolated posterior repair 8/42 (19%) developed urinary retention. At the 3-months follow up, there were no more voiding complaints.[Steinberg 2010]

If there are postoperative voiding problems with residuals exceeding 150 ml, clean intermittent catherisation is superior to an indwelling catheter for three days with regards to bacteriuria, urinary tract infection and length of required catheterisation according to one RCT [Hakvoort 2011] and intermittent transurethral catheterisation is equivalent to a suprapubic catheter regimen.[Stekkinger 2011] Insertion of a suprapubic catheter however resulted in more related complications including dislodgment or blockage of the catheter and haematuria.[Stekkinger 2011].

Another RCT [Huang 2010] reported on the duration of postoperative urethral catheterisation between two and four days after anterior repair and found no differences in voiding dysfunction. This was confirmed by an RCT comparing two and five days of routine postoperative indwelling catheter placement. Longer hospital stay and more urinary tract infections were associated with the five days protocol.[Weemhoff 2011] Patients do not seem to benefit from postoperative urethral catherisation beyond two days.[Huang 2010; Weemhoff 2011].

Summary

Assessed trials were considerably heterogeneous regarding inclusion and exclusion criteria, clinical testing for stress urinary incontinence and operations performed. Also, the lack of separate reports of bladder symptoms account for a difficult interpretation of outcomes.

Continent women undergoing anterior compartment POP surgery have a lower rate of de novo SUI after anterior repair than armed mesh procedures. (**Grade A**)

Data are conflicting on whether colposuspension should be performed prophylactically in continent women undergoing sacral colpopexy. (**Grade C**)

In continent women undergoing POP surgery with occult SUI the addition of continence surgery reduces the rate of postoperative SUI (**Grade A**).

In women with POP and SUI prolapse procdures alone (transobturator mesh and anterior repair) are associated with low success rates for SUI. Concomitant continence procedures reduce the risk of postoperative SUI .

No clear conclusion can be made regarding the management of continent women undergoing POP surgery without occult SUI.

Preoperative bladder overactivity may resolve in 40% undergoing POP surgery and denovo bladder overactivity occurres 12%.

No valid conclusions regarding voiding dysfunction following POP surgery can be drawn from the available data.

Level 1 evidence demonstrates there is no need to leave an indwelling catheter beyond two days and a suprapubic catheter yields similar outcomes to clean intermittent self catheterisation however is associated with more complications.

Table 22. Studies reporting on de novo stress urinary incontinence (SUI) or cured SUI

Author, year	Study design / LoE	Operations	Follow up months	SUI status preop	De novo SUI	Cured SUI	Persistent SUI	De novo OAB

IX. COMPLICATIONS AND METHODS OF PREVENTION

Pelvic reconstructive surgery for genital prolapse, with or without mesh, results in improved prolapse related symptoms and quality of life improvement in most of the cases [Jia 2008; Iglesia 2010; Maher 2010] (Level 1). While the use of non-absorbable synthetic mesh in the anterior compartment subjectively and objectively decreases the rate of anterior vaginal wall prolapse recurrence in comparison to native tissue repair Cochrane 2012(Level 1) however, short term improvement of quality of life or reduced reoperation rates have yet to be demonstrated [Jia 2008; Iglesia 2010; Maher 2010; Altman 2011]. Furthermore, the use of non-absorbable synthetic mesh exposes patient to moderate to severe specific complications.

The first objective of this section is to report non specific and specific complications related to pelvic reconstructive surgery for genital prolapse with mesh, in comparison to surgery with no mesh. The second objective is to describe the recognised methods of prevention of these complications.

1. CLASSIFICATION OF COMPLICATIONS

Recently, the IUGA (International Urogynecological Association) and the ICS (International Continence Society) have published a specific classification of complications related to pelvic reconstructive surgery [Haylen 2011]. That classification has been developed to be sensitive to all possible physical complications involving the use of a prosthesis or graft in a female pelvic floor surgical procedure. Both insertion complications (e.g trocar related) and healing abnormalities are covered. Whilst this creates a large number of possible complication scenarios, appropriate organisation has still been possible by category (C), time (T) and site (S). A key advantage of a standardised classification is that all parties involved in female pelvic floor surgery will be referring to the same clinical issue. It is anticipated that in time this classification will significantly add to clarity in reporting mesh related complications.

2. REOPERATION AFTER VAGINAL MESH SURGERY

Table 23 shows the reoperation rates after vaginal mesh surgery for both non specific (linked to surgical dissection) and specific (linked to the mesh) complications. Only randomised trials have been used for analysis. Although meta-analysis shows a decreased rate of anatomical recurrences after mesh surgery, the total reoperation rate is increased after transvaginal mesh surgery (8.5%) as compared to surgical procedures using native

Table 23. Reoperation rates after Polypropylene and porcine dermis vaginal surgery from randomised control trials

Abreviations : SUT, sub urethral tape ; SBM, sub bladder mesh; PD, porcin dermis ; CF, cadaver fascia ; MD, missing data ; GT, goretex ; PE, polyester ; PP, monofilament polypropylene ; PPM, polypropylene multifilament ; PPPE, polypropylene + polyester ; PPS, monofilament polypropylene-dimethyl siloxane (silicone) ; PTFE, polytetrafluoroethylene.

tissues (3.2%)(Level 1). The rate of reoperation for prolapse is similar in both the transvaginal mesh group and native tissue repair. Altman, 2011 #137} [Maher 2004; Meschia 2007; Nguyen 2008; Sivaslioglu 2008; Natale 2009; Hviid 2010; Nieminen 2010; Withagen 2011] (Level 1). Denovo apical or posterior compartment prolapse surgery is significantly more frequent after anterior compartment polypropylene mesh (17.7%) as compared to native tissue repair (9.5%)[Nieminen 2010; Vollebregt 2011].

Similarly, a meta-analysis from Diwadkar et al, including prospective or retrospective observational studies with at least 50 patients and a minimum follow-up of 3-months, has shown an increased rate of reoperation after vaginal mesh surgery in comparison to native tissue repair. (8.5% versus 5.7%) [Diwadkar 2009].

In the only randomised trial that has compared vaginal mesh surgery to laparoscopic sacrocolpopexy with a mean follow-up of 2-year Maher et al has also shown a increased rate of reoperation after vaginal mesh surgery (22% versus 5%, p=0.006) [Maher 2004] (Level 2). Nieminen et al demonstrated a 24% [25/104] rate or reoperation after self styled polypropylene anterior compartment mesh at 3 years [Nieminen 2010].

A recent retrospective study on 524 patients who received a Prolift mesh with a median follow-up of 38 months [range, 15-63], has reported a global reoperation rate of 11.6% including postoperative urinary incontinence (6.9%), mesh-related complications (3.6%), and prolapse recurrence (3%) [de Landsheere 2011].

3. REOPERATION AFTER ABDOMINAL SURGERY

Mean rates of reoperation for prolapse recurrence and for de novo stress urinary incontinence after open abdominal sacral colpopexy are 4% and 5%, respectively [Nygaard 2004; Culligan 2005; Elneil 2005; Handa 2007; Meschia 2007; Jeon 2009].

Table 16 demonstrates the total reoperation rate for laparoscopic sacrocolpopexy is 5.9%. with 2.9% representing complications and 1.7% representing reoperations for prolapse. [Agarwala 2007; Maher 2007; Sarlos 2008; Stepanian 2008; Deprest 2009; Granese 2009; Sabbagh 2010; Price 2011; Sergent 2011].

The rate of reoperation for recurrences after laparoscopic sacrocolpopexy is significantly higher with the use of porcine dermis grafts in comparison to polypropylene mesh [Deprest 2009] (Level 3).

Tijdink et al [Tijdink 2011] reported on the surgical management of 60 mesh complications following mesh prolapse surgery. Twelve followed sacral colpopexy and 48 vaginal mesh surgeries. Most women reported more than one complication however the principle presentation requiring surgical intervention was pain in 77% (vaginal pain, dyspareunia or other chronic pain buttock, abdomen or thighs). They detected a distinct difference in symptoms related to mesh complications following transvaginal mesh and ASC. Vaginal pain and dyspareunia were the most commonly reported symptoms necessitating surgical intervention following transvaginal mesh and vaginal discharge and bleeding following ASC. Previous mesh excision procedures had been performed in 29% and complete mesh excision was required in 37% of cases. Peri-operative complications occurred more frequently in those requiring complete excision of mesh. Furthermore perioperative complications were more common in those who had undergone ASC as compared to vaginal mesh surgery (23% versus 1% p=0.001). Finally, recurrence of prolapse was significantly more likely if complete excision of the mesh was required and occurred in 29% as compared to 5% after partial excision of mesh. Resolution of preoperative symptoms was reported in 92% who underwent surgical management of mesh complications.

4. VAGINAL MESH EXPOSURE

It is difficult to know the exact rate of vaginal mesh exposure, as the definition of exposure is variable between studies and meshes used are different. **Table 24** shows the rate of exposures after vaginal mesh surgeries in the current available randomised controlled trials. In these trials, the mean rate of exposure was 13.1% [Meschia 2007; Nguyen 2008; Sivaslioglu 2008; Natale 2009; Hviid 2010; Iglesia 2010; Lopes 2010; Nieminen 2010; Altman 2011; Maher 2011; Vollebregt 2011; Withagen 2011](Level 1).

Abreviations : RCT, randomised controlled trial; L, Level; SBM, sub bladder mesh; PD, porcine dermis ; CF, cadaver fascia ; MD, missing data ; GT, goretex ; PE, polyester ; PP, monofilament polypropylene ; PPM, polypropylene multifilament ; PPPE, polypropylene + polyester ; PPS, monofilament polypropylene-dimethyl siloxane (silicone) ; PTFE, polytetrafluoroethylene.

95% CI for 13.1% [10.4-15.8] for PP and 0.9% [0-2.1] for PD

The mean rate of vaginal mesh exposure after open sacrocolpopexy was 3% [Nygaard 2004; Culligan 2005; Elneil 2005; Wu 2006; Handa 2007; Jeon 2009]. **Table 16** shows the rate of exposures after laparoscopic sacrocolpopexy is 2.5% [Cosson 2002; Antiphon 2004; Gadonneix 2004; Maher 2004; Paraiso 2005; Ross 2005; Rozet 2005; Agarwala 2007; Rivoire 2007; Sarlos 2008; Stepanian 2008; Claerhout 2009; Deprest 2009; Granese 2009; Sabbagh 2010; Price 2011; Sergent 2011] Paraiaso(Level 2).

Table 24. Rate of vaginal exposure after vaginal graft surgery from randomised control trials

Author	Year	Total sample size	Number of mesh procedure	Number of vaginal exposure	Rate of vaginal Exposure	f.u. (months)	Mesh

Total (PD)	-	-	**224**	**2**	**0.9% 95%CI (0-2.1)**	-	-

Abreviations : RCT, randomised controlled trial; L, Level; SBM, sub bladder mesh; PD, porcine dermis ; CF, cadaver fascia ; MD, missing data ; GT, goretex ; PE, polyester ; PP, monofilament polypropylene ; PPM, polypropylene multifilament ; PPPE, polypropylene + polyester ; PPS, monofilament polypropylene-dimethyl siloxane (silicone) ; PTFE, polytetrafluoroethylene. 95% CI for 13.1% (10.4-15.8) for PP and 0.9% (0-2.1) for PD

Maher et al, have shown a non significant increased rates of vaginal mesh exposure and reoperation for vaginal mesh exposure after vaginal mesh surgery in comparison to laparoscopic sacrocolpopexy (13% vs 2%, p=0.07 and 9% vs 2%, p=0.11, respectively) [Maher 2004] (Level 2). However, that was not the primary endpoint of the study, and that study was underpowered for this parameter.

5. VISCERAL (BLADDER, RECTUM) MESH EXPOSURE

There was no visceral mesh exposure reported in the randomised controlled trials after vaginal mesh surgeries, but follow-up were short [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Iglesia 2010; Nieminen 2010; Altman 2011]. Late bladder or ureteric and rectal exposure were reported after both sacrocolpopexy [Nicolson 2009; Paine 2010] and vaginal surgery [Huffaker 2009 ; Karateke 2010]. The rate of late visceral exposure after laparoscopic sacral colpopexy is between 0.5 and 1% [Sabbagh 2010] (Level 4).

6. INFECTION, ABSCESS, CELLULITIS, SPONDYLODISCITIS

There is no clear definition of bacterial colonisation around a mesh or mesh infection. Consequently, the rate of infection is currently unknown [Jia 2010]. Some studies have reported up to 80% bacterial mesh colonisation [Boulanger 2008; Vollebregt 2009]. However, the rate of relevant clinical infection (abscess, cellulitis, spondylodiscitis) does not seem to be more than 1%, after both sacrocolpopexy (Level 4) [Akl 2009; Donnez 2009; Walid 2009; de Tayrac 2011], or vaginal mesh surgery (Level 4) [Chen 2009; Lewicky-Gaupp 2009]. In a cohort of 684 polypropylene mesh implanted vaginally (TVM procedure), the rates of pelvic abscess and cellulitis have been reported to occur in only 0.29% and 0.15%, respectively [Caquant 2008] (Level 4).

7. PAINFUL MESH CONTRACTION

Feiner et al defined mesh contraction as an adverse outcome following armed polypropylene mesh repair in which patients experience vaginal pain with movement and dyspareunia and on examination have localised areas of prominent, tense and tender mesh under the vaginal epithelium[Feiner 2010]. They reported a case series of 17 painful meshes and in that series, 90% of the patients have been improved by a reoperation for partial mesh removal, however in three patients a second reoperation with wider excision of the mesh was required. The rate of polypropylene mesh-related pain reported ranged between 4 and 11% according to the definition used (Level 3) [Caquant 2008; Nguyen 2008; Sivaslioglu 2008; Lunardelli 2009; Feiner 2010; Iglesia 2010; Lopes 2010; Moore 2010; Nieminen 2010; Withagen 2011].

Maher et al have reported a rate of reoperation for mesh contraction significantly greater after vaginal mesh surgery than after laparoscopic sacrocolpopexy (7% vs 0%, p=0.05) [Maher 2004] (Level 2). Ridgeway et al [Ridgeway 2008] reported a cases series of 19 polypropylene mesh complications that underwent a variety of vaginal and abdominal procedures to partially remove mesh. Six underwent excision for severe pain and one had residual pain following partial excision.

In the 2011 American FDA report regarding transvaginal mesh, vaginal pain and dyspareunia

were the most common adverse event reported and vaginal pain and dyspareunia were also the most common indications for reoperation following transvaginal mesh in the report by Tijdink et al.[Tijdink 2011] These reports contrast with the common perception in the literature that mesh exposure is the commonnest complication associated with transvaginal meshes and requires ongoing evaluation.

8. OTHER COMPLICATIONS

Other rare but severe complications have been described after mesh surgery, such as massive haemorrage after a trans-obturator mesh procedure, major vessel injury during sacrocolpopexy, trocar hernia, bowel obstruction, ureteric complications, thrombo-embolism.

9. METHODS OF PREVENTION

a) Influence of non specific factors on mesh-related complications (obesity, smoking, age, sexual activity)

Concerning vaginal mesh surgery, obesity (BMI>30 kg/m², OR=10.1) and smoking [OR=3.7] are independent risk factors for mesh exposure [Araco 2009] (Level 3). With regard to sacrocolpopexy, smoking [OR=5.2 ; IC95% 1.7-16] is also an independent risk factor for vaginal mesh exposure [Cundiff 2008] (Level 3). Although there is no specific study in prolapse surgery, to demonstrate the cessation of smoking prior to surgery will decrease the post-operative complication rate (healing problems) in many other surgical specialties these data exist (Level 2).

Current data on the impact of aging on mesh complications are conflicting and no conclusion can be drawn. [de Tayrac 2006; Cundiff 2008; Araco 2009; Ganj 2009; Nosti 2009; Kaufman 2011].

Sexual activity has been reported to be a risk factor for vaginal mesh exposure after vaginal mesh surgery [Letouzey 2010 ; Kaufman 2011] (Level 3) however this could simply reflect that those who are sexually active are more likely to identify a mesh exposure than those who are not.

No study has shown that the following are significantly associated with mesh exposure : diabetes mellitus, corticosteroid use, immunosuppressive therapy, previous pelvic irradiation, history of previous mesh exposure, vaginal atrophy. However, many studies have shown in other surgical specialties that poorly controlled diabetes mellitus is a risk factor for post-operative infection.

b) Oestrogen therapy

Although some authors report routine use of local oestrogen therapy for the pre and post-operative course of prolapse surgery in post-menopausal women [Altman 2011], others did not give any details on such prescription, and there is no comparative study. In multivariate analysis, local oestrogen therapy has no protective effect of vaginal erosion, after vaginal mesh surgery [Guillibert 2009] (Level 3), or after sacrocolpopexy [Kohli 1998] (Level 4).

c) Antibiotic prophylaxis

There is not specific study on the use of antibiotic prophylaxis at the time of mesh reconstructive surgery for prolapse. However, most of studies report their use during surgery [Withagen 2011] [Hiltunen 2007; Carey 2009].

There are no data on the need to identify a urinary tract infection in the preoperative course, nor to perform a vaginal bacteriological test or to use antiseptic or antibiotic meshes.

Prolonged post-operative bladder catheterisation increases the risk of lower urinary tract infection. [Liang 2009].

d) Mesh implantation and visceral injury

Although there is no comparative study, most of authors would consider the use of mesh after a rectal injury during dissection as a contraindication to mesh insertion, due to a perceived higher risk of mesh infection and subsequent recto-vaginal fistula [Jacquetin 2010] (Level 4).

In the anterior compartment, a small series of five cases of recognised intra-operative bladder injury (out of 704 Trans-Vaginal Mesh procedures) has shown that mesh surgery was feasible without subsequent complications after appropriate bladder repair [Popovic 2007] (Level 4). These data are limited and further evaluation is required.

e) Surgeon training

Regarding sacral colpopexy, a learning curve has been shown, with a reduction of operative time and laparoconversion over the first 80 procedures [Claerhout 2009] (Level 3). However, the incidence of severe complications does not seem to be related to the learning curve [Claerhout 2009] [Akladios 2010].

The data regarding the impact of the learning curve for transvaginal meshes on the incidence of post-operative complications is conflicting. Some authors have reported that learning has a significant effect on the complication rate [Dwyer 2004] while others did not [Fatton 2007] [Sentilhes 2007] (Level 3).

10. VAGINAL MESH SURGERY

a) Choose the right mesh for vaginal surgery

For vaginal mesh surgery, the use of non-absorbable synthetic meshes was associated with a reduced rate of short-term recurrences in comparison to the use of absorbable biological or synthetic meshes, for both primary and recurrent cases [Jia 2008] [Iglesia 2010] [Maher 2010] [Altman 2011] [Withagen 2011] [Nieminen 2010] [Natale 2009] (Level 1). Contrarily, the use of

absorbable biological or synthetic meshes is associated with a lower risk of vaginal mesh exposure and re-operation in comparison to non-absorbable synthetic meshes [Jia 2008] [Natale 2009] (Level 1).

Concerning the type of non-absorbable synthetic mesh, the use of polyester is associated with an increased risk of vaginal exposure in comparison to polypropylene [33.3% vs 8.8%, p<0.03] [Sentilhes 2008] (Level 4). Furthermore, the use of multifilament polypropylene is associated with an increased risk of vaginal exposure than monofilament polypropylene [Sentilhes 2008] [Deffieux 2009] (Level 4), and the use of microporous monofilament polypropylene is associated with an increased risk of vaginal exposure than macroporous monofilament polypropylene [Baessler 2005] [Guillibert 2009] (Level 4). Composite polypropylene/ polyglactin meshes do not seem to reduce the vaginal exposure rate [7.2% vs 6.9%, p=0.4] [Achtari 2005] (Level 4). Finally, lower-weight meshes, titanium or collagen-coated meshed have currently shown a significant reduction rate of vaginal mesh exposure rates [de Tayrac 2007; Deffieux 2007 ; Milani 2008; Cervigni 2011] [Sergent 2011] (Level 4). However, comparative studies would be necessary to compared new ultra-light-weight or composite to existing meshes.

b) Interest in mesh kits

The rate of intra-operative complications does not seem to be reduced by the use of a mesh kit rather than a self-prepared mesh [Caquant 2008] (Level 4). However, the rate of vaginal mesh exposure was shown to be reduced by the use of the same mesh in a kit format (4.5% versus 11%, p=0.048), in a retrospective study where the same surgeons had the experience of the technique with the self-prepared mesh before to use the kit [Caquant 2008] (Level 4).

Only one small randomised controlled trial has compared commercial transvaginal mesh kits to self styled mesh, however the techniques used where different (the kit only was trans-obturator) [Finamore 2010] (Level 2).

c) Concomitant hysterectomy

Several studies have shown an increased rate or vaginal mesh exposure with concomitant vaginal hysterectomy [Ganj 2009] [Guillibert 2009)] [de Tayrac 2007] [Cervigni 2011] [Collinet 2006] [Lowman 2008], while others did not find any differences [Deffieux 2007] [Sentilhes 2008] [Achtari 2005] **Table 25**. Meta-analysis demonstrates demonstrates that the addition of hysterectomy to a transvaginal mesh surgery significantly (p<0.001) increases the risk of mesh exposure from 7.3% (98% CI 4.1 to 9.6) without hysterectomy as compared to 19.2% [98% CI 15.8 to 22.7] with hysterectomy.

d) Surgical incision

Although some authors recommend avoiding sagittal or inverted T colpotomy and trimming of excessive vaginal epithelium in order to reduce the rate of vaginal mesh exposure [Fatton 2007], this has not been evaluated by other authors.

11. ABDOMINAL SACROCOLPOPEXY

a) Choice of surgical route for sacrocolpopexy

Laparoscopic sacrocolpopexy is as efficient as open abdominal sacrocolpopexy, with a reduced rate of intra-operative bleeding, hospitalisation and wound complications [Paraiso 2005] [Klauschie 2009] [Hsiao 2007] (Level 3).

The risk of vaginal mesh exposure is higher if the mesh is sutured vaginally during sacrocolpopexy [Higgs 2005] [Visco 2001; Tan-Kim 2011] (Level 4).

Although the feasibility of robotic-assisted and single-port sacrocolpopexy have been demonstrated there is currently not enough evidence to determine if these interventions will have an impact on complication rates.[Xylinas 2010; Paraiso 2011].

b) Choose the right mesh for abdominal surgery

In a retrospective comparative study of open abdominal sacrocolpopexy, Quiroz et al have shown that the short-term mesh-related complication rate was significantly higher with polypropylene than with porcine dermis [24/102 vs 12/134, p=0.003] [Quiroz 2008] (Level 3), however the prolapse recurrence rate using porcine dermis was higher [7/93 vs 0/105, p = 0.004]. Another study comparing fascia lata and polypropylene meshes with 5-year review, has shown a long-term increased recurrence rate, but

Table 25. Compares mesh exposure rate at transvaginal polypropylene mesh surgery with and without hysterectomy

Author	Year	Number	Review months	Surgical technique	Mesh exposure hysterectomy	Mesh exposure no hysterectomy	*p value*
Deffieux	2007	138	32	Polypropylene gynemesh	20/103	7/35	
Ganj	2009	127	18	Polypropylene mesh	6/21	7/106

Collinet	2006	277	2	Polypropylene mesh	30/164	4/113	
Guillilbert	2009	208	36	Polypropylene mesh awaiting raw data	24/77	7/40	
Chu	2011	91	9	Perigee & apogee Polypropylene mesh	5/39	2/52	
Neuman	2007	79	29	Posterior intravaginal slingplasty	6/44	4/35	
Total					97/505 (19.2%)	34/467 (7.3%)	<0.001

with no differences in the rate of complication (Tate) (Level 2). Concerning laparoscopic sacrocolpopexy, in a prospective comparative non randomised study, Deprest et al have shown that recurrences at the level of anterior and apical compartment occur significantly more often when using a biograft, in comparison to polypropylene [21% vs 3%, p<0.01 and 36% vs 19%, p <0.05, respectively] [Deprest 2009] [Level 3]. Partially absorbable composite meshes (polyglactin + polypropylene) also seems to increase the risk of short-term recurrences [Granese 2009] (Level 4).

The risk of vaginal mesh exposure seems to be higher with the use of polytetrafluoroethylene than with polypropylene meshes at ASC If you are going to abbreviate you must do it throughout or not at all [15% vs 0%, p=0.03] [Jeon 2009] (Level 4) and 19% vs 5% [Cundiff 2008] (Level 2). Similar results were observed with the use of silicon-coated polyester (19% vs 0%, p<0.05) [Govier 2005] (Level 4).

c) Choose the right fixation to the promontory, vaginal wall and levator ani

Most of authors perform a direct fixation to the vaginal wall using absorbable or non-absorbable sutures, and to the promontory using non-absorbable sutures [Agarwala 2007] [Rozet 2005] [Ross 2005] [Gadonneix 2004] [Antiphon 2004].

Fewer authors use staples for the mesh fixation, both to the vaginal wall and to the levator ani muscle [Cheret 2001] [Claerhout 2009], or tackers to the promontory [Maher 2004], with no specific reported complications. Several cases of spondylodiscitis were reported after the use of tackers to the promontory [Cosson 2001] however this complication also occurs if sutures are utilised. [Sergent 2011] [Rivoire 2007] [Ross 2005] [Antiphon 2004]. Whatever the fixation material use for the vaginal wall, the main method to prevent the occurrence of vaginal mesh exposure seems to avoid breaching the vaginal epithelium. [Paraiso 2005] [Cheret 2001] (Level 4).

d) Concomitant hysterectomy

The risk of vaginal mesh exposure is significantly increased in cases of sacrocolpopexy associated with concomitant total hysterectomy (8.6%), in comparison to 2.2% in those with previous hysterectomy [Wu 2006] [Stepanian 2008] [Cundiff 2008] [Nosti 2009] [Quiroz 2008] (Level 4), 1.5% at sacral hysteropexy and 1.7% subtotal hysterectomy [Jeon 2009] [Costantini 2005] [Bensinger 2005] (Level 4) (**Table 8 and10**).

12. PERITONEAL CLOSURE

Most of authors close the peritoneum after a sacrocolpopexy, both after open [Culligan 2005] [Wu 2006] [Stepanian 2008] [Maher 2004; Brubaker 2006] or laparoscopic approach [Maher 2011] [Rivoire 2007] [Rozet 2005] [Antiphon 2004].

13. TREATMENT OF VAGINAL MESH EXPOSURE

Vaginal mesh exposure, both after vaginal mesh surgery or sacrocolpopexy is usually associated with vaginal discharge, and sometimes pain, dyspareunia, vaginal infection, and rarely abscess or cellulitis [Deffieux 2007] [Costantini 2011] (Level 3).

The choice of treatment has to take into account the type of mesh implanted (need to obtain previous surgical records), clinical symptoms, location and size of exposure.

All cases with abscess or cellulitis need a immediate reoperation to withdraw the maximum (if possible all) of the foreign material.

In cases of mesh exposure after vaginal mesh surgery, if there is no abscess or cellulitis, medical treatment is usually undertaken using local oestrogens and/or local antiseptic. However, medical treatment efficacy is low at 23.5% as seen **Table 26**. [Withagen 2011] [Feiner 2010] [Moore 2010] [Achtari 2005] [Cervigni 2011] [Collinet 2006] After failure of medical treatment, a reoperation under local or general anesthesia is generally performed, in order to remove the exposed portion of the mesh and to close the vaginal epithelium.

In cases of mesh exposure after sacrocolpopexy, most of authors report a reoperation by the vaginal approach as first line [Wu 2006] [Stepanian 2008] [Claerhout 2009] [Kohli 1998] [Bensinger 2005] [Begley 2005], because of the risk of spondylodiscitis and of the very low success rate of medical treatment (<15%) [Price 2011] [Stepanian 2008] [Cundiff

Table 26. Efficacy of medical treatment for vaginal mesh exposure after vaginal mesh surgery

Author, Year	Mesh	Efficacy of medical treatment
Cervigni Natale, 2011	PP coated collagen (AVAULTA)	3/21

Abbreviation: PP, polypropylene

2008] [Lowman 2008]. When recurrence occurs after vaginal mesh excision, or in case of associated pelvic infection, total mesh removal by laparoscopy or laparotomy has been described [Quiroz 2008] (Level 4).

Conclusion

The use of mesh for pelvic reconstructive surgery is associated with a risk of specific complications, whatever the surgical approach and whatever type of mesh (**Level 1**).

Preoperatively, patients must be informed of these risks and give their consent for the use of a mesh. Patients must also be informed of conservative and alternative surgical techniques.

PROPOSED RECOMMENDATIONS TO REDUCE THE RATE OF COMPLICATIONS

Grade A

Transvaginal mesh have a higher re-operation rate than native tissue vaginal repairs.(grade A)

Grade B

Concerning Vaginal Surgery:

- If a synthetic mesh is placed by the vaginal route, it is recommended that a macroporous polypropylene monofilament mesh should be used.
- Polyester mesh is not recommended.

Concerning Sacral Colpopexy:

- It is recommended that the mesh should not be introduced or sutured by vaginal route when a sacral colpopexy is performed.
- The use of silicone-coated polyester, porcine dermis, fascia lata, and polytetrafluoroethylene meshes is not recommended.
- It is recommended to avoid total hysterectomy

Grade C

Whatever the Surgical Route:

- There is no evidence to recommend routine local or systemic oestrogen therapy before or after prolapse surgery using mesh.
- The first cases should be undertaken with the guidance of an experienced surgeon in the relevant technique.

Concerning Sacrocolpopexy:

- Laparoscopic approach is recommended for sacral colpopexy
- The use of polyester (without silicone coating) or polypropylene meshes is recommended.
- Suture of the meshes to the promontory can be performed using thread/needle or tacker.
- Reperitonealisation is recommended to cover the meshes.

.Expert opinion

Whatever the Surgical Route:

- As with any surgery, cessation of smoking preoperatively is recommended.
- It is recommended to comply with the prevention of nosocomial infections.
- Antibiotic prophylaxis is recommended, regardless of the approach.
- It is recommended that pre-operative urinary tract infections are identified and treated.
- It is recommended that the type and commercial name of mesh used in the operative report .

Concerning Vaginal Surgery:

- It is recommended that a non-absorbable synthetic mesh should not be inserted into the rectovaginal septum when a rectal injury occurs.
- The placement of a non-absorbable synthetic mesh into the vesicovaginal septum may be considered after a bladder injury has been repaired if the repair is considered to be satisfactory.
- It is possible to perform a hysterectomy in association with the introduction of a non-absorbable synthetic mesh inserted vaginally but this is not recommended routinely .
- It is recommended to minimise the excision of vaginal tissue.
- Currently, there are not sufficient data to recommend the use of a mesh kit rather a self-prepared mesh.

X. PELVIC ORGAN PROLAPSE AND SEXUAL FUNCTION

Sexual health is an essential component of a women's well-being. Female sexual dysfunction is defined as a sexual desire, sexual arousal, orgasm and /or sexual pain disorder which causes personal distress [Basson 2000]. Up to 64% of sexually active women attending a Urogynecology clinic suffer from female sexual dysfunction [Pauls 2006]. The data on sexual function after prolapse surgery are conflicting although in most cases sexual function will improve or remain the same.

Apart from anatomical outcome, clinicians increasingly understand the importance of functional data after POP surgery. To measure sexual function, validated questionnaires on sexual function

are necessary. Some validated quality of life and symptom questionnaires are inclusive of sexual function[Baessler 2010] or there are dedicated questionnaires specific to sexual function that provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ)[Rogers 2001] and the Female Sexual Function Index(FSFI) [Rosen 2000] are two questionnaires frequently used.

1. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITHOUT MESH

Overall, sexual function improves after prolapse surgery without mesh[Ghielmetti 2006; Rogers 2006; Komesu 2007]. In two randomized controlled trials, sexual function was measured after sacrospinous hysteropexy and vaginal hysterectomy. No differences were found between the two groups [Jeng 2005; Dietz 2010]. No validated questionnaires were used.

2. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH MESH

Increasing data on sexual function after mesh repair are becoming available. Excellent randomised controlled trials on efficacy of mesh prolapse surgery have been published and while most have not utilised validated questionnaires regarding sexual function most do include data on dyspareunia. Data from level 1 studies comparing transvaginal mesh and native tissue repairs are summarised in **Table 27**. When comparing sexual function in the anterior compartment with or without mesh, no differences in de novo dyspareunia, post-operative dyspareunia or PISQ scores were found [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Nieminen 2010; Altman 2011; Milani 2011; Vollebregt 2011]. Most women improved or remained the same. In one study by Vollebregt [Vollebregt 2011], baseline dyspareunia disappeared more often after anterior colporrhaphy than after mesh implant [80% vs 20%, p=0.018]. Natale et al showed that the use of Porcine dermis graft (Pelvicol), compared to polypropylene mesh (Gynemesh) in the anterior compartment, was associated with an improvement in the PISQ scores[Natale 2009]. Possibly, porcine dermis allows more flexibility to the anterior wall resulting is less pain, however this requires further evaluation.

In the posterior compartment, fewer RCT's have been performed comparing native tissue repairs to mesh repairs. Paraiso et al compared three techniques (posterior colporrhaphy, site- specific repair and use of porcine small intestine sub mucosa) [Paraiso 2006]. No differences in sexual outcome were found between the groups and PISQ scores improved after surgery in all three groups. Trials which analysed anterior and posterior mesh together also reported no differences in sexual outcome between native tissue and mesh repairs.[Iglesia 2010; Milani 2011; Withagen 2011]. Overall, after mesh surgery in the anterior and/or posterior compartment, de novo dyspareunia ranged from 5-28% of women [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Vollebregt 2011; Withagen 2011]. Data on the apical compartment using mesh showed less dyspareunia after abdominal sacral colpopexy as compared to vaginal sacrospinous colpopexy [Benson 1996; Maher 2004; Maher 2010].

Meta-analyses from all RCT comparing transvaginal mesh and native tissue repairs shown in **Table 25** demonstrated no difference in the rate of denovo dyspareunia (mesh 10.6% versus 11.8% native tissue),

Table 27 Meta-analysis sexual function data from randomized controlled trials comparing transvaginal mesh to native tissue repairs

post-operative dyspareunia (14.4% versus 12.5%), and PISQ scores (WMD 0.09 95% CI -0.17 to 0.36).

Although data from RCT's is valuable, sexual function was a secondary outcome measurement and most studies are underpowered to detect differences in sexual function. Therefore, reports from Level 3 cohort studies on the use of mesh were evaluated. The rate of de novo dyspareunia after anterior and/or posterior mesh in these cohort studies was comparable to the RCT's mentioned before and varied between 21-43% (**Table 28**) [Fayyad 2011; Milani 2011]. Milani et al stated that mesh should be abandoned because of high scores on dyspareunia [20% more dyspareunia after anterior mesh and 63% more dyspareunia after posterior Mesh)(Milani 2005]. However, when measuring sexual function with questionnaires, the impact of transvaginal meshes was variable with some demonstrating poorer sexual outcomes [Altman 2009; Su 2009; Wetta 2009][lower PISQ scores] and some improved outcomes or no change following surgery. [Moore ; Sentilhes ; Milani 2011; Sayer 2011]. Altman et all showed lower scores on sexual function one year after mesh surgery (anterior repair and posterior repair), however this was related to behavioral-emotional function and partner related items, not to physical function [Altman 2009]. Pain and dyspareunia before surgery with mesh was a risk factor for pain and dyspareunia after mesh surgery [Withagen 2011]. There is some evidence that light meshes, partly absorbable meshed or non anchored meshes have less negative side effects on sexual function, however comparitive studies or RCT's on this subject have not been performed [de Tayrac 2007; Zyczynski 2010; Milani 2011].

Recommendations

Grade B

With regard to the anterior compartment, the use of mesh is neither associated with a worsening in sexual function nor with an increase of de novo dyspareunia compared to traditional anterior colporrhaphy.

Grade D

There is insufficient information to provide evidence based recommendation on sexual function after vaginal mesh in the posterior compartment.

There is insufficient information to provide evidence based recommendation on sexual function after new light of partially absorbable vaginal meshes.

It is essential to use validated questionnaires measuring sexual function in women before and after prolapse surgery. We also recommend reporting sexual activity and dyspareunia rates pre and post intervention in all patients.

XI. ECONOMIC EVALUATION

Vaginal prolapse is an increasingly common problem affecting approximately 3-6% [Bradley 2008; Lawrence 2008] of community dwelling American women and the lifetime risk of surgery for pelvic organ prolapse varies between 6-19%. [Olsen 1997; Smith 2010]The need for pelvic organ prolapse surgery increases with age and it has been conservatively estimated that the surgical workload related to pelvic organ prolapse will increase by 46% over the next 4 decades as our population ages [Wu 2009]. Despite the high prevalence and frequency of surgery for POP, there is a little information on costs of medical care for this condition. A study in the United States (US) estimated that the direct costs of POP surgery were substantial accounting for $1012 million (95% confidence interval $775, 1251 million) for a total of 226,000 in patient surgical procedures during 1997[Subak 2001].

A European study showed that the number (rate) of admissions for POP surgery was 36,854/ 0.87 per 1000 women) in Germany, 36,679 (1.14 per 1000 women) in France, and 28,959 (1.13 per 1000 women) in England during the year 2005[Subramanian 2009]. The total costs were €144,236,557, €83,067,825, and €81,030,907 in Germany, France and England respectively which are also considered to be substantial and required more attention in order to decrease the burden on the countries studied.

Traditionally a Gynaecologists have based their decisions on surgical interventions upon the success rate, patient satisfaction, peri-operative morbidity and complications. With rising health care cost and in a setting of finite resources it is now imperative that clinicians include the financial costs of surgical interventions as a vital part of our decision making process. Despite considerable consumable costs there is a scarcity of cost effectiveness data on pelvic organ prolapse surgery.

Hullfish designed a study to compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy POP[Hullfish 2011]. The authors used a Markov decision analysis model to assess and compare the relative cost effectiveness of expectant management, use of a ring pessary, and Vaginal Reconstructive Surgery (VRS) and open or robotic sacral colpopexy for obtaining months of quality adjusted life over 1 year. Laparoscopy for prolapse and vaginal mesh kits were excluded as the authors do not utilise those two procedures at their institution and colpocleisis was excluded as the baseline case desired preservation of coital function. Only two decision alternatives were found to be cost-effective: pessary use and VRS. Pessary use achieved 10.4 quality-adjusted months at a cost of $10,000 per patient. This cost includes all events for patients initially assigned to pessary use including costs for those patients who eventually underwent to surgery within the 12-month time frame. The VRS alternative obtained 11.4 quality-adjusted months, at $15,000 per patient. Each of the other alternatives achieved fewer quality-adjusted months at greater cost.

Abdominal sacral colpopexy (ASC), in rudimentary analysis of inpatient cost has been shown to be more expensive than vaginal sacrospinous colpopexy for vault prolapse mainly reflecting the longer operating time and inpatient stay for the ASC. Two cost-minimisation studies have evaluated the relative inpatient cost of robotic sacral colpopexy (RSC), laparoscopic sacral colpopexy (LSC) and ASC [Patel 2009; Judd 2010] with both finding the ASC was the least costly inpatient option. Patel reviewed 15 cases, 5 each of ASC, LSC and RSC performed in Connecticut USA in 2008 [Patel 2009]. Results showed that ASC was the least expensive at $13,149, LSC $19.308 and RSC most expensive at $24,161. Importantly in this model there were no differences in length of stay and all procedures had long operating time with the robotic procedure being over 2 hours quicker than the laparoscopic procedures which does not reflect common practice in the literature.

Judd et al, using a decision model, estimated the hospital cost of ASC at $5792, LSC at $7353 and RSC at $8508 (excluding the cost of the robotic system)[Judd 2010]. In this model, RSC and LSC became cost equivalent only when robotic operating times was reduced to 149 minutes, robotic disposables were reduced to $2132 or laparoscopic disposables were increased to $3413. Both models of analysis only included inpatient care and may not reflect other benefits of minimally invasive approach such as quicker recovery and possibly faster return to work.

As already reported in the apical prolapse section of this document Parasio et al [Paraiso 2011] performed a RCT comparing RSC [38] and LSC [40] for vault prolapse and reported cost analysis alongside the clinical outcomes which the authors of this document would prefer to see as the standard reporting requirements. The robotic group incurred significantly greater cost than the laparoscopic group [mean difference +$1,936; 95% CI $417-$3,454; P=.008]. Importantly in this study the authors were experienced laparoscopic surgeons who had also completed the learning phase of the RSC.

Over the last decade both clinical efficacy and cost efficiency of the suburethral tapes in continence surgery has been demonstrated. Transvaginal mesh kits have been introduced to prolapse surgery in an attempt to replicate this benefit for the community. Unfortunately a paucity of cost analysis data is available for review. A study on the analysis of the cost-effectiveness of tradition-

al anterior colporrhaphy (AC), non kit mesh and commercial mesh kit for anterior vaginal prolapse repair showed that commercial mesh kits are not cost effective [Murray 2011]. The authors included estimated cost of managing recurrent prolapse and extrusions in the analytic model after performing a meta-analysis of 18 papers relating to anterior compartment repair to determine operating and admission time, recurrence rate and mesh extrusion rate for the three groups. The cost of non kit mesh was $3,380, AC was $3,461 and mesh kit $4,678. Non kit mesh repair is cost-effective, compared with AC, if extrusion rates remain below 25%. One way cost sensitivity analysis demonstrates that when the reoperation rate for AC reached 28% the commercial mesh kits became cost effective. The balance of cost of AC and non-mesh kits depends significantly on recurrence and extrusion rates. Two-way cost sensitivity analysis demonstrated that if re-operation rate of AC is below 20%, AC is more cost effective even if extrusion rate is 0%. When reoperation rate of AC is 30% the non-mesh kit repair is the most effective option if the extrusion rate is less than 25%.

Recently, Maher et al reported a cost minimisation analysis of a RCT comparing total vaginal mesh [TVM n=55] and LSC [n=53] in the management of vault prolapse at 2 years[Maher 2011]. The clinical outcomes have been reported in this document previously. Similarly to Hullfish's model above the authors captured inpatient, consumable and direct reoperation cost within the two year period. Opportunity cost defined as economic cost to the women associated with recovery time were added to above cost to define total economic cost. Mean total economic costs were significantly lower in the LSC group as compared to the TVM ($4,013.07 95% CI 3107.77, 4918.37). Labour costs were significantly greater for the LSC reflecting that the operating time was twice as long as compared to the TVM procedure. These higher labour costs were offset by lower consumable, inpatient, opportunity? and reoperation costs for the LSC as compared to the TVM.

One way cost analysis for the LSC and TVM demonstrates that cost equivalence would be achieved once the consumable cost reduced to zero, or the reoperation rate was zero in the TVM group or the operating time in the LSC was 130 minutes longer than the TVM. The cost model reported by Maher et al would provide an excellent model that all clinicians could utilise in audit and authors when reporting prolapse outcomes, by simply substituting their own institutions and community cost. The reporting of such cost analysis data is urgently required so that we can deliver efficient and cost effective pelvic organ prolapse procedures that our community requires.

Conclusion

In conclusion, despite the high prevalence and frequency of surgery for POP, there is little information relating to cost. Our findings can be summarised as:

- Economic cost of POP surgeries annually is significant in United States and Europe and over the next decades will grow at twice the rate of population growth due to our aging population
- Programs aimed at reducing the burden of this disease are urgently needed.
- In a single institution study vaginal reconstructive surgery and pessary use were more cost-effective than expectant management, traditional abdominal sacral colpopexy (ASC) or robot-assisted sacral colpopexy (RSC) (**Grade C**).
- Two studies have demonstrated that ASC has lower inpatient cost than LSC or RSC (**Grade C**)
- Data from a single RCT demonstrated the LSC to have lower inpatient cost than RSC specifically relating to lower operating time in the LSC group (**Grade B**)
- Data from a single RCT demonstrated LSC to be a more effective cost minimising surgery than total vaginal mesh for vaginal vault prolapse.(Grade B)
- Data from a meta-analysis of anterior vaginal compartment prolapse operations demonstrated that commercial mesh kits for anterior repair are less cost-effective than non kit mesh and anterior colporrhaphy. (**Grade B**)

I. INTRODUCTION

The definitions of anal incontinence and faecal incontinence, adopted at the previous consultations, [1] are maintained:

"Anal incontinence is the involuntary loss of flatus, liquid or solid stool that is a social or hygienic problem."

"Faecal incontinence is the involuntary loss of liquid or solid stool that is a social or hygienic problem."

There is no consensus on the best definition, anal incontinence or faecal incontinence, to use for an outcome in treatment trials or evidence to guide when one may be more appropriate; this impacts comparison and evaluation of study findings because different criteria for successful outcomes have been employed. The committee recommends that whichever outcome is used in studies and publications, the conceptual and operational definition be made explicit and used in a consistent manner. The terms anal incontinence and faecal incontinence are not synonymous. As the majority of intervention studies have focused on faecal incontinence rather than anal incontinence as an outcome measure, faecal incontinence is covered in this chapter, except where anal incontinence is specified.

This chapter addresses assessment and diagnosis, and conservative management, including medications, of faecal incontinence in adults and the impact of faecal incontinence on quality of life as assessed by qualitative methods. New to this chapter are the topics of faecal incontinence assessment and quality of life. The following related topics, some of which may have appeared in this chapter previously, are reviewed by other committees, often together with their urinary incontinence counterpart: epidemiology of faecal incontinence (Committee 1), faecal incontinence in frail or institutionalized older adults (Committee 11), faecal incontinence in persons with neurological disease or injury (Committee 10), faecal incontinence in children (Committee 9), surgical management of faecal incontinence (Committee 17), faecal incontinence management using technologies (e.g., products and devices) (Committee 20), and quality of life and faecal incontinence severity as measured by quantitative instruments of patient reported outcomes (Committee 5B), primary prevention of faecal incontinence (Committee 21). The one study of primary prevention of faecal incontinence (avoiding or delaying the initial occurrence) using conservative therapies [2] is included in this chapter.

As some knowledge gained in these specific groups may have applications to an adult population, the interested reader is encouraged to reviews the work of those committees. There is at present a relatively limited evidence base from high quality experimental trials of faecal incontinence, and it remains challenging to provide strong evidence for most interventions. However, expert consensus in this committee and the world literature is unanimous in recommending conservative interventions, singly or in combination, for the majority of patients with faecal incontinence as first-line management.

Conservative management is defined as a non-operative intervention designed to improve faecal incontinence incontinence or prevent deterioration. It includes pharmacological treatments. Reducing the severity and related complications of faecal incontinence are included from the view of conservative management outcomes rather than secondary and tertiary prevention. Patient selection for operative versus conservative management remains largely empirical. The committee recommends a trial of conservative management, in the vast majority of patients, before considering surgical options, because these conservative options are comparatively inexpensive and involve no significant morbidity (see algorithm). Exceptions would be patients with acute traumatic anal sphincter rupture or an endosonographically confirmed major defect in the external anal sphincter in the presence of gross faecal incontinence: these patients would be referred for surgical evaluation as first line treatment.

II. CLINICAL ASSESSMENT

Normal anorectal physiologic function is complex and relies on a several different factors, including

anatomic and neurology factors. Consequently, anorectal dysfunction may affect all ages [1] and symptoms necessitate careful clinical assessment and sometimes specialised tests to assess the background to patients' symptoms. Several different questionnaires and tests are used and they are frequently used in conjunction with each other, but the clinical utility is sometimes limited.[2, 3]

1. SEARCH STRATEGY

The following search terms were used for PubMed, Web of Science and Cochrane reviews: faecal incontinence, anal incontinence, symptoms, signs, clinical assessment, history, examination, digital examination, clinical features.

2. HISTORY

History gathering requires sensitivity in dealing with this taboo symptom, but also a willingness to ask direct questions about the complaint. Although there are questionnaires about the severity of faecal incontinence or anal incontinence and their impact on quality of life (See Chapter 5B), they are most often used in research and sometimes in clinical practice. Currently there are no uniform set of questions to elucidate the comprehensive set of factors involved in faecal incontinence, and recommended approaches of experts [3] and clinical experience continue to guide practice. In taking a history, the necessary first step is to determine the nature of the incontinence being experienced by the patient. The aim of a history and examination is to identify conditions that are amenable to management and to characterise symptoms so they might be reduced.

a) Type of incontinence

Additional characteristics of faecal incontinence or types of incontinence other than faecal and anal may be identified during assessment. *Passive faecal incontinence* is the involuntary soiling or leakage of faeces without forewarning of the patient. *Flatus incontinence* is the inability to control flatus. *Passive and flatus incontinence* are frequently related to internal anal sphincter dysfunction.[4] *Urge incontinence* is an inability to defer defecation once the urge is perceived, for long enough to find a toilet. *Soiling after defecation* can also occur, and is typically related to either a defect in the internal sphincter or poor "snapping shut" of the external sphincter after voiding.[5] It is also important to determine if the incontinence is for liquid stool only, and, if so, then the possibility of a colonic cause of diarrhoea needs to be considered.[6]

b) Etiology

The history of faecal incontinence should include questioning about its potential etiology:

- Dietary history - including intake of caffeine and sorbitol as they may stimulate GI transit or diarrhoea.[7] **(Recommendation Grade C)**
- Medical history – particularly anti-anginal and antihypertensive medications which may reduce sphincter tone and ferrous sulphate or antacids which may provoke diarrhoea.[8] **(Recommendation Grade C)**
- Presence of benign anal disease – haemorrhoids, fistula, anal warts.[9] **(Recommendation Grade B)**
- History of chronic straining or constipation.10 **(Recommendation Grade B)**
- Obstetric history[11] **(Recommendation Grade B**)- particularly with regard to number of vaginal deliveries, need for forceps or Ventouse, birth weights of all children, duration of second stage(s) of labour, episiotomy
- Perianal surgery history [12,13] **(Recommendation Grade B)** particularly:
- Anal fissure surgery (sphincterotomy or anal stretch), fistula surgery, rectal resection surgery
- History of pelvic radiation – due to risk of radiation proctitis (that can cause decreased rectal compliance) and internal anal sphincter radiation damage.[14] **(Recommendation Grade B)**
- Symptoms of other pelvic floor problems (urinary incontinence and pelvic organ prolapse), which have similar risk factors [15] **(Recommendation Grade C)**
- Cognitive assessment in appropriate patients [16] **(Recommendation Grade C)**

3. PHYSICAL EXAMINATION

a) General, perianal, and digital rectal exam

Examination is focused towards the detection of evidence of incontinence and identifying the cause of incontinence, if possible. Physical examination should include inspection of underclothing for soiling and staining by stool, pus, or mucus. Perianal skin should be examined for signs of irritation such as erythema, rash, and excoriation [17] **(Recommendation Grade C)**. Perianal inspection should also include attempts to identify a patulous anus or one which gapes on gentle traction of the anal verge and/or a "keyhole" deformity of the anal canal which suggests a persisting sphincter defect [18-20] **(Recommendation Grade B).** Inspection may reveal scars from previous episiotomies or obstetric tears. Abnormalities at the anal verge from previous surgery or a gaping anus suggestive of marked loss of function may be present. Perianal inspection or digital rectal examination should identify the following [14,18,20] **(all recommendations Grade C)**:

- Scars from previous surgery
- Perianal disease – prolapsing haemorrhoids, fistula, anal warts

- External prolapse at rest
- Absence of perineal body – suggestive of obstetric trauma; at its worst this may manifest as a cloacal deformity
- Inspection for sphincter asymmetry whilst patient contracts sphincter – suggestive of regional sphincter defect
- Function of the puborectalis muscle (palpable at the anorectal junction) -- assessed by asking the patient to squeeze the sphincter at which time the puborectalis should push the examiner's finger anteriorly.

Digital examination should also assess for [18-20] **(all recommendations Grade C)**:

- Rectal contents – if faecal impaction is present this could explain incontinence
- Resting tone – indicative of internal anal sphincter function
- Voluntary and reflex squeeze pressure – indicative of external anal sphincter function and potential function, respectively. The latter is elicited most commonly by asking the patient to cough while assessing sphincter tone – a cough causes a reflex near-maximal external sphincter contraction (analogous to the guarding reflex in the bladder)
- Regional sphincter defects – detected as asymmetry
- A thickened sphincter – suggestive of chronic straining and occult rectal mucosal prolapsed
- Paradoxical puborectalis contraction – this may be valuable in assessing constipated patients to identify paradoxical contraction as a cause of retained stool, and hence overflow incontinence

True faecal incontinence must be differentiated from conditions that cause seepage such as prolapsing external haemorrhoids, fistulas, low rectal or anal tumors, and poor perineal hygiene. Diagnostic administration of an enema may be useful in this respect; retention of the enema suggests that the patient does not have clinically significant faecal incontinence. This serves to both clarify the patient's history, but also begins to suggest the anatomical deficit causing the incontinence.

If suggested by earlier findings (history of straining, thickened sphincter), the patient should be asked to sit on a commode and attempt voiding – the perineum should then be inspected for evidence of a rectal mucosal or full thickness prolapsed on straining10 **(Recommendation Grade C)**.

b) Proctoscopy

Proctoscopy with a rigid instrument, or flexible sigmoidoscopy, is a bedside test of value in excluding potentially treatable causes of faecal incontinence: anal tumors or polyps, rectal cancers or adenoma [21] **(Recommendation Grade B)**, solitary rectal ulcer syndrome – a functional disorder of evacuation, in which repeated straining at stool and or rectal self-digitalization may result in an ulcerated area of the anterior rectal wall [22] **(Recommendation Grade B)**.

c) Vaginal examination

Vaginal examination using a Simms speculum may show a rectocele, cystocele and/or uterine prolapse, all of which may contribute to developing faecal incontinence [23] **(Recommendation Grade C)**. Physiological and complimentary radiological tests are used to confirm clinical suspicions and provide objective data on the function of the anorectum. Pelvic floor dysfunction is a complex problem and multiple tests may be needed based on the initial findings and complexity of the planned intervention.

d) Recommendations for practice

- Perform a baseline assessment including a focused medical history, a general physical examination, and an anorectal examination with inspection of perinanal skin. **(Recommendation Grade B-C)**
- Several conditions should be specifically assessed for in the history and physical examination, as they may be amenable to definitive treatment, including rectal prolapse, haemorrhoids, faecal loading, potentially treatable causes of diarrhoea (e.g., Inflammatory bowel disease and irritable bowel syndrome, infection, adenomas), acute anal sphincter injury, and acute disc prolapse/cauda equina syndrome. **(Recommendation Grade B)**
- Conduct a digital exam **(Recommendation Grade C)**
- Perform a proctoscopy **(Recommendation Grade B)**

e) Recommendations for research

- Assess inter-rater variability of digital rectal examination
- Assess positive and negative predictive value of digital rectal examination to diagnose pelvic floor diseases associated with faecal incontinence

III. SPECIALIZED TESTING

1. ANORECTAL MANOMETRY

a) Indications

Anorectal manometry measures the pressures in the anal canal and the distal rectum. This test

serves as one of the most accepted and used investigations to measure the function of the internal anal sphincter and the external anal sphincter. Evaluation of the sphincter function in patients with faecal incontinence is the primary indication for manometry [24-26] **(Evidence Level 2)**. However, preliminary evidence suggests that rectal sensation should be treated as well.[27]

b) Equipment and testing

Anorectal manometry can be performed with different types of catheters, including solid state, water perfused, air charged, or microballoon catheters. [28] The diameter of the probe should not exceed 5-6 mm and the probe usually includes sensors radially distributed to measure several pressures at each level. Any manipulation of the rectum, such as digital rectal examination or administration of enema prior to a test should be followed by a minimum of 5 minutes of rest to allow sphincter activity to return to baseline.

The stationary pull-through technique is today commonly used, since this technique avoids the reflex sphincter contraction caused by some dynamic techniques. The stationary pull-through measures the resting pressure and the squeeze increase at 6, 5, 4, 3, 2, and 1 cm from the anal verge by extracting the probe in increments of 1 cm from the rectum to the anal verge. Allowing a waiting period between each measurement minimizes artifacts.

c) Anal resting pressure

The anal resting tone is a composite pressure generated by the internal anal sphincter (55%), external anal sphincter (30%) and the anal cushions (15%). [29] There is some radial asymmetry in pressures in the different parts of the anal canal [30] and therefore the pressures in the four quadrants is usually averaged to account for this asymmetry.[25] New equipment provides a more precise measurement of radial asymmetry, but more complete evaluation of this high resolution technique is still lacking. The length of the functional anal canal or high pressure zone is defined as the length of the anal canal with resting pressures exceeding 30% of the rectal pressure.[31]

Patients with faecal incontinence usually have a lower anal resting tone than continent patients or normal controls **(Evidence Level 2)**. [24,32] The degree of faecal incontinence will however not only depend on the anal sphincter tone, since there are many other factors (i.e. stool consistency, rectal compliance, etc.) that play an important role. There is also a lack of defined values of what is the normal range for the anal resting tone.

d) Squeeze increase

The squeeze increase of the anal canal pressure is generated by contraction of the external anal sphincter and can be calculated as the increase in pressure from the anal canal resting tone during maximal anal squeeze. The squeeze increase is also usually measured at 6, 5, 4, 3, 2, and 1 cm from the anal verge with the stationary pull through technique. Decreased squeeze pressures are frequently correlated to injuries in the external anal sphincter, neurologic damage or just poor patient compliance/ voluntary control.

The fatigability of the external anal sphincter can be estimated by measuring the patients' ability to sustain the squeeze effort over time. The squeeze duration is often reduced in patients with incontinence. The squeeze durability may be measured as a fatigue index.[33]

e) Recto-anal inhibitory reflex

Rectal distension or attempted defecation results in an inhibition the tonic activity of the internal anal sphincter and relaxation of this muscle. Presence of an intact internal anal sphincter is dependent on an intact myenteric plexus and it is usually impaired in patients with severe constipation due to Hirschsprung's disease. The value of react-anal inhibitory reflex testing in patients with faecal incontinence is limited.

f) Rectal sensation and compliance

Rectal sensation (and rectal compliance) can be measured by intermittent balloon distension in the distal rectum and simultaneously monitoring the patient's response. The first sensation, the first urge and the maximal tolerable volume are usually recorded. Rectal compliance can also be assessed by measuring the pressure and volume relationship when a balloon is inflated in the rectum.

Reduced sensory threshold levels of the rectum (rectal hypersensitivity) in patients with faecal incontinence could indicate a presence of urge faecal incontinence and increased frequency of defecation [34,35] **(Evidence Level 3)**, whereas incontinent patients with increased sensory threshold levels (rectal hyposensitivity) may suffer from passive (overflow) incontinence [36] **(Evidence Level 3)**.

g) Recommendations for practice

- Anorectal manometry can objectively assess anal sphincter function in patients with faecal incontinence. **(Recommendation Grade C)**
- Focused expertise to perform manometry is required; each center/laboratory should establish its own control values for anorectal manometry and check for reproducibility of the test. **(Recommendation Grade B)**

h) Recommendations for research

- Assess normal values for rectal manometry in large healthy control samples spanning all ages to serve as comparisons for abnormalities in faecal incontinence

- Assess capability of an-rectal physiology testing results (anal pressure-rectal sensation-compliance) on predicting outcomes of medical and/ or surgical treatments for faecal incontinence
- Assess rectal manometry reproducibility in large control and patients samples
- Evaluate the utility of high definition and high resolution manometry in the assessment of patients with faecal incontinence

2. ENDOANAL ULTRASOUND IMAGING

a) Introduction

Endoanal ultrasound (EAUS) is established as am important part of a colorectal diagnostic work-up [37] and has been recommended as the gold standard investigation to identify anal sphincter injury by the International Urogynecological Association/ International Continence Society joint report.[38]

b) Endoanal ultrasonography technique

EAUS is usually performed with high multi-frequency (9-16 MHz), 360° rotational mechanical probe or radial electronic probe (frequency: 5-10 MHz). During examination, the patient may be placed in the dorsal lithotomy, in the left lateral or in the prone position. However, irrespective of the position, the transducer should be rotated so that the anterior aspect of the anal canal is superior (12 o'clock) on the screen, right lateral is left (9 o'clock), left lateral is right (3 o'clock), and posterior is inferior (6 o'clock). The length of recorded data should extend from the upper aspect of the PR to the anal verge.

Three-dimensional (3D) EAUS offers a synthesis of a high number of parallel transaxial 2D images and it is possible to analyze coronal, anterior-posterior, or posterior-anterior as well as sagittal right-left views, together with any oblique image plane. The 3D image can be rotated, tilted, and sliced to allow the operator to infinitely vary the different section parameters. Volume Render Mode (VRM) is a special feature that can be applied to high-resolution 3D data volume so information inside the cube is reconstructed to some extent. The volume-rendered image provides better visualization performance when there are not large differences in the signal levels of pathologic structures compared with surrounding tissues.[39]

With EAUS, the anal canal is divided into three levels of assessment. The upper level corresponds to the hyperechoic sling of the puborectalis muscle and the concentric hypoechoic ring of the internal anal sphincter. In males, the deep part of the external anal sphincter is also identified at this level. The middle level corresponds to the complete ring of the superficial external anal sphincter (concentric band of mixed echogenicity), the conjoined longitudinal layer, the complete ring of internal anal sphincter, and the transverse perinei muscles are visualized. The lower level corresponds to the subcutaneous part of the external anal sphincter.

c) Endoanal ultrasonography in faecal incontinence

EAUS has become the gold standard for the morphological assessment of the anal canal. It can differentiate between incontinent patients with intact anal sphincters and those with sphincter lesions (defects, scarring, thinning, thickening, and atrophy) due to vaginal delivery or anal surgery (i.e., hemorrhoidectomy, sphincterotomy, fistula surgery).[40]

Tears are defined by an interruption of the circumferential fibrillar echo texture. Scarring is characterized by loss of normal architecture, with an area of amorphous texture that usually has low reflectivity. The operator should identify if there is a combined lesion of the internal anal sphincter and external anal sphincter or if the lesion involves just one muscle. The majority of lesions of the internal anal sphincter are easily recognized given the prominent appearance of the internal anal sphincter in the mid anal canal, and they appear as hyperechoic breaks in the normally hypoechoic ring. The appearance of an external anal sphincter defect is a break in the circumferential integrity of the mixed hyperechoic band. A defect can have either a hypoechoic or a hyperechoic density pattern. This corresponds to replacement of the normal striated muscle with granulation tissue and fibrosis. A limitation of EAUS remains the identification of external anal sphincter atrophy in patients with idiopathic faecal incontinence because of the vague contours of the muscle ring.

The number, circumferential (radial angle in degrees or in hours of the clock site) and longitudinal (proximal, distal or full length) extension of the defect should be reported. In addition, 3D EAUS allows to measure length, thickness, area of sphincter defect in the sagittal and coronal planes and volume of sphincter damage.[40,41] Two scoring systems have been proposed to define the severity of the sphincter damage.[42,43] Both systems have demonstrated a good intraobserver and interoberver agreement in classifying anal sphincter defects. [41,44]

EAUS has an important role in detecting clinically occult anal sphincter injuries after vaginal delivery. [45,46] In another study, Oberwalder et al.[47] reported that faecal incontinence related to sphincter lesions is likely to occur even in an elderly population of women who experienced vaginal deliveries earlier in life. They found that 71% of women with late-onset faecal incontinence (median age 61.5 years) had occult sphincter defects on EAUS.

Ultrasonographic imaging is useful to evaluate the result of treatments. Dobben et al.[48] reported that patients with a persistent ultrasonographic external anal sphincter defects after sphincteroplasty had a worse clinical outcome than those without an external anal sphincter defect. Using 3D-EAUS, de la Portilla et al. [49] demonstrated that all the implants of silicone to treat faecal incontinence were properly located in the intersphincteric space three months after injection.

d) Alternative Ultrasound Modalities in Faecal Incontinence

1. Transperineal ultrasonography

Perineal ultrasound is performed with the patient placed in the dorsal lithotomy position. Conventional convex transducers (main frequency between 3 and 6 MHz, field of view at least 70°) are applied in the perineum between the mons pubis and the anal margin.[40,41] Perineal ultrasound provides sagittal, coronal and oblique sectional imaging, with the mid-sagittal plane the most commonly used as this gives an overall assessment of all anatomical structures (bladder, urethra, vaginal walls, anal canal and rectum) between the posterior surface of the symphysis pubis (SP) and the posterior part of the levator avulsion (LA). The imaging is usually performed at rest, on maximal Valsalva maneuver and on pelvic floor muscle contraction. The access to the mid-sagittal plane allows the following evaluation of the integrity of the perineal body, measurement of ARA, and dynamic assessment of the posterior compartment.

3D perineal ultrasound imaging may be performed with volumetric probes developed for obstetric imaging. The most important clinical application is the assessment of LA injuries. At these injuries, the muscle disconnects from its insertion on the inferior pubic ramus and the pelvic sidewall and is a common consequence of overstretching during the second stage of labor.[50,51]

2. Endovaginal Ultrasonography

Endovaginal ultrasound is performed with the patient placed in the dorsal lithotomy position. The most frequently used transducer for pelvic floor 3D transvaginal ultrasound is a high multi-frequency (9-16 MHz), 360° rotational mechanical probe. The pelvic floor is divided into four levels of assessment.[52] At level I, the bladder base is visualized on the screen in the 12 o'clock position and the inferior third of the rectum in the 6 o'clock position. Level II corresponds to the bladder neck, the intramural region of the urethra and to the anorectal junction. Level III: corresponds to the midurethra and to the upper third of the anal canal. Level IV corresponds to the perineal muscles, the perineal body, the distal urethra and the middle and distal third of the anal canal.

e) Summary of Evidence

- EAUS is considered as an integral part in the investigation of faecal incontinence. **(Evidence Level 2).**

f) Recommendations for practice

- EAUS is an important part in the assessment of patients with faecal incontinence, since the examination will define the possible presence of anal sphincter injuries. **(Recommendation Grade A)**
- Pelvic floor ultrasound may define conditions, for instance, rectal intussuception, and enterocele, which may play a role in patients' faecal incontinence symptoms. **(Recommendation Grade C)**

g) Recommendations for research

- Evaluate the role of levator ani damage, visualized with pelvic floor ultrasound, on faecal incontinence symptoms and therapy results
- Further characterize and standardize the utility of pelvic floor ultrasound in patients with faecel incontinence.

3. MAGNETIC RESONANCE IMAGING

a) Introduction

Recently, there has been evidence to show that magnetic resonance imaging (MRI) is accurate in detecting external anal sphincter defects potentially suitable for repair in patients presenting with faecal incontinence [53-66] **(Evidence Level 2)**. MRI can be performed with endoluminal MRI technology or surface phased-array antennas. MRI is an alternative, with relative accuracy in the detection of external anal sphincter defects, although there is reduced local spatial resolution using this technology and less experience in the specific assessment of external anal sphincter defects.[67-71] Recently, there has been evidence to show that the longer-term functional outcome following sphincteroplasty for obstetric-related external anal sphincter defects (the principal cause of clinical faecal incontinence in this population) is somewhat dependent upon the presence of attendant pudendal neuropathy [72-74] and that worse outcome is correlated with neuropathy-associated external anal sphincter atrophy. [75-77] This technique has also been shown to accurately identify external anal sphincter atrophy in comparison with endoanal ultrasound.[78,79]

b) Normal anal sphincter anatomy at MRI

The bulk of useful images are obtained with T2-weighting where contrast is described in relation to the surrounding structures, as there are no absolute values for tissue contrast (as there are, for example in computed tomography). In a series of 100 normal volunteers, age- and gender-related differences are demonstrable on endoanal MRI,[80] as women have a significantly shorter external anal sphincter than men.

c) Anal sphincter defects on MRI

External anal sphincter lesions are detected as alterations in the normal external anal sphincter anatomical integrity or as scarring, local atrophy, or a definitive defect. The full extent damage is best appreciated in a combined evaluation of the axial and longitudinal plane sequences. Secondary changes to the architecture of adjacent structures (longitudinal muscle, perianal fat) provide

supportive evidence of a sphincter tear. Variations in normal anatomy of the anal sphincter may be misdiagnosed as sphincter defects, with constitutive differences in the external anal sphincter being observed.

Internal anal sphincter defects are identified as either internal anal sphincter discontinuity or as replacement of the normal smooth muscle by fibrous tissue with concomitant muscle thinning. Internal anal sphincter defects are often found in combination with external anal sphincter defects, especially in women presenting with incontinence. Solitary internal anal sphincter defects are more common in iatrogenic cases of incontinence.

Several studies have evaluated the accuracy of endoanal MRI in detecting anal sphincter defects. Tears of both the internal anal sphincter and external anal sphincter are readily visualized, with an accuracy of 95% for external anal sphincter lesions.[56,58,63]

d) Anal sphincter atrophy at MRI

Recent publications on endoanal MRI imaging reemphasize the importance of external anal sphincter atrophy with its potential predictive clinical implications on sphincteroplasty outcome. [54,56,58,81]

e) Role of MRI in the assessment of faecal incontinence

EAUS can be used as a primary imaging technique, given the similar results when compared with endoanal MRI in detecting sphincter defects, the widespread availability of endoanal ultrasound, and the lower costs. There is no doubt, however, that endoanal MRI technology is accurate. Its role in defining and diagnosing external anal sphincter atrophy can both direct sphincter repair and provide some prognostic information.

f) Recommendations for practice

- The place for MRI assessment of anal sphincters is limited. **(Recommendation Grade D).**
- Patients with faecal incontinence after repeated anorectal surgeries may benefit from assessment with MRI. **(Recommendation Grade C)**
- Patients with possible, but not proven, external sphincter defect on ultrasound may benefit from further assessment with MRI. **(Recommendation Grade C)**

g) Recommendations for research

- MRI can define atrophy of the anal sphincter muscles. Study to assess the degree of atrophy influences the outcomes after treatment with surgical sphincter repair and sacral nerve stimulation.

4. DEFECOGRAPHY

a) Introduction

Defecography, also termed as evacuation proctography, is the radiological assessment of the voluntary rectal evacuation of semisolid contrast material, and provides information on anorectal structure and function. It is useful and widely used in the diagnosis and management of obstructed defecation, but the technique is less often utilized in the assessment of faecal incontinence. [82-84] Rao [85] did not include defecography in commonly performed diagnostic tests for faecal incontinence in an evidenced-based summary and American Gastroenterological Association medical position statement [86] concluded that defecography is not of established value in patients with faecal incontinence. Whitehead et al.[87] concluded that defecography is useful in the assessment of perineal descent, pelvic organ prolapse, rectocele, defecation and puborectalis contraction, but they did not include it in the algorithm for the diagnosis and management of faecal incontinence.

On the other hand, defecography was used by 56% of physicians in the routine diagnostic work-up of patients with faecal incontinence in a recent Dutch study.[88] There are several studies reporting that surgical correction of rectal intussusception [89-92] or rectocele [93,94] result in improved faecal incontinence.[93,94]

There is a suboptimal correlation between symptoms and defecographic findings. Abnormal findings of defecography can be seen in many normal subjects without any anorectal symptoms.[86,95-98] Another problem in performing defecography in patients with faecal incontinence is that those with weak anal sphincters have problems retaining the semisolid contrast material in the rectum when seated on a commode.

b) Examination technique

There are no universally consented standard methods of defecography. Usually, a viscous barium contrast material is injected into the rectum of the patient in the left decubitus position. The semi-solid contrast material can be made by mixing barium with flour, oatmeal or mashed potato. The volume of the injected material is either fixed at around 150ml or up to the volume at which the patient feels the urge to defecate. A radiopaque marker can be placed close to the anus to facilitate interpretation. Barium contrast in the vagina facilitates interpretation of enterocele and prolapse in the anterior and middle compartments.

The patient sits on a commode attached to the footboard of the fluoroscopy table and lateral views of the film are taken at rest and maximum squeeze before rapid film sequences are taken at one frame per second during evacuation, followed by a film taken after the completion of the evacuation at maximum straining. The sequential films is usually by a video recording; cinedefecography.

c) Parameters studied at defecography

The anorectal junction is the distally tapered point of the rectal contrast column caused by posterior impression of the puborectal muscle. The anorectal angle (ARA) is measured by the angle between the line along the anal canal and the axis of the rectum. Normal subjects should be able to evacuate more than two thirds of rectal contrast material within 30 seconds. In addition to assessing rectal evacuation, defecography can reveal rectal intussusception, rectocele, sigmoidocele and enterocele. Rectal intussusception is defined as the invagination of the rectal wall into itself and the degree of rectal intussusception can be classified by Oxford. [89] Rectocele is defined as the outpouching of the anterior rectal wall beyond the normally expected anterior rectal wall at straining. Sigmoidocele and enterocele are defined as the herniation of the lining of the peritoneum by the sigmoid colon or the small bowl, respectively, into the rectovaginal septum and may push on the anterior rectal wall.

Perineal descent may be a sign of the weak pelvic floor muscles and possible pudendal neuropathy. An obtuse ARA implies weakening of the puborectal muscle and possibly the entire pelvic floor muscles. In a study by Piloni et al.,[99] the mean ARA at rest differed significantly between patients with faecal incontinence and those without. The normal range of ARA, however, is wide and some patients with normal ARA are incontinent to stool, whilst some with abnormally obtuse ARA are continent.

Karasick[100] stated that the major indication for performing defecography in patients with faecal incontinence is to diagnose rectal intussusception **(Evidence Level 3)**. Collinson et al.[89] performed defecography in 40 patients whose faecal incontinence could not be explained by anorectal physiology and endoanal ultrasound, recto-anal intussusception was observed in 63% of the patients. Surgical correction of rectal intussusception has been shown to improve faecal incontinence, indicating a possibility that rectal intussusception can be a cause of faecal incontinence **(Evidence Level 3)**. Lazorthes et al.[90] performed defecography in 51 patients with faecal incontinence. Fourteen patients had a recto-anal intussusception and were operated with transabdominal rectopexy. Faecal incontinence improved in all 14 patients and completely resolved in 6 patients. When Collinson et al.[89] performed laparoscopic ventral rectopexy in 24 patients with rectal intussusception and a combination of obstructed defecation and faecal incontinence, incontinence symptoms significantly improved in 92% of the patients.

It is more controversial whether a rectocele can cause faecal incontinence **(Recommendation Grade C)**. Collinson el al.[89] claimed that one of its mechanisms is faecal trapping in the rectum that allows post-defaecatory leakage to occur.

d) Recommendations for practice

- Defecography is of limited value and not always utilized in the diagnosis and management of faecal incontinence. **(Recommendation Grade B)**
- Defecography can be useful in the diagnosis and management of faecal incontinence by measuring perineal descent and ARA, evaluating involuntary leakage of the contrast material as well as diagnosing rectal intussusception and rectocele. **(Recommendation Grade B)**
- Defecography might be useful in diagnosing the existence and extent of rectal intussusception and rectocele as a cause of faecal incontinence. **(Recommendation Grade B)**

e) Recommendations for research

- Identify and characterize the degree of rectal intussusception and prolapse at defecography and correlate this to treatment outcomes after ventral rectopexy.
- Defecography may be superseded by magnetic resonance imaging (MRI) defecography, which can visualize the pelvic floor and organs as well as avoids radiation exposure.[101-103] The latter technique is, however not widely available at present, because of higher cost and most equipment does not allow examination in the sitting position.[83,104] Further investigation is needed to determine whether an open-magnet unit of MRI may solve this postural problem.

5. CLINICAL NEUROPHYSIOLOGIC TESTING

a) Introduction

The clinical use of neurophysiologic testing in patients presenting with incontinence has a long history, but appears to be diminishing in practice because of improvements in clinical sphincter imaging and as a result of the understanding that some neurophysiologic parameters have only minimal influence on decision-making.[105,106] Despite the rise of sacral neuromodulation (SNS) in the selective management of incontinent patients, there is no clear guideline for specific predictive neurophysiologic testing,[107,108] relegating its specific use in complicated cases of incontinence secondary to particular neurological diseases and following spinal injury.

b) Types of neurophysiologic testing for faecal incontinence

Neurophysiologic testing for faecal incontinence incorporates a range of different testing modalities, including somatic motor testing, somatosensory testing, determination of clinical reflexes, and autonomic nervous system (ANS) testing. Somatic

motor testing assesses the somatic nervous system responsible for skeletal muscle motor innervation plus sensory innervation from cutaneous sites to the muscle spindles. This testing incorporates all forms of electromyography (EMG), including pudendal terminal motor latency studies (PNTML), motor nerve conduction studies, and motor evoked potentials. Somatosensory testing includes somatosensory evoked potentials and sensory neurography. ANS testing: assesses the ANS which provides motor innervation to the viscera and other end-organs and which assess its visceral afferent pathways at peripheral, spinal and supraspinal levels

c) Elelectromyography

The specific use of this EMG technology in faecal incontinence in the past was for the differentiation of those patients with potential voluntary sphincter defects from those without sphincter defects thought to be reparable but who had an attendant presumptive neurological cause for their incontinence. Concentric needle electromyography (CN-EMG) is performed with single- use needles used at multiple sites. Inherent differences exist at rest in sphincter musculature when compared with peripheral (non-sphincteric) musculature showing basal resting activity whereas non-sphincter musculature is electrically silent. [109,110] Denervation is diagnosed as a reduction in the number of continuously firing low-threshold MUPs. CN-EMG has disappeared with improved accurate sphincter imaging; however, it may have a specific place in those patients where ultrasonography and/or MR imaging is equivocal. Single Fibre EMG (SF-EMG) has a smaller recording surface with a pickup of activity from a smaller muscle volume than that recorded with CN-EMG, recording generally 1-3 single muscle fibres from the same MU.

d) Pudendal nerve conduction testing

Pudendal nerve conduction testing measures the nerve conduction velocity in the pudendal nerve. There is a customized (Dantec Electronic Tonsbaaken 16-18 DK-2740 Skovlunde, Denmark) St. Mark's electrode that has been designed. Prolongation of the pudendal nerve terminal motor latency (PNTML) is common after vaginal delivery and with aging. [111-113] It has been suggested that the delay in PNTML is associated with a worse overall prognosis of external anal sphincter repair for patients presenting with faecal incontinence, [75-77] although there is little available evidence to suggest that PNTML measurement alters specific surgical decision-making. [114] There is little available evidence that the presence or extent of a pudendal neuropathy correlates with objective incontinence[106] or with the specific response to biofeedback therapy with or without the presence of an external anal sphincter defect. [115]

e) Sensory system testing

Anorectal sensitivity plays a significant role in the defecation process and in maintaining faecal continence. Variation in anorectal sensibility is also important in pain disorders and in irritable bowel syndrome. Basic sensory testing of light touch and pinprick and sensation of bladder filling is standard. The ano-cutaneous sensation of the perianal area and in the anal canal below the dentate line is conveyed by the efferent fibers of the pudendal nerve (S2-S4).[116]

f) Anal mucosal electrosensitivity

Anal mucosal electrosensitivity (MES) testing was originally described independently by Roe et al.[117] and Siegel [118] using two electrodes with a constant square wave of current with variable intensity. It is unknown precisely which receptors are involved in this standardized and reproducible response.[119] Incontinent patients invariably have a high MES whereas patients with anal sphincter defects, (with or without faecal incontinence), show an increased MES with the highest values found in patients with a combined internal anal sphincter and external anal sphincter sphincter defect.

g) Recommendations for practice

- Neurophysiologic testing is of limited value in the assessment of patients with faecal incontinence. **(Recommendation Grade C)**
- PNTML may be useful in the preoperative assessment of patients before sphincteroplasty or sacral nerve stimulation. **(Recommendation Grade C)**
- PNTML may be useful in the assessment of patients with possible pudendal neuralgia. **(Recommendation Grade D)**
- CN-EMG may have a specific role when ultrasonography and/or MR imaging is equivocal. **(Recommendation Grade D)**

h) Recommendations for research

- Assess reproducibility of testing of anorectal sensation on predicting outcome of surgical and medical treatment for faecal incontinence in large patient samples

IV. EDUCATION AND LIFESTYLE INTERVENTIONS

1. BACKGROUND

Most patients with faecal incontinence do not know how the bowel works and what might improve bowel function. Many patients also have attitudes toward defaecation that are influenced by stigma and taboos present in their particular family and their wider cultural group within a society.[120] Expert opinion supports the use of general health education, patient teaching about bowel function and advice on lifestyle modification,[121,122] but the evidence

base is small. Little is known about whether interventions designed to modify lifestyle factors might improve faecal incontinence.

2. SEARCH

Because a small number of studies on these topics were identified in past reviews, two independent searches using their own search strategy were conducted to maximize yield. The following databases were searched: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008- Nov, 2011 and EMBASE 2008- Nov, 2011. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence was also reviewed.[123]

Searches included both Medical Subjects Heading (MeSH) terms that were exploded and text searches. The following terms were searched: anal, anorectal, bowel, faecal, faecal, f?ecal, feces, rectal, stool and continent$ or incontinent$, or diarrhea, diarrhoea, diarrh?a; and the relevant lifestyle or intervention term: education, educat*, health education; exercise, exercise*, exercis*, exercise therapy, exercise movement techniques, physical exertion; primary prevention, prevent*, preventive health services, preventive health services for older people; weight loss, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free, diet reducing; irrigat$ and rectal, rectum, anal, transanal; smoking, tobacco smoke pollution, tobacco use disorder, tobacco, tobacco$, cigarette$, smok$, smoking cessation; toileting, toilet$, toilet facilities; herbal medicine, plant extracts, drugs, Chinese herbal, plant preparations, plants, medicinal, medicine, Chinese traditional; carer, caregiver, spouse, family, families, famil*, parent$, caregiver burden, caregiver support, and nursing or care. All seemingly relevant abstracts were reviewed, then salient articles were retrieved and reviewed, and the reference lists searched for further studies. Results of the two searches were virtually identical.

3. REVIEW OF EVIDENCE ON THE EFFECT OF EDUCATION AND LIFESTYLE CHANGES ON FAECAL INCONTINENCE

a) Weight loss

Obesity has been proposed as a risk factor for faecal incontinence but the evidence is inconsistent. In 2008, one study of the effect of weight loss after bariatric surgery on faecal incontinence was identified with positive results. In the current review, results of two new studies are included, one using surgery; neither showed a benefit for decreasing faecal incontinence. The effect of a weight loss (i.e., dieting) versus a control (i.e., education) intervention, on reducing faecal incontinence, was compared in a subgroup analysis of 80 women with dual (faecal and urinary) incontinence who participated in a study examining the ability of weight loss to improve UI.[124]

There was no significant difference in the Faecal Incontinence Severity Index (faecal incontinenceSI) or faecal incontinence type (i.e., consistency) between the weight loss and control groups. The 6 month intervention focusing on dietary intake was not correlated with a decrease in faecal incontinence. Women who showed improvement in faecal incontinence had a lower weight at baseline (89 kg) than those with no improvement in faecal incontinence or no faecal incontinence (97 kg). In one study of women who underwent bariatric surgery for morbid obesity (mean (sd) body mass index (BMI) = 48.9 (7.2) kg/m2), there was a decrease in the prevalence of faecal incontinence of solid or liquid stool from 19.4% preoperatively to 8.6% at 12 months (p=.018; 95% CI= 2.1–19.4%).[125] In a later study of 193 morbidly obese patients, bariatric surgery was not beneficial in reducing faecal incontinence.[126]

Faecal incontinence was worse two years after gastric bypass or gastric banding surgery than before surgery despite an average 48 kg weight loss in more than half of the patients. Worsened faecal incontinence was attributed to diarrhoea that occurred postoperatively. When men and women were analyzed together, liquid stool was significantly more common after gastric bypass than gastric banding surgery, a finding not seen when either gender was analyzed separately.

b) Smoking

Nicotine is thought to slow upper gut motility and increase total transit time,[127] but it seems that it can speed recto-sigmoid transit,[128] and this stimulation of distal colonic motility may exacerbate a tendency to faecal urgency. This fits with many anecdotal reports that smoking a cigarette facilitates initiation of defaecation. No association has been found between antenatal smoking and postnatal faecal incontinence.[129] In a survey of 271 pairs of identical twin sisters, smoking was not significantly related to faecal incontinence or flatus incontinence.[130] In a longitudinal observational study of community-living elderly men and women, smoking was not predictive of prevalent or incident faecal incontinence.[131] No new or intervention studies were identified in the current literature search.

c) Medication side-effects

Medication used specifically to treat faecal incontinence is covered in section 6 below. A vast number of drugs have direct or indirect effects on the gastrointestinal system, tending to cause constipation, diarrhoea, or either in different people. A case report was found reporting that a combination of olestra in the diet and orlistat given to treat obesity led to symptoms of faecal incontinence, which resolved when the olestra was stopped.[132] Patients reporting soiling while on treatment with orlistat for obesity

have been found to have pre-existing impaired anorectal function, thus predisposing them to symptom development.[133] It is beyond the scope of this chapter to review drug effects in detail, and prescribers should be aware of the possible unintended side-effect of faecal incontinence. A careful drug history (including all over the counter or "herbal" preparations) should be taken in each person with faecal incontinence. No studies were identified that evaluated the benefits of patient or provider education regarding the gastrointestinal side-effects of medications in the past or current literature search.

d) Toilet facilities

An environment with physical or social obstacles may impair the ability to maintain continence. This is particularly relevant to individuals who have physical or mental disabilities. Environmental obstacles include toilet facilities that are physically inaccessible, too few, or distant, require obtaining a key or money to access, or are restricted to the public altogether; they also include clothes that are difficult to manipulate in a hurry and a variety of other fac¬tors which vary with abilities of the individual. The toilet itself may be too high, leaving the feet dangling and thus making abdominal straining difficult. The toilet may be too low, making sitting and rising difficult for those with immobile hips. Commode use is reviewed in by Committee 20.

Public laws, such as those in some U.S. states that require businesses in public spaces that have toilet facilities to make them accessible for public use, reduce environmental obstacles to continence.[134]

There are many adaptations that can be made to a toilet to facilitate access and stability in use.[135] Effective bowel evacuation is helped by sitting well-supported, with feet slightly raised upon a small step stool if needed to enable appropriate use of abdominal effort, and leaning forward slightly.[136] Horizontal grab rails assist pushing up from a seated position, while vertical ones can enable pulling up. A raised seat or foot blocks can adjust the height as needed. For lateral transfer from a wheelchair, both seats need to be at the same height. Where it proves impossible for a person to use the toilet, alternative commodes or chemical toilets are available with appropriate features for the individual's needs. No studies were found examining the effect of modifying the physical or social environment for toileting to manage faecal incontinence in the previous or current literature search.

e) Patient and care-giver education and attitudes

The strongest data on education and lifestyle comes from a single RCT identified in the previous review. The study compared nurse-led education and advice about conservative faecal incontinence management (e.g., advice on diet, medication titration, and bowel retraining) alone or as part of a combined intervention that added exercises and/or biofeedback.[137] The education and advice group showed reduced frequency of faecal incontinence and was as effective as the combination therapies.[137] Other support for the benefits of patient education comes from a study reported in abstract form [138] which showed that education and standard medical care, when provided systematically to a group of faecal incontinence patients, who had failed prior attempts at medical management, led to a successful outcome in 38%. Success in this trial was defined as a patient's report that they had experienced adequate relief of bowel symptoms.

An RCT of a nurse-led education-focused intervention for bowel problems, in 146 stroke patients found that a single educational visit with a detailed information booklet increased patients' help-seeking from their family practitioner for bowel problems, demonstrating a heightened awareness of the possibility of treatment.[139] Education also changed diet and fluid behaviour, up to one year later, compared to controls who received routine care. However, there was no difference in the rates of faecal incontinence between the intervention and control groups. No new studies using an education focused intervention to reduce faecal incontinence were identified in the current literature search.

For people with dementia or other severe intellectual impairments, expert opinion holds that the attitude and management methods adopted by care providers are as important as bowel function in maintaining continence.[139] An assessment checklist of toileting difficulties in individuals with intellectual disabilities, has been developed to identify the need for intervention, and guide its focus, was identified in the current literature search.[140] No controlled studies on managing faecal incontinence in this population were found. One quasi-experimental study examined care-givers' knowledge and compliance before and after an educational intervention.[141]

Forty home care-givers of people with dementia, over half of whom had some degree of faecal incontinence, completed a study-specific questionnaire before and after receiving a videotape and information booklet entitled, "A practical approach to maintaining bowel control in people with dementia." Ninety percent of the care-givers accessed the information and there was an improvement in post-intervention knowledge scores, measured on a 55-point scale, with the mean score increasing from 23 pre-test to 32 post-test ($p=<0.001$). However, it is not known if this improved knowledge translates into improved care or reduced faecal incontinence.

f) Complementary therapies

There have been no studies of the use of acupuncture, reflexology, homeopathy or any other complimentary therapeutic approach identified in the previous or current literature search. The use of cognitive therapy for managing incontinence has been proposed but not studied.[142]

g) Summary of evidence on education and lifestyle interventions in faecal incontinence

There is at present limited evidence for any lifestyle intervention for faecal incontinence.

- Educating patients and caregivers about their bowel function and faecal incontinence can improve faecal incontinence **(Evidence Level 5)**
- Obesity: no benefit from weight loss without surgery **(Evidence Level 5)** and conflicting evidence about the effect of weight loss after bariatric surgery for morbid obesity **(Evidence Level 3)**
- Smoking: No association with faecal incontinence **(Evidence Level 3)**; no studies of effects of smoking cessation on faecal incontinence
- Medication side effects may cause faecal incontinence related to diarrhoea **(Evidence Level 4)**
- Environmental modifications in public facilities or private homes to reduce faecal incontinence **(Evidence Level 4)**

h) Recommendations for practice

- Medication side effects: consider alternatives if causing diarrhoea **(Recommendation Grade C)**
- Ensure appropriate toilet facilities and convenient access especially for people with disabilities **(Recommendation Grade C)**
- Improvement in education of patient **(Recommendation Grade B/C)**, and of carer **(Recommendation Grade C)**
- Complementary therapies cannot be recommended: no evidence **(Recommendation Grade D)**

There is insufficient evidence to recommend or discourage most lifestyle modifications either for the prevention or treatment of faecal incontinence. The committee recommends patient education about the causes of faecal incontinence and a systematic effort to remove barriers to effective toileting, as an intervention that is likely to be beneficial, based on the consensus of experts **(Evidence Level 3 evidence)**. This may be provided at relatively low cost and involves no significant risk to the patient.

i) Recommendations for research

- Based on encouraging preliminary reports that patient education, combined with conservative management, can reduce the frequency of faecal incontinence, we recommend further research. An RCT may not be possible, due to the challenge of identifying a suitable control for expectancy and attention, but a study which demonstrates a sustained benefit from a limited educational intervention (provided to patients or caregivers), would provide useful guidance for clinical management.
- Further investigation of the benefits for faecal incontinence of weight reduction, especially in moderately obese patients, using non-surgical interventions
- Exercise programmes, when incorporated into a multi-component intervention, have produced promising preliminary results and should be tested further. Such trials should differentiate between constipation-associated faecal incontinence and diarrhoea-associated faecal incontinence, as exercise may be more beneficial to the former group.
- Evaluation of the incremental or additive value of different lifestyle interventions in the patient pathway.
- Research on the contribution of complementary therapies.

V. DIET AND FLUIDS

1. INTRODUCTION

Community-living adults and elderly individuals, especially women, report that they manipulate their diet and eating patterns as a strategy for managing their faecal incontinence.[143-145] Dietary manipulation is employed by the approximately 20% of patients with irritable bowel syndrome (IBS) who also have faecal incontinence [122,146] and by the approximately 19% to 40% of patients with inflammatory bowel disease who have faecal incontinence.[122,147-151] Empirical observations of a suspected relationship between diet and changes in bowel pattern are not limited to faecal incontinence but have been reported by, individuals with constipation, those with IBS with constipation (IBS-C) and some healthy individuals, and together with physiological principles of gastrointestinal (GI) function, supported an investigation of the evidence and discussion of possible mechanisms.

2. LITERATURE SEARCH

The following databases were searched for studies to include in this review of dietary interventions for faecal incontinence management: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008-Nov, 2011, and EMBASE 2008-Nov, 2011. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence [140] was also reviewed.

The following terms were searched: anal, anorectal, bowel, faecal, faecal, rectal, stool, continent or

incontinent, with diarrhea, diarrhoea, digestive or digestive disease with : alcohol, ethanol, alcoholism, alcoholic beverages, ethanol, drinking; beverages, fluid, fluid intake; liquid, water; coffee, caffeine, cola; diet, dietary therapy, diet, eat, intake, consum and fat or lipid, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free; dietary fibre, fiber, fibre and also with constipation; lactose, lactose intolerance, lactose tolerance, lactose tolerance test, lactose factors, lactose synthase, dairy, dairy products, milk; prebiotic, probiotic, symbiotic; oligofructose, oligofructose, oligosaccharides, fructans, fructose, fos, fructooligosaccharide; sorbitol, glucitol, isosorbide, meglumine; spice, spicy, hot; yogurt, bifidibacteria, Bifidobacterium, Lactobacillius acidophilus, acidophil. All seemingly relevant abstracts were reviewed; then salient articles were retrieved and reviewed, and the reference lists of these articles searched for further studies.

a) Criteria for considering studies for this review

• Types of studies

Only studies in the English language were reviewed. Systematic reviews and meta-analyses of randomised controlled trials and full-length manuscripts reporting individual studies published in a peer-reviewed journal were considered.

• Types of study participants

Studies that involved people who were 18 years or older, had faecal incontinence, and received a dietary intervention were included. People who were tube-fed or had an intestinal ostomy of any type were ineligible.

• Types of dietary interventions

A dietary intervention was defined as any type of food, supplement, dietary product, or fluid that is purposefully consumed or restricted, limited or avoided to manage faecal incontinence. Studies were excluded if it was not possible to distinguish any direct effect of the dietary intervention from other interventions introduced simultaneously. For example, a study was excluded if it combined pelvic floor muscle training and a dietary intervention and compared it to another intervention such as drug therapy making it impossible to determine the effect of the dietary intervention alone.

• Types of outcome measures

A change in faecal incontinence was required to be a primary outcome measure of the studies. Studies which focused primarily on the outcomes of stool consistency or form, stool amount, volume or bulk, defecation frequency, diarrhoea, or constipation, without including any measure of faecal incontinence, were excluded.

• Method of review

The reviewers examined the list of citations and abstracts yielded from the electronic search strategy. Potentially relevant papers were retrieved in full text. The reviewers were not blind to the journal titles, authors' names or their institutional affiliations.

3. REVIEW OF EVIDENCE ON DIET AND FLUIDS

a) Diet modification

Studies of diet modification primarily used observational survey or qualitative research methods and provide background and rationale for examining the effects of diet. One new descriptive study with a large sample size was identified in the current literature search. Findings support those of earlier studies. A survey about faecal incontinence and self-care practices, administered to 1,352 community-living elderly people, showed that many of the respondents changed their diet and skipped meals as a management strategy for faecal incontinence. Changing diet was a significantly more common practice among women (35.4%) compared to men (12.5%).[144]

A qualitative interview of 10 women with faecal incontinence revealed that some avoided eating anything on days they were going to be away from home or restricted the amount eaten while out in public. [145] Many also restricted foods that they thought worsened faecal incontinence (for example, fried or spicy foods or caffeinated beverages and chocolate), or foods that increased flatus (for example, cabbage, onions); a few purposely ate certain foods as a therapy to decrease faecal incontinence (for example, yogurt). Using a trial and error approach, women with faecal incontinence often modified their diet based on recommendations for other gastrointestinal problems (e.g., lactose intolerance and IBS) that were available in the professional or lay literature. [145] Interviews of 189 community living men and women showed similarities with previous reports regarding aggravating types of foods that are restricted to lessen faecal incontinence. [152] In order of frequency these were: vegetables, spicy foods, fruits, fatty or greasy foods, caffeine containing foods, and dairy. More women (40%) than men (18%, p=.008) avoided foods. There were also differences by age. Younger adults were likely to report that fatty foods and alcohol worsened their faecal incontinence. Individuals with faecal incontinence also modified how they prepared food preferring blander and baked foods.

The effectiveness of these diet modifications was unmeasured and described as variable. Concerns of diet manipulation are nutritional deficiencies and subsequent poor health. However, Bliss et al. [7] found few significant differences in the nutritional composition of usual diets of persons with faecal incontinence compared to the usual diets of age and gender matched controls with normal bowel function.

Those faecal incontinence had a greater intake of carbohydrates, manganese, and vitamin B1.

b) Fluids

Faecal incontinence occurs in association with faecal impaction or constipation, mainly in elderly residents in long-term care institutions.[153,154] General clinical recommendations for faecal incontinence management in these cases are for an adequate intake of fluid to prevent hard stool consistency and constipation (See Chapter 11). Some community-living individuals report increasing fluid intake especially when faecal incontinence is loose or liquid to replace additional fluid lost.[145] However, there are no research-based data to support the recommendation of increased fluids either for constipation or for faecal incontinence, and there is no evidence that the diets of patients with faecal incontinence or constipation are deficient in fluids.

c) Lactose, yogurt, sorbitol, fructose, caffeine, and alcohol

Certain dietary components such as lactose, sorbitol, fructose, caffeine, and alcohol may cause loose stools that can potentially aggravate faecal incontinence. A deficiency of the intestinal enzyme, lactase, prevents hydrolysis of the disaccharide lactose and its absorption. The presence of lactose creates an osmotic shift of intestinal water into the small intestine and speeds transit. In the large intestine, fermentation of lactose by colonic bacteria may result in flatulence, distension, diarrhoea, and cramps. However, the majority of adults who have lactase deficiency can tolerate a small amount of lactose in foods.[155] Yogurt is usually well tolerated by lactose maldigesting individuals because the lactose is partially digested by the beta-galactosidase of the bacteria used to ferment the yogurt. However, yogurt has not been found to aid the digestion or tolerance for additional lactose simultaneously consumed with it.[156]

Due to its prevalence in approximately two-thirds of the world's population, hypolactasia is currently regarded as a normal physiological pattern rather than a disease.[157] The prevalence ranges from highs of nearly 100% in some Asian countries and 70% in Italy to lows of 2% in Scandinavia and 15% in U.S. Whites.[158] Malabsorption of fructose and sorbitol results in osmotic diarrhoea and adverse symptoms, similar to lactose. A diet, reduced in fructose and sorbitol content, is suggested for some patients with irritable bowel syndrome to reduce adverse GI symptoms.[159] No studies in the current literature search on the effect of modification of intake of lactose, sorbitol, or fructose, on faecal incontinence were found.

Caffeine, of which coffee is a popular source, induces a desire to defecate.[160-164] Caffeine has also been observed to stimulate defaecation urgency in some patients with faecal incontinence.[131] However, regular consumption of coffee was not associated with prevalent or incident faecal incontinence in elderly men and women.[131] No studies were found on caffeine restriction to improve faecal incontinence.

Chronic consumption of alcohol has been associated with accelerated gastric emptying and small bowel transit in animal studies whereas a single large dose has an inhibitory effect on these parameters.[165-167] Excessive alcohol consumption leads to damage to the duodenal and upper jejunal mucosa and inhibition of sodium and water absorption. There is an increased prevalence of bacterial overgrowth in the small intestine of alcoholics, which may contribute to loose stools, diarrhoea, incontinence, and other GI symptoms.[168] No studies were found in which alcohol restriction was reported to reduce faecal incontinence.

d) Prebiotics, probiotics, and synbiotics

A prebiotic is a general term describing a food ingredient that is not digested in the human small intestine and thus stimulates the growth and/or activity of one or more types of bacteria in the colon that have the potential to improve the health of the host. Because of its ability to stimulate growth of bacteria in the colon, dietary fibre can be considered a prebiotic. Fructo-oligosaccharides and galacto-oligosaccharides are popular prebiotics. A probiotic is a food supplement containing live non-pathogenic and non-toxic microbes that have the potential to affect the balance of colonic microbes and thereby improve the host's health. Bifidobacteria and lactobaccilli are the most commonly used probiotics, and yogurt which has active microbial cultures can be considered a probiotic. A synbiotic refers to a product that combines a prebiotic and probiotic. Probiotics have been investigated for their ability to prevent or reduce diarrhoea associated with antibiotics, Clostridium difficile infection, ulcerative colitis, acute infant dehydration due to diarrhoea and in treating Heliobacter pylori infections.[169,170] However, there are no published data on the use of probiotics or synbiotics to treat faecal incontinence.

e) Dietary fibre

1. Background

Dietary fibre is the non-starch, polysaccharide component of plant cell walls and lignin that resists digestion by human intestinal enzymes.[171] In a recent study of weight loss for incontinent and overweight women, analysis of a subsample of 55 women with faecal incontinence showed that those with faecal incontinence were 2.5 times as likely to have a low fibre intake (≤ 10 g/d) than those without faecal incontinence.[124] Moreover, persons with normal bowel function, who had diarrhoea induced by administration of phenolphthalein, reported that they had fewer days with urgency to defaecate, or fear of faecal incontinence, when they ingested the soluble fibre psyllium compared to wheat bran, cal-

cium polycarbophil, or placebo in an unblinded manner.[172] On the other hand, there are reports that dietary fibre may exacerbate faecal incontinence in some patients. It has been observed that some patients with faecal incontinence benefit from moderating their intake of foods containing largely insoluble fibre, such as whole grain breads and cereals, nuts, beans, fruits and vegetables with skin, and sweet corn.[173] Moreover, one clinical letter reported that treating constipation in elderly immobile people with a supplement of insoluble fibre and bran, resulted in faecal incontinence in half of them.[174] Thus, fibre supplements appear to benefit diarrhoea-associated but not constipation-associated faecal incontinence. Larger studies are needed to determine the indications and overall efficacy of dietary supplements for faecal incontinence.

Adverse gastrointestinal (GI) symptoms are a potential problem mediating tolerance of dietary intervention, including dietary fibre supplementation,[175] but few studies have examined this outcome systematically. In a recent secondary analysis of a larger trial that compared the symptoms associated with supplementation of 16g of fiber from psyllium, gum arabic, or CMC supplements to placebo among 189 community living adults living with faecal incontinence, the severity of symptoms in all groups was minimal.[176] Adjusting for study segment and day, a greater feeling of fullness in the psyllium group was the only symptom that differed from symptoms in the placebo group. However, subjects with greater symptom severity, especially a feeling of fullness or bloating, were more likely to request a reduction in the amount of fibre to be ingested or withdraw from the study, across groups. There was a positive association between symptom severity and being emotionally upset.

2. Review of evidence on dietary fibre

There are four studies investigating the effect of dietary fibre for managing faecal incontinence.[177-180] Two are RCTs [177,178] and were included in the previous review (**Table 1**). The methods and findings of these previously reported studies differed. In three of the four studies of dietary fibre for faecal incontinence in this review, dietary fibre was adjunctive to other therapies.[177,179,180] In two of those studies, dietary fibre was the initial treatment of a staged intervention [179,180] and, in the third study, dietary fibre was added to antimotility medication in an RCT design.[177] In the fourth study,[178] supplementation with one of two soluble dietary fibres of, moderate (psyllium) or high fermentability (gum arabic), was compared to placebo in an RCT design.

In one RCT,[178] subjects were community-living adults living in the United States with incontinence of loose or liquid stools. The intervention was supplementation with one of two soluble dietary fibres of moderate (psyllium) or high fermentability (gum arabic) compared to placebo. This study provided Evidence Level 1 evidence suggesting that dietary fibre can reduce the percentage of incontinent stools. The percentage of stools that had a loose/liquid consistency was also significantly lower in the fibre groups.[178]

Lauti et al.[177] investigated two combination treatments consisting of an antimotility medication, a diet advice sheet for a high or low fibre diet, and a fibre supplement or placebo in an RCT design. Subjects were outpatients of a colorectal service in Australia who were incontinent of mucus, liquid, or solid stools (i.e., this study was not limited to patients with faecal incontinence of loose or liquid stools). Results showed no additional benefit of a dietary fibre supplement and advice for a high vs.low fibre diet, over use of the antimotility medication, loperamide, for reducing incontinence of flatus, mucus or solid or liquid stool.[177] This study had a low level of control of threats to internal validity and intervention fidelity.

Two studies included dietary fibre as part of a staged intervention and used a non-randomized design. [179,180] In one study using a tailored staged intervention,[179] female outpatients with faecal incontinence of either liquid or solid faeces, who agreed to follow the intervention, were instructed to consume one heaped tablespoon of methylcellulose twice per day that could be increased to two heaped tablespoons as needed. If faecal incontinence did not cease within two weeks, the women were instructed to add one capsule of loperamide twice a day that could be increased up to two capsules three times per day as needed. Fluid intake was also regulated by subgroups: those with solid stool were instructed to drink 60 ml per day (doesn't seem much!) and those with liquid stool were to avoid drinking 30 minutes before and after every meal. The control group was comprised of women who did not agree to follow the intervention but who agreed to report follow-up data. faecal incontinence was cured in 46% of women in the intervention group and none in the control group.[179]

In another study, 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited from two clinics in the Netherlands, and 47 completed the protocol.180 For two months, patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water daily for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily. Faecal soiling resolved completely in 79% (37/47) of patients. In 12 patients (24%), soling resolved after psyllium supplementation alone. Of the 37 who added rectal irrigation to psyllium supplementation, 24 (48% of 50) resolved soiling. Of the remaining 11 who added cholestyramine to psyllium supplementation rectal irrigation, 2 (2% of 50) resolved soiling.

One study of institutionalized frail elderly showed that treating faecal impaction or constipation using

Table 1: Randomised Trials Using Dietary Fibre to Manage Faecal Incontinence

Study	Design and sample	Intervention and Outcomes	Findings	Strengths	Limitations
Bliss et al.[178]	Randomised, parallel-group, placebo-controlled, single blind trial Subjects, statistician, lab technician, and subjects' clinicians were blinded. 39 adults (79% female) completed study Subjects had faecal incontinence of loose or liquid stool at least weekly. A block scheme resulted in equal numbers (n=13) in each group. Groups' characteristics were comparable at baseline.	Intervention was one of the following soluble fibre supplements mixed into fruit juices: 7.1g of psyllium/d, 21.5 g of gum arabic/d, or placebo (0.2 g pectin/d). Supplements taken for 31 days in addition to usual diet Subjects reported faecal inconti-nence daily on a stool diary for 8 d in each period Primary measure was the proportion of incontinent stools. Secondary clinical measures were stool consistency and frequency, and flatulence reported daily. Secondary lab measures were stool wet and dry weights, % of water, pH, total fibre content, water-holding capacity of stool solids, and faecal short chain fatty acids.	Proportion of incontinent stools in psyllium or gum arabic groups was significantly lower than placebo. Percent of loose/unformed or liquid stools in psyllium or gum arabic groups was significantly lower than placebo. The water-holding capacity of stool solids was highest for the psyllium group. No significant differences among the groups in other measures.	The inclusion and exclusion criteria were reported. Sample size was based on a power analysis. Data collection interval during the baseline and intervention was equal. There were attempts to control concomitant treatments, e.g., no subject was also doing biofeed-back. Supplements were pre-mixed and ready-to-take. 95% of subjects completed the study and reasons for attrition were reported. Standard lab measures were used.	Details of the procedures for random assignment and allocation concealment were not provided. Although adequately powered, small group sizes reduce generalizability of findings.
Lauti et al.[177]	Double-blind, randomized, cross-over design using blocks of 10 63 adults with inconti-nence of mucus, or liquid or formed stools. started study: Treatment A = 31 and B = 32 49 crossed-over Treatment A = 27 and B = 22 47 subjects (91% female) completed the study	Treatment A: self-titrated dose of loperamide (starting at 2 mg twice/d), 1 teaspoon of a food thickener containing starch, maltodextrin, and locust bean gum twice/d, and a diet advice sheet about a low-fibre residue diet. Treatment B: same self-titrated dose of loperamide, one teaspoon of psyllium fibre in water twice/d, and a diet advice sheet about a high and low fiber residue diet. Treatments were for 6 weeks each Primary measure was self-reported anal incontinence for the last 4 weeks of each treatment using a faecal incontinence severity index (FISI). Secondary clinical measures were faecal incontinence quality of life (FIQL) and SF-36, a measure of general health.	67% of treatment A fibre and 73% of treatment B fibre were taken. The mean difference in the FISI score between treatments was not statistically significant.	A power analysis was used for sample size calculation. Independent pharmacists dispensed the treatments. The interval for data collection during both treatments was the same. 75% of subjects completed the study protocol and reasons for attrition were reported.	Period and sequence effects were not reported prior to combining all subjects on Treatments A or B for analysis. Attrition resulted in low statistical power. There was no theoretical or physiological rationale for use of dietary fibre for leakage of mucus or solid stools. Subjects mixed their own fibre supplements and intake was uncontrolled. Doses of the anti-motility medication and supposito-ries for constipation were uncontrolled.

lactulose, a nondigestible sugar with osmotic properties, and a laxative or enema did not reduce faecal incontinence, [181] but no studies were found treating faecal incontinence associated with constipation in non-institutionalized adults.

3. Summary of evidence

Patients consider diet a factor affecting the severity of their faecal incontinence and they use diet modification as a self-care strategy **(Evidence Level 3)**. Dietary fibre supplementation appears to be a safe and tolerable intervention that reduces faecal incontinence of loose stools **(Evidence Level 1)**. However, findings about its effectiveness when added to an anti-motility medication differ **(Evidence Level 2)**. Dietary fibre as an adjuvant to rectal irrigation can reduce faecal incontinence **(Evidence Level 3)**.

4. Recommendations for practice

- Soluble dietary fibre is recommended for the management of faecal incontinence especially when stool consistency is loose or liquid. **(Recommendation Grade B)**.
- Soluble dietary fibre is recommended as part of a combination therapy involving rectal irrigation **(Recommendation Grade B).**
- No recommendations about the use of dietary fibre as an adjuvant to antimotility medications can be made because evidence is conflicting and study methods vary in quality. **(Recommendation Grade B)**
- The effectiveness of food restrictions, timing of eating schedules, and modifications of eating patterns and food preparation on reducing faecal incontinence should be evaluated for their usefulness. **(Recommendation Grade C)**
- Patients should be asked about dietary restrictions and meal skipping to assess nutritional impact especially in groups who may be at higher risk for malnutrition. **(Recommendation Grade C)**

5. Recommendations for research

Further studies on the effect of dietary fibre and other diet modifications on faecal incontinence are encouraged to build a greater body of evidence:

- Determine the optimal type and amount of fibre to use for faecal incontinence as dietary fibres differ in their chemical composition and properties
- Determine the extent to which a dietary intervention can augment other behavioural interventions, such as pelvic floor muscle exercises or bowel training, needs further study.
- Assess the effect of modifying usual diet and eating pattern as a management strategy for faecal incontinence
- Assess the role of specific foods, caffeine, and alcohol in the management of faecal incontinence
- Assess ability of fibre and fluid in relieving constipation related faecal incontinence

There are several recommendations for methodological rigour in future studies. Theory-based, adequately powered, controlled trials are sought. Studies should control for variability in an individual's baseline severity of incontinence and any adjuvant therapies. In staged interventions, the effect of the order of dietary fibre and other components, should be assessed. Monitoring adherence to the dietary intervention and intervention fidelity are recommended. A common set of outcome measures that includes tolerance to diet interventions is recommended. Reporting outcomes of faecal incontinence in addition to those of anal incontinence (which incorporates flatus incontinence) is recommended.

VI. BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

1. BACKGROUND

Bowel management programmes are used by individuals with constipation and although constipation is a risk factor for faecal incontinence in children and older people, it has not been found to be a consistent risk factor for faecal incontinence in adults of other ages. Committees 9 and 11 have reviewed the evidence for bowel retraining programmes in children and older adults, respectively. Bowel management after spinal cord injury also involves other bowel problems in addition to faecal incontinence, such as constipation or incomplete evacuation; therefore, combinations of therapies for both faecal incontinence and constipation are common. Few bowel management approaches have been tested for their effectiveness for faecal incontinence only in adults with non-neurogenic faecal incontinence. Any studies found which addressed bowel management or training for multiple bowel problems in adults with non-neurogenic faecal incontinence that did not separate results for faecal incontinence, were excluded from this review.

2. SEARCH

The following keywords were searched: anal, anorectal, bowel, faecal, faecal, rectal, stool and continent or incontinent, or diarrhea, diarrhoea and the relevant lifestyle or intervention term: bowel and train or retrain; digital and stimulat); crede or massage; enema; and suppository, toileting, toile, toilet facilitiest. The following databases were searched: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/ Academic Edition, CINAHL 2008-November, and 2011 MEDLINE 2008- Nov, 2011 The Cochrane library and a recent systematic review of the epidemiology

and prevention of urinary and faecal incontinence was also reviewed.[123]

All seemingly relevant abstracts were reviewed, after which salient articles were retrieved and reviewed, and the reference lists searched for further studies. Studies that included patients with a variety of bowel disorders, but did not report results of bowel management/retraining for patients with faecal incontinence separately, were excluded. Studies in which results of retrograde irrigation were not reported separately from those of antegrade irrigation were also excluded.

3. REVIEW OF EVIDENCE ON BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

a) Bowel habit and toileting

Expert opinion supports the importance of attempting to establish a regular, predictable pattern of bowel evacuation by patient teaching and adherence to a routine.[121,182] Because peristaltic contractions of the colon, that are associated with defaecation, increase in frequency following awakening from sleep and following meals,[183,184] the period after breakfast is the best time for scheduled defaecation. No studies of bowel habit training or regular toileting in non-institutionalised adults with mobility or cognitive limitations, or with normal cognitive function, were found in the current literature search.

b) Resisting urgency

The strong sensation of urgency to defecate is frequently associated with diarrhoea, and it is a recognized risk factor for faecal incontinence in adults.[185] In contrast to urinary incontinence, particularly the overactive bladder syndrome (Committee 14), for which a body of knowledge has developed on the efficacy of bladder training techniques (i.e., voiding at specific intervals rather than in response to urge and deferment techniques), the possibility of bowel retraining for resisting urgency to defaecate is relatively unexplored. Some biofeedback protocols focus on altering rectal sensory thresholds as discussed below.

In the previous review, one RCT[173] that compared patients who received education, including urgency resistance techniques and dietary advice, to a group of patients who received the same training plus anal sphincter exercises with or without home or clinic biofeedback showed no significant difference in outcomes.[137] No new studies of resisting urgency to reduce faecal incontinence were identified in the current search.

c) Evacuation training

A common factor in the genesis of pelvic floor problems may be chronic straining with perineal descent from constipation; this may lead to pelvic floor damage (direct or neurological),[186,187] and may be associated with pelvic organ prolapse or UI or faecal incontinence. In one small study, women who reported straining were more likely to develop urogynaecologic symptoms such as prolapse and stress urinary incontinence.[188] However, straining has not been shown to be a risk factor for faecal incontinence. No studies were identified in the previous or current search that examined the effect of decreasing straining on preventing or treating faecal incontinence in non-institutionalised adults.

Clinically, many patients with faecal incontinence are taught evacuation techniques or are encouraged to use laxatives, suppositories or enemas in an attempt to ensure that the rectum remains empty most of the time, thus giving less chance of faecal incontinence. This is known to improve continence in children (Committee 9) and elderly patients (Committee 11). One RCT of a combination treatment package for faecal incontinence in adults included training on evacuation techniques and noted that patients reported improved ease of evacuation after treatment.[137] No separate data on faecal incontinence were presented. No new studies were found utilising specific evacuation training to treat faecal incontinence in younger adults in the current literature search.

Committee 10 has reviewed the evidence for digital rectal stimulation and manual evacuation in patients with neurogenic faecal incontinence. The use of these techniques to assist complete evacuation in non-neurological populations has not been evaluated.

d) Rectal irrigation

Irrigation of the lower bowel has been used for many years to manage both faecal incontinence and constipation by patients with spinal cord damage (Committee 10). Surgical construction of a portal for antegrade irrigation is covered by Committee 17. Various equipment has been used for retrograde irrigation, including a stoma irrigation cone held in place manually against the anus;[189,190] a mechanical pump[191] and specifically designed anal irrigation equipment.[192,193] Rectal irrigation for faecal incontinence secondary to spina bifida is common.[192]

Five studies that investigated rectal irrigation for faecal incontinence and met the criteria were found in the current literature review. Three of the studies examined the effect of rectal irrigation in patients whose faecal incontinence did not improve after using other conservative therapies.[194-196] Three studies had an observational design [180,194,197] and two studies reported results of one group before and after using rectal irrigation.[196,198] One study included rectal irrigation as part of a staged intervention along with dietary fibre,[180] and two studies allowed addition of other therapies such as laxatives or dietary fibre on an uncontrolled basis.[196,198] Sample sizes were small in all studies and none used a randomized between groups design.

The effects of rectal irrigation using tap water for a mean duration of 18 months to treat faecal incontinence were reported in one study of 32 patients who had faecal soiling (n=16) or faecal incontinence (n=16) (the distinction between the two conditions was not defined).[197] Overall, approximately half (57%) of subjects reported improvement of faecal incontinence on a questionnaire; improvement was less in those with faecal incontinence (38%) compared to those with faecal soiling (79%). Ten patients discontinued rectal irrigation after 1 month due to lack of benefit, adverse symptoms or time required.

In a survey of patients with a variety of different bowel disorders, retrograde colonic irrigation was observed as being effective in reducing soiling in 41% of 32 individuals and reducing faecal incontinence in 47% of 71 persons.[194] However, irrigation was discontinued by 67% of those with soiling and 17% of those with faecal incontinence despite a benefit. Reasons for discontinuation included the time required, difficulties with the irrigating procedure, and incontinence of irrigation fluid later in the day.

One prospective study followed 18 patients with faecal incontinence who used a rectal irrigation pump and tap water. Subjects could add soap to the irrigation fluid and take laxatives or dietary fibre as needed.198 Six patients added psyllium dietary fire and three added medications. Compared to baseline Parks incontinence scores (3.6 (0.50 SD)), faecal incontinence significantly decreased at 3 months (2.3 (1.03)), 6 months (2.7 (1.3)) and one year (1.6 (.92)). Eleven patients (61%) were considered “pseudo” continent at 3 months.

A prospective study of a nurse practitioner-led rectal irrigation program for adult and pediatric patients (age = 52 (5-85 mean (range) years)) with functional bowel disorders included 51 adult patients with predominant faecal incontinence.[196] faecal incontinence symptoms were reported on a non-validated linear analogue scale at the start and after an average of 42 months using rectal irrigation with water, plus laxatives if needed. faecal incontinence symptom scores improved in the faecal incontinence only group from 7.5 (6.5-8.5 range) before to 4.9 (3.5-6.4) after the rectal irrigation program.

Rectal irrigation was included as part of a staged intervention for faecal incontinence in an already mentioned, study of 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited.[180] For two months, all patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily; 47 patients completed the protocol. Faecal soiling resolved in 12 patients (24% of 50) consuming psyllium alone, 24 of 37 (48% of 50 patients) who added rectal irrigation to psyllium supplementation, and 2 of 11 (2% of 50 patients) who added cholestyramine to psyllium supplementation rectal irrigation.

e) Combinations of therapies

It is recognised that in many people, the symptom of faecal incontinence is the result of a complex combination of disordered anatomy and physiology, stool consistency and gut motility, emotional and psychological status and restricted access to toilet facilities, amongst other factors (see Committee 5). Hence in clinical practice many patients use a combined approach, for example, adjusting diet, medications, lifestyle, muscle function and bowel habit simultaneously, depending on the result of an initial assessment. [199,200] Studies of combinations of education, diet or fluid, and behavioural therapies, which have been identified in this review, are included by topic of the intervention in the respective section above. A limitation of these studies is that the contribution of the individual components to the overall effect, or the effect of the order of components, has not been determined and remains unknown.

f) Summary of evidence on bowel management and retraining programs

There is limited evidence on many topics in this area. In particular there are no studies on effects of bowel habit training, scheduled toileting, resisting urgency, and rectal evacuation in adults with faecal incontinence. However, rectal irrigation can reduce faecal incontinence when first-line conservative therapies fail **(Evidence Level 2)**.

g) Recommendations for practice

- Rectal irrigation is recommended for patients who do not respond to other conservative therapies and as part of a combined approach of therapies **(Recommendation Grade C)**
- Attempt to establish a bowel routine **(Recommendation Grade C)**
- Urgency resistance training is possibly useful for urgency. **(Recommendation Grade D)**
- No recommendation on toileting methods is given due to lack of evidence. **(Recommendation Grade D)**

h) Recommendations for research

- Randomized clinical trials of rectal irrigation are needed.
- Research is needed in all other areas of bowel training.

VII. TREATMENT WITH MEDICATION

1. GOALS

With the recognition that severity is subjective, treatment should be allocated according to symptom

profile and patient lifestyle. The goals of this section are to identify the drugs and other medical interventions that have been used to treat faecal incontinence and to evaluate the evidence regarding their efficacy (**See Table 2**). Drugs can be combined for synergistic effect, helping reduce individual doses; loperamide plus codeine phosphate, and loperamide plus amitriptyline are examples. Conservative management of faecal incontinence has focused exclusively on three mechanisms:

- Reduction of diarrhoea. Diarrhoea is consistently found to be a strong risk factor for faecal incontinence.
- Increasing resting anal canal pressure. Low resting anal canal pressure is a risk factor for passive faecal incontinence, and is commonly seen following some types of anorectal surgery (e.g., ileal pouch procedures, sphincterotomy, abdominoperineal pull-through for imperforate anus).
- Treatment or prevention of constipation. Constipation is frequently found to be a risk factor for faecal incontinence, especially in children and the elderly.

2. SEARCH METHODS

The Medline database and the Cochrane reviews [201,202] were searched for studies in any language and any year through October 2011 which matched the following search terms: “Faecal incontinence” OR “anal incontinence” AND “drug” OR “medical management” OR “medical treatment;” “Faecal incontinence” OR “anal incontinence” AND “loperamide” OR “diphenoxylate;” “Faecal incontinence” OR “anal incontinence” AND “laxative” OR “polyethylene;” “Faecal incontinence” OR “anal incontinence” AND “phenylephrine gel.” Additional articles were identified by examining systematic reviews.[202-204]

3. REVIEW OF EVIDENCE ON MEDICATIONS FOR FAECAL INCONTINENCE

a) Treatment of diarrhoea-associated faecal incontinence with antidiarrhoeal drugs

1. Loperamide and diphenoxylate

The most extensively tested drug treatment for diarrhoea-associated faecal incontinence is loperamide. We identified 7 studies in adult subjects [177,205-209] and 3 studies in children.[210-212] These studies all have methodological weaknesses including small sample sizes, use of crossover designs, or they are case series. Loperamide is a synthetic opioid with μ-agonist activity and coincidental calcium channel blocking actions. By slowing gut transit, increasing fluid reabsorption and reducing secretion, loperamide thickens stool consistency and reduces stool frequency. It also has direct sphincter actions, attenuating the anorectal inhibitory reflex and increasing resting anal pressure. It is at least as effective as codeine, and superior to diphenoxylate in chronic diarrhoea, with a tendency to reduce faecal incontinence more effectively than the other agents. The availability of a syrup formulation offers the opportunity of titrating the dose more finely to avoid the side-effect of constipation. Some authors advocate using the drug before meals to reduce postprandial bowel urgency. Tolerance does not seem to develop with chronic administration, and the safety profile is excellent with both regular and as-required use.

Diphenoxylate, a natural opioid, is usually combined with atropine to reduce abuse potential. It crosses the blood–brain barrier to produce central nervous system side-effects and, when combined with atropine, can cause anticholinergic effects. It is less effective than loperamide. Codeine phosphate is another opiate derivative, with side-effects of nausea, tolerance and dependence. Its clinical effects are similar to those of loperamide, but it is harder to titrate and adverse effects become prominent with time.

Studies generally support the efficacy of loperamide for decreasing diarrhoea-associated faecal incontinence. The most important of these studies are briefly summarized below: Palmer and colleagues[205] compared loperamide (average of 4.6 mg per day) to codeine (average of 103 mg per day) and diphenoxylate (average of 12.5 mg per day) in 30 patients with diarrhoea, of whom 19 had faecal incontinence prior to treatment. However, change in faecal incontinence was not the primary outcome measure. Loperamide was superior to diphenoxylate and similar to codeine with respect to decreased stool frequency, improved stool consistency, and reduced side-effects. Although not statistically significant, there was a trend for less faecal incontinence while taking loperamide compared to diphenoxylate.

Fox and colleagues [209] tested different doses of loperamide against placebo in a double-blind crossover study of 10 obese subjects who were soiling as a result of taking orlistat for weight control. These 10 subjects were selected for study because they had previously been found to soil while taking orlistat. In this study, loperamide decreased soiling and faecal incontinence and increased resting anal canal pressure. Lauti’s group [177] compared loperamide plus fibre supplementation to loperamide with a low fibre diet and placebo fibre supplement in the first adequately powered study. This was a double-blind crossover study with order of treatments counterbalanced. Results showed a significant improvement in continence relative to baseline in both groups, but the addition of fibre to loperamide did not increase benefit.

Sze and Hobbs [179] investigated the additional benefit of loperamide over methylcellulose in an unblended study of 69 patients. Forty-six percent of patients were “cured” by the combined treatment, although loperamide had a tendency to cause constipation, which

Table 2: Effectiveness of Drug Therapy

Citation	Sample	Study Design	Major Findings	Adverse Events	Comments
Guillemot et al.[228]	24 patients (16 biofeedback (BF) treated and 8 anti-diarrhoeal and enema treated), mixed aetiology. 12 controls. 30 month follow-up	Unblinded RCT	At 30 months, non-significant change in Wexner score in both BF-treated (17.8 to 14.4) and medical-treated (17.0 to 18.0) groups. More marked BF change at 6 months.	Nil significant	Low quality study.
Santoro et al.[213]	18 patients and 24 controls (latter for anal physiology measurements)	Open study of 20 mg amitriptyline for 4 weeks	Faecal incontinence scores reduced from median 16 (maximum 18) pre-treatment to 3. Treatment reduced amplitude and frequency of rectal contractions and improved sphincter pressure.	Dry mouth or drowsiness in 4 patients (22%) nil withdrew	Effects suggested to be mediated by anti-muscarinic slowing of transit, and improved ano-rectal coordination.
Demirci et al.[229]	Two stage study. Stage I: 287 tertiary referred patients. Multiple aetiologies (including transit disorders), mixed treatments based on consensus algorithm. Stage II: 36 patients, mixed aetiology including transit disorders outcomes measured at median of 2 months after treatment.	Stage I: intention to assess proportion of patients suitable for medical treatment. Quantified by Pescatori scale. Stage II: uncontrolled trial of efficacy of medical therapy – unclear duration of treatment. Wexner score outcome	Stage I: 44% recommended drug treatment (anti-diarrhoeal, laxatives, enemas or anti-depressants), 18% biofeedback and 35% surgery. Stage II: 22% "cured," 39% improved, 39% unchanged (non-compliance 11%, untreatable transit issues 17%, faecal incontinence despite "normalising" transit 11%).	None reported	Low quality – time lapse of many years between stages, not clear algorithm applied prospectively in all subjects. Stage II – small numbers, no attrition rate details
Lauti et al.[177]	63 randomised (49 completed both phases of cross-over) consecutive referrals to specialist centre.	Double-blind randomized cross-over trial, each treatment was 6 weeks. Treatment A = low-residue diet sheet, placebo fibre and loperamide Treatment B = psyllium fibre, low and high residue diet sheet and loperamide.	Faecal incontinence severity index (FISI) scores fell from baseline 31 to 18 for treatment A and 19 for treatment B. No differences between treatments in terms of faecal incontinence severity or quality of life (FIQL).	Nil major – palatability of supplements caused 1 patient (3%) to withdraw	Marked inter-individual variation, hence importance of tailoring fibre to individual symptom profile.
Remes-Troche et al.[230]	21 patients with faecal incontinence treated with cholestyramine plus biofeedback and matched cohort of 21 with faecal incontinence who underwent biofeedback alone.	Prospectively collected data which was retrospectively compared between groups. Median cholestyramine dose 4gm	Improved stool frequency and consistency with cholestyramine only, not biofeedback. faecal incontinence symptoms and global satisfaction similar in both groups. Physiological measures improved in both groups.	Side effects in 7 (33%), constipation 4 (19%), bloating (9%) and headache 1 (5%).	Poor palatability side effects improved with dose reduction.
Sze & Hobbs[179]	59 patients and 10 controls (latter recruited if declined active treatment). Outcomes: overall improvement and Pescatori score at 8 weeks.	Prospective unblinded controlled study of methyl-cellulose with or without loperamide.	27 patients (46%) "cured" by intervention, equally whether solid or liquid stool incontinence.	Constipation with loperamide, relieved by dose alteration.	40 of 59 used loperamide. Power calculation aimed to detect 46% difference in open study.
Bharucha et al.[217]	12 women with urge-predominant faecal incontinence and mixture of sphincter integrity. Outcomes: diary data, faecal incontinence symptom severity score, faecal incontinence QoL, anorectal physiology	Open label, uncontrolled study of 4 weeks clonidine via patch (0.2mg/day).	Clonidine reduced stool frequency and proportion of patients with >50% reduction of faecal incontinence episodes (9 of 12, 75%) and faecal incontinence days (8 of 12, 67%). No changes manometry, but slight increased rectal capacitance with clonidine.	6 (50%) had adverse effects. 5 (42%) had skin reaction, 3 (25%) fatigue, 2 (16%) postural hypotension and 2 (16%) dry mouth.	Unclear whether effects most marked in those with baseline looser stool

was modified by dose reduction. Taken together, these studies suggest that loperamide may be more effective than fibre supplementation alone for the treatment of diarrhoea-associated faecal incontinence. An earlier study by Bliss et al.,[178] which is reviewed in Section 16.5, showed that fibre supplementation with either psyllium or gum arabic improved diarrhoea associated faecal incontinence, more than placebo.

2. Other antidiarrhoeal drugs

Santoro and colleagues [213] carried out an uncontrolled study of the tricyclic antidepressant, amitriptyline, given 20 mg at bedtime, in 18 patients with faecal incontinence; diarrhoea was not required. Thirteen of 18 became continent and 3 reported improvement. The authors attributed the benefits to increased anal resting pressure and decreased numbers of "rectal motor complexes." This study suggests that amitriptyline and other tricyclic antidepressants are of possible benefit for treating faecal incontinence. Sucralfate is a formulation of aluminium hydroxide used primarily for the treatment of duodenal ulcers; it has the property of coating the stomach lining. An early study suggested that sucralfate might reduce diarrhoea secondary to radiation proctitis in patients receiving radiotherapy for pelvic cancer.[214] However, subsequent large randomized controlled trials have shown no significant benefit for diarrhoea [215] and a worsening of faecal incontinence [216] in this patient population. Bharucha et al.[217] undertook a 4 week trial of a clonidine patch. There was a modest reduction of stool frequency and improvement of continence.

3. Mechanism of action

Three possible mechanisms of action have been identified in these studies of the drug treatment of diarrhoea-related faecal incontinence: loperamide, diphenoxylate, amitriptyline and clonidine appear to work in part by decreasing bowel movement frequency through an effect on motility and absorption. Fibre supplements (reviewed in Section 4 above), on the other hand, work by binding more water into the stools. Resting anal canal pressures were reported to be increased in response to loperamide [206,207] and amitriptyline.[213]

b) Drugs for increasing anal canal pressure in patients with passive faecal incontinence

A subgroup of patients with faecal incontinence has passive incontinence, defined as faecal incontinence that is not preceded by a sensation of urgency to defecate and that occurs without awareness. This is believed to be related to decreased resting pressure in the anal canal, due to an impaired internal anal sphincter and/or to decreased sensation for rectal distension. A specific aetiology for passive faecal incontinence is the patient with a colectomy (usually for ulcerative colitis) with a surgically constructed ileal reservoir connected to the anal canal.[218]

1. Phenylephrine gel

Phenylephrine gel, an alpha-1 adrenergic agonist, has been investigated for the treatment of passive faecal incontinence in several studies.[219-223] In an initial study of 36 patients with intact sphincters, no significant benefit was seen.[223] Two subsequent studies [219,222] suggested a benefit of phenylephrine gel, but a recent randomized controlled trial in 35 patients with passive incontinence secondary to low anterior resection failed to show a benefit.[221] Thus, the clinical utility of phenylephrine gel (if any) may be limited to patients with passive incontinence associated with ileal pouches.L-erythro methoxamine gel, an alpha-1 adrenoreceptor agonist similar to phenylephrine, has also been shown in two proof-of-concept studies to increase internal anal sphincter resting pressure,[224,225] although no clinical trial data are available as yet.

2. Valproate sodium

The gamma-amino butyric acid transaminase inhibitor, valproate sodium, also increases anal canal resting pressure. It was compared to placebo in a double-blind, randomised crossover study [226] in 17 patients with diarrhoea-related faecal incontinence secondary to colectomy and ileoanal anastamosis. The drug decreased faecal incontinence episodes and stool frequency relative to baseline and increased anal canal pressure, whereas placebo did not have these effects. In a second randomized controlled trial by the same investigators [227] patients with ileal pouches were treated with valproate sodium or placebo. There was a significant improvement in anal canal pressures, pouch capacity, and continence. Therefore, valproate sodium is of possible benefit in this population.

c) Drug treatment of constipation-associated faecal incontinence

Constipation-associated faecal incontinence, sometimes referred to as "overflow incontinence." It is more common in children, nursing home residents, and in patients with spinal cord injury. The proportion of faecally incontinent nursing home residents whose faecal incontinence is attributable to "overflow constipation" is not known. No studies of treating constipation-associated faecal incontinence in adults, outside these groups, were found.

1. Summary of evidence on medication and faecal incontinence

- Loperamide is useful for diarrhoea-associated faecal incontinence. There is some evidence that the loperamide may be superior to diphenoxylate **(Evidence Level 2).**

2. Recommendations for practice

- Treat faecal incontinence with diarrhoea with anti-diarrhoeal medication **(Recommendation**

Grade C); titrate the dose to individual response. **(Recommendation Grade C)**

- We are unable to recommend sphincter modifying drugs. **(Recommendation Grade D)**

3. Recommendations for research

- Additional, well-designed studies are needed to validate the common clinical practice of using laxatives to treat constipation-associated faecal incontinence.
- There is a need for further research on preparations, doses and combination therapies for all types of faecal incontinence and all patient subgroups
- The potential for topical treatments is high, but there will need to be formal clinical trials of such agents.

VIII. PELVIC FLOOR MUSCLE EXERCISES, BIOFEEDBACK, AND ELECTRICAL STIMULATION

Pelvic floor muscle training (PFMT), biofeedback, and electrical stimulation are distinctly different therapeutic techniques for treating faecal incontinence; see descriptions below. These techniques are compared to each other or combined in some studies (e.g., biofeedback combined with electrical stimulation).

1. PELVIC FLOOR MUSCLE TRAINING

Pelvic floor muscle training (PFMT) is also called Kegel exercise training, after its developer. [231] The patient is instructed to contract the pelvic floor muscles including the external anal sphincter and puborectalis while keeping abdominal wall muscles relaxed and to do this multiple times each day with the goal of strengthening pelvic floor muscles. In a typical protocol, the patient may be instructed to squeeze for 10 seconds while continuing to breathe deeply so that the abdominal wall muscles do not also contract. Ten to 20 such 10-sec squeezes are separated by 20 second periods of pelvic floor relaxation. Often patients are instructed to squeeze 10-20 times in a block and to repeat this block of exercises 3-5 times a day. The patient may be taught how to perform this exercise using only verbal or written instructions,[232] or they may be given verbal feedback on their performance by the therapist during a digital rectal examination.[233,234] However, electronic or mechanical devices are not often used to amplify the sensory information available to the patient on how well they are performing the exercises.

2. BIOFEEDBACK

Biofeedback training is distinguished from PFMT by the use of electronic or mechanical devices to augment the intrinsic sensory information available to the patient on how well they are contracting their pelvic floor muscles. The purpose of this type of training is to ensure that patients learn the appropriate way to contract the pelvic floor muscles while keeping abdominal wall muscles relaxed. Such training is intended to strengthen pelvic floor muscles and it is usually combined with instructions to practice PFMT at home between clinic visits. Another feature of many biofeedback training protocols is sensory training or coordination training. As a consequence of neurological injuries, many patients lose the ability to recognize sensations associated with the movement of stool into the rectum and may fail to contract the pelvic floor muscles in order to avoid stool leakage. In sensory training, a balloon-tipped catheter is introduced into the rectum and distended with varying volumes of air to help the patient learn to recognize weaker distensions. Coordination training is a variant of sensory training and refers to having the patient practice contracting pelvic floor muscles in response to any sensation of rectal distention until this becomes a well-practiced habit.[138]

3. ELECTRICAL STIMULATION

Electrical stimulation from probes placed in the anal canal or from electrodes on the perineum adjacent to the anus has also been used to treat faecal incontinence. In typical applications, stimulation is performed daily at home using a battery operated electrical pulse generator connected to the anal electrodes. [234] Different theories have been advanced to account for how this might facilitate continence. [234] In the earliest applications, electrical stimulation was used at intensities that triggered a contraction of the pelvic floor muscles, and patients were encouraged to try to augment the contractions produced by electrical stimulation or to try to reproduce these contractions. [234] Others have suggested that the stimulation of afferent nerves by lower intensities of electrical stimulation may help by increasing the sprouting of synapses peripherally or the size of the receptive fields for these nerves in the brain. [235] Electrical stimulation is sometimes combined with biofeedback. [236]

4. METHODS

The effectiveness of PFMT, biofeedback, and electrical stimulation was assessed by this committee in 2008. In this review, we summarize the recommendations made in the Fourth International Consultation on Incontinence [173] and update the recommendations for PFMT, biofeedback, and electrical stimulation from non- implanted devices by reviewing in detail articles published between January 2008 and January 2012. The faecal incontinence surgery committee (Committee 17) updated the review on electrical stimulation. Databases searched were PubMed, Web of Science,

Cochrane Reviews, and (for drug treatment) EMBASE. These searches were limited to studies in which the subjects were adult humans. No restrictions were placed on language of publication. The search terms were: (Faecal incontinence OR Anal incontinence) AND (Biofeedback OR Neuromuscular conditioning OR Pelvic floor exercise OR Kegel exercise OR Neuromodulation OR Drug treatment OR Antidiarrheal OR Loperamide OR Laxative OR Nifedipine OR Phenylephrine OR Cholestyramine OR Clonidine). In addition, the following individual authors were searched: A Bharucha, C Norton, B Southwell, SS Rao, M Kamm, A Wald, F Azpiroz, P Enck, M Crowell, and R Mittal. The bibliographies of identified studies were also searched for additional references.

This search identified 665 references which were reviewed by title and abstract for relevance and the relevant ones were assigned to the following 4 sets. Minor overlap between lists was allowed and reviews were included to allow us to check for additional references. The reference sets were (1) Biofeedback (69 references), (2) Pelvic floor exercise (9 references), (3) Electrical stimulation without implanted device (13 references), and (4) Drug treatment (25 references). These reference sets were assigned to separate reviewers and read carefully to identify randomized controlled trials (RCTs), cohort studies with appropriate comparison groups, and a few uncontrolled cohort studies which were included because they addressed key issues such as long-term maintenance of treatment effects. After eliminating duplicate references and studies containing fewer than 10 patients per treatment condition, 6 studies published since January 2008 met inclusion criteria (**Table 3**).

5. SUMMARY OF ICI 2008 ASSESSMENT

a) ICI 2008 assessment of pelvic floor muscle exercises

The review of the literature in the previous ICI report [173] identified several RCTs in which PFMT was used as a control condition to determine whether the addition of biofeedback to PFMT yielded greater improvements, but only one RCT which attempted to isolate the contribution of PFMT by comparing education and advice alone to education and advice plus PFMT. [137] This study (described above) was well designed and adequately powered. No greater benefit was observed for PFMT compared to advice. Based on this evidence, the reviewers in 2008 concluded that PFMT may be as effective as biofeedback and that advice alone may be as effective as PFMT.

b) ICI 2008 assessment of biofeedback therapy [173]

In the last International Consultation on Incontinence [173] the working committee concluded that, "In contrast to the mostly favourable outcomes reported in uncontrolled studies, randomized controlled trials have generally found no additional benefit when biofeedback was added to either a comprehensive behavioural and medical management program, or to digitally taught sphincter exercises" [page 1358]. The reviewers noted that very few studies have reported process measures, such as pre-post changes in sphincter strength or rectal sensory thresholds, which are targeted by biofeedback therapy, and presumed to account for any improvements in continence, and they questioned whether this should be required, before a biofeedback treatment protocol can be said to be responsible for an improvement in faecal incontinence. The committee concluded that biofeedback "…is possibly effective but currently unproven" [page 1359]. Only the following three RCTs were available for review in 2008:

Heymen et al. [237] randomized 40 patients with faecal incontinence to one of 4 groups: (a) EMG biofeedback during clinic visits, (b) EMG biofeedback plus sensory training with a balloon during clinic visits, (c) EMG biofeedback in the clinic plus use of an EMG biofeedback trainer at home, and (d) EMG biofeedback plus sensory training in the clinic plus daily use of an EMG biofeedback trainer at home. There were no significant differences between groups, but the study was underpowered with only 10 patients per group.

Norton et al. [137] randomized 171 patients to one of 4 groups: (a) education and management advice provided by a nurse clinical specialist; (b) advice plus PFMT taught verbally and by digital rectal exam; (c) advice, PFMT, and instrumented biofeedback which included both sensory and strength training; and (d) advice, PFMT, biofeedback, and daily home practice with an EMG biofeedback unit. There were up to nine 40-60 minute sessions in each group (median number of sessions completed was 5). There were no significant differences between groups in subjective rating of improvement, change in Vaizey Continence Scale scores, or change in frequency of faecal incontinence. Specifically, there was no greater rate of improvement in the biofeedback group (53% improved) compared to the advice and education only group (54% improved). A limitation of the study was that 49% of patients rated their incontinence severity as "minor" at baseline, and the median frequency of incontinence before treatment was only once per week.

Solomon et al. [233] randomized 120 patients with mild to moderate faecal incontinence to one of three groups: (a) manometric biofeedback, (b) trans-anal ultrasound biofeedback in which the ultrasound image was visible to the patient in real time, and (c) PFMT taught by a therapist who provided verbal feedback during digital rectal exami-

nation. There were no differences between groups on the Pescatori or St. Mark's incontinence severity scales, subjective ratings of improvement, quality of life, or manometrically measured squeeze pressures. However, there were significant differences from pre-treatment to post-treatment on most outcome measures.

c) ICI 2008 assessment of tibial nerve transcutaneous electrical stimulation from non-implantable devices

In the previous ICI report, [173] studies of tibial nerve transcutaneous electrical stimulation were reviewed by the faecal incontinence surgery committee. [238] In the absence of any controlled studies, this committee concluded that tibial nerve stimulation was an investigational technique and did not endorse it for clinical use.

6. UPDATE: REVIEW OF EVIDENCE FOR 2008-2012

Five studies published between January 2008 and January 2012 met criteria for review (**Table 3**). Two studies were RCTs comparing manometric biofeedback to PFMT, [232,239] a third RCT compared different methods of performing PFMT, [240] and the last evaluated the effects of PFMT vs. no PFMT on the prevention of anal incontinence (i.e., inclusion of flatus incontinence) during pregnancy and post-partum. [241] Another large cohort study [242] was included because it addresses the duration of biofeedback effects by following subjects until 60 months.

The Heymen et al. study [232] is important because of its novel design: All patients were first treated for 4 weeks with a conservative treatment protocol that emphasized patient education and normalization of stool consistency with fibre or non-prescription medication. This run-in protocol included only what is considered standard care for faecal incontinence, but the educational component was enhanced by (a) using schematics of the anatomy of the pelvic floor and images from defaecography to teach them why they were incontinent, and (b) having patients keep diaries of bowel accidents and stool consistency. At the end of 4 weeks, patients were asked whether they had experienced "adequate relief" of faecal incontinence, and the 21% who answered affirmatively were excluded from the rest of the trial. The remaining patients who did not report adequate relief had been randomly assigned before the run-in period to either biofeedback plus PFMT or PFMT alone. These interventions were presented in such a way that there were no differences between groups in the expectation of benefit. The biofeedback intervention combined strength training with sensory and coordination training, and was delivered in 5 one-hour sessions spaced approximately 2 weeks apart. PFMT was taught by verbal instruction, not with the benefit of digital rectal examination. The primary assessment was at 3 months follow-up as determined a priori, and patients who reported adequate relief at 3 months were followed up again at 12 months. All patients not reporting adequate relief at 3 months were assumed to be non-responders at 12 months.

An intent-to-treat analysis at 3 months showed that significantly more patients in the biofeedback group reported adequate relief compared to the PFMT-only group (76% vs. 41%). Continence (zero faecal incontinence episodes in the previous month) was achieved by 44% of biofeedback-treated patients compared to 21% of PFMT-only patients. Scores on the validated Faecal Incontinence Severity Index [243] confirmed significantly greater improvement in the biofeedback patients compared to the PFMT-only patients at 3 months and again at 12 months follow-up. Heymen et al. [232] also showed that biofeedback-treated patients increased their anal canal squeeze pressures and decreased their abdominal wall tension during pelvic floor contractions significantly more than PFMT-treated patients, but changes in sensory thresholds were not significantly different.

The results of Heymen et al. [232] suggest that biofeedback plus PFMT is superior to PFMT alone in patients with moderate to severe faecal incontinence. They also show that treatment benefits for both biofeedback and PFMT are not explained by nonspecific treatment effects of conservative management such as education and normalization of stool consistency. Furthermore, these data provide evidence that PFMT is more effective than conservative management alone.

Bols et al. [239] reported an RCT which also compared manometric biofeedback plus PFMT to PFMT alone. Eighty patients with moderate to severe faecal incontinence were randomized to these two conditions. Up to 12, 35-minute training sessions were provided, and the primary outcome was the Vaizey Incontinence Severity Score. There was no significant difference between groups, although there was a trend favouring manometric biofeedback: 82.5% of the manomeric group vs. 66% of the PFMT-only group improved by more than one point on the Vaizey scale. Limitations of this study were lack of power, only 75% of the numbers calculated beforehand as needed for adequate power were enrolled, and the fact that the intervention was provided by 25 different physiotherapists in private practice settings.

Bartlett et al.[240] compared exercise regimens, i.e., whether the patients were trained to perform fast twitch exercises (1 sec duration contractions) in addition to slow contractions (10 second squeezes) or they only performed slow contractions (10 second squeezes). The 72 patients enrolled in this

Table 3: Studies of Biofeedback, Pelvic Floor Muscle Training, and Electrical Stimulation from Surface Electrodes

Reference Country	Population	Intervention	Control	Outcome	Comments
Heymen et al.[232] USA	108 patients with faecal incontinence, Mean age=59.6 years, 77% females. Patients excluded if they responded to run-in of medical management. Patients randomized to groups prior to run-in	Manometric biofeedback (**BF)** taught in 6 biweekly sessions of 60 min each. Patients taught to coordinate sphincter contraction with sensation of balloon distention. Also performed pelvic floor muscle exercises (**PFME**) daily. Only difference from control was BF.	**PFME** taught by verbal instruction. Instructed to squeeze 100X/day. Returned for biweekly sessions to review diary and receive further instructions. Matched to BF group on therapist contact time and expectancy.	Groups comparable at baseline. At 3 mo. follow-up, BF showed greater decrease in FISI than PFME. 76% of BF reported adequate relief at 3 mo vs. 41% PFME. Greater improvement maintained at 12 mo follow-up. Complete continence in 44% of BF vs. 21% of PFE.	Strengths: Exclusion of subjects responding to medical management and use of intent to treat analysis. Weakness: Most assessments not performed by blinded assessor. No differences in quality of life improvement.
Bols et al.[239] Netherlands	80 FI patients with Vaizey severity score >12 (possible range 0-24). Excluded patients with absent squeeze pressure, chronic diarrhea, overflow incontinence, rectal prolapse, and soiling only. Mean age 60; 90% females	**Rectal balloon training (RBT) + PFME**. RBT was individualized: For insensitive rectum, patient was trained to respond to smaller volumes; for hypersensitive rectum, patient was trained to tolerate larger volumes using progressive distension and urge resistance. All patients received coordination training. PFME training was individualized with goal of improving strength and duration of squeeze. Sessions were 45 min.	**PFME** training was individualized with goal of improving strength and duration of squeeze. In both arms patients received up to 12 sessions in 9-week period. Sessions were 35 min. long.	Primary outcome was Vaizey severity score which was not significantly different between groups. 82.5% of RBT group and 66% of PFME-only group improved >1 on Vaizey scale. Some secondary outcomes favoured RBT.	Limitations: Lack of power: only 75% of required sample size for adequate power was included. The use of 25 different physiotherapists from private practice may have resulted in inconsistent treatment.
Bartlett et al. [240] Australia	72 patients with onset of faecal incontinence following colorectal cancer surgery were randomized to two groups. Mean age 62 years; 73.6% female	All patients received 4 weekly manometric **BF** sessions plus **PFME** training in sustained, 10 sec squeezes. The experimental group received additional practice of **1/sec rapid maximal contractions**.	Equivalent number and type of BF sessions combined with **PFME** training of **sustained, 10 sec contractions**. The only difference was no rapid exercises.	Both groups improved with no difference between groups. Attrition rate was 22-29%.	Major limitation: Heterogeneity of population and small sample sizes (type 2 error
Bo et al.[241] Norway	105 sedentary primiporous women without history of faecal incontinence	**PFME** taught as part of group exercise class 2X/week for 12 wks. Patients performed 3 sets of 12 maximal contractions per class. Only group verbal instructions provided.	Controls received usual care.	No difference in number of women reporting flatus or faecal incontinence during pregnancy or at 6 wks. post-partum.	Study was underpowered.
Lacima et al.[242] Spain	Cohort of 95 patients incontinent of solid stool referred for BF. Mean age 61 years; 85% females. Excluded patients with recent obstetric injury, cloaca defect, and rectal prolapse	**Manometric BF** combined strength training, sensory training, and coordination training for five 45-min.sessions. Daily **PFME** were also prescribed.	**No treatment.** Cohort of 40 patients referred to the same clinic for evaluation but BF was not recommended and no treatment for faecal incontinence was prescribed.	At **60 months follow-up** 86% of the BF group were continent or had >75% reduction in faecal incontinence frequency compared to 26% of untreated controls.	Strength: 60 month follow-up. Weakness: patients were not randomized to treatment. The BF group had greater average faecal incontinence severity than controls at baseline.

study had an onset of faecal incontinence following colorectal cancer therapy. Both groups improved with no difference between groups.

Lacima et al. [242] followed a cohort of 95 patients whom he treated with biofeedback and PFMT and followed up 60 months later. What makes this study worth including is that the authors showed that even at 60 months following training, 86% of the biofeedback/PFMT group were continent or had at least a 75% reduction in the frequency of faecal incontinence.

7. TIBIAL NERVE PERCUTANEOUS STIMULATION

There has been persisting interest in the use of tibial nerve stimulation for the treatment of faecal incontinence, reflected by the publication of several uncontrolled case series. [244,245] The theory behind this treatment derives from traditional Chinese medicine which identifies the posterior tibial nerve as an acupuncture point where stimulation can inhibit bladder contraction. Stimulation is done either using surface electrodes applied over the tibial nerve at the level of the ankle or by inserting a needle electrode into the region of the tibial nerve. Published case series [244,245] show a modest benefit for approximately half of patients tested, and in the absence of controlled studies, this technique must still be regarded as investigational.

Another variation of electrical stimulation is transabdominal electrical stimulation accomplished by passing electric current between an electrode on the abdominal wall and one on the back. This has so far been used only in children with slow transit constipation, [246] many of whom have encopresis. Reports show improved transit time, [247] improved quality of life, [244] and reduced encopresis. [245] This technique may find application in adults with overflow faecal incontinence but is currently regarded as investigational.

8. SUMMARY OF EVIDENCE

- Manometric biofeedback training is possibly effective. A new high quality study provides support for the hypothesis that biofeedback, when provided by an experienced therapist, is more effective than pelvic floor exercises alone, but the variability between studies suggests that results may be dependent on the training and experience of the therapist. (**Evidence Level 1**)
- PFMT is possibly effective for the treatment of faecal incontinence. New evidence shows that PFMT alone significantly improves outcomes for patients who have not responded to conservative management. [232] (**Evidence Level 2**)
- There is no support for the hypothesis that adding “fast twitch” contractions to PFMT improves continence outcomes. (**Evidence Level 2**)
- There is no support for the addition of electric stimulation from non-implanted devices in the treatment of faecal incontinence. (**Evidence Level 2**)

9. RECOMMENDATIONS FOR PRACTICE

- PFM exercises are recommended as an early intervention in the treatment of faecal incontinence as part of a conservative management bundle of interventions, based upon low cost and morbidity and weak evidence suggesting efficacy. (**Recommendation Grade B**).
- The use of biofeedback as a treatment for faecal incontinence is recommended after other behavioural and medical management has been tried, if adequate symptom relief is not obtained, given the numerous positive outcomes from uncontrolled trials, limitations in the current RCTs and low morbidity associated with its application. (**Recommendation Grade B**).
- Based on currently available evidence it is not possible to recommended electrical stimulation for faecal incontinence. (**Recommendation Grade C**)

10. RECOMMENDATIONS FOR RESEARCH

- There is a need to conduct further RCTs to determine whether specific biofeedback and pelvic floor muscle exercise protocols can alter physiological parameters of ano-rectal function with concomitant changes in bowel control.
- Clear description of modalities and evaluation of different elements of biofeedback
- Adherence monitoring
- Standardisation of outcome measures
- Long term follow up
- Robust patient-focused outcome measures
- Understanding of physiological effect and relationship to symptom change
- Work on clinically meaningful improvement and distinguishing cure from improvement rates
- The exploration of possible synergies between urinary and faecal incontinence interventions and evaluations should be considered in study designs.

IX. QUALITATIVE RESEARCH ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

1. BACKGROUND

The experience of faecal incontinence has been studied from a qualitative perspective since 1999 and tied with quality of life. Qualitative methods focus on

the intensive investigation of the particular, and the meaning of a phenomenon, in this case, faecal incontinence. Because qualitative studies generate large amounts of quality text data small purposeful sample sizes are used to accomplish their aims. These studies focus on studying the context or experience of a phenomena rather than measurement of variables. Sample sizes in the 14 studies included in this review ranged from 9 to 100 for qualitative phenomenological, grounded theory and descriptive studies, to 186 participants in an open ended questionnaire interview, for a total of 462 participants. Three studies received a grade of C but were included in the review because the evidence was relevant and substantiated by other quality studies.

The studies below have used a number of qualitative methods to explore the experiences of quality of life using phenomenological, grounded theory and qualitative descriptive designs using in-depth interviews, one study used one question with a rating scale, and one study used a semi-structured interview questionnaire. A thematic analysis was completed on the content of the quality of life studies, and the following five themes were derived and used as categories for the review of content: issues relating to relationships, time, body, sexuality and diet. Of the twelve studies reviewed on faecal incontinence, 4 studies focused on community living women, one study of women in a nursing home with pelvic floor dysfunction, one study of community living men, 4 studies of community living adults, and studies of specific diseases causing faecal incontinence including spinal bifida and multiple sclerosis.

2. CRITERIA FOR EVALUATION

Over the last 25 years there has been an extensive debate about the best methods and criteria to evaluate qualitative research studies. Criteria for the evaluation of qualitative research was synthesized using the most recent literature on quality and rigor, and is included here. These criteria were used to critique studies, strengths and limitations were noted, and a grade was given for practice recommendation.

In the last 10 years new ideas and criteria have been designed and are now being applied to evaluate qualitative studies.[248-257] The qualitative research studies on faecal incontinence (faecal incontinence) and quality of life, related to faecal incontinence, will be analyzed according to these new criteria summarized below. The strength of the evidence provided by an individual study depends upon the individual study design to maximize application to practice. A grading procedure has been developed here to rate studies for their applicability to practice from A to C.

a) Type of study – The qualitative evidence pyramid

1) Qualitative metasynthesis

2) Interpretive designs including phenomenology, grounded theory, ethnography.

3) Descriptive qualitative designs using content analysis (including inductive and deductive content analysis approaches, analysis of focus group data, photovoice, participatory action research, single or multiple case studies).

4) Surveys with semi-structured open-ended questions.

b) Criteria for evaluation of qualitative studies

1) There is a set of discernable research purposes or questions that are suitable for qualitative inquiry.

2) The purpose or questions are linked with a critical review of the literature and key studies are included identifying a gap or misunderstanding of the phenomenon.

3) There is a guiding frame of reference for the study that fits the target phenomenon.

4) There is congruence between the method and the research purpose.

5) The sampling plan is purposeful and fits the purpose and method.

6) The sample size and configuration fit the purpose and sampling strategy.

7) Inclusion and exclusion criteria are described and appropriate for the purpose.

8) Data collection techniques and sources fit the purpose, method and sample.

9) The analysis plan fits the purpose and method.

10) Data are sufficiently analyzed and interpreted, data is re-represented and category or thematic meaning is apparent. The interpretation or description is distinguishable from the original data collected.

11) The participants' voices are heard through examples highlighting the categories or themes of the findings.

12) Concepts and ideas are well developed and linked to each other and to the data.

13) The results offer new insight into the phenomenon studied and transferability of findings is evident.

14) Reflexivity is addressed within the context of the study.

15) Evidence of an audit trail of how key decisions were made is clear. Strategies to achieve rigor are described.

16) Study specific limitations are summarized.

17) Ethical considerations are attended to and described.

c) Levels of evidence

Level 1: A study would include all criteria. Excellent evidence leads to a practice recommendation.

Level 2: A study should include criteria numbered 1, 4 - 13, 17. Moderate evidence leads to a possible practice recommendation (more evidence is needed).

Level 3: A study does not include the majority of criteria for evaluation. Poor evidence that does not lead to a practice recommendation.

d) Grades of recommendation

Grade A recommendation: Grade A recommendation includes studies with evidence levels 1-2 (the qualitative evidence pyramid).

Grade B. Grade B recommendation includes studies with evidence levels 2-3.

Grade C. Grade C recommendation includes studies with evidence levels 3 or lesser quality.

3. SEARCH METHOD

In order to gain a deeper understanding of the experience of having faecal incontinence from the perspective of the client, the PUBMED database (from 2000 to 2011) was searched using the following subject headings and key words: qualitative research; anal, bowel, faecal and incontinence; quality of life and faecal incontinence; and quality and rigor in qualitative research. Additional articles were identified by examining reference lists from articles, articles in press by the authors and other systematic reviews. This search yielded over 600 studies of which only 16 used qualitative methods and 11 were used for evaluation of qualitative methods. These articles included topics on the experience of faecal incontinence from the perspectives of men and women, faecal incontinence and colorectal cancer, incontinence and sexuality, quality of life and faecal incontinence, pelvic floor dysfunctions and frail elderly women, diet strategies to manage faecal incontinence, goals of faecal incontinence management, life with post-natal faecal incontinence, and spina bifida.

4. REVIEW OF EVIDENCE ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

The review of the evidence on the experience of faecal incontinence and quality of life begins with a study review including the study purpose, design and critique of the design and the evidence level. The findings were overlapping for most studies so that the study findings are summarized in a following section using five categories of experience/quality of life that were identified: relationships, time, bodily symptoms, sexuality, and diet.

A descriptive qualitative study conducting unstructured interviews of 20 women's experiences of faecal incontinence from Britain focused on the assessment of symptoms of incontinence, coping strategies and the provision of continence aids.[258] The quality of the study was fair to good. Details of the analysis procedure were not clear and participant's voices were not included in the report. Additionally reflexivity concerns were not addressed.

The purpose of a descriptive qualitative study in the United Kingdom was to identify question items for a quality symptom and quality of life assessment for individuals with anal incontinence.[259] Three substudies addressed the purpose. First, seven clinical experts were asked to characterize symptom items of anal incontinence, second,[284] free text comments from patients involved in a treatment intervention trial were collected, and third, 31 qualitative interviews were conducted with people with anal incontinence. The study design was strong and inclusive of clinicians and patients. A grounded study method was mentioned as the study design but no substantive theory was developed and reflexivity was not addressed.

Another descriptive qualitative study in Sweden explored faecal incontinence in adults with spina bifida.[260] Using semi-structured interviews with 11 subjects, themes were generated using content analysis. The rigor of this study was good with insightful findings and powerful quotations used to illustrate the interpretations of the participants' experiences. Specifics of the analysis process were not given which was a weakness. The concept of reflexivity was not addressed.

A phenomenological study using 10 community dwelling women was conducted on dietary issues in the US.[145] The study was a secondary analysis of the dataset collected in a larger study by Peden-McAlpine, Bliss, and Hill.[261] Content focused specifically on diet and the meaning of the role of diet and food related to faecal incontinence. Narrative interviews were conducted with the women and the design of the study was strong with few limitations although reflexivity was not mentioned.

A descriptive qualitative study, conducted in the US on frail elderly women, with pelvic floor dysfunction, in nursing homes, interviewed 25 women ages 65-96.[262] The purpose of the study was to increase understanding of the views of frail elderly women in residential care related to quality of life, and values and preferences for pelvic floor care. The study design was strong and used NVIVO as a tool to identify representative categories. The categories derived were not specifically related to the aims. One limitation was that the criterion of reflexivity was not addressed.

A study in the U.S.[263] interviewed clients about their goals for faecal incontinence management as part of a RCT on dietary fibre. The main purpose and source of data in this study was not an interpretive qualitative

exploration. A semi-structured interview questionnaire was used to elicit goals from 189 people with faecal incontinence. The study design was methodologically sound and the overall quality was excellent.

A phenomenological study on community living women was conducted in the USA to investigate the lived experience of women managing faecal incontinence.[261] The study used in-depth narrative interviews with women between the ages of 37 and 78. The study design was excellent although issues of reflexivity were not mentioned.

A phenomenological study on 11 community living men, between the ages of 48-85, was conducted in the USA to investigate the lived experience of men managing faecal incontinence.264 The study used in-depth narrative interviews with men between the ages of 37-78. The study design was excellent although issues of reflexivity were not mentioned.

A study from England was conducted to explore the impact of incontinence on an individual's sexuality and to identify the impact of health interventions for the management of incontinence on sexuality.[265] A quota sample of 27 subjects who were being successfully managed and those being unsuccessfully managed were interviewed. The study design was strong although the inclusion/exclusion criteria used for quota sampling was not specific and reflexivity and limitations were not addressed.

One study from Denmark explored how post-partum women experience and cope with faecal incontinence. [266] In-depth unstructured interviews were conducted with 9 women ages 28-50 and analyzed with a grounded theory analysis technique for analysis. This study was of good quality however reflexivity, ethical considerations, and limitations were not noted.

A qualitative analysis was conducted on letters sent to the Multiple Sclerosis Society in the UK after a letter regarding constipation was printed in the Society's newsletter.[267] More than 100 letters and emails were received from Society members discussing their bowel problems and were analyzed using a qualitative approach. The study quality was good however the detail of the analysis was lacking.

A study in the UK investigated aspects of distress, expressed by colorectal cancer patients, to produce a more detailed account of the illnesses' impact on their identities and self-understanding.[268] Thirty-nine men and women participated in in depth interviews from across the UK. The sample included 19 men and 20 women ranging from 33 to 87 at the time of the interview. The study design was strong and the findings portrayed a powerful experience of these participants. No report of reflexivity was noted.

A qualitative descriptive study conducted unstructured interviews with 10 women who had flatal or faecal incontinence, post-vaginal delivery, with a view to improve an existing quality of life scale for faecal incontinence.[269] The authors came to interesting conclusions about relevant parameters to measure in younger women with faecal incontinence, but it is not clear if these concepts are reflective of the participants' voices. The collection technique, analysis and concept development were not explained.

A qualitative descriptive study completed guided interviews with 22 community living adults with faecal incontinence.[270] The aims of the study were to explore the participants' experiences of faecal incontinence on lifestyle, quality of life and how they adapted management strategies. Another aim was to learn about their disclosures and reasons for seeking help from health professionals. Grounded theory was stated as the method although a substantive theory was not produced in the findings. The findings were not well interpreted and linked together. Some insightful information was learned from the study, about faecal incontinence, that was corroborated by other quality studies.

A descriptive qualitative study was conducted in Britain to validate a draft questionnaire measuring quality of life issues with community living women with faecal incontinence.[271] Twenty-seven women with longstanding faecal incontinence problems were invited to participate in one of 2 focus groups. The mean age of the women was 51. No specific procedures for data analysis were included and reflexivity and ethical issues were not mentioned. Study findings were similar to those of other quality studies.

5. LIVING WITH FAECAL INCONTINENCE AND RELATIONSHIPS – SUMMARY OF EVIDENCE

- Men and women found that faecal incontinence was a perceived threat to their social acceptability, privacy and relationships. [258,261,262,264,265,269] **(Evidence Level 1)**
- Who to tell about the faecal incontinence problem and when was a matter of great concern. Usually family, close trusted friends and coworkers were told because it could not be kept a total secret,[258,261,264] **(Evidence Level 1)**
- Discussing the problems with others who suffered from faecal incontinence was comforting and allowed conversation about how to manage the problem.[261,264] **(Evidence Level 1)**
- Humor was used as a resource to avoid humiliation and embarrassment in dealing with daily symptoms of faecal incontinence and relationships, even though feelings of shame and humiliation persisted.[259, 261, 264] **(Evidence Level 1)**
- Men and women spoke about their discomfort in being with 'mixed company' and their concerns about a possible accident. Gender was an issue in relation to perceived social risk [261,264] **(Evidence Level 1)**

- Men and women described trying to protect themselves from the unpredictability of their symptoms and kept up a façade to keep the secret of faecal incontinence from others. [259] **(Evidence Level 2)**

- Support from spouses was noted to be very important for men and women.[258, 261, 264, 266] **(Evidence Level 1)**

- Relationships with healthcare providers were not helpful in providing advice concerning symptom management and control. Misinformation or no information was commonly given.[258-261, 264] **(Evidence Level 2)**

- Women reported feeling embarrassed and humiliated by having their faecal incontinence problem minimized or trivialized by rude or blaming health care providers leading, to the feeling of marginalization.[259,261] **(Evidence Level 1)**

- Women had concerns about entering into new relationships and there was an expressed concern about fear and shame of having to disclose their bowel problems.[259] **(Evidence Level 2)**

- Anxiety was present in both men and women who suffered from the uncertainty of social isolation because of faecal incontinence. [145,258-261,264,266] **(Evidence Level 2)**

a) Recommendations for practice

- Health care providers need to acknowledge the problem of faecal incontinence compassionately, and initiate the assessment and discussion of faecal incontinence symptoms, so they can be properly managed. The stigma, embarrassment and sensitivity associated with faecal incontinence compel clinicians to refrain from giving dismissive or blaming responses that may retard future care seeking and contribute to the under reporting of faecal incontinence. **(Recommendation Grade A)**

- Health care professionals can facilitate gender sensitive support groups and sharing of practical knowledge of faecal incontinence symptom management. **(Recommendation Grade A)**

- Primary care/generalists should refer patients to incontinence specialists when unable to provide therapeutic advice or treatment. **(Grade B)**

b) Recommendations for research

- Investigate the use of humour as a therapeutic coping strategy for dealing personally with the symptoms of faecal incontinence

- Defining the attitudes and treatment goals of health professionals treating faecal incontinence would be helpful to the identify some of the barriers to effective treatment.

- Assess the value of gender sensitive support groups to facilitate sharing of practical management strategies for faecal incontinence symptom management.

6. LIVING WITH FAECAL INCONTINENCE AND TIME AND PLANNING – SUMMARY OF EVIDENCE

- Participants describe spending a significant amount of time planning for and worrying about accidents.[261,264] **(Evidence Level 1)**

- Men and women perceived that their symptoms of faecal incontinence grew worse with aging in relationship to severity, onset and duration.[261,264] **(Evidence Level 1)**

- Men and women had symptoms for months or years before seeking help for the condition. [261,264] **(Evidence Level 1)**

- Women reported that the frequency of stool leakage was unpredictable and because of this, they needed to be vigilant and prepared for the unexpected. [259,261] **(Evidence Level 2)**

- Planning and management strategies of faecal incontinence to avoid an accident included: morning bathroom rituals, changing the location of their workstation (relative to the bathroom), altering eating habits (foods and timing), taking a fibre supplement, or using anti-diarrheal products.[258-261,264] **(Evidence Level 2)**

- Many women discussed packing 'kits' of absorbent products, cleansing supplies, extra clothing as a routine part of planning to leave their home.[258,261] **(Evidence Level 2)**

- Women postponed business meetings because of the faecal incontinence.[261] **(Evidence Level 1)**

- Women reported the frequency of stool leakage was unpredictable and because of this they needed to be vigilant and prepared for the unexpected.[258,261] **(Evidence Level 2)**

- Space was experienced as a measure of risk exposure for faecal incontinence and personal space shrank inward or expanded related to perceived comfort or lack of perceived social safety.[258, 260, 261, 264, 265, 268, 272] **(Evidence Level 2)**

- Seeking out the location and availability of a bathroom was a major consideration in all dimensions of space outside the home.[258-262,264,267] **(Evidence Level 2)**

- Travel was limited to places that felt comfortable and significant planning was done to prevent an accident. faecal incontinence limited travel for the family.[254,261,264,266] **(Evidence Level 2)**

- Women and men experienced heightened anxiety about faecal incontinence symptoms

and the risk of accidents in public spaces. [258,260,261,264] **(Evidence Level 2)**

- Work life presented complicated situations for both men and women and limited some people's ability to engage in productive work outside the home.[261,264,268] **(Evidence Level 2)**

- Symptoms related to faecal incontinence were a common reason for early retirement for both men and women.[268,261,264] **(Evidence Level 2)**

a) Recommendations for practice

- Recommend that clinicians share findings of practical management strategies, such as preparing cleansing kits and locating public restrooms, with other patients who have faecal incontinence to help them self-manage their experiences better. **(Recommendation Grade A)**

- Recommend coaching clients on how to plan for and reduce unpredictable incontinence accidents and/or their embarrassment; teach patients strategies to go to social situations and into public more confidently by supporting self-efficacy (this could include education on products, packing a change of clothes, disposable wipes, using a bowel diary to plan schedules, etc.). **(Recommendation Grade B)**

b) Recommendations for research

- Study interventions that promote enhanced self-efficacy

- Evaluate effectiveness of using a bowel diary or keeping a routine schedule to reduce incontinence accidents in public

- Evaluate effect of public education campaigns on normalizing elimination and raising awareness that incontinence is a treatable condition

7. LIFE LIVING WITH FAECAL INCONTINENCE AND BODILY SYMPTOMS, SELF ESTEEM AND BODY IMAGE – SUMMARY OF EVIDENCE

- Across all studies feelings of shame and embarrassment related to faecal incontinence were noted. **(Evidence Level 1)**

- Women felt stigmatized because of the faecal incontinence problem and stigmatized themselves.[258,261,266] **(Evidence Level 2)**

- Men and women reported that their emotional life and self-confidence was undermined because of the faecal incontinence and embarrassment.[258,261,264,266] **(Evidence Level 2)**

- Men and women reported changes in body image and self esteem as a result of their inability to control the symptoms of faecal incontinence. [259,261,264] **(Evidence Level 2)**

- Not talking about the problem and denying the faecal incontinence was a coping mechanism used to protect themselves from a threat to self-esteem and to prevent public embarrassment.[266] **(Evidence Level 2)**

- faecal incontinence caused women to view themselves as shameful, impure, or unworthy. [260,266] **(Evidence Level 2)**

- Some women reported the need for psychological consultations because of the feeling of being insufficient and vulnerable.[259,266] **(Evidence Level 2)**

- Unpredictability of the type and timing of an faecal incontinence event and its magnitude were key issues discussed by men and women.[145,261] **(Evidence Level 2)**

- faecal incontinence was a consequence of exercise, heavy chores, and lifting.[260] **(Evidence Level 2)**

- Bodily sensations associated with the symptoms included sensations in the intestines, itching, burning, cramping, feelings of incomplete bowel movements, and odour associated with flatus. Other symptoms discussed included leaking stool without feeling the need to defecate and false abrupt and urgent sensations usually indicative of defecation. Men lost confidence in symptoms to alert them to faecal incontinence due to the unpredictability of faecal incontinence.[260,261,264] **(Evidence Level 2)**

- Skin excoriation around the anus was reported, because of frequent bowel movements, soiling and excessive cleaning.[261] **(Evidence Level 2)**

- Women were attentive to their body image and dressed carefully to conceal pads and wore dark clothing when outside the home to hide stains if an accident should happen. [259,261,265] **(Evidence Level 2)**

- Men and women wore only small disposable pads that were not obvious through their clothing. Large diaper like, pads were avoided because of their visibility beneath clothing. [259,261,264] **(Evidence Level 2)**

- The essential theme in the phenomenological study of men managing faecal incontinence was 'secret resignation' where men came to accept that the consequences of faecal incontinence were normal for them.[264] **(Evidence Level 1)**

- The essential theme in the phenomenological study of women managing faecal incontinence was 'controlling the body out of control' as women tried to control all aspects of their life in relationship to the faecal incontinence and avoiding accidents.[264] **(Evidence Level 2)**

- Major goals of people experiencing faecal incontinence were to have fewer dietary restrictions, eliminate faecal leakage especially during exercise, less reliance on public toilet accessibility, more confidence in controlling faecal incontinence symptoms and a normal daily routine.[263] **(Evidence Level 2)**

- A sense of mastery and new self-confidence was perceived by some after years of successfully dealing with the symptoms of faecal incontinence.[270] **(Evidence Level 2)**

a) Recommendations for practice

- Acknowledge and provide empathy for the common feelings of shame and embarrassment **(Recommendation Grade B)**

- Raise awareness with clients and general public that faecal incontinence can often improve with conservative treatment and is not something that must be "put up with" in private **(Recommendation Grade A)**

- Recommend that conservative symptom management for faecal incontinence includes education about causes of faecal incontinence, diet modifications including fibre supplements, behavioural strategies such as pelvic floor muscles exercises and biofeedback, anti-motility medications, and use of absorbent products such as pads and briefs. **(Recommendation Grade A)**

- Recommend that health care professionals share positive coping strategies identified by participants, with other people managing the symptoms of faecal incontinence, that include privacy issues in the bathroom, counselling, restricting activity, carrying a change of clothes, humour, knowing the location of toilets when out, care of diet, choosing clothes carefully, careful cleansing and use of pads. **(Recommendation Grade B)**

- Recommend that clinicians consider patient's goals when developing a plan for faecal incontinence. **(Recommendation Grade A)**

- Requesting that people complete a daily stool diary is recommended when accurate information of faecal incontinence severity is important. **(Recommendation Grade A)**

- Appropriate referral to psychologists should be made to manage issues of self-efficacy, self-esteem and depression. **(Recommendation Grade B)**

b) Recommendations for research

- Determine how goal setting and tailoring interventions for faecal incontinence is effective in promoting adherence to a management plan.

- Evaluate whether training to pay attention to body sensations might reduce incontinence accidents.

- Studies of the effectiveness of interventions to promote a positive body image and increase self-esteem despite faecal incontinence are needed,

- Future studies should focus on the phenomenon of secret resignation as a method of coping by men, and effective techniques for treating these attitudes to assist them with improved communication with healthcare providers and care seeking.

- Studies are needed on approaches to educate and support men and women in adopting practices for managing faecal incontinence, the associated odour and urgency symptoms as well as to evaluate the successfulness of their practices.[264]

8. LIVING WITH FAECAL INCONTINENCE AND SEXUALITY – SUMMARY OF EVIDENCE

- Although asked about sexuality and intimacy women were reticent to discuss their sexuality or the effect of their symptoms on their sexual functioning.[259,261] **(Evidence Level 2)**

- Some women felt there were no changes in their sexual drive.[266] **(Evidence Level 2)**

- Women arranged timing of sex to meet their needs and the needs of their husbands in relation to the symptoms of faecal incontinence. [266] **(Evidence Level 2)**

- Women reported a range of psychosocial issues including lack of sexual arousal or a desire for abstinence.[259,260,265] **(Evidence Level 2)**

- Choice of clothing was an outward expression of sexuality and faecal incontinence and UI restricted clothing to wearing patterned materials in order to avoid people detecting an accident. [265] **(Evidence Level 2)**

- Men and women reported continually washing themselves to avoid smelling.[272] **(Evidence Level 2)**

- There was a lack of discussion of sexual concerns by health care providers after surgeries that affected sexual functioning.[265,268] **(Evidence Level 2)**

a) Recommendations for practice

- Recommend that clinicians ask directly about the impact of faecal incontinence on clients' sexuality. **(Recommendation Grade B)**

- Recommend that clinicians establish a comfortable, stigma-free climate in order to elucidate

the impact on sexuality and teach practical strategies. **(Recommendation Grade A)**

b) Recommendations for research

- Interventions that minimize stool leakage during intercourse, such as pelvic floor muscle therapy
- Develop and test intervention s to improve sexuality altered by faecal incontinence

9. LIVING WITH FAECAL INCONTINENCE AND DIET ISSUES – SUMMARY OF EVIDENCE

- Men and women discussed fasting or not eating for a number of hours or days as a strategy to deal with faecal incontinence symptoms outside the home.[145,259,261,264,266] **(Evidence Level 2)**
- Altering the timing of meals to avoid an accident was a common management strategy for faecal incontinence.[145,258,261,264] **(Evidence Level 2)**
- Restricting foods noted to lead to faecal incontinence, included sweets, alcohol, onions.[145] **(Evidence Level 2)** chocolate, rich and spicy foods, caffeine, fruits, greasy, fat, fried foods, and dairy products [145] **(Evidence Level 2)**
- Limiting portion or meal size was a strategy to limit faecal incontinence.[145,261] **(Evidence Level 2)**
- Avoiding gas producing foods such as pea soup, onions, cabbage, cauliflower and dairy products, was used as a treatment for flatus. [145,254,261,264] **(Evidence Level 2)**
- Increasing fluids was another practice used as a management technique for constipation. [145,261] **(Evidence Level 2)**
- Some women reported using protracted voluntary constipation as a management technique for leakage for up to 1 month.[260] **(Evidence Level 2)**
- Increasing dietary fibre and taking fibre supplements along with digestive enzymes and yogurt were noted as treatments for faecal incontinence.[145,261,264] **(Evidence Level 2)**
- Women reported eating foods they enjoyed at home and then dealt with the consequences of faecal incontinence symptoms.[145,261,269] **(Evidence Level 2)**
- Women lacked therapeutic guidance regarding diet modifications and adapted recommendations from other gastrointestinal disorders such as IBS and lactose intolerance or approached diet modification by trial and error.[145,261] **(Evidence Level 2)**

a) Recommendations for practice

- Diet is an important self-care strategy for faecal incontinence. Recommend that clinicians include teaching of successful strategies including timing of food intake, restricting food amounts to minimize leakage, avoiding aggravating foods, increasing water intake, and increasing the consumption of yogurt, high fibre foods or a fibre supplement. **Recommend Grade B**
- Recommend clinicians ask about dietary restrictions, as not all strategies employed by clients with faecal incontinence are helpful or evidence-based. **(Recommendation Grade B)**

b) Recommendations for research

- Determine the effectiveness of diet restrictions and supplementation and modifications in food preparation in reducing faecal incontinence
- Assess the effect of timing of food intake in a bowel management program

X. ALGORITHM

A revised algorithm for the initial management of faecal incontinence has been developed based on a review of new evidence in the literature within the context of previous evidence and consensus of an international group of experts on faecal incontinence. (See summary of the recommendations and algorithms at the end of this book.)

I. INTRODUCTION

Therapy for faecal incontinence is readily divided into non-surgical and surgical therapy. Selection of specific therapy is based upon a number of considerations, including the severity of incontinence and structural integrity of the anal sphincter.

Conservative therapy is most applicable to relatively mild cases of incontinence. Biofeedback retraining can be attempted for incontinence of any cause or severity, as the therapy is painless and risk-free. These treatments are discussed in detail elsewhere in this monograph.

The most widely accepted surgical therapy for faecal incontinence is overlapping sphincteroplasty. Typical of other well-established therapies, the evidence base supporting this approach is paradoxically less robust than that supporting more recent treatment options. Sphincteroplasty is useful only in cases in which there is an anatomic sphincter defect, and it has been reported to provide satisfactory results in many case series. However, several recent studies have now shown that results of sphincteroplasty deteriorate with time [1,2].

A number of operations were developed in the early to mid 20th century to provide a treatment option for patients whose native sphincter was either intact but weak or not reparable. Muscle transposition procedures using either gluteus maximus or gracilis were devised to create a functional biological neosphincter, but the approach did not gain widespread popularity. The Parks postanal repair was devised in 1975 to treat patients with incontinence due to pelvic neuropathy [3].

Dissatisfaction with available operations for faecal incontinence led to development of a variety of novel procedures during the last 20 years. The stimulated (dynamic) graciloplasty and the artificial anal sphincter were devised as salvage procedures for patients who had failed or were not candidates for standard therapy. A more recent approach is the use of sacral nerve stimulation, which was adopted for this purpose from its previously better-defined role in detrusor overacitivity incontinence and idiopathic urinary retention. Moreover, there has also been a trend towards development of minimally invasive approaches to faecal incontinence, such as the use of injectable biomaterials.

Several important caveats apply to interpretation of the results of surgery for faecal incontinence reported in the literature. First, the vast majority of reports are uncontrolled case series. Randomised controlled studies are rare, and those reported include only small numbers of patients [4]. Second, numerous quantitative measures have been used to report outcomes, but only recently have any of these been validated, such as the Faecal Incontinence Quality of Life (FIQL) instrument. Third, criteria for "successful" outcomes have been variable and often arbitrary. Fourth, the quality of data reported is variable, though it has generally improved with the passage of time. Chart review has been supplanted by patient questionnaires and interviews by independent data auditors; daily continence diaries, the most stringent form of data collection, have become increasingly commonplace (though not routine). Despite the fact that studies using lax data collection are certain to report better results than those using methodology that is more stringent, of necessity, composite reviews of surgical results include studies using various methods of data collection. Finally, results are not always reported on an intention to treat basis, particularly in the implantable device literature.

Search Methods

Pubmed search was conducted to identify studies published on the use of surgery for faecal incontinence in children and adults. Keywords used were faecal incontinence and surgery. Full text copies of studies deemed to be potentially relevant were obtained. Priority was given to systematic reviews, randomised controlled trials, and controlled clinical trials; if those were unavailable or inadequate, comparative observational studies, case series, case reports and narrative reviews were also included. Reviewers were not blinded to the names of studies' authors, institutions or publications. In view of the nature of the guideline, priority was given to the

reports with large number of patients and long follow-ups assessing efficacy of surgical interventions. Particular emphasis was placed on those reporting techniques and functional outcome including quality of life after an operation.

Non-English language papers were noted but excluded from the review unless they contained an English-language abstract providing sufficient information.

II. SURGERY FOR ADULT FAECAL INCONTINENCE

1. SPHINCTER REPAIR

Anal sphincter repair is the term used to describe primary repair of the anal sphincter mechanism following direct trauma. The most common indication is following childbirth and repair in this situation is usually performed by the attending obstetrician. Colorectal surgeons are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma. Occasionally, the anal sphincter mechanism is damaged during anorectal surgery for other anal pathology particularly surgery for anal fistula.

In Western obstetric practice, the incidence of overt anal sphincter injury (grade 3 or 4 tear) is low, 3- 5% following primiparous delivery and 0.5-1% following second and subsequent deliveries [5]. When prospectively looked for with endoanal ultrasound, the actual incidence of anal sphincter injury is higher [6,7]. A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2D endoanal ultrasound [8]. 3D ultrasonography suggests that the incidence is somewhat less, perhaps 11%, following primiparous delivery [9]. The risk factors for sphincter injury include instrumental vaginal delivery, prolonged second stage of labor, fetal macrosomia, and a persistent occipital position of the fetal head [7,10-12]. Midline episiotomy is associated with higher incidence of anal sphincter injury and the angle of mediolateral episiotomy may also influence perineal outcome [13]. A policy of restrictive use of episiotomy may reduce the incidence of anal sphincter injury [14].

Obstetric injury of the perineum is classified as a first degree tear if confined to vaginal epithelium and skin, second degree if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: IAS torn) or fourth degree if both EAS and IAS and rectal or anal mucosa are torn [15]. Primary repair of an obstetrical tear is correctly termed anal sphincter repair and is usually performed by the obstetrician immediately after delivery, most commonly in the delivery room under local or epidural anaesthetic. However recent guidelines issued by the Royal College of Obstetricians and Gynaecologists in the UK recommend that all such repairs should be performed in an operating room with adequate exposure, lighting and adequate anaesthesia [16]. By tradition, the technique of repair has been a direct oppositional repair of the severed EAS, however an overlapping technique, as commonly used in secondary repair (vide infra), has been recommended as it obligates identification and adequate mobilization of the severed ends of the EAS [17]. The IAS, if damaged, is difficult to identify separately and is usually repaired en block with the anal canal mucosa in a complete or 4th degree tear. Mahoney et al [18] however have shown that persistence of an IAS defect is adversely associated with continence outcome following repair of a 3rd or 4th degree tear, while Roos et al [19] have found that women with major tears (grade 3c or 4) were significantly more likely to have ultrasound evidence of a persisting IAS or combined IAS and EAS defect following obstetric repair. Such women were more likely to have poor functional outcomes. Separate repair of the IAS has been advocated [17]; however as with overlapping EAS repair, separate repair of the IAS requires good anatomical knowledge and meticulous technique and it is probable that these factors are reflected in the improved outcomes reported, rather than the actual technique used. Thus, McNicol et al [20] have reported full continence in 39/45 (86%) women who underwent primary repair using a standardized overlapping repair without separate identification and repair of the IAS.

There have been six randomised clinical trials [17,21-25], one meta-analysis [26], and a systematic review [27] that have investigated different techniques of immediate primary anal sphincter repair following obstetric injury. Four trials have found no difference between the overlapping and end-to-end repairs. One trial found the overlapping procedure superior and one found the end-to-end procedure to be superior. Thus it appears inappropriate to favor one type of repair over another [26]. **[LEVEL OF EVIDENCE: 1**] However, all studies were small and it is difficult to control for the skill of the individual obstetrician performing the repair. With regard to the suture material used in repair, a randomised trial found no difference in outcomes between braided and monofilament absorbable sutures with 12 months follow-up [22], while Parnell et al [28] found no difference in outcome in a case series of patients between absorbable and permanent sutures. [**LEVEL OF EVIDENCE: 2**]

As colorectal surgeons are in general more familiar with the anatomy of the anal canal, it has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon than an obstetrician [29]. Nordenstam et al [30] concluded, in a single institution study of 165 women, that technique and expertise impact on the outcome of pri-

mary repair and that if needed, the repair could be safely delayed until such expertise was available. In a similar study, Soerensen et al [31] found no adverse outcome with delayed primary repair; thus, repair can be safely delayed until adequate expertise is available. Co-operation between obstetric and colorectal surgical colleagues can result in much improved outcomes [20], while a structured training programme for obstetric trainees also improves clinical outcomes [32]. [**LEVEL OF EVIDENCE: 2**]

There have been two randomised trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent [33,34]. [**LEVEL OF EVIDENCE: 1**]

Alteration in faecal continence occurs in approximately 13 - 17% of women following primiparous vaginal delivery, even in the absence of a recognised sphincter tear [6,35,36]. The prevalence is greater if urgency of defaecation is included as a symptom [7]. MacArthur et al [37] found flatal incontinence in 27% of 7,879 women surveyed 12 weeks after delivery. [**LEVEL OF EVIDENCE: 2**] Fenner et al [38] found that women who had sustained third and fourth degree tears were more likely to have bowel incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Samarasekera et al [39] have found long-term effects on anal continence and quality of life following postpartum anal sphincter injury. Oom et al [40] have suggested that concomitant injury to the pelvic floor may be an associated determinant of outcome in addition to adequacy of sphincter repair. [**LEVEL OF EVIDENCE: 2**]

Management of subsequent labor following a previous anal sphincter tear must take account of obstetric risk factors, symptoms of incontinence and patient preferences. Harkin et al [12] found an approximately 5 fold increase in the incidence of recurrent sphincter tear compared to the incidence of first sphincter injury during second labor. Fynes et al [41] found that women with altered continence after first vaginal delivery were at risk of deterioration if delivered vaginally on their second pregnancy. Cesarean delivery before the onset of the second stage of labor was found to be protective [42]; however, Nelson et al [43] in a systematic review found that pregnancy rather than delivery was a more important in predicting post partum continence. Recently, Scheer et al [44] have confirmed that subsequent vaginal delivery is reasonable in asymptomatic women after a previously repaired third degree tear. [**LEVEL OF EVIDENCE: 3**]

A number of studies have looked at long-term outcomes after repair of a 3rd or 4th degree tears and all have shown an increasing prevalence of continence disorders with age. These findings parallel those of the general population of parous women who have not had a recognised tear [45-47]. Eogan et al [48] found in a study of women, 10, 20 and 30 years following delivery that onset of menopause was the most significant determent of symptoms, whereas Mous et al [49] found the incidence of incontinence increased with age irrespective of menopausal status. Fornell et al [50] found that subjective and objective anal function after anal sphincter injury deteriorates with time and subsequent deliveries. A persistent defect in the IAS was also found to be an important determinant, an observation supported by Mahony et al [18]. [**LEVEL OF EVIDENCE: 3**] There is some evidence that hormone replacement therapy may be of value in women who develop symptoms post menopause [51]. [**LEVEL OF EVIDENCE: 2**]

2. SPHINCTEROPLASTY

The term anal sphincteroplasty is used to describe secondary or delayed reconstruction of the anal sphincter musculature, injury to which has either not been recognised at the time of injury or the outcome of primary repair has been unsatisfactory. Anterior sphincteroplasty is the most common type of reconstruction performed because of the association with obstetric injury. In this situation, the anal sphincter muscles and perineal body have separated leaving a horseshoe type configuration to the anal sphincter mechanism, with a large defect in the anterior quadrant. Occasionally, the defect is such that the anal and vaginal mucosa have healed to form a cloacal defect. Anal sphincter defects related to previous anal fistula surgery or direct trauma are usually less complex and are not associated with a deficient perineum.

The decision to perform anal sphincteroplasty is based on an assessment of symptoms and the anatomical extent of the sphincter defect [52] . In assessing symptoms one of several continence scores should be used. The two most commonly applied are the Cleveland Clinic Continence Score [53] and the St Mark's Continence Score [54]. In addition a quality of life instrument should be applied [55] . Endoanal ultrasound is helpful in defining the extent of anal sphincter injury. 3D endo anal ultrasonography may provide further information [9]. Pelvic floor assessment using fMRI [56] or multiple contrast defeacating proctography [57] are valuable in the assessment of a more global pelvic floor injury. The American Society of Colon and Rectal Surgeons considers as surgical indication those symptomatic patients with localized defects, without defining exactly the minimum size of the injury detected as indication for this surgery [58]. [**LEVEL OF EVIDENCE: 4**]

Other causes of disordered continence should be excluded e.g. inflammatory bowel disease, colorectal cancer and neurological lesions. Patients with background IBS are more likely to be symptomatic

than those more predictable bowel habit and equivalent anal sphincter defects [59] . Pelvic floor electrophysiological assessment, while not essential, if performed, should be comprehensive and not confined to measurement of pudendal nerve terminal motor latency [60].

For symptomatic patients with a less than one quadrant anal sphincter defect, a trial of dietary modification, stool regulating drugs and physiotherapy is appropriate. There are limited data regarding the role of biofeedback with or without electrical augmentation [61,62], however a recent Cochrane review concluded there were insufficient data to allow definitive assessment [63]. [**LEVEL OF EVIDENCE: 2**]

For patients with a more than one quadrant anal sphincter defect, anal sphincteroplasty is appropriate [4,15,52]. Preoperative counseling should identify post operative wound healing as the most common difficulty. The majority of patients can expect significant improvement in continence after the procedure with a mean of 66% reporting excellent of good results in the short term [52]. Concomitant repair of a cloacal defect or vaginal fistula should be undertaken [64-66]. There is no evidence that a defunctioning colostomy improves outcome. The results of anal sphincteroplasty in recent series reporting more than 50 patients are given in **Table 1** [1,2,52,67-84].

Anal sphincteroplasty is usually performed in the lithotomy position although adequate exposure can be obtained in the prone jack-knife position. Full bowel preparation is not needed, although most would give a cleansing enema pre-operatively. The conventional incision is an inverted 'V' that may be closed as an inverted 'Y' as described by Parks [85]. If anterior levatorplasty or rectocele repair is contemplated, a posterior fourchette incision with the patient in lithotomy may have advantages [76]. The external anal sphincter is usually repaired using an overlapping technique without separate identification and repair of the IAS [15], however, Maslekar et al [82] attribute their good long term results to a selective policy of separate repair of the IAS. There has been one small randomised trial of direct versus overlapping sphincteroplasty which showed similar outcomes [86]. Occasionally the EAS defect is not full thickness and overlapping repair in such circum-

stances would require division of the residual intact fibres to facilitate overlap. Oberwalder et al [87] have found in a small series of patients that imbrication of the EAS in such cases is associated with outcomes similar to formal overlapping sphincteroplasty.

Initial success of sphincteroplasty is related to whether the anal sphincter defect is corrected [68,88]. Early failure is usually associated with a persisting defect identifiable using endoanal ultrasound [89]. This may be amenable to a further attempt at repair [88,90,91]. There is however increasing evidence that continence outcomes deteriorate with long-term follow-up [15,52,92]. Zutshi et al [93] found in a cohort of 31 patients followed for 10 years after overlapping sphincteroplasty that continence deteriorates over time. Mevik et al [94] also identified significant deterioration over time while Bravo Gutierrez et al [77] found that only 6% of patients retained full continence 10 years following anal sphincteroplasty. The effect of age at time of operation on long-term function is controversial [93,95,96], however long-term effects of aging and menopause coupled with atrophy of the sphincters may be relevant [15,97]. [**LEVEL OF EVIDENCE: 3**]

Pre-operative physiologic testing is helpful in the overall management of patients with faecal incontinence, however the value of anal manometry and pelvic floor electrophysiological assessment as prognostic indicators for outcome following sphincteroplasty is controversial [98]. There are no established parameters that reliably predict outcome following sphincteroplasty [82,99]. Patients with an unsatisfactory clinical outcome follow sphincteroplasty may be considered, if sufficiently symptomatic, for adjunctive sacral neuromodulation (vide infra) [100]. [**LEVEL OF EVIDENCE: 4**]

3. POST-ANAL REPAIR

Post-anal repair was first reported by Sir Alan Parks in 1975 [3]. This procedure was designed to increase the length of the anal canal, restore the ano-rectal angle and re-create the flap valve mechanism, which at the time was thought essential for maintaining faecal continence. Success rates ranged from 15% to 83%, depending on the definition of the success, the length of follow-up, and possibly the cause of incontinence. The published studies regarding post-anal repair include three systematic reviews of randomised controlled trials (level 1) [4,101,102], two randomised controlled trials (level 1 [103] and 2 [104]), two non-randomised cohort studies (level 2) [105,106], 8 case series of good quality (level 3) [107-114] and 11 case series of poor quality (level 4) [3,115-124]. The results of post-anal repair are shown in **Table 2** [3,103-124].

ns: not stated; PAR: postanal repair; ALP: anterior levatorplasty; TPFR: total pelvic floor repair

Subsequent observational studies with a median follow-up of more than 5 years revealed that continence deteriorated with time. Despite 60% to 80% of patients reporting persisting symptomatic improvement, only one-third were actually continent to liquid or solid stool [109,112,114,123]. Even in the most recent study reporting the long-term outcome of post-anal repair [124], only 26% reported none to minimal incontinence, with the Cleveland Clinic incontinence score being between 0 and 5, while 79% improved symptomatically with a mean follow-up of 9.1 years. Possible explanations for deterioration of continence following initial improvement included unrecognised denervation and/or muscular injury of the sphincter and pelvic floor musculature, and the presence of occult anal sphincter disruption, particularly in the studies reported before endoanal ultrasonography or magnetic resonance imaging were available. Moreover, physiological and radiological evaluations before and after postanal repair have not demonstrated consistent changes in anal canal length, resting pressure, voluntary contraction pressure, anorectal sensitivity and movement of the ano-rectal angle [104-107,125]. These reports of increasingly poor outcomes have diminished the popularity of this procedure significantly.

Deen et al [103] in a randomised controlled trial, comparing three procedures in 36 women with neuropathic faecal incontinence, found that complete continence was achieved in 42% of patients after post-anal repair, 33% after anterior levatorplasty and 67% after total pelvic floor repair. In contrast, van Tets et al [104] conducted a randomised controlled trial comparing post-anal repair and total pelvic floor repair in 20 women with neurogenic faecal incontinence. Complete continence to solid or liquid stool was achieved in 27% of patients after post-anal repair and in 22% after total pelvic floor repair.

4. NON-STIMULATED MUSCLE TRANSPOSITION

A variety of muscle transposition procedures have been devised for the treatment of faecal incontinence. Early efforts focused upon the use of transposed skeletal muscle to supplement the function of a weak or disrupted anal sphincter. Early in the 20th century, a number of surgeons utilized gluteus maximus muscle, transposed in a variety of configurations, to create a neosphincter [126,127]. In 1952, Pickrell et al [128] described the use of transposed gracilis muscle to create a neosphincter for incontinent children.

Published series of gracilis transposition are uncontrolled and demonstrate variable success rates [129-138]. [**LEVEL OF EVIDENCE: 3**] One study reviewed the functional results of graciloplasty longitudinally in 22 patients followed for a median 63 months [139]. 18 patients (81%) were improved at 6 months, though only one regained normal continence. Results deteriorated in 5 patients during subsequent follow up. Bilateral gracilis transposition has been used successfully in several small series [130,140].

Success rates following gluteus transposition have likewise been variable [141-145]. [**LEVEL OF EVIDENCE: 3**] A prospective randomised trial in women with post-obstetric neuropathic incontinence showed similar significant degrees of improvement following both gluteus maximus transposition and total pelvic floor repair [146]. A recent retrospective review of 25 gluteoplasty patients reported restoration of continence in 18 patients (72%) and partial restoration in an additional 4 patients (16%). Donor-site and peri-rectal complications occurred in 16 patients (64%) [147].

5. STIMULATED MUSCLE TRANSPOSITION

The transposition of the gracilis muscle to reconstruct the anal sphincter was first performed in children in 1952 [128]. The blood supply is primarily from a single proximal artery that allows excellent mobility for transposition [148]. Successful electrical stimulation of a previously transposed gracilis muscle was first reported in 1988 [149], and case series from 2 independent centers were simultaneously reported in 1991 [150,151]. Baeten et al [150] showed improved continence in 8 of 10 patients; Williams et al [151] in 12 of 20.

Even after successful muscle transposition, functional outcomes are limited by two physiological factors. First, patients are unable to consciously maintain tonic contraction of their neosphincters over long periods of time. Furthermore, even if patient volition were not a problem, gracilis muscle is poorly suited to tonic contraction. While the external anal sphincter comprises predominantly slow-twitch, fatigue-resistant type I fibres, the gracilis muscle comprises predominantly type II, fast-twitch fibres that are rapidly fatigable [152]. Graded electrical stimulation transforms type II into type I muscles fibres [153], and use of an implantable electrical pulse generator has been shown to convert transposed gracilis to a muscle with predominantly type I fibres [150-152]. The gracilis muscle is well suited to electrical stimulation due to the relatively constant proximal location of the neurovascular bundle, which is easily identified at surgery [154].

The results of stimulated graciloplasty are shown in **Table 3** [155-165]. [**LEVEL OF EVIDENCE: 2**] In 1995, Baeten reported his results in 52 patients, with 38 (72%) becoming continent after surgery [155]. In a subsequent paper by this group published in 2003, 200 patients followed for a median of 261 weeks were reported [163].

Table 3. Dynamic Graciloplasty: General measures of continence

Authors (ref)	Year	Number of patients	Follow-up	Percentage continent*
Baeten et al [155]	1995	52	25.2 months (mean)	73

Hassan et al [169]	2010	31	67 months (median)	71

** variable definitions; does not necessarily denote perfect continence. Issues of divergence in technique arose from these studies, each of which has seen increasing consensus in the literature despite a lack of randomised trial data. Thus, intramuscular (vs. epineural) electrodes are now universally employed, and diverting stomas and 'vascular delay' prior to muscle transposition are no longer utilized.*

The overall success rate was 72%. Patients with incontinence due to trauma had the best results (82% success), while patients with incontinence due to congenital anorectal malformation had the worst results (52% success). 138 complications were reported, including disturbed evacuation in 32 patients (16%), infection in 24 (12%), pain in 16 (8%) and pulse generator displacement in 12 (6%). Ten patients (5%) had anorectal perforations, 7 of whom eventually obtained a successful outcome. Rosen et al [166] reported restoration of continence in 9 of 10 patients treated by dynamic graciloplasty using a "split-sling" wrap configuration. Sielezneff et al [167] treated 16 patients and 13 had improved continence. However, 8 patients suffered morbidity, resulting in 33 subsequent admissions and 23 reoperations.

Three multicenter prospective trials of dynamic muscle plasty have been performed to date [158-160]. In each of these studies, patients served as their own controls. No randomised prospective trials have been performed.

Madoff et al [158] studied 139 patients from 12 centers, 128 of whom had gracilis wraps and 11 gluteus wraps. Of those patients, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There were a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 (3%). Centers with significant prior experience with the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Mander et al [159] reported the results of dynamic graciloplasty in 64 patients with refractory faecal incontinence treated at 7 centers. There were 24 infectious complications, 5 of which involved perineal wound breakdown and 3 of which required reoperation. 44 (69%) patients became continent to solid stool 1 month following stoma closure. Evacuation problems developed in 16 patients (25%), and this lead to failure in 14. At a median of 10 months follow-up, 29 patients had a good functional result.

Baeten et al [160] reported the results of dynamic graciloplasty in 123 patients treated at 20 centers as part of the Dynamic Graciloplasty Therapy Study Group (DGTSG). The aims of this study were

to assess both the safety and efficacy of this treatment; 189 adverse events occurred in 91 patients, including one death due to pulmonary embolism. There were 18 major and 31 minor infectious complications. There were 42 instances of therapy-associate pain, occurring variably in the donor leg, at the anal canal, or at the device site. There were 11 lead dislodgements but no problems with lead breakage or pulse generator malfunction. A follow-up study showed full or partial recovery from these complications in 87% of patients. [161] This study, in contrast to others, was based upon data from daily continence diaries. A successful result (defined as a 50% or greater decrease in incontinent events in patients without pre-existing stomas) was achieved in 63% of patients after one year. Another follow-up of this patient cohort demonstrated stable success rates at 18 months (55%) and 24 months (56%) [162]. Statistically significant improvements in the physical and social function scales of the SF-36 were also recorded at 12 months.

A multicenter retrospective trial from Belgium using dynamic graciloplasty treated 60 patients with 27 failures [164]. Continence was achieved in 78% of the group. However, more than half (26 patients) required the use of antegrade continence enemas or other measures to maintain continence. Seven patients had a permanent stoma constructed. Seventy-five complications occurred with 61 total reoperations. Loss of muscle stimulation occurred in 22 patients; 10 were due to issues specific to the stimulator and leads, 4 were due to technical failure of the muscle wrap. Functional outcome was directly associated with a maintenance of stimulation and initiation of stimulation within 50 days of surgery.

Very few studies have examined the long term results with dynamic muscle wraps. Thornton et al [168] reported on the 5-year follow up of 38 patients who had undergone dynamic graciloplasty. Of the 33 patients available for follow-up by telephone interview, obstructive defaecation was a problem for 11% of the cohort and 16% had been converted to a permanent colostomy. Of those with a functioning graciloplasty (22 patients) who reported a faecal incontinence score of less than 12 (range 0-24), 50% reported problems with obstructive defaecation and 64% felt their bowel habits had negatively impacted their quality of life. Long-term complications were primarily related to stimulator issues; ten patients required 15 operations to replace stimulator components. However, 72% of patients reported pain, swelling or paresthesias of the donor leg and 27% reported sexual dysfunction. Hassan et al [169] reported follow-up of 31 patients who underwent gracilis muscle transposition with periodic electrical stimulation and postoperative supplement of biofeedback. Twenty-two patients (71%) reported improvement at five-years. Nine patients (29%) were deemed failure requiring further surgical intervention (colostomy formation, contralateral dynamic gracilis muscle transposition, implantation of artificial bowel sphincter). Six patients developed perineal wound infections (5 resolved with antibiotics, 1 required surgical drainage), and 2 patients had evacuation difficulties requiring regular enemas. Those who underwent operation due to traumatic injury to sphincters had better outcome (82% improvement) compared to patients with congenital faecal incontinence (55%).

Tillin et al [165] performed a prospective case-comparison study of 49 patients who had a dynamic graciloplasty and 87 patients who either refused the surgery or were not offered the surgery. The primary outcomes evaluated were symptoms, quality of life, anxiety, and depression. Of the treated group, the procedure failed completely in 15 patients. At two year follow-up, two-thirds of patients were either never or rarely incontinent to liquid or solid stool. Up to 50% of patients with a satisfactory outcome reported disordered evacuation and 8 other patients were deemed failures due to this problem. However, in comparison to the 87 patients who did not undergo treatment, there were significantly more patients in the dynamic graciloplasty group who reported a greater than 20% improvement in their incontinence scores. However, the treated group also had a significantly worse pain as assessed on a validated pain scale.

Chapman et al [170] performed a systematic review of dynamic graciloplasty for faecal incontinence on behalf of the Australian Safety and Efficacy Register of New Interventional Procedures- Surgical (ASERNIP-S). The authors reviewed 37 original articles published between 1991 and October 2000. All of the papers were judged to be of low-evidence quality, as all but one paper were case series, and the sole comparative study utilized historical controls. Mortality excluding cancer deaths was 1% (95% confidence interval 1-3%) and morbidity 1.12 (95% CI 0.14 - 2.08) events per patient. Success was variably defined between studies, but was reported as ranging from 42-58%. The ASERNIP-S Review Group determined that “the safety of the procedure cannot be determined at the present time due to an incomplete and/or poor-quality evidence base” and that “efficacy is established.” Tan et al [171] examined three treatments for faecal incontinence including dynamic graciloplasty, artificial bowel sphincter and end stoma. They concluded that the most cost effective intervention was an end stoma, the artificial bowel sphincter was most cost-effective after 10 years and that dynamic graciloplasty should only be considered as an alternative in highly specialized centers.

6. ARTIFICIAL ANAL SPHINCTER

Artificial sphincters can be defined as any kind of implanted device intending to replace or reinforce the sphincteric mechanism that normally closes the bowel end. They aim to be a substitute to the normal sphincters. As such, it is necessary that they be efficient for both terminal bowel functions: continence and evacuation; that their implantation be safe and reproducible, with a limited need for patient/medical

intervention and follow-up after implantation; and finally that they be cost effective.

There is active laboratory research at a preclinic phase for new artificial devices. Different parts of the world are involved, including China with a novel electro-magnetic anal sphincter with sensor feedback currently tested on animals [172-174], US with bioengineered tissue designed to mimic the function of the internal anal sphincter [175,176], and Germany with a new version of the previously described "German artificial sphincter system" (GASS), now consisting of an inflatable cuff connected to a combined implantable micropump, fluid reservoir and microprocessor [177]. These various prototypes have not been implanted yet in humans but clinicians have to be aware of any development of these innovations.

Artificial sphincters currently used in humans are silicone-made, pressure-regulated devices restoring continence through an inflatable cuff placed around the lower rectum or upper anal canal. Three models have been proposed on the market. Over the 5 last years, no publication has reported any results from the implantation of two of them: the prosthetic bowel sphincter (PBS) developed by Finlay in UK and the Agency for Medical Innovations (AMI) soft anal band system once popular in Germany and Austria. The only currently available data concern the Acticon Neosphincter (American Medical Systems, AMS) artificial bowel sphincter (ABS).

The ABS, a modified model of the AMS 800 artificial urinary sphincter has been in use since 1996 for faecal incontinence management. In short, it comprises a fluid-filled cuff that encircles and compresses the anal canal. A pressure-regulating balloon is implanted in the retropubic space of Retzius. The system is controlled by a pump placed in the labia majora or scrotum which is accessible to the patient. To initiate defaecation, squeezing the pump empties the cuff by a fluid transfer into the balloon, allowing for the passage of stool. The cuff then refills automatically from pressure built up in the balloon.

The role of the ABS in the treatment of faecal incontinence has been confirmed in reports from different groups [178-182]. [**LEVEL OF EVIDENCE: 2**] ABS use has been supported in the current recommendations of both the United Kingdom's National Institute for Health and Clinical Excellence (NICE) and the American Society of Colon and Rectal Surgeons (ASCRS) [58,183]. The ABS is especially indicated for patients with "severe end-stage faecal incontinence," especially those with major sphincter disruptions that preclude direct sphincter repair, or those in whom sphincter repair has failed. For many of these patients, creation of a permanent end colostomy is the only remaining therapeutic alternative. However, generalizability of the published results remains doubtful as the majority of the series come from expert centers that have developed particular expertise in the implantation of artificial sphincters.

a) Functional Results of ABS

The artificial bowel sphincter provides good restoration of continence for solid and liquid stool in patients who retain the device, with all studies reporting almost similar data (**Table 4**) [179-181,184,185]. Implantation of an ABS was successful in 27 out of 33 patients in a Dutch series with a significant improvement in Williams faecal continence score at 17 month follow-up [180]. In a series from France, a new transvaginal approach to implant the cuff has been tested [178]. It was successful in 23 out of 32 patients (71.9%), with a device that remained activated for a mean follow-up of 41 (range 18-75) months, resulting in a significant decrease in Wexner incontinence score from 18.4 to 6.8 and no dyspareunia in sexually active patients [179]. Long term data from Spain reported a final success with an activated ABS in 9 out of 17 cases (53%) allowing for a decrease in CCF score from a median of 17.5 preoperatively to 10 at 66 month follow-up and a significant improvement in QOL [184]. In the report of a large single-center experience of ABS implantations, including 52 patients (46 women) implanted over the past 10

Table 4. Artificial anal sphincter for faecal incontinence with Acticon Neosphincter®

Authors (ref)	year	No of pts	mean or median Follow-up (mo)	No (%) of functioning device	Overall Complication (%)	"Success" in patients with a functioning device	Evidence level

CCF-FI:Cleveland Clinic Florida Fecal Incontinence (0: full continence - 20: worst incontinence); ns: not stated.
"Success" is defined as "continence to solid and liquid stool without significant obstructed defaecation, otherwise defined in each study"

years with 85 devices and a mean follow-up of 64.3 ± 46.5 months, 35 patients (67.3%) had a functioning device at review. A significant improvement in both CCF (P < 0.0001) and FIQL (P = 0.0286) was observed [185]. Some patients of this study with an activated ABS were matched to a group of successful SNS patients to compare their respective functional outcomes. Although this study had several limitations, it showed that the ABS achieved significantly better control of continence, albeit at the expense of more symptoms of outlet obstruction postoperatively and a similar quality of life for the 2 groups of 15 patients each [186]. [**LEVEL OF EVIDENCE: 2**] This risk of constipation after implantation of an ABS is a real concern as the cuff, even when opened, can narrow enough the anal canal to prevent a complete and easy evacuation. It has been well measured in a series of 44 patients with 55% of them expressing some sort of constipation or outlet obstruction [187].

b) Surgical Risks and Postoperative Complications of ABS

Besides an evident beneficial effect in treating severe faecal incontinence, the above-mentioned studies have confirmed the high risk of failure after implantation due to infection and mechanical failure. However severe morbidity is rare and no mortality has been ever reported. Explantation of the device generally solves the problems without long term sequelae.

The primary concern with ABS implantation is infection. In the report from the Cleveland Clinic 23 of 51 (41.2%) implantations became infected [181]. Among these, 18 (35.3%) developed as an early-stage (before ABS activation) and 5 (5.9%) a late-stage infection. On multivariable analysis the authors found that the time between ABS implantation and first bowel movement and a history of perineal sepsis were independent risk factors for early-stage infection. This may explain some variations in infection rate when compared to European reports where great care is taken in bowel preparation before device implantation. Series from France and Holland each reported a 21% infection rate [179,180].

Mechanical failure is now a well-recognised complication after ABS implantation. The most common cause is microperforation at the folds of the cuff membrane, which leads to a loss of fluid and pressurization of the system. Cuff perforation is easily perceived by the patient as both a return to incontinence and development of a non-functioning control pump. Cuff perforation reflects intrinsic wear-and-tear of the device components over time and contributes to the number of revision procedures, especially in patients with satisfactory functional ABS results. Revision rate is directly proportional to the length of follow up. With a mean follow-up of more than 5 years, half of a series of 52 patients required revision surgery after a mean of 57.7 ± 35.0 months, with 73.1% due to a leaking cuff [185]. Although ABS reimplantation is usually easy in the encapsulated area of the previous device, the risks of infection and impaired function are real and account for some long-term failures. Furthermore, the need for reimplantation increases the overall treatment costs. These concerns suggest that an appropriate component upgrade by the manufacturer might lead to improved long term results and a lower cost basis for this therapy.

Cost issues have been assessed in a complex health economics study [188]. The authors aimed to assess cost-effectiveness of ABS, dynamic graciloplasty and end-stoma in the treatment of faecal incontinence. Based on an assessment of incremental cost-effectiveness ratio (ICER), they concluded from published data and expert opinion that the all three procedures were cost-effective with the end-stoma most cost-effective over a 5-year period (ICER GB£4,719 /QALY) and the ABS most cost-effective over a 10 year period (GB£5,387/QALY).

Careful patient selection and sound operative technique are critical components of success for artificial sphincter implantation. Exclusion criteria include morbid obesity, insulin-dependent diabetes mellitus, Crohn's disease, pelvic sepsis and radiation proctitis. Individuals who practice anoreceptive intercourse are not candidates for the procedure. It is also vital to ensure that all patients are adequately motivated and have sufficient manual dexterity to operate the device independently.

At present, ABS is not commercially available due to a manufacturing hold by the FDA. This situation is especially difficult for those waiting for revision surgery.

Studied in small trials, but not yet clinically available, the magnetic anal sphincter (MAS) (FENIX™; Torax Medical, Inc., Shoreview, MN - US) is a novel device designed to augment the native anal sphincter. It consists of a series of titanium beads with magnetic cores hermetically sealed inside. The beads are interlinked with independent titanium wires to form a flexible ring that rests around the external anal sphincter in a circular fashion. The device is manufactured in different lengths based on the number of beads (14 to 20) necessary to accommodate the variation in anal canal circumferences.

One of the advantages of this still investigational device over the previous artificial sphincters is that it begins working immediately once implanted, without the need for further manipulation by either the patient or surgeon. The procedure for implantation is also substantially simpler than the ABS because access to the perineum alone is required. The device is place under fluoroscopic guidance.

A recent multicenter feasibility study demonstrated good short-term restoration of continence with limited complications [189]. In a subsequent non-randomised comparative cohort study assessing results of the magnetic anal sphincter and the ABS,

it was shown that the 2 devices were similarly effective in restoring continence and quality of life, without any difference in morbidity [190]. [**LEVEL OF EVIDENCE: 3**] Further comparative studies with other innovative treatments of faecal incontinence such as SNS are getting underway.

Based on these results, FENIX™ has been granted CE mark on November 2011 and its commercial use has started in selected centers in Europe. Further reports from more centers are expected.

Presently the place of the magnetic anal sphincter in the treatment algorithm of faecal incontinence remains to be determined. It appears to be a promising innovation as it offers a less invasive and simpler alternative of anal reinforcement than the ABS. However, with only short-term follow-up available, it remains to be seen if the MAS can withstand the test of time.

7. SACRAL NERVE STIMULATION

Sacral nerve stimulation (SNS) was first applied for the treatment of faecal incontinence in 1994 by Matzel et al [191] in patients with functional deficits of the anal sphincter but no morphologic defect. The concept of recruiting residual function of an inadequate anorectal continence organ by electrostimulation of its peripheral nerve supply, i.e. the sacral spinal nerves, was adapted from the field of urology in the early 1990s [192], where it has been used since 1981 [193]. The rationale for applying SNS to faecal incontinence was based on both clinical observations and anatomic considerations (from the former, the beneficial effect on bowel habits and anorectal continence function and increased anorectal angulation and anal canal closure pressure seen in urologic patients; from the latter, the demonstration by dissection of a dual peripheral nerve supply of the striated pelvic floor muscles that govern these functions [192], with the sacral spinal nerves being the most distal common location of this dual nerve supply). It was hypothesized that stimulating the sacral spinal nerves could both enhance physiologic function and improve the symptoms of faecal incontinence.

a) Technique

SNS has become a minimally invasive technique with low morbidity. The surgical technique can be divided into two stages:

As no other predictors of SNS outcome exist at present, patients are uniformly selected for operative implantation of a permanent neurostimulation device on the basis of clinical improvement during test stimulation. This first stage, termed percutaneous nerve evaluation (PNE), is used to confirm a satisfactory neural response and then to evaluate the clinical effect of stimulation before implantation of a permanent device. Therapeutic trial stimulation is performed for one to three weeks, a period sufficient to prove its therapeutic effect--commonly considered a decrease in the frequency of incontinence episodes (documented by bowel-habit diary) by at least 50% and reversibility after discontinuation. Two technical options are used for PNE: a temporary, percutaneously placed, unipolar test stimulation lead (or multiple leads) that will be removed at the end of this phase; or operative placement of a quadripolar lead, the so-called “foramen electrode,” close to a target nerve. This electrode can stay in place and be used for permanent stimulation if the trial is effective. Today most commonly a minimally invasive technique places this foramen electrode with a modified anchoring device, the so-called “tined lead,” through a trochar. For screening, both types of leads are connected to an external pulse, the tined lead with a percutaneous extension cable.

The second stage is implantation of a permanent electrode and neurostimulator if screening is successful. Patients with a temporary lead require simultaneous implantation of the pulse generator and the quadripolar lead, most commonly as a tined lead procedure. Those with a foramen electrode already in place for screening will undergo removal of the percutaneous extension before placement of the pulse generator (so-called “two-stage implant”) [194]. Bilateral placement of foramen electrodes remains the exception, based either on improved outcome of bilateral stimulation during the screening phase [195] or on conceptual considerations [196]. The pulse generator is placed subcutaneously, usually in the gluteal area or under certain circumstances in the abdominal wall. It is activated and stimulation parameters are set early after surgery by telemetry; it can be deactivated by the patient with a small, handheld device commonly referred to as a “patient programmer.”

A small retrospective study, comparing the earlier use of an open electrode placement technique to the current tined lead placement demonstrated no difference in outcome [197]. The infection rate was slightly higher in patients undergoing open electrode placement (11% vs. 8%). Although responses to temporary stimulation and the permanent device are comparable, therapeutic outcome for permanent SNS appears to be best when both sensory/anal motor and toe flexion responses are achieved during test stimulation [198].

b) Patient Selection and Indications

Today, a variety of causes leading to faecal incontinence can be treated with SNS. During the initial SNS experience, only patients presenting with deficient function but no morphologic defect of the striated anal sphincter and levator ani were eligible [192,199,200]. However, because of the high predictive value of the test stimulation, a more pragmatic, trial-and-error approach to patient selection evolved. Patients are now selected for SNS based upon PNE results rather than conceptual considerations of the potential mechanism of action. Test stimulation is in-

dicated, not by an underlying physiologic condition, but by the existence of an anal sphincter with reduced or absent voluntary squeeze function and existing reflex activity, indicating an intact nerve-muscle connection (confirmed by intact anocutaneous reflex activity or by muscular response to pudendal stimulation with the St. Mark's electrode) [199].

At present, the test stimulation is the only reliable mode for selecting patients who will likely benefit from permanent therapeutic stimulation. Various studies have focused on potential predictors of success of SNS. In a study by Gourcerol et al [201], age was the only variable related to success of temporary stimulation. In patients with a permanent implant, neurologic disorders, delay of the left bulbocavernosus reflex and a prolonged or absent bulbocavernosus reflex were more frequent in patients with successful outcome. In another cohort analysis, the need for repeated temporary procedures was associated with failure during the screening in univariate and multivariate analysis [202]. A low threshold to obtain motor response during temporary lead placement was revealed to be associated with improved outcome only in univariate, but not in multivariate, analysis. Evidence of anal sphincter injury was related to a greater risk of failure during temporary testing, but not with permanent implant.

In a large single-center study comprising 245 patients with test stimulation and 169 patients with permanent implant, Govaert et al [203] determined in univariate analysis that older age (>70 years), presence (but not size) of an external sphincter defect, and the need for repeated procedures after initial failure were significantly related to failure of test stimulation. In multivariate regression analysis presence of an external sphincter defect and need for repeated procedures remained significant. The permanent implant was successful in 76.9% of the patients, but no predictor was found to be significantly related. In a cohort of 55 patients with permanent SNS, Brouwer and Duthie [100] demonstrated that continence scores did not differ significantly in those with a defect, pudendal neuropathy, or previous sphincter repair. Melenhorst et al [204] found no difference in outcome with chronic SNS in patients after sphincter repair and those with an external sphincter lesion of up to 33% of the circumference; they concluded that a morphologically intact sphincter is not a prerequisite for successful SNS. In 244 patients undergoing test stimulation with a success rate of 78.3%, Maeda et al [205] determined that low amplitude of the sensory threshold during PNE and lead placement anterior to the sacral cortex are positive predictors of PNE outcome. No other demographic, physiologic or morphologic variable was a negative predictive factor. In a cohort of 200 patients with permanent SNS from 6 centers [206] only loose stool consistency, a history of diarrhoea management by medical treatment, and low stimulation intensity were associated with improved medium-term outcome. Multivariate regression analysis confirmed that stool consistency and stimulation intensity were independent predictive factors of success or failure of SNS.

In a cohort of 45 consecutive patients, temporary stimulation was successful in 32 (71%). At a median follow-up of 33 months, the neurostimulator remained in place in 25 (55%) and active in 23 (51%). No statistically significant differences were found in the characteristics (including anorectal physiological workup) of the 32 patients who underwent implantation and the 13 who did not or in those 23 with a functioning stimulator [207].

Altomare et al [208] in a comparative study of 48 patients demonstrated in univariate and multivariate analysis that quadripolar electrode use for test stimulation leads to better clinical outcome than a unipolar electrode.

In summary, none of the variables usually considered in a preoperative workup are of any help in selecting the appropriate patient for chronic SNS. [**LEVEL OF EVIDENCE: 3**]

Contraindications to SNS include pathologic conditions of the sacrum preventing adequate electrode placement (such as spina bifida), skin disease at the area of implantation, anal sphincter damage requiring a sphincter substitute (e.g. artificial bowel sphincter, dynamic graciloplasty), trauma sequelae with micturition disorders or low bladder capacity, pregnancy, bleeding complications, psychological instability, low mental capacity, limited cognitive function that interferes with the operation of the neurostimulation device, need for magnetic resonance imaging, and the presence of an implantable defibrillator or a cardiac pacemaker. A case series has shown the relative safety of the use of SNS in the presence of a cardiac pacemaker when monitored intraoperatively. If the distance between the devices is greater than eight inches, interference is unlikely [209].

c) Mechanism of Action

The mechanism of action of SNS remains uncertain. Clinical outcome has been seen to correlate with results of anorectal physiology studies, but the effect of chronic stimulation varies greatly among published reports [199,200]. Data are in part contradictory and inconclusive and sometimes not reproducible. The effect appears to be somatomotor [210-217], somatosensory [210], autonomic nervous system-based [210,212,218], and mediated by somatovisceral reflexes [219,220]. The effects appear not to be limited to the continence organ per se, but also to the central nervous system: corticoanal excitability in patients with faecal incontinence was found to be reduced with SNS [221]; in successfully treated

patients cerebral somatosensory evoked potential (SEP) latencies were higher at baseline than in the normal population, whereas they were normal in patients with SNS failure. Success was also associated with a fall of the SEP latency to the normal range after one month of SNS at 40 Hz [222]. SNS induces changes in anal representation on the primary somatosensory cortex [223]. The central nervous effect induced by SNS changes during its course: at its initiation, changes are seen in the contralateral frontal cortex, reflecting focus attention; subsequent changes are found in the ipsilateral caudate nucleus, an area related to learning [224].

Qualitative (or quantitative?)changes are seen in anal, rectal and colonic motility, such as reduction of spontaneous rectal motility complexes [225,226], spontaneous anal sphincter relaxation [225], reduction of antegrade transport from the ascending colon and increased retrograde transport from the descending colon at defaecation [227], increase rectal perception thresholds [228,229] and improve pelvic floor contraction during SNS [229]. The findings on rectal capacity with SNS have been inconsistent: unaltered [230-232] or increased [225,233]. No changes in gastric retention, gastric emptying, small bowel transit or colonic passage were seen with scintigraphic measurements during SNS [234].

An effect on mucosal neurochemistry during SNS has also been shown, with elevation of Substance P and TRPV1 levels [235], although the relevance of each of these has not been proven in specific pathophysiological conditions. The mechanism of action is most likely multifactorial and dependent on the underlying condition. [**LEVEL OF EVIDENCE: 4**]

d) Outcome

The results of permanent SNS after pragmatic, trial-and-error, patient selection are shown in **Table 5** [100,206,207,210-213,235-251]. Most studies have encompassed patients with heterogeneous pathophysiologic conditions, and they vary with regard to design and patient number, but there is general agreement regarding the test stimulation for selection for permanent implant. Most commonly, clinical outcome is reported as an improvement in the number of incontinence episodes or days with incontinence during the period of observation, changes in the Cleveland Clinic Incontinence Score, and quality of life.

In a first multicenter prospective trial of SNS adherent to the initial, confined spectrum of indications, Matzel et al [238] reported 37 patients, 34 of whom underwent a permanent implant. Not only were the frequency of incontinence episodes and the CCIS score improved significantly, so too was the ability to postpone defaecation. These effects were attained immediately.

Leroi et al [240] reported a double-blind, cross-over multicenter study in 34 patients with faecal incontinence treated with SNS. Three months after implantation, patients were randomised in a double-blind manner to on- or off-stimulation for a 2-month period, with reversal of the activation mode after 1 month. Of these, 24 of 27 randomised patients completed the 2-month trial. A significant decrease in median frequency of faecal incontinence episodes was noted during the on-stimulation period. No significant change was observed between on- and off-stimulation for frequency of urgency episodes, delay in postponing defaecation, or median number of bowel movements per week (10.2 and 11.1 for on and off, respectively). There was a trend towards greater improvement in the Cleveland Clinic Incontinence Score during on-stimulation (8.5 vs. 10.5; ns). A total of 24 patients (89%) considered that they had improved during the on period compared with 17 (63%) during the off period.

Melenhorst et al [213] published the largest mid-term follow-up, single-center study, with 100 patients undergoing permanent SNS. Late failure occurred in 21 patients as defined by a relapse of symptoms to less than 50% improvement over baseline, implementation of another therapy for faecal incontinence, or patient dissatisfaction. The mean time for definitive failure was 13.6 months (range 3–42.4). There was no evidence of technical failure such as lead migration or lead breakage.

A report by Rosen et al [210] highlights the effect of SNS in a cohort of patients of whom 75% suffered from faecal incontinence of neurologic origin. Frequency of incontinence episodes/week was reduced from 6 to 2 at 15 months' follow-up.

In a recent larger multicenter study Wexner et al [247] confirmed the efficacy of SNS in reducing symptoms of faecal incontinence: of 112 patients with permanent SNS followed for a mean of 28 months (2-69), 83% experienced a ≥50% improvement, including 41% who gained complete continence (at 12 months).

Mellgren et al [251] reported the same cohort after a mean follow-up of 3.1 years (0.2 – 6.1 years). With a complete or partial data set available in 64% of the patients, a ≥ 50% reduction of incontinence episodes was seen in 86%, with 40% achieving perfect continence. Symptom improvement resulted in improved quality of life, which was stable over follow-up. If a "last observation carried forward analysis" is performed, the 50% reduction of symptoms at 3 years is a 78% success rate; in a "modified worst-case analysis"--with all missing data classified as failure--the success rate at 3 years is 59%.

The findings of sustained symptomatic improvement with extended follow-up are in accordance with several other series focusing on long-term outcome: a sustained effect was seen in 74% of 52 patients after 5 years [245]; in 84% after a median follow-up of 7.1 years (5.6-8.7) [252]; and in 6/9 with follow-up of 7 – 14 years [253].

**CCIS: Cleveland Clinic Faecal Incontinence Score: 0 = fully continent, 20 = worst incontinence;*
†Limited to studies reporting incontinence episodes/week and/or CCIS at last follow-up
‡Denotes median; otherwise all data are presented as mean. ns: not stated; FU, follow-up

In most studies, quantitative measures are used to describe the clinical benefit, such as days with incontinence episodes or absolute numbers of incontinence episodes per period of observation, ability to postpone defaecation (in minutes), and percentage of improvement. Even though published reports differ with regard to patient population, a general pattern of outcome can be observed: when compared with baseline status, the clinical outcome is significantly improved.

The majority of studies report the outcome based on a per protocol approach (PP): the outcome reporting is limited to those patients with a permanent implant after successful testing. The infrequently used intention-to-treat protocol (ITT) approach analyses all patients considered for the therapy and undergoing PNE test. Thus, those are included who failed PNE, who are lost for follow-up or who died. In one study with 245 patients undergoing PNE and 176 patients subsequently being implanted, 132 patients were treated with SNS for a median follow up of 33 months (ITT 53.9%, PP. 75.0%). Outcome was good or acceptable in 103 patients (ITT: 42,1%, PP: 58.5%), limited or reduced requiring additional or alternative treatment in 20 patients (ITT: 11.8 %, PP: 16.5%) [254].

In a meta-analysis of publications from 2000-2008 comprising 790 patients, 28 studies compared incontinence episodes per week before and with SNS, and 14 studies compared incontinence scores. Both outcome criteria were significantly decreased. Another nine studies documented the ability to postpone defaecation, and this criterion also was significantly improved [255]. [**LEVEL OF EVIDENCE: 2**]

An increasing body of evidence indicates that SNS may also be a treatment option for patients with sphincter defects, unrepaired or after attempted anatomic reconstruction. The presence of an internal anal sphincter defect on endoanal sonography is reportedly unrelated to the success of permanent SNS [202]. Since the first report that three of five patients with ultrasound evidence of sphincter disruption measuring 25–33% of the circumference benefited from chronic SNS [256], several studies have been published (**Table 5**) [100,204,257-262]. The origins and morphologic findings regarding the extent of the sphincter gap differ in these studies, but lesions up to 180° have been treated. It appears that outcome is not dependent on the radial extent [257,260]. A significant improvement in clinical function, measured either as frequency of incontinence episodes or Cleveland Clinic Incontinence Score, has been seen in a substantial number of patients in all studies [100,204,257-262]. Follow-up is still limited.

Melenhorst et al showed that the primary use of SNS in patients with a sphincter gap 17-33% of the circumference appeared to result in an outcome similar to its use after failed sphincter repair [204]. In another study, SNS in 6 of 8 patients with faecal incontinence related to obstetric full-thickness anal sphincter lesions of >30-150º resulted in improved frequency of incontinence episodes (from 5.5 to 1.5 per week), improved ability to postpone bowel emptying, and improved FIQL quality-of-life scores at a median follow-up of 26.5 months [257]. No correlation between improvement and the radial extent of the sphincter defect was seen. In patients with internal and external sphincter disruption owing to Crohn's disease SNS was demonstrated to be beneficial in one study [258].

In a comparative cohort study [259], the effect of permanent SNS was reported in 53 patients with either an intact external anal sphincter (N= 32 (37.5% after sphincter repair)) or an external anal sphincter lesion (N=21 (81% after prior sphincter repair)) of <90° (N=11) or 90-120° (N=10). Improvement in symptoms and quality of life was achieved, and outcome after 12 months was not statistically significantly different between both groups. [**LEVEL OF EVIDENCE: 3**]

The therapeutic potential of SNS has also been demonstrated in some, mostly small, case series and individual case reports of patients with distinct pathological conditions or well defined anorectal physiology findings (**Table 5**) [196,242,263-268]: e.g. muscular dystrophy [269], proctocolectomy with ileoanal J-Pouch reconstruction for colitis [270], neurologic dysfunction including spinal disc prolapse [267], rectal prolapse repair [265,266], and rectal resection for cancer [263] with or without neoadjuvant chemoradiation [196,264,271], and after neoadjuvant and adjuvant chemoradio/radiotherapy for endometrial and anorectal cancer [272,273]. [**LEVEL OF EVIDENCE: 4**]

In a randomised controlled trial Tjandra et al [274] compared the effect of SNS for severe faecal incontinence with supervised optimal medical therapy that comprised pelvic floor exercises, bulking agents, and dietary manipulation. Permanent SNS in 53 patients was significantly better than conservative treatment in 60 patients: Cleveland Clinic Continence Score 1.2 vs. 14.1; incontinence episodes/week 3.1 vs. 9.4; days with incontinence/week 1 vs. 3.3; lifestyle 3.31 vs. 2.31; coping/behavior 2.68 vs. 1.86; depression/self-perception 3.25 vs. 2.64; embarrassment 2.76 vs. 1.78. [**LEVEL OF EVIDENCE: 2**]

e) Quality of Life

As with indications, outcome assessment has also evolved, and aspects of quality of life have been added to the evaluation (Cleveland Clinic Continence Scoring System, SF-36 and FIQL Score.) The therapeutic impact of SNS is most evident when a disease-specific quality-of-life instrument, the FIQL scale, is applied.

In the first study to apply this instrument, the multicenter clinical trial by Matzel el al [238], FIQL score was significantly increased in all 4 scales; SF-36

scores improved in 7 of 8 scales, the greatest being social functioning and mental health, but only the former reached statistical significance. A similar result was published by Leroi et al [240] with the French version of the FIQL: at the final follow-up visit, improvements in lifestyle, coping behavior, depression, and self-perception and embarrassment were significant. Hetzer et al [243] demonstrated a significant improvement of the median Gastrointestinal Quality of Life Index score with permanent SNS from a baseline of 96 (range 47–128) to 107 (range: 36–128) at 6 months post-implantation.

In most studies on outcome, quality-of-life evaluation is a secondary endpoint [196, 200, 210, 238, 240, 242, 243, 249 - 252, 259, 263, 265, 267, 274, 275]. When used, the finding of improved quality of life is consistently related to symptom relief and remains stable with longer follow-up [245, 251, 252, 276].

In a meta-analysis [255] of 34 studies with 790 patients, SF-36 score data were analysed from 7 studies with 98 to 102 patients and ASCRS FIQL data from 9 studies comprising 199 patients: SF-36 outcome was significantly increased in all categories (physical functioning, social functioning, role physical, role emotional, mental health, vitality, general health) with one exception (bodily pain). FIQL outcome was significantly increased in all categories (lifestyle, coping/behavior, depression/self-perception, embarrassment).

In a two-center study of patients with permanent SNS for a median of 46 months (11-122), 108 of 127 patients responded to questionnaires regarding bowel habits and quality of life. Using a non-validated score, 75.8% reported satisfaction, which in most was related to clinical improvement. However, at last follow-up 11 of 23 patients who had failed to achieve a 50% reduction in incontinence episodes reported satisfaction, and 6 of these had more incontinence episodes than at baseline [268]. [**LEVEL OF EVIDENCE: 2**]

f) Cost Benefit

Permanent SNS is expensive; however, its cost-effectiveness has been demonstrated in several European nations. Hetzer et al [277] compared the costs of SNS with those of conservative treatment, anterior sphincteroplasty, dynamic graciloplasty, and stoma creation in 34 consecutive patients. The 5-year cumulative cost for SNS was €19,333, compared with €35,965 for a stoma (with annual costs of €5,339) and €34,953 for dynamic graciloplasty (annual costs €1,659). The equivalent cost for conservative treatment was €3,895, and the overall median real cost for an anterior sphincteroplasty was €5,327. Muñoz-Duyos et al [276] analysed the direct medical costs of SNS in a series of 47 patients undergoing 57 PNEs and the consequent 29 patients with a permanent unilateral implant for a median follow-up of 34.7 (2.3-81.2) months. The cost totaled €371,434, including €31,7791 for the devices. In patients without anal sphincter damage SNS provided 0.34 incontinence-free life-years and entailed additional costs of €1,054, which generates a cost-effectiveness ratio of €16,181 per quality-adjusted life-year (QALY). The nationally accepted threshold is around €30,000/QALY. The economic impact of the introduction of SNS would be to add 0.07-0.1% to the care of these patients.

In a decision-analysis model based on prospectively collected data in 70 patients undergoing test stimulation and implantation of the permanent SNS device, incontinence episodes/week were reduced from 6 at baseline to 0.5. Dudding et al [278], based on direct medical and non-medical costs, found an incremental cost-effectiveness ratio (ICER) for SNS of GB£25,070 per QALY gained. It cost GB£1,038 per year to achieve a median reduction of 238 incontinence episodes, equal to GB£3.61 per reduced episode. The ICER of GB£25,070 per QALY was within the nationally accepted GB£30,000 per QALY threshold.

In a similarly designed study based on published reports and expert opinion, Indinnimeo et al [279] found that the ICER is €28,285 per QALY gained in patients with a structurally deficient anal sphincter and €30,662 per QALY in patients with an intact anal sphincter. Both are below the national threshold of €40,000 per QALY gained. Budget-impact analysis demonstrated that the implementation of SNS would have an estimated impact of 0.56% over a 5-year period on the budget allocated for faecal incontinence treatment. [**LEVEL OF EVIDENCE: 3**]

g) Safety

SNS is a relatively safe procedure [247,280]. A recent meta-analysis [255] is in accordance with earlier reports, which describe a relatively low late of complications [199,200] and a need for device removal in only approximately 5% because of loss of effect, symptom deterioration, pain from lead dislocation, or infection. The results of the meta-analysis, which covered the period 2000 – 2008 and included patients undergoing the more invasive, open-approach electrode placement technique, found a complication rate of less than 15% in 665 patients with a permanently implanted device. In only 3% did the device need to be removed. In patients in whom infection has necessitated removal, re-implantation at a later date has reportedly been successful [274].

In a recent FDA study with strict monitoring of adverse events, 334 were reported in 99 patients at three-year follow-up; 67% occurred in the first year, and most required no or minimal intervention. The adverse events included pain at the implant site (28%), paresthesia (15%), change in the sensation of stimulation (12%), implant site infection (10%) [247], urinary incontinence (6%), diarrhoea (6%), and leg pain (6%). Half of the infections required surgical intervention with removal of the device in 5 of 6 patients [251]. A single report with a consecutive series of 87 patients over a mean follow-up of 48.5

months describes the need for revisional surgery in 41%, one-third for device-related failure, including 24% for removal [281]. In a French multicenter study comprising 200 consecutive patients with a mean follow-up of 12 months, the rate of device-related adverse events was 24.5% [206].

Major complications are rare: one case report of a life-threatening haemorrhage after elective tined lead electrode removal has been published [282].

A recent review of 48 cohort studies (45 for faecal incontinence and 3 for constipation) documented the postoperative issues in the 1661 patients with test stimulation and 1600 patients with a permanent SNS implant [283]: it found that the incidence of suboptimal outcome was 12.1%, pain 13%, and infection 3.9%. The most common problem during test stimulation was lead dislodgement (5.3%). The reported incidence rate for suboptimal outcome – loss of efficacy or lack of efficacy – ranged between 0% and 27%. Systematic literature review suggests a possible underreporting of suboptimal outcome and adverse events. In one single study, the rate of adverse event reached up to 85.2% in patients with a median follow-up of 11 months: loss or lack of efficacy and pain or discomfort accounting for 88.5% of these [254]. [**LEVEL OF EVIDENCE: 3**]

8. POSTERIOR TIBIAL NERVE STIMULATION

a) Introduction

Posterior tibial nerve stimulation has it origin in pain treatment as transcutaneous electrical stimulation (TENS). Its use for the treatment of faecal incontinence (first published in 2003 [284]) is an adaptation of its successful application in the field of urology, stemming from the early 1980s [285-287]. Only recently, based on the therapeutic success of sacral nerve stimulation, has there been an increasing interest in this alternative approach of neuromodulation. The number of publications is still limited and the evidence low; however, several clinical trials are currently ongoing. Larger patient studies are awaited.

b) Techniques

Two different techniques are used: percutaneous stimulation with a needle electrode [288] and transcutaneous stimulation with surface adhesive electrodes [289]. In both techniques current is delivered by positioning the active electrode close to the posterior tibial nerve proximal to the medial malleolus. Adequate placement is confirmed by inducing digital plantar flexion, and the ground pad is placed in the proximity. Both systems are powered by a portable pulse generator. The stimulation parameter are set arbitrarily, mostly to 0.2 ms, a current below the threshold for motor response ranging between 0.5-9.0 mA, and a frequency usually to 10 – 20 Hz.

Although the stimulation parameters themselves are fairly uniform, there is no general agreement regarding the protocol: duration and pattern of stimulation; interval between sessions; basic or “top-up” treatment (**Table 6**) [289-295].

c) Patient Selection and Indications

Indications vary substantially among the proof-of-principle studies. A prospective observational design

CCIS: Cleveland Clinic Faecal Incontinence Score: 0 = fully continence, 20 = worst incontinence

predominates, with mostly single-center trials and a limited number of patients. Inclusion criteria range from idiopathic faecal incontinence [289,290,292] and incontinence owing to inflammatory bowel disease [294], to faecal incontinence with internal or external sphincter lesions or a combination of both, some after obstetric trauma [290,292,296]. PTNS has been applied for passive, urgency, and mixed incontinence [293]. Symptom improvement has been demonstrated with PTNS for faecal incontinence after partial spinal injury in two cases [297].

d) Mechanism of Action

No studies have been performed to elucidate distinctly the effect of PTNS on symptoms of faecal incontinence. Several hypotheses of a potential mechanism of action have evolved based on the experience of the use of PTNS in urology and on an analogy drawn from findings of physiological changes with sacral nerve stimulation, but none of these hypotheses has been systematically explored. In one study significant changes in maximal squeeze pressure only was seen after 6 months [290]; others demonstrated no changes in physiological measurements [289]. An improvement in rectal sensory threshold and resting and squeeze pressures was reported in two patients after partial spinal injury [297]. In another study the clinical efficacy of PTNS was found to be independent of damage to the anal sphincter [298]. [**LEVEL OF EVIDENCE: 4**]

e) Outcome

All studies demonstrate an improvement in outcome measures, although outcome is not described uniformly (**Table 6**). Most commonly, clinical efficacy is monitored with the Wexner Incontinence Score and/or the recording of faecal incontinence episodes. Where incontinence episodes per month were reported and differentiated by stool consistency, in a study of 13 patients, reduction at 3 months was significant for all categories: wind, baseline 6 (0-17.5) vs. 0 (0-0) episodes/month; liquid, 10 (5-29.5) vs. 0 (0-4); and solid, 18 (0-30) vs. 0 (0-0) [290].

In all studies outcome reporting is limited to short-term follow-up. Postponement of defaecation was found to be significantly increased at 6 weeks and sustained at 12 months [291]. In one study the median increase in the ability to defer was 3 minutes (0-26) in patients suffering from urge incontinence [292]. [**LEVEL OF EVIDENCE: 4**]

f) Quality of Life.

If measured, instruments of quality-of-life recording also demonstrate an improvement with therapy [291]. Comparisons between success and failure, however, have not depicted conditions predictive of symptomatic improvement [291,295]. In patients with subjective improvement, quality of life was significantly better after 3 and 6 months' follow-up [295,296]. [**LEVEL OF EVIDENCE: 4**]

g) Safety

Reports on safety are limited, but none of the studies found relevant side effects. Mild, procedure-related reversible adverse events, such as gastrodynia and numbness in the leg for 2 hours, were reported in one study [291]. [**LEVEL OF EVIDENCE: 4**]

9. INJECTABLE BIOMATERIALS

Injection of bulk-enhancing agents into the anal canal to treat faecal incontinence has continued to gain popularity since the last review. Although injectable agents for urinary incontinence (UI) have had variable success, they offer the benefit of performing an outpatient procedure without anesthesia and with minimal morbidity. This has resulted in their continued use for urinary incontinence [299,300], as well as in more research on different injectable agents for use in faecal incontinence. The ideal agent for injection should be biocompatible, non-allergenic, non-immunogenic, easy to inject, and should not migrate within the tissues. No agent currently has all these properties. Agents that have a diameter of 80 mm are felt to be less prone to migration, but agents with a larger particle size require a larger bore needle to inject, which put them at a higher risk for leakage from the injection site. The results of all injectable biomaterials used for faecal incontinence to date are shown in **Table 7** [301-324].

Injectable agents for faecal incontinence were first used in 1993 when Shafik [301] treated 11 patients with injections of polytetrafluoroethylene paste into the anal submucosa. After 18-24 months of follow-up, 64% reported complete cure and 36% had partial improvement. Shafik [302] subsequently treated 14 patients with autologous fat injections with a reported 100% success rate at 2-3 months and all patients who lost continence to gas or stool became continent after repeat injections. There were no complications using either agent. However, other reports of autologous fat injection have resulted in death from pulmonary fat embolism [325], and a randomised clinical trial using fat for UI demonstrated no efficacy over placebo; thus, it is currently not used for faecal incontinence [325].

Other agents used for injection in the past, that have not achieved widespread use include micro balloons, bovine dermal collagen, and polyacrylamide hydrogel (Bulkamid). A series of six patients injected with self-detaching cross-linked silicone micro balloons with a biocompatible filler material demonstrated fairly good results, with Browning-Parks incontinence scores for the group decreasing from 16 to 5 (range 0-20) [305]. However, sterilization issues have prevented the ongoing use of this product.

The first reported injections of glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen) for faecal incontinence included 17 patients [303], 11 (65%) of whom showed marked

symptomatic improvement at 8 months. A much larger series of 73 patients was then reported [308] in which subjects received injections of 1.7 ml of collagen transanally into the rectal submucosa in three separate areas just proximal to the anal canal. Overall, 63% reported an improvement in their incontinence and the 49 patients with idiopathic incontinence (no sphincter defect and no pudendal neuropathy) had a significant decrease in their Wexner Faecal Incontinence Score (CCF-FIS, range 0-20). The disadvantages of using synthetic collagen are its potential to be allergenic and degrade over time. Furthermore, its success in urinary incontinence has been limited [299].

A pilot study conducted in 2008 examined two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [313]. Ten patients with passive faecal incontinence to liquid or solid stool who had failed conventional treatments were prospectively randomised to receive either of the two products. The needle was first inserted into the skin 2 cm from the anal margin and the product was then injected trans-sphincterically. The median volume to achieve closure of the anal canal under direct vision was 9 ml for Bulkamid and 15 ml for Permacol. The St Mark's incontinence score decreased at 6 weeks for both groups, but this decrease was sustained at 6 months only for the Bulkamid group. This pilot study lacked power to determine if these two treatments for faecal incontinence differed significantly. Unfortunately, no other follow-up studies have been reported.

Several other injectables have been used for faecal incontinence with variable results. In one of the few adequately powered, randomised controlled trials using injectables, 44 patients were randomised to receive transdermal injections of polydimethylsilozane elastomer silicone biomaterial (PDMS) or saline into the intersphincteric space [310]. Three 2.5ml injections were performed using local anesthesia. Only the patients were blinded to the treatment. There was no difference in the percentage of patients in the two groups who had a successful treatment, defined as having a CCF-FIS score <8 or the decrease in CCF-FIS scores post treatment. The saline group tolerated treatment better and had fewer adverse effects overall. Thus, the study concluded that the use of PDMS should not be recommended.

Three smaller studies using other products have shown some promise although the testing was much less rigorous. In one of these studies, calcium hydroxylaptatite ceramic microspheres (Coaptite) were injected transphincterically to four submucosal sites using 1ml at each site with the patient under local anesthesia. The average Faecal Incontinence Scoring System (FISS) score for 10 patients decreased from 85.6 to 28 at 12 months (p=0.008) and the lifestyle, coping and behavior/embarrassment subscales of the Faecal Incontinence Quality of Life Scale (FIQL) showed improvements (p<0.05). Anorectal manometry also showed better resting pressures (40 to 47 mmHg, p=0.018). There were no complications, but one patient experienced leakage of product from the injection site that required another injection [314]. In the second of these smaller studies, 21 patients received ethylene vinyl alcohol (EVOH) injections with 1-2 ml in up to 8 sites in the intersphincteric space under general or local anesthesia. At 12 months, Faecal Incontinence Severity Index (FISI) scores dropped from 32.8 to 22 and CCF-FIS scores decreased from 11 to 6.9. Two subscales of the FIQL improved significantly and repeat anorectal manometry demonstrated some increase in anal canal length and resting pressures [302]. The third and most recent of these small studies reported on 14 patients who received transdermal injections of polyacrylonitrile cylinders (Gatekeeper prosthesis) into the intersphincteric space. The CCF-FIS score decreased from 12.7 to 5.1(p<0.01) and there were no complications. Location of the prostheses was documented by ultrasound and no dislodgement was seen at 1 year [323].

The two most common injectables used to treat faecal incontinence are silicone biomaterial (Macroplastique, Bioplastique, PTQ implants) and pyrolytic carbon-coated zirconium oxide beads (Durasphere). Injectable silicone biomaterial has been used extensively for urinary incontinence. It consists of polydimethylsiloxane particles suspended in a bioexcretable carrier hydrogel of polyvinylpyrrolidone. Two pilot studies using Bioplastique for faecal incontinence in 2001 and 2002 [304,326] led to increased use of this product in Europe and it was renamed PTQ implants (PTP implants in Australia). Malouf et al [304] studied 10 patients with passive incontinence who received circumferential or single site injections of Bioplastique. At six weeks, six patients showed either marked improvement or complete cessation of leakage and an additional patient improved after a second injection. However, after six months, only two of seven patients had maintained marked improvement. Complications included anal pain and ulceration at the injection site. In the largest study of PTQ injection to date [307] 82 patients with severe faecal incontinence were randomised to receive PTP implants either with or without endoanal ultrasound guidance for injection. All patients had a significant improvement in their CCF-FIS. At 12 months, this score decreased from 14.5 to 3 in the ultrasound guidance group and from 14.5 to 11 in the non-ultrasound group. Six patients, two from the ultrasound guidance group, complained of pain at the injection sites. There were no other complications. The ultrasound guidance group had more significant improvement in resting pressures and quality of life scores. The same investigators injected PTQ into seven patients with passive incontinence after haemorrhoidectomy and found significant improvement CCF-FIS and quality of life scores in all patients [327].

Several other series have been reported PTQ use for faecal incontinence [311,315,317,319]. In all of them, 2.5ml of product was injected into 3-4 sites in the intersphincteric space and CCF-FIS decreased significantly. In one study of 20 patients, the CCF-FIS decreased significantly from 13.5 to 4.5 at one month and slowly increased to 9.4 at two years, which was a still a significant improvement from the baseline score. Quality of life scores also improved, but there was no effect on resting and squeeze pressures measured at baseline and 3 months after injection. Seventy percent of patients experienced pruritus ani and one patient developed an infection at an injection site [311]. In a study of 33 patients, CCF-FIS decreased from 12.7 to 10.4 at one year, yet quality of life was not improved [315]. Both of these studies examined implant migration and 63-84% of patients had detectable implants at the site of injection by ultrasound, though this did not seem to affect clinical response. The largest of these studies is notable for its sample size of 74 patients and that half of these subjects were men. It found that 70% of patients reported complete satisfaction with their continence (post-treatment CCF-FIS =0) and in the remaining 30%,CCF-FIS decreased from 12 to 3.5 at 33 months with associated improvements in quality of life measures. All patients, but especially those who became continent, had significant improvements in mean resting pressures, squeeze pressure and mean anal canal length. Worse results were seen in women with pudendal neuropathy or those for whom biofeedback had already failed [317]. Another study specifically compared the anorectal manometry of patients injected with PTQ with that of normal controls and found that after injection in the symptomatic patients there was a similar decrease in CCF-FIS with associated improvements in FIQL scores. The symptomatic patients had lower resting and squeeze pressures than controls at baseline and these pressures did not improve with injection. However, these patients did have elongation of their high pressure zone, as well as improvements in the asymmetry index, indicating that morphologic but not physiologic changes had occurred with injection [319]. The only report of long-term results for injectable agents was for Bioplastique [328].The 5-year outcome for 6 patients injected with Bioplastique in 1999 included a median St. Mark's incontinence score that was essentially unchanged from 11 to 13 (range 9-20). One patient had undergone a colostomy, but four of the five remaining patients reported subjective improvement in their incontinence and better quality of life scores.

The other commonly used injectable, Durasphere, is non-reactive and not biodegradable. However, the beads are known to migrate within the tissues and require a large bore needle to inject the substance. The injected substance is placed in the submucosal plane using either a transanal or intersphincteric approach. The initial trial [306] assessed the short and long-term efficacy in 18 patients with an internal anal sphincter defect refractory to conservative management. About 1.3ml was injected in the submucosal plane at the site of the sphincter defect in 1-4 sites until adequate anal sphincter symmetry was restored. At 12 months, CCF-FIS and patient satisfaction scores were significantly improved. Fifteen of 18 patients reported improvement in their incontinence. An abstract presented by Weiss et al [329] also demonstrated improvement in ten patients who were only followed for 3 months. In a larger study, 33 patients with minor or medium severity faecal incontinence (CCF-FIS < 14 and/or American Medical Systems (AMS) score < 89) received injections (mean of 8.8 ml (range 2-19 ml) of Durasphere into the submucosa at the level of the dentate line using an 18-gauge needle at four different sites [312]. After a mean follow-up period of 21 months, the CCF-FIS for the group decreased significantly from 12 to 8 and the AMS score from 89 to 73 but the faecal incontinence specific quality of life measures did not change. Resting and squeeze pressures also increased 12 months after injection. Adverse events included anal pain in two patients, asymptomatic leakage of material in one patient, and distal migration of product in two patients. A study of 11 patients in which about 2.8ml of Durasphere was injected into 3-4 sites in the submucosal space reported a decrease in CCF-FIS from 12.7 to 4.9 at 2 years with improvements in the coping and embarrassment subscales of the FIQL at 6 months. Although manometry pressures did not change initially, the resting and cough pressures were higher at 2 years than at 1 year [318].

The most recent study using Durasphere injected the product using a slightly different approach. In all 23 subjects, the product was injected into the intersphincteric space in four sites. Again, about 2.8ml of product was injected at each site. At 12 months, patients had a decrease in the CCF-FIS from 18.7 to 10.9 and an increase in FIQL score from 46 to 55.8. Mean squeeze pressures on anorectal manometry increased significantly at 12 months. Adverse complications included prolonged pain in one patient and a sterile perianal fluid collection in another [321].

Only one trial compared the safety and efficacy of PTQ and Durasphere [316]. Sample size was calculated to detect a 50% reduction in the CCF-FIS post injection. Thus, 40 patients with faecal incontinence (mean CCF-FIS 11.45) were randomised to receive either PTQ or Durasphere. Both groups were similar in terms of age, medical history, faecal incontinence severity and quality of life scores, as well as anorectal manometry results. Although the Durasphere group had a more significant reduction in CCF-FIS at 2 weeks (11.45 to 8.25 vs. 11.45 to 10.9), the PTQ group had a greater reduction in CCF-FIS at 6 weeks, 6 months and 12 months (4.6,2.95 and 3.8 vs. 7.65, 6.2 and 7), and had no complications. The Durasphere group had several complications including anal pain (5%), mucosal erosion (10%),

arthritis and skin rashes (5%). Furthermore, the PTQ group demonstrated significant improvements in general and faecal-incontinence-specific quality of life scores that were not seen in the Durasphere group. Thus, the conclusion was that PTQ was safer and more effective than Durapshere for the treatment of faecal incontinence [316].

The newest injectable agent to be used for faecal incontinence is dextranomer- hyaluronic acid co-polymer (Zuidex, NASHA Dx). Dextranomer microspheres are suspended in non-animal stabilized hyaluronic acid. As with other injectable agents, Zuidex has been used to treat urinary incontinence [330] and a pilot study of four patients reported no adverse events and a median decrease in St Marks incontinence score of 3.5 points(19.25 to 15.75) [309]. In a subsequent study of 34 patients who received transanal injections into the submucosa just above the dentate line (about 1ml of product was injected into four sites), the median number of incontinent episodes in a four-week period dropped from 22 to 9 [320]. When response was defined as a 50% or greater decrease in number of incontinent episodes, 56% of patients were defined as responders at 12 months. No adverse events were reported. These findings led to a randomised double-blinded sham-controlled trial of 206 patients randomised in a 2:1 fashion to receive NASHA Dx or placebo injection [324]. The patients and the evaluating investigators were blinded to the treatment. More patients in the treatment group had 50% or greater reduction in the number of incontinence episodes (52% versus 31% of controls; p=0.009), but the change in CCF-FIS did not differ after treatment between groups (14 to 2.5 in the treatment group vs. 13 to 1.7 in placebo group). The FIQL was only significantly improved compared to placebo for the coping and behavior subscale. Both groups had a high retreatment rates: 82% of patients in the NASHA Dx group received reinjection of product and 87% of patients in the control group had repeat sham injection. The NASHA Dx group had significantly more adverse events, including proctalgia, rectal bleeding, pruritus, diarrhoea, constipation, fever, and two serious complications of rectal abscess and prostatic abscess. The control group had more injection site bleeding [324]. The most recent study of NASHA Dx was reported in an abstract of 21 patients who received injections of 1ml of product in four sites of submucosa. There were no adverse events and 61% of patients had a significant decrease in incontinence episodes at 3 months and 56% had a sustained improvement at 22 months. The CCF-FIS decreased from 16.8 to 12.3 but was not significant. Improvement in FIQL scores were noted [331].

In summary, studies of injectable biomaterials comprise several small case series that in general show short-term efficacy and only three randomised trials, two of which compared PMDS and NASHA Dx to placebo, and a third that compared PTQ to Durasphere. These trials indicated that PMDS should not be used, PTQ appears to be better than Durasphere in terms of both safety and efficacy, and that NASHA Dx has some evidence of efficacy compared to placebo. Two systematic reviews [332,333] and a Cochrane review [334] have been published recently that review the data for all injectable agents for faecal incontinence. Due to the poor methodology and small sample sizes of most of these studies, none of these reviews could establish adequate evidence to support the efficacy of any of these agents. However, one review did find that in a multivariate analysis, use of the intersphincteric, instead of transanal or trans-sphincteric routes of injection, was associated with a higher complication rate. Furthermore, PTQ and Coaptite were significant predictors of short-term outcome and use of local anesthesia was associated with a lower likelihood of success [332]. [**LEVEL OF EVIDENCE: 3**]

10. COLOSTOMY

A permanent colostomy is usually formed as a last resort for severe faecal incontinence when all other interventions have failed. Because colostomy is generally regarded as a failure of treatment, its effectiveness, perioperative complications, and impact on the quality of life have never been properly evaluated except for patients with functional bowel disorders after spinal cord injury [335,336]. For a specific role of colostomy for these patients, please refer to the specific chapter. Not only for patients with spinal cord injury, but also for general population with severe faecal incontinence, colostomy is a frequently successful management strategy that restores dignity and allows them to regain social function.

No randomised controlled trials or non-randomised cohort studies have been reported regarding colostomy for faecal incontinence, and only one systematic review (level 4) [188], one case control study (level 4) [337] and two case series (level 4) [338,339] were identified.

Colquhoun et al [337] conducted a cross-sectional postal survey, comparing quality of life between 71 patients with faecal incontinence and 39 with a colostomy created for rectal cancer, complicated colonic diverticular disease or faecal incontinence. Analysis of the Short Form 36 General Quality of Life Assessment revealed significantly higher social function score in the colostomy group than in the faecal incontinence group (0 vs. -0.6, p=0.022). An age- and gender-adjusted regression analysis of the Faecal Incontinence Quality of Life score revealed significantly higher scores in the coping (2.7 vs. 2.0, p=0.005), embarrassment (2.7 vs. 2.2, p=0.014), and lifestyle scales (3.2 vs. 2.7, p=0.14) in the colostomy group compared to the faecal incontinence group. The authors concluded that a colostomy is a viable option for patients who suffer from severe faecal incontinence and offers a definitive cure with improved quality of life.

Tan et al [188] performed a systematic review, specifically comparing the cost-effectiveness between end stoma (ES), artificial anal sphincter (AAS) and

dynamic graciloplasty (DG). The quality-adjusted life years (QALYs) and the incremental cost-effectiveness ratio (ICER) were compared between the three procedures, by obtaining the probability estimates for patients with faecal incontinence from published data, with being supplemented by expert opinion. The end stoma was the most cost-effective therapy at 5 years, with a QALY gain of 3.45 for GB£16,280 and an ICER of GB£4,719 /QALY, compared to AAS (4.38 for GB£23,569; GB£5,387 /QALY) and DG (4.00 for GB£25,035; GB£6,257/QALY). After 10 years, AAS became the most cost-effective surgical intervention, with a QALY gain of 8.384 for GB£32,397 and an ICER of GB£3,864/QALY, compared to ES (6.9 for GB£27,910; GB£4,046 /QALY) and DG (7.678 for GB£35,165; GB£4,580 /QALY). The results of this study, however, must be interpreted with great caution, because it is not an interventional study but a systematic review with a rather complicated methodology and a variety of possible biases.

Norton et al [338] examined patients' view of a colostomy by conducting a questionnaire study of patients who had a colostomy created to manage their faecal incontinence. Sixty-nine people (58 women) responded. When patients were asked to rate their ability to live with their stoma now on a scale of 0-10, the median score was 8 (range 0 – 10). The majority (83%) felt that the stoma, within the past month, restricted their life "a little" or "not at all". Eighty-four percent answered that they would "probably" or "definitely" choose to have the stoma again. When they were asked the question "compared to when you were incontinent, how much change has having a stoma made to your overall quality of life?" on the scale of -5 (much worse) to +5 (much better), the median rating was +4.5 (range -5 to +5). The authors concluded that health care professionals should discuss the option of a stoma with incontinent patients because of the overwhelming positive outcomes.

An end sigmoid colostomy without proctectomy is usually recommended as a procedure of choice for patients who elect colostomy for the management of their refractory faecal incontinence. Creating such a colostomy, however, does not always solve all the problems of patients with faecal incontinence. Catena et al [339] reported a retrospective chart review of 44 patients (35 women) who underwent elective end sigmoid colostomy for faecal incontinence of various etiologies. After colostomy formation 19 patients (43%) were asymptomatic, while the other 25 experienced such problems with their rectal stump as diversion colitis and mucus leakage. Of the 25 patients, 12 (27% of the total) underwent a secondary proctectomy due to the rectal stump problems sufficient to warrant the operation. Histological examination revealed diversion colitis in 6 patients. The factor associated with proctectomy was age, with younger patients being more likely to require rectal excision. The authors concluded that data are insufficient to recommend primary proctectomy in patients with severe faecal incontinence warranting permanent end sigmoid colostomy.

11. PUBORECTAL SLING

The puborectal sling operation was first reported by O'Rourke in 1974 [340]. In this procedure, an artificial sling is routed behind the anorectal junction and its two ends are fixed to the pubic bone, pulling the anorectal junction up forward with some tension. Similar to the postanal repair, the rationale of this operation is the restoration of the anorectal angle normally maintained by puborectal muscle. For the treatment of female urinary stress incontinence, a similar procedure, called tension free vaginal tape (TVT), has been performed with a reasonable success rate of 81-93% [341].

No systematic reviews, non-randomised cohort studies or case control studies have been reported regarding puborectal sling operation for faecal incontinence, whilst one prospective comparative study (level 2) [342], one case series of good quality (level 3) [343] and three case series of low quality (level 4) [340,344,345] were identified. Results of the puborectal sling operation are shown in **Table 8** [340,342-345].

O'Rourke [340] first reported the sling operation using Dacron mesh for the treatment of 3 patients with full rectal prolapse as well as 4 with mucosal partial rectal prolapse and faecal incontinence. Two patients developed a sinus or sinus discharge at the site of the insertion of the sling, and the sling was removed in one. Out of the 4 patients with faecal incontinence and partial prolapse, 3 were reported to have "benefited considerably" from the procedure although a formal evaluation of the faecal incontinence was not performed and the follow-up period was not documented.

Table 8. Puborectal sling

Authors (ref)	year	Study design	Material used	No of pts	mean or median follow-up (mo)	No (%) of functioning slings	Overall Complication	"Success" in patients with a functioning sling	"Success" in intention to treat	Evidence level
O'Rourke [340]	1974	case series	Dacron band sling	4	ns	4 (100%)	25%	75%	75%	4
O'Rourke & Egerton [344]	1985	case series	rolled mersilene mesh	2	ns	ns	ns	ns	ns	4
Shafik [345]	1991	case series	Teflon sling	31	24-48	31 (100%)	3%	84%	84%	4
Yamana et al [343]	2004	case series	polyester mesh sling	8	6	7 (88%)	25%	100%	88%	3
Shafik & Shafik [342]	2009	PCS	two fascia lata slings	22	12	22 (100%)	9%	64%	69%	2
			one fascia lata sling	22	12	22 (100%)	0%	36%	69%	
PCS: prospective comparative study ; ns: not stated										

O'Rourke and Egerton [344] reviewed 24 patients in whom the sling operation was performed using a strip of rolled mersilene mesh. This procedure, however, was performed mainly for the treatment of rectal prolapse, while it was conducted because of faecal incontinence alone only in two out of the 24 patients, and the outcomes regarding the continence were not formally evaluated.

Shafik [345] reported another sling operation called puborectoplasty utilizing a Teflon sling for faecal incontinence. Out of the 31 patients who had been incontinent to solid stool and underwent this procedure, "good results" were achieved in 26 patients (84%) after a follow-up period of between 2 and 4 years: 20 became continent to solid and liquid stool as well as flatus; 6 to solid and liquid stool but not to flatus; 4 to solid stool only; and only one remained incontinent to solid stool. Postoperative complications included a wound infection only in one patient, which responded to antibiotics without requiring the sling removal.

Shafik and Shafik [342] conducted a prospective study comparing two fascia lata slings (double loop) in 22 patients and one fascia lata sling (single loop) in 22 for the treatment of faecal incontinence. After 12 months follow-up, "good results" were achieved in 14 (63%) and 8 (36%) by the double loop and the single loop, respectively, and its difference was statistically significant. Postoperative complications included superficial infection in two patients of single loop, which responded to antibiotics without requiring the sling removal.

Yamana et al [343] performed the perineal puborectalis sling operation in 8 patients with passive faecal incontinence using polyester mesh sling. A wound infection developed in one patient which responded to antibiotics, while a rectal ulcer developed in one requiring the sling removal. In the 6 month evaluation of the remaining 7 patients, all reported some extent of improvement of their faecal incontinence. Both the Faecal Incontinence Severity Index and the Cleveland Clinic Faecal Incontinence Score significantly improved from 27 to 9 and from 13 to 5, respectively. Moreover, all parameters in Faecal Incontinence Quality of Life Scale significantly improved: lifestyle from 2.1 to 3.6; coping/behavior from 1.5 to 3.4; depression/self perception from 2.3 to 3.7; and embarrassment from 2 to 3.6.

III. SURGERY FOR PAEDIATRIC FAECAL INCONTINENCE

Faecal incontinence is common in children who have anorectal malformations, spinal problems and surgery for Hirschsprung's disease. Despite advances in technique for anatomic corrective surgeries, many patients continue to suffer from persistent incontinence. This guideline mainly focuses on anorectal malformations and corrective surgeries along with their results and subsequent management in case of persistent incontinence. Other surgical interventions used less frequently were also reviewed.

1. ANORECTAL MALFORMATIONS

Anorectal malformations occur once in every 3000-5000 live births. Although the severity of malformation varies, it is invariably associated with defaecatory problems including incontinence. The surgical advances have been most prominent in last few decades, particularly with the advent of posterior sagittal approach. [**LEVEL OF EVIDENCE: 3**] This technique has enabled surgeons to visualise the anatomy under direct vision and perform corrective surgeries more accurately [346,347]. In brief, a mid-sagittal incision is performed and the sphincter mechanism is completely divided in the midline. The rectum is separated from the genitourinary tract and moved down to the perineum. The most challenging aspect of the operation is the separation of the rectum from the vaginal or urinary tract, which effectively requires creating two walls out of one septum without damaging each structure. This approach can also used for reoperation in anorectal malformations [348] and can also be applied for reconstruction of severe perineal trauma [349].

For both male and female babies, urethral-perineal fistula is the simplest fistula to correct. These require the so-called 'minimal posterior sagittal approach' which enlarges the stenotic orifice and relocates the rectal orifice posteriorly within the limits of the sphincter complex. For males with recto-urethral-bulbar fistula or recto-urethral-prostatic fistula and females with recto-vestibular fistula or cloaca with short (less than 3cm) common channel, posterior sagittal approach is the main operation performed. For males with higher fistulas such as recto-bladder neck fistula and other complex and unusual defects and females with cloaca with long (greater than 3cm) common channel and complex defects, the posterior sagittal approach needs to be coupled with abdominal access which can be either laparoscopy or laparotomy [350]. There has been no robust evidence to suggest superiority of laparoscopy in terms of outcome [351,352] though better visualisation and assessment of fistula have been advocated as an advantage of this approach [353,354].

Cloacal repair is the most challenging amongst the corrective surgeries for anorectal malformations. A recent operative advance in cloacal repair is a maneuver called total urogenital mobilization whereby the rectum is separated from the vagina and both vagina and urethra are then mobilized together. The advantage of this technique is to avoid separating rectum, vagina and urethra completely which is not feasible all the time and risks damaging these structures during the procedure. This technique avoids the risk of urethrovaginal fistula and vaginal stricture previously reported as complications in 10% of the cloacal repair and also gives enough mobilization to allow more than 50% of all cloacal repairs without opening the abdomen [355,356].

Functional outcomes depend on the severity of the malformations. A review of more than 1000 anorec-

tal malformation cases showed 100% of babies who had perineal fistula repair achieved continence. Approximately 55% of patients who had been operated for recto-vestibular fistula had bowel control. Any malformations more complicated resulted in only up to 30% achieving continence. All patients who had recto-bladder neck fistula repair were incontinent. In cloacal repair the length of the common channel, shorter or longer than 3cm, appears to be the distinct prognostic factor in terms of functional outcome [357]. Overall it is estimated that nearly 40% will have voluntary bowel movement and no soiling but some of them may still lose bowel control in case of severe diarrhoea and 25% of all repairs will result in total incontinence [358].

For the group of patients with persistent incontinence following the corrective surgery, the next aim will be to keep the colon clean to avoid unpleasant accidents and improve quality of their life. A good option is implementation of a bowel management programme whereby the patient and family are instructed in the use of daily enema, manipulation of diet and medication to remain clean [359]. This is also a good treatment for constipation, which is the most common difficulty after corrective surgery [360].

Although most young children accept their parents administering enemas, when they get older they want privacy and rectal enemas on daily basis becomes an unpleasant routine. In such cases, continent appendicostomy is a feasible option, whereby a conduit for the administration of an antegrade continence enema (ACE) is created. First described by Malone [361] it has become an important option in paediatric surgery for functional bowel disorder.

According to the initial description by Malone, appendicostomy was created by dividing the appendix at its base and reimplanting by a reverse manner into the cecum, which was then exteriorized through the right lower quadrant. Malone later revised it and the reimplantation of appendix is no longer considered necessary [362]. Levitt et al [363] introduced utilizing the appendix in situ and added caecal plication to prevent reflux of stool and exteriorizing through umbilicus fold rendering it less noticeable. This appears to yield good long-term results [364] though a recent study has shown that caecal fixation and wrap may be unnecessary for appendicostomy [365]. The benefit of a variation called orthotopic continent appendiceal stoma is not clear [366]. However, construction of appendicostomy with burial of the appendiceal tip appears to help avoid problems of exposed mucosa such as bleeding and mucus discharge. From this perspective, a few techniques have been suggested such as V-Y flap [362] and Y-appendicoplasty [367]. For patients without an appendix, a neoappendix could be formed from ileum or cecum [368-370]. Laparoscopic antegrade continence enema procedure has been reported to yield as good result as open procedure [371-374].

This procedure is not a cure to the problem but a more acceptable method for many children to engage in a bowel management programme without the need for rectal enemas. Success rate is variable between 61-96% [362,368,375-379] with older children benefiting more [380]. Satisfaction with the treatment is reported to be as high as 93% [363,381,382]. [**LEVEL OF EVIDENCE 3**]

As with any operation, there are known complications associated with antegrade continence enema. Stomal stenosis is the most common complication and the use of ACE stopper will prevent it in the short-term [383]. Leakage of stool from appendicostomy is another common complication. These complications cause 10-33% of patients to undergo revision of the appendicostomy [358,384]. Stoma prolapse, pressure sore, wound infection, anastomotic leak, stomal granulation, caecal-flap necrosis and caecal volvulus are less common complications reported after ACE [385-387].

2. OTHER CAUSES OF FAECAL INCONTINENCE

Some children with Hirschsprung's disease following pull-through operations and severe constipation may also present with symptoms of incontinence [388]. Patients with spinal problems often lack bowel control due to paralysis and absence of sensation; 50% of the children with spina bifida suffer from incontinence [389]. The majority of these cases can be successfully managed with above mentioned bowel management programme including appendicostomy although wheelchair-bound children with spinal neuropathy is a predictive factor for poorer outcome with ACE [377].

The mechanism of incontinence after an operation for Hirschsprung's disease, anorectal malformations and severe constipation is thought to be due to impaired bowel motility. Impaired bowel motility causes faecal impaction, which can lead to development of a dilated segment of bowel called 'megarectosigmoid'. This can subsequently lead to overflow incontinence due to incomplete evacuation [390]. Once the rectum is dilated it is refractory to conservative management, and resection of megarectum or megasigmoid has been associated with improvement [390-392]. A small minority of patients (5%) who fail these options may need colostomy [393].

3. OTHER OPERATIONS

Sphincter augmentation by either palmaris longus transposition, gluteus muscle transposition, graciloplasty or levatorplasty has been used for children with faecal incontinence albeit in small series [394-403]. Dynamic graciloplasty has also been piloted and 50% of patients achieved complete continence although the study only contained four patients [404]. Sacral nerve stimulation has been used in a small open label study with nearly 80% of positive response [405]. [**LEVEL OF EVIDENCE: 4**]

IV. CONCLUSIONS

Data regarding the surgical treatment of faecal incontinence are generally weak. Randomised, controlled studies are few, and practical considerations make the likelihood of such studies improbable. The quality of data reported in older studies was often poor. Problems included heterogeneous patient populations; variable definitions of “continence,” “incontinence,” “success,” and “failure”; non-standardized and non-validated continence scales; underreporting of validated symptom-specific quality of life measures; variable patient follow up and lack of independent assessment of continence outcomes. However, there has been a notable improvement in the quality of studies reported in the past decade.

The spectrum of surgery for faecal incontinence is broad and expanding. Interventions range from simple outpatient procedures to major reconstructive surgery. As the reported outcomes of these various operations are often similar, a sound general principle is to proceed first with the simplest and least invasive procedure. Major operations associated with more profound morbidity should be restricted to patients who have failed simpler measures.

1. SPHINCTER REPAIR (GRADE B)

Sphincter repair is indicated for patients with acute traumatic sphincter disruption, such as following obstetrical injury, but many patients experience persisting symptoms.

2. SPHINCTEROPLASTY (GRADE B)

Overlapping sphincteroplasty can be offered to patients with significant faecal incontinence and a documented sphincter defect. Most patients improve after sphincteroplasty, but outcomes deteriorate over time.

3. POST-ANAL REPAIR (GRADE C)

Post-anal repair can be performed with modest success in carefully selected patients. However, this procedure is now rarely performed due to the advent of newer treatments.

4. NON-STIMULATED MUSCLE TRANSPOSITION (GRADE C)

Non-stimulated muscle transposition repair can be performed with modest success in carefully selected patients, notably in children. However, this procedure is now rarely performed due to the advent of newer treatments.

5. STIMULATED MUSCLE TRANSPOSITION (GRADE C)

Stimulated muscle transposition has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in selected patients with significant perineal tissue loss or in those who have failed other treatments.

6. ARTIFICIAL ANAL SPHINCTER (GRADE B)

Artificial anal sphincter has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in carefully selected patients, particularly those who have failed other treatments.

7. SACRAL NERVE STIMULATION (GRADE B)

SNS is an effective therapy for most patients with clinically significant incontinence who fail conservative management. The technique is safe, minimally invasive, and has the unique advantage of allowing a therapeutic trial prior to permanent stimulator implantation.

8. POSTERIOR TIBIAL NERVE STIMULATION (GRADE D)

Posterior tibial nerve stimulation is an investigational technique with few available data regarding efficacy and outcome.

9. INJECTABLE BIOMATERIALS (GRADE C)

Most series of injectable biomaterials report reasonable success rates. However, the optimal injectable bulking agent and the technique for its insertion have not been established.

10. COLOSTOMY (GRADE C)

Formation of an end colostomy is a reasonable treatment option for patients with refractory faecal incontinence who are able to accept the associated alteration in body image. Colostomy provides restoration of a more normal lifestyle and improves quality of life. It also could be the most cost-effective in the short to medium term, compared to more complicated surgical procedures such as artificial anal sphincter and dynamic graciloplasty. Colostomy should not be regarded as a treatment failure but rather a reasonable treatment option for patients whose lives are restricted by faecal incontinence that is not amenable to other therapies. An end sigmoid colostomy alone, without proctectomy, is recommended. The minority of patients who develop significant symptoms from their retained rectal stump may eventually require proctectomy as a secondary procedure.

11. PUBORECTAL SLING (GRADE D)

The puborectal sling operation seems promising because it is a simple procedure and yielded reasonably good results so far with low complication rate, although the number of patients was small with a short follow-up period. More prospective studies of larger number of patients with a longer follow-up period are warranted. They are expected to closely evaluate complications such as sling infection, erosion and rectal ulcer that might require the removal of the sling.

12. SURGERY FOR PAEDIATRIC FAECAL INCONTINENCE (GRADE C)

Anorectal malformations should undergo surgical repair, most commonly by a posterior sagittal repair.

An antegrade continence enema procedure can be considered for children with persistent or refractory faecal incontinence.

V. RESEARCH PRIORITIES

Despite steady progress in the clinical management of faecal incontinence, including the development of novel treatment methods since the last International Consultation, there remain numerous areas where additional research is needed.

1. BASIC SCIENCE AND PATHOPHYSIOLOGY

Several animal models of faecal incontinence have now been developed that are capable of provided interesting insights into the physiology of normal continence and the pathophysiology of faecal incontinence [223,406-412]. Further use of these and other animal models can be expected to yield valuable information about pathophysiology and treatment, and is strongly encouraged.

2. CELLULAR THERAPY

There is a body of basic research on the use of stem or precursor cells of different tissue of origin (muscle, fat, bone marrow) in supplementation of urinary continence [413]. Recently, Frudinger and colleagues[414] have reported successful treatment of faecal incontinence using autologous myoblasts cultured from a pectoralis muscle biopsy, harvested, and injected into the external anal sphincter defect using ultrasound guidance. Further research relating to the tissue of origin, harvesting and processing of graft cells, the technique of implantation and clinical outcomes is urgently needed.

3. OUTCOME MEASURES

While there is general agreement that patient-based outcome measures are most appropriate for studies of faecal incontinence, standardization of the optimal instrument or combination of instruments remains a central challenge in clinical incontinence research. These instruments should be selected based upon eight general criteria and applied to the specific field of faecal incontinence: appropriateness, reliability, validity, responsiveness, precision, interpretability, acceptability and feasibility [415].

It is unknown if the main outcome measure following incontinence treatment ought to be incontinence severity, incontinence-related quality of life, or a combination of these factors. The FIQL is a well-validated quality outcome measure but it yields separate scores on 4 individual scales. It is desirable that a single score outcome be developed. Furthermore, quantitative changes in FIQL have not been anchored to the corresponding impact on patient quality of life and thus remain rather abstract. Additional studies, for example using time trade-off techniques, are needed to understand the clinical meaning of a given change in FIQL.

The FISI severity score is not as broadly used as the FIQL, and it appears to require additional validation work. Continence diaries have been considered to be the gold standard measurement, but these are highly influenced by the patient's willingness to stray from a nearby toilet. Standard definitions are needed for such terms as seepage and leakage, and a standardized measure of faecal urgency should be developed. Additional validation work is needed to assess the potential effect of recall bias in recall-based scoring systems such as the Wexner and Vaizey scales. The International Consultation on Incontinence Bowel module (ICIQ-B) has recently been developed, but additional experience with this instrument is required [416].

4. CLINICAL TRIALS

There remains a paucity of randomized, controlled trials in the field of faecal incontinence. Proof of efficacy of novel therapies, numerous in the field of faecal incontinence therapy, is best demonstrated using a randomized trial design, and these types of studies are strongly encouraged.

Long-term outcomes following sphincteroplasty have demonstrated a substantial fall-off in function over many years. Similar long-term data are not available for other therapies, including especially the more recently developed ones such as SNS and injection therapies. Prospective trials funded for long-term follow-up and creation of treatment specific registries are needed.

Much recent research has been industry funded and designed to assess the efficacy of a specific novel therapy. There have been very few studies prospectively comparing different treatments, and randomized comparative treatment trials are urgently needed. The Committee has in particular noted the need for a randomized trial of SNS versus sphincteroplasty for individuals with faecal incontinence associated with a sphincter injury.

5. DECISION AND COST-BENEFIT ANALYSIS

Given the broad range of potential treatments for faecal incontinence and the usual costly proposed devices, additional research is needed in the areas of decision analysis and cost-benefit analysis. In severe faecal incontinence a comparison against stoma care cost would be appropriate.

6. TREATMENT DELIVERY

While there is ongoing research on the epidemiology of faecal incontinence, little is known about the true number of patients who have had treatment, who have access to treatment, or who have adequate knowledge to seek treatment. Research should be directed to identify current treatment needs, improve the accessibility of treatment, and improve the transmission and distribution of information about acceptable treatment options.

GENERAL INTRODUCTION

In the developing world fistula are often a consequence of poor peri-natal care. The epidemiology, aetiology, diagnosis, treatment and prevention have been described in detail during the recent International Consultations on Incontinence.[1, 2]

In contrast to the field of obstetrical fistula where the numbers of patients are high, the prevalence of non-obstetrical fistula seems to be much lower. The published series deal with small numbers, are usually retrospective and have a low level of evidence. The published obstetrical series show impressive numbers and demonstrate the level of skill that many of the fistula surgeons have obtained while working in difficult and isolated situations.

In this consultation the main focus has been put on iatrogenic fistula in the developed world. An entirely new chapter was compiled on this subject.

Despite the fact that the main focus was to write a chapter on iatrogenif fistula, in this edition the scientific summary of the International Consultation on Vesicovaginal fistula in the developing world, which was held in Marrakech, Marocco in 2010 was added to the text.

Both committees are convinced that obstetric fistula surgeons in the developing world and reconstructive pelvic surgeons in the developed countries can learn a lot from each other. Combining the obstetrical and iatrogenic fistula into one chapter will facilitate interaction and exchange of knowledge and ideas in this difficult field of fistula repair.

A. Obstetrical fistula

I. INTRODUCTION

The First ICUD-SIU Consultation on Vesico-Vaginal Fistula was held at the SIU meeting in Marrakech, Morocco, October 13th – 16th 2010. The recommendations are evidence-based, following a thorough review of the available literature and the opinion of recognised experts serving on the six committees. The individual committee reports were developed and peer-reviewed by open presentation and comment. Review of the literature showed no Level 1 evidence in that there were no randomised controlled trials. All evidence was confined to case series and observational data: Level 3 and 4 evidence. Hence, all recommendations were Grade B and C.

The Scientific Committee includes the chairmen of the six committees, who refined the final recommendations. These recommendations published in 2011, will be periodically re-evaluated in the light of clinical experience, technological progress and research. These recommendations are taken from the full versions of the six Consultation chapters, from Epidemiology through to Social Reintegration. These chapters provide the full documentation of the existing scientific literature on the six topic areas.

II. WOMEN, FISTULA SURGEONS, NGOS AND GOVERNMENTS

The effect on a woman, in the developing world, of having a VVF resulting from obstructed labour, is disastrous from her point of view, the family perspective and for her society. It is estimated that there are two million women, in developing countries, mainly in sub-Saharan Africa, the Indian sub-continent and South- East Asia, who have either undetected or untreated VVFs. New fistulas are probably occurring at the rate of 82,000 new cases per year, yet only 10,000 operations for fistula closure are being done annually. Hence, this leaves a huge unmet need.

VVF, in itself, is bad enough, but it is also inextricably linked with high maternal mortality rate and high infant death rate. Hence the solution to fistula is similar to the solutions that will drive down the maternal mortality rate and the infant death rate. The solutions are not only medical, but also social and political.

At present, women in developing countries are often dependent on donations that reach their country

through non-governmental organisations (NGOs) and charities. The relationship between the NGOs and the fistula surgeons are critical. The fistula surgeons are the experts and those to whom fistula women turn for help. Hence, it is vital that the NGOs allow themselves to be guided by the fistula surgeons as to the priorities within their sphere of work. The vital role of the NGOs is to provide financial and logistical support. Support is also essential to allow the fistula surgeons to write up their work. This is often a considerable problem, as their commitment to the women means that their academic time is restricted. Nevertheless, the data the fistula surgeons generate is their intellectual property, and it is vital that they retain primary authorship of all published material.

There are an enormous number of committed and dedicated individuals from both within the developing countries and from developed countries who have committed themselves to the cause of helping women with this dreadful condition. However, the long-term solution must see the responsibilities for women's and children's health passing to the governments of the individual countries. Nevertheless, in the meantime, those many dedicated individuals will continue to strive to help as many women as possible return to a life in their own community.

1. EPIDEMIOLOGY OF VVF

Epidemiological studies on obstetric fistula are inadequate.

- They are mainly institutionally-based, retrospective cases series, often written from the perspective of a single fistula surgeon
- The geographical coverage of epidemiological reports is uneven
- However, better and more relevant information is emerging.

The incidence of fistula is expressed per 1,000 deliveries and would appear to be between 0.1% rising to 1.5 per 1,000 pregnancies in rural areas.

The major risk factors appear to be age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment and illiteracy.

The consequences of obstetric fistula include divorce (16-92%), social isolation, worsening poverty, malnutrition, sexual dysfunction and mental illness (including anxiety/depression), insomnia, general ill health and thoughts of worthlessness and suicide.

There are few detailed reports documenting these women's obstructed labours. The time of onset of labour is rarely recorded and reports from delivery locations may disregard the fact that the woman has laboured at home for days prior to attending the delivery location. The reason for the woman not receiving help rarely differentiates between the absence of health-seeking behaviour and the lack of services. The only observational study showed no substantial difference between VVF patients and women who delivered without fistula, both in terms of their use of orthodox health care services and more traditional forms of support before childbirth.

Recommendations

1. Community-based epidemiological studies using standardised and validated collection tools with acceptable sensitivity and specificity are highly recommended.
2. A validated standardised collection tool should be developed and used in national surveys to facilitate the collection and comparison of data when assessing the regional, continental and global magnitude of VVF and the distribution of fistula world-wide.
3. Prospective longitudinal community-based studies are needed to estimate the incidence of obstetric fistula.
4. Observational studies are needed, utilising advanced epidemiological analyses for:
   - Risk factors (multivariate analysis controlling potential biases)
   - Impacts and consequences of VVF
   - Determining health-seeking behaviour
5. Research that identifies the different profiles of women who manage to overcome the obstacles and successfully access health care, compared to those who do not, is recommended.
6. The contribution of other factors, such as ethnic background and malnutrition, needs to be researched and understood.
7. It is recommended that there is long-term follow up of patients following fistula repair to understand their ongoing quality of life and any long-term sequelae and their ongoing needs.

2. PREVENTION OF VVF

VVF is a characteristic of abject poverty, a clear marker of failure of political, social and health systems to protect and promote women's health and their rights. Prevention of VVF is ultimately linked to prevention of maternal and infant mortality and is a requirement of MDG5 of 2000.

Prevention, from the medical and public health point of view, mitigates the effect of VVF in the overall burden of pain and suffering the condition imposes, not just on the patient herself, but her family and the entire community. History has shown that improvements in the functioning of local health services dramatically reduce the incidence of maternal death, infant mortality and vesico-vaginal fistula. The following areas of health system improvement and capacity building need to be considered:

- Enhancing professionalism among health care workers to make the system work better.
- Massive infrastructural developments through strengthening existing government health facilities, and advocacy, to maximise the benefits that a political environment sensitive to the needs of these women, is required.
- Ensuring that facilities are properly equipped, monitored and supervised with an emphasis on quality as well as quantity of service provision.

Systematic improvements are required to address the social and economic inequalities, such as the low status of women, lack of education for girls, early marriages and pregnancy, malnutrition, poverty, inadequate health and transportation infrastructure, and harmful traditional practices, such as female genital mutilation.

Health and maternal care are inextricably linked to the availability of financial resources, to the individual in the community and within the country as a whole: as economic conditions improve, the risk of VVF diminishes.

Another key stratagem, in preventing VVF, is the empowerment of women and their spouses, to develop birth preparedness plans, within the context of family planning. Family planning in wealthy regions is available according to the choice of the individual, whilst in other developing areas, such as China, it is actively encouraged, or even enforced. Other components of public health care, such as addressing the special nutritional needs of girl children and the requirements of improving their physical health, in order to improve their physical growth and maturity, are also very important.

Education of the community is vital so that young women understand what VVF is, are made aware of the need to engage in the ante-natal care process, and plan for their delivery, including making transportation plans for use when they go into labour.

Prevention strategies can be considered in public health terms as primary, secondary or tertiary:

- Primary prevention addresses many of the indirect causes which are essential the root causes of fistula. It attempts to reduce or eliminate the risk of the disease and by, amongst other actions, reducing the high levels of illiteracy among women. It also seeks to widen the cadre of care workers by involving, for instance, traditional birth attendants (TBA)
- Secondary prevention attempts to limit the severity of the disease by detecting it at its earliest stages.
- Tertiary prevention aims to mitigate the effects of the existing disease, for example by effective treatment.

The work of Haddon and Maine in the Haddon Matrix and Maine's Three Delays provide documented approaches to the problems.

Maine's Three Delays:

- The first delay: the decision to seek care is influenced by the socio-economic and cultural factors in that woman's environment. These can include the need to obtain permission from a husband or male family member to seek care, or the community perception that only weak women need assistance with delivery and that strong women can manage delivery on their own.
- The second delay is delayed arrival at the health facility. Once the first delay has occurred, the second delay becomes more serious. Road conditions, transportation and communication deficiencies may conspire to delay the woman's arrival at a hospital or birthing centre.
- The third delay is the delayed provision of adequate care at the facility, and may be due to lack of staff, supplies, or electricity. If the lights are out and there is no back-up generator or fuel, a caesarean section cannot be done. If there is no way to reach a doctor or medical officer because there are no telephones, or if equipment hasn't been sterilised, then timely surgery cannot be performed.

These three stages of delay disproportionately affect the world's poor and, in particular, those women living in rural areas.

Table 1. Categories of Prevention Strategies: The Haddon Matrix

Primary Prevention	Secondary Prevention	Tertiary Prevention
• Nutrition • Education of girl child and engagement of TBAs • Delayed marriage • Training of medical staff/midwives • Roads, ambulance, functioning health facilities • Communication • Adequate facilities, equipment and staff • Electricity	• Transportation • Maternity waiting houses • Field surveys • Partographs • Low gynaecological age • Caesarean section (Symphysiotomy) • Foley catheter drainage	• Treatment /repairs (surgery) • Physical / social / economic rehabilitation and re-integration • Media campaigns

Recommendations

1. Strong community support is required to develop solidarity groups which include village volunteers working with trained, skilled and traditional birth attendants, depending on the local customs and resources.
2. The components of the three delays need to be identified and targeted in order to minimise the effect of obstructed labour. By this process there will be other benefits for maternal and child health.
3. There should be provision of adequate health facilities and birthing centres to which women move either as soon as they go into labour, or if labour is delayed. Such facilities must provide emergency obstetric care, including caesarean section.
4. National policies for maternity care should be developed for all countries whether or not VVF is a common complication of childbirth
5. Data collection by local, national and regional bodies should help to define the incidence of birth complications, and factors leading to the "3 Delays".
6. The components of the "Three Delays" need to be identified and targeted for each community where there is a high prevalence of complications of childbirth.
7. Girls, women and communities should be educated about normal and abnormal labour, and facilities such as waiting houses should be available for pregnant women at risk for complicated deliveries.
8. Solidarity groups including local volunteers and skilled and trained traditional birth attendants should be developed for maternal care.
9. Birthing centres with the capability for caesarean section should be accessible and sufficiently affordable for women to use.
10. Funding should be made available to retain adequate trained staff for waiting houses and birthing centres.
11. Partographs should be employed to track the progress of delivery in order to identify problems and for data collection.

3. UNMET NEEDS IN VVF

There is unmet need at every level of the healthcare service in those developing countries where VVF is a significant problem. These needs span from family planning through obstetric care, the availability of emergency obstetric services and the provision for dealing with maternal and infant post-partum problems.

Unmet need has not clearly been defined, although the increasing gulf between the prevalence and incidence of fistula and its prevention and treatment is exceedingly worrying.

In low resource countries there is a need for stable and enduring collaboration and partnerships between governments and non-governmental organisations (NGOs), such as, UNFPA, Engenderhealth, WHO and MSF. These partnerships will go some way to identifying unmet need and ensuring that unmet need is reduced.

One of the most important aspects of the unmet needs in fistula surgery training has been the lack of standardization. In order that the recommendations below can even be partially met, there has to be a global strategy in developing training, education, and ancillary support for the surgeons and their associated teams. This will be partially met by the creation of the global competency-based fistula surgical training manual, created by the International Federation for Gynaecology and Obstetrics (FIGO) with International Society of Fistula Surgeons (ISOFS). The purpose of this manual is to enable health care providers to acquire the required knowledge, skill and professionalism to prevent fistula and provide holistic care to fistula patients that includes medical, psychosocial and surgical care. A multi-disciplinary team-based approach is encouraged in the training of each doctor and his/her team nurses, physiotherapists and other health professionals. The course is structured at three levels: standard, advanced and expert levels of fistula training.

The manual is made up of several components:

- Curriculum Modules

Each module has an outline of the course content, that the trainee is expected to be aware of. It needs to be used in conjunction with recommended references, and in some cases with specific Performance Based Assessments (PBAs). There are 7 modules that need to be undertaken.

- Logbooks of Competency

These are records of the work carried out by each trainee. Each must be signed off by each trainer, who will determine if the trainee has observed a procedure, has assisted with a procedure or is able to work independently. The trainer will determine if the trainee needs further training in a particular area.

- Performance Based Assessment (PBA)

Each aspect of surgical training will be assessed separately and specifically. The trainees will complete each PBA to a standard, advanced or expert level and ideally need the signature of two or more trainers, from two or more training centres. It is expected that each trainee will undergo a prolonged period of fistula training at one or more centres. There are 15 PBA to be completed before a fistula surgeon would be deemed to be an expert, and will often require the full 24 months of training. However, this is a competency-based training manual and each trainee will require different lengths of time to achieve each level of expertise.

This structured approach of the competency-based manual will attempt to standardise and support surgical training in fistula repair. In the process of achieving this aim, it is envisaged that there will eventually

be an increase in the number of training centres accredited for training and eventually surgeons trained.

Recommendations

1. Unmet need has to be defined in each country, and within each country, in each geographical region.
2. The unmet need in ante-natal services needs to be rectified urgently in order to minimise the number of new fistulae occurring.
3. The need for education and training has to be addressed for birth attendants, community nursing and fistula surgeons.
4. Training centres for fistula surgeons need to be identified and new ones established, according to population matrix. Training should be systematic and structured, using assessment tools such as those developed by FIGO with ISFOS.
5. Audit and research must be developed in order to ensure that quality and advances in treatment methods are ensured.
6. National strategies need to be developed to empower individual nations to take charge of the women's and children's services in their country.

4. MANAGEMENT OF NEW AND ESTABLISHED VVFS

Management of VVF depends on whether the fistula is diagnosed within two or three months of its occurrence or whether the woman presents late with an established fistula. There is evidence that early catheter care will result in the cure of a significant minority of VVFs. Algorithm 1 (**Figure 1**) describes the management of women who have both early fistulas, defined as those that have occurred within 75 days of presentation, and established fistulas, that is those that are discovered more than 75 days after obstructed labour.

5. CLASSIFICATION OF VVF

The Consultation believes that fistula audit research is considerably hampered by the plethora of VVF classification systems, of which we believe there are 32. The Consultation feels that the fistula system that is able to relate its classification to outcome is the classification that should be used in the next few years. The Waaldijk Classification is the only one that has been used to document sufficient numbers of patients from diagnosis to follow-up (**Figure 2**). **Figure 2** shows the Waaldijk Classification which involves precise measurements of the distances between the external urinary meatus and the distal edge of the fistula, together with the widest diameter of the fistula. Fistulas are classified into types 1, 2 and 3. Type 3 fistulas are those fistulas other than vesico-vaginal fistulas and include recto-vaginal fistulas and uretero-vaginal fistulas. The Waaldijk Classification of Types 1 and 2 is illustrated in **Figure 3** and described below.

If catheter drainage fails, then fistula repair will be necessary. There are certain principles behind fistula repair:

- Necrotic tissue must be removed prior to fistula repair.
- Fistula repair must only be undertaken by a properly trained surgeon.
- Adequate post-operative care is essential.
- Proper follow-up should be arranged.

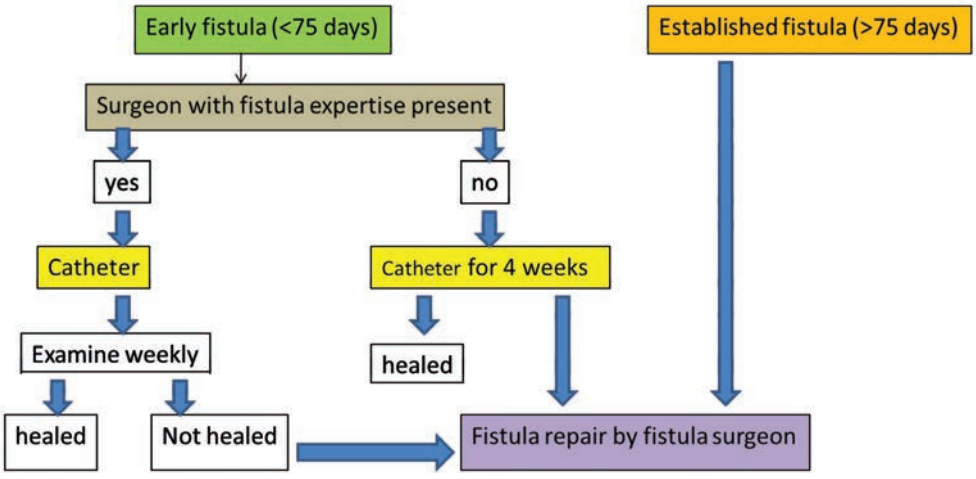

Figure 1. Algorithm to describe the management of fistula detected early (less than 75 days after obstructed labour) or later

Table 2 indicates the type of fistula closure that should be used depending on the type of fistula.

Bladder / urethra direction of closure Pubocervical fascia / urethral support Ant vagina wall closure

Recommendations

1. The comprehensive use of an indwelling catheter with free urinary drainage should be instituted for all patients who have undergone either an emergency caesarean section or a traumatic vaginal delivery after obstructed labour.
2. When fistula surgery is necessary the woman must be assured of the surgeon's competence to carry out her procedure.
3. It is recommended that further research is needed into the classification of fistula, not only to further validate the Waaldijk Classification, but also if other classifications are proposed for development.
4. There is a need to compare different surgical approaches to fistula within the context of randomized controlled trials, using the Waaldijk Classification to precisely describe the fistulas.
5. Long-term follow up of fistula patients is recommended in order to study the outcome of both conservative and surgical management and, in particular, to determine its effect on quality of life.

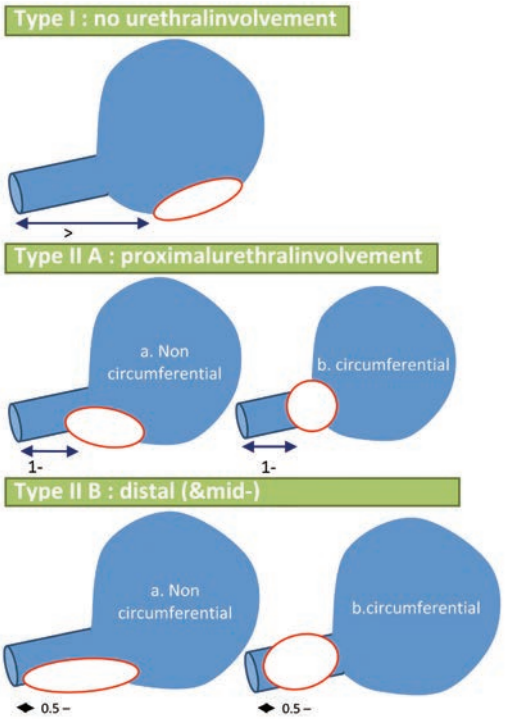

Figure 3. The Waaldijk Classification for Vesico-Vaginal Fistulas

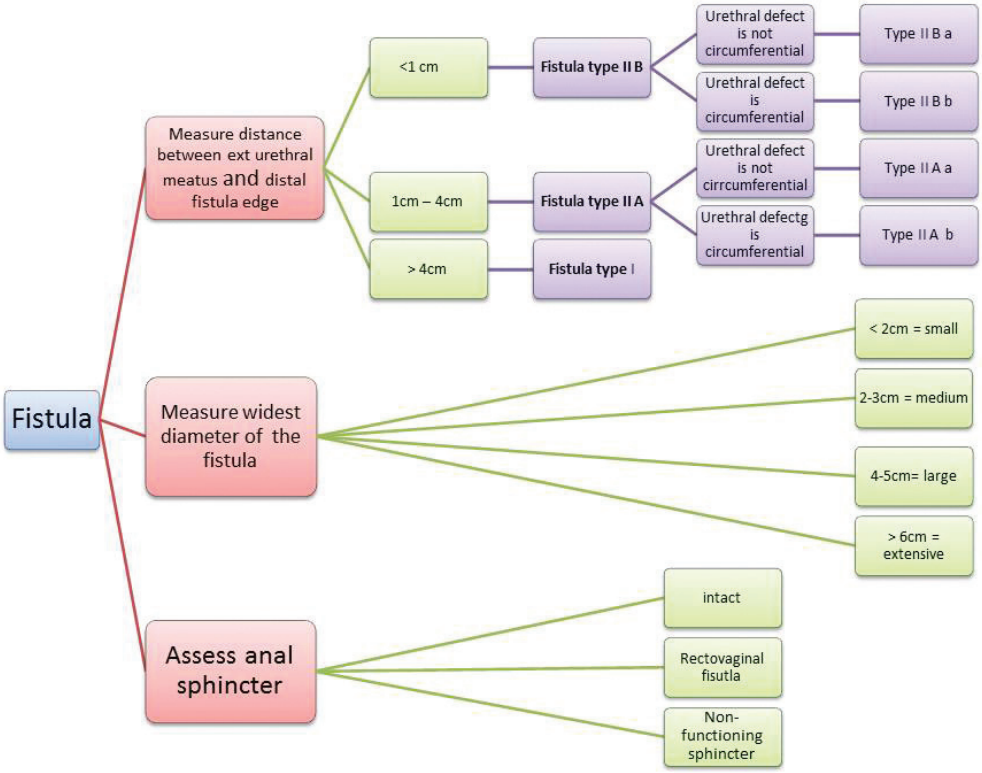

Figure 2. The Waaldijk Classification for Fistula

6. When reporting the outcome after fistula repair, authors should make a clear distinction between fistula closure rates and post-operative incontinence rates, specifying the time at which follow-up was carried out.

6. MANAGEMENT OF THE COMPLICATIONS OF VVF

The complications of Vesico-vaginal fistula are many but include:

- Persistence or recurrence of urinary incontinence
- Persistence of lower urinary tract symptoms or occurrence of new lower urinary tract symptoms, including overactive bladder
- Urinary tract infections
- Upper urinary tract symptoms, including loin pain
- Dyspareunia and sexual dysfunction
- Infertility
- Neurological symptoms
- Psychological problems and mental illness

Recommendations

1. A care programme for failed repairs with persisting incontinence after a successful repair, needs to be in place.
2. It is recommended that surgical treatment of post-operative stress incontinence should only be considered six months after fistula repair.
3. Autologous material should be used when a graft or sling is required and there is no place for synthetic sling material.
4. In order to prevent new fistulas in women who become pregnant after a fistula repair, waiting homes should be provided to ensure that each woman is able to have an elective caesarean section when she goes into labour.
5. In recurrent identifiable fistula make sure of the size and number and this kind of fistula is better repaired by a well experienced fistula surgeon. It is important to use tissue interposition like a Martius flap or fibrin glue.
6. With urinary tract infections or abscess formation, antibiotics must be given before and after the repair, according to culture and sensitivities.
7. Patients complaining of persistent leakage due to urgency incontinence may try antimuscarinics, botulinum toxin injection or even augmentation cystoplasty in small contracted or poorly compliant bladders.
8. Those with a shortened or disrupted urethra, before or after repair, must be treated with urethral reconstruction, autologous slings or injection of bulking agents, delivered trans or peri –urethrally.
9. In cases with unilateral or bilateral ureteric ligation or injury, the early diagnosis is life saving. Patients must be promptly treated by endoscopic ureteral stenting, PCN or ureteric reimplantation.
10. Patients complaining of contracted vagina and dysparunea with sexual dysfunction may use local estrogen, vaginal dilatation or may require the surgical creation of vaginal flaps to augment the vagina.
11. Patients who develop dropped foot may respond to physiotherapy or require tibialis tendon transfer. Women with neurogenic OAB may benefit from detrusor muscle botulinum injections if antimuscarinic drugs fail.
12. Psychological trauma, social isolation and depression is best treated by counselling and psychological rehabilitation.

Table 2. Surgical Techniques for the Closure of Type I and Type II VVFs

	Bladder / urethra direction of closure	**Pubocervical fascia / urethral support**	**Ant vagina wall closure**
Type I	Any according to common sense	No special measure	Approximate vag edges
Type IIAa	Transverse	Transverse repair (+ fixation) / sling	Transverse adaptation
Type IIAb	Circumferential end-to-end	Refixation / sling	Transverse adaptation
Type IIBa	Longitudinal (+ transverse) urethra tissue	Fixation / sling	Flap
Type IIBb	Longitudinal + circumferential non-urethra tissue	Refixation / sling	Flap

Table 3. Social Re-integration Matrix

ELEMENT	LEVEL		
	Facility	Community	Political
Physical Improved physical health	Early detection Rehabilitation Skilled surgeon Timely repair Designated space	Outreach Health education Follow up	Allocate funds for treatment
Psychological Improved mental health	Psychosocial therapy e.g. stigmatisation	Advocacy and sensitisation Follow up	Raise awareness on issues of counselling
Socio-economic Increased social connection	Vocational skill training Linkage with Existing programmes	Microcredit or finance Follow up	Link up with ongoing national poverty alleviation programmes

7. SOCIAL RE-INTEGRATION OF TREATED WOMEN

Social integration is defined as appropriate interventions that help women with obstetric fistula overcome physical, psychological and socio-economic challenges, freely identified by themselves, in order to enhance their return to the communities and social networks of their choosing, such that the risk of them presenting with another fistula is minimized.

The aim of social re-integration is to break the fistula recurrence/occurrence cycle in which the woman's physical state is inextricably connected to her mental state and her socio-economic situation.

Social re-integration should be seen as happening from the time the leaking of urine becomes manifest, and every subsequent intervention should have the re-integration of the woman, back into her community, as the primary goal. So, social re-integration is the responsibility of everyone who cares for the woman.

Social re-integration can be usefully looked at within a matrix, as shown in **Table 3** where the three elements of physical, psychological and socio-economic status are looked at in terms of the facility for treating the patient within her community and the political environment.

Recommendations

1. Social re-integration is important for all women with obstetric fistula. It is the process by which women are helped to overcome physical, psychological and socioeconomic challenges, freely identifiedby themselves, in order to enhance their level of social functioning in communities and social networks of their choosing, so that the risk of will presenting with another fistula is minimised.

2. Social re-integration should be used for all women. However this series of interventions can be performed by any trained care worker, providing it focuses on making the woman part of her social fabric again, and commences from the time leaking of urine becomes manifest.

3. Social re-integration should be designed to break the fistula recurrence cycle in which the woman's physical state is inextricably connected to her mental state and her socio-economic situation.

4. Early successful surgical repair or catheter management is highly recommended and is likely to be the only thing needed for social re-integration. Surgery should be performed as soon as possible by a skilled surgeon, and preferably within 3 months of developing the fistula, as this is likely to limit the length of time the woman is seen as abnormal by her family or community and thus perceived as an outcast.

5. Social re-integration should start in a designated space where women can recuperate, perhaps within the repair facility or nearby, rather than going home and encountering the risk of behaviours which may make it likely that a recurrence of fistula occurs, due to an exacerbating physical event such as early sexual intercourse or heavy work. Also, peer counselling is more likely to be available in this space.

6. Surgeons and other care workers should consider social re-integration as not just a social tool but also as a means of ensuring that adequate follow-up of the postsurgical improvement in quality of life is done and reported on. At the least, there should be a review of individually defined success of surgery and surgical outcomes, including continence and return to fertility and/or sexual life, as desired by the woman.

7. Appropriate counselling messages about the risk factors and causes associated with fistula should be targeted at family members (including husbands) and the community, as this can help to overcome the stigma, discrimination and misconceptions surrounding the condition and enhance her community inclusion. It is then an opportunity to make changes so that

the woman does not present with another fistula in the future.

8. Counselling should be seen as an opportunity for health providers to understand the socioeconomic, psychological and physical experiences that are faced by girls and women living with fistula, before and after surgery, so that they may give meaningful help. This will also help to generate knowledge on social re-integration processes and will help in the planning of a broader range of outcomes for women living with fistula.

9. Social re-integration should include assistance with education and life skills, and encouragement of private initiatives through vocational skills development and microcredit support. If this is freely chosen, it will not keep a woman away from her community unduly, and will help her regain or improve her previous economic status and enhance her self-sufficiency and community inclusion.

10. Social re-integration should include vocational skills training with the aim of providing women with alternative ways to generate income, without jeopardising their recuperation, by teaching them a trade which is economically viable within their community.

11. Institutional re-integration services should be incorporated into existing community activities or programmes directed to empower women (e.g. education, skills training, income generation, self-esteem).

12. Re-integration programmes should develop criteria to determine where support with socioeconomic interventions should be given, as funds may be limited and fistula consequences can vary dramatically by country and region. They should also be careful not to increase the burden of stigma and therefore inadvertently impede re-integration. Of particular concern should be women who are still incontinent, those who are deemed incurable, those who have no children and those who have lived with fistula for a long period of time.

13. Social re-integration programmes need to consider the potential ethical dilemmas in re-integration such as providing targeted financial support or high value goods to women with fistula in poor communities, other than as part of a community approach.

14. Social re-integration should seek to involve women who have been successfully re-integrated into their communities. These women can be termed motivational mobilisers and can contribute to community mobilisation movements for safe motherhood, fistula case mapping and referrals for treatment. Women should have a choice as to whether they wish to be involved in such advocacy activities.

15. Social re-integration programmes should be monitored and evaluated in order to collect correlates of success and failure and to help understand socio-cultural backgrounds, so that a context specific approach can be used to design and deliver effective, feasible reintegration programmes.

Below is set out the committee structure for the Consultation, within whose chapters full details of each committee's work can be found.

Scientific Committees for 1st Consultation on VVF (Chairpersons in bold)

1. Epidemiology

B. Non-obstetrical fistula

I. INTRODUCTION

Iatrogenic urogenital fistulae are known complications of pelvic surgery and oncological treatments such as radiotherapy. For example a high quality population-based case-control study from Sweden found that the risk of urogenital fistula was 25 times higher amongst women undergoing hysterectomy (n=180,000) compared to an age matched control population (n=525,826) without hysterectomy. The risk appeared to be highest for laparoscopic hysterectomy and lowest for sub-total hysterectomy but absolute numbers were small with a number needed to harm of 5,700.[3]

This section is based on electronic searches of Medline, EMBASE (from 1980 to November 2011), the Cochrane Database of Systematic Reviews, Central Register of Controlled Trials (CENTRAL), Database of Abstracts of Reviews of Effects (DARE), Database of Health Technology Assessments, and Database of NHS Economic Evaluations, and the NICE website (all accessed November 2011); references included in identified systematic and non-systematic reviews were evaluated separately. Hand searching of recent (Jan-December 2011) issues of major American, European and British journals in urology, gynaecology and urogynaecology was undertaken, to capture recent publications not yet included in the online databases. ICS, IUGA, AUA, AUGS and SGS conference proceedings for 2011 were also reviewed. It was assumed that studies and trials presented earlier than this would be in press if they were of sufficient quality and maturity to justify inclusion; hence older abstracts have not been considered.Papers offering any relevant data were considered. This included systematic reviews, randomised and quasi-randomised trials, non-randomised cohort studies, case controlled studies, longitudinal studies and case series or reports. Those papers considered for inclusion were assessed for quality where relevant, in terms of sequence generation, allocation concealment, blinding, and handling of incomplete data, selective reporting and freedom from other biases. An evidence level [EL] was then assigned to all included studies according to the ICUD modified version of the Oxford Centre for Evidence-based Medicine system. [4) Where quality was considered to be poor – as in most of the studies included in these sections – the evidence level was reduced accordingly. Recommendations (graded A-D) were made on the basis of consistent or 'majority evidence' identified.[4]

II. EPIDEMIOLOGY

1. POST-GYNAECOLOGICAL SURGERY

Fistulae involving the lower urinary tract can occur following any surgical procedure or traumatic event to the female reproductive tract, bladder, or rectum. In developing countries, the most common aetiology of fistulae involving the lower urinary tract is clearly obstetric trauma. [5] In most developed countries in which antenatal and intrapartum care is more readily available, obstetrical fistulae are relatively rare and the majority of fistulae are related togynaecological surgery. The ratio of obstetric to gynaecological fistula appears to be consistent at about 10:90 in developed countries. [6] In some developing countries, as gynaecological procedures to treat benign and malignant conditions of the female reproductive tract are more commonly performed, the rate of iatrogenic fistulae is increasing (e.g. Pakistan). [7]

The types of fistulae associated with gynaecological procedures may include communication between any reproductive organ (uterus, cervix, Fallopian tube, vagina), intestinal tract (colon, rectum), genitourinary organ (bladder, ureter, urethra), and cutaneous system (abdominal wall, perineum). The combinations, locations, and severity of gynaecological fistulae vary with each patient. In general, vesicovaginal fistulae (VVF) are the most common type. The most common causes of VVF as a consequence of surgery, in developed countries isan injury injury to the urinary tract during hysterectomy for benign conditions (60-75%), followed by hysterectomy for malignant conditions (30%), caesarean section (6%), and obstetric injuries (1%). [8][9] At the ZekaiTahirBurakcentre in Turkey 25,998 gynaecologic and obstetric operations were performed over a 3-year period. The bladder was the most frequently injured organ. Urinary tract injury rates were reported to be 0.49% for the bladder and 0.24% for the ureter in gynaecological operations, and 0.18% for the bladder and 0.01% for the ureter in obstetric operations.[10] Overall, the risk of pelvic organ fistula following hysterectomy has been reported to be between 0.1 and 4%. [11]. It is important to recognize that most urinary tract injuries do not result in a fistula.

The prevalence of genitourinary injury and fistulae vary slightly from centre to centre. In one US retrospective study from the Mayo clinic, gynaecologic surgery was responsible for 82% of the fistulas, obstetric procedures for 8%, and various forms of irradiation for 6%, and trauma or fulguration for 4%. The majority of fistulae followed treatment for benign conditions. [12] The relative proportions of the types of urinary fistula have changed with urethral fistulae having increased from 6 to 13%, while ureteral, bladder and/ or urethral fistulae having dropped from 20 to 16 and 11 to 7%. [2]

Given the various indications for, and types of hysterectomies, it is important to have an understanding of the type of hysterectomy since genitourinary or colonic fistula is reported with all of these procedures. The overall incidence of hysterectomy complications is estimated to be <2%, with bladder injury (1.3%) and ureteral injury (<1%) being most commonlyreported. [13] Traditionally, the most common route used to

remove the uterus for benign and malignant gynaecological conditions is abdominal (open incision, laparotomy); referred to commonly as total abdominal hysterectomy (TAH). The types of hysterectomies also include total vaginal (TVH), laparoscopically-assisted vaginal (LAVH), total laparoscopic (TLH), and subtotal or supracervical abdominal (SCH) or laparoscopic (LSH). Laparoscopic procedures may be done using traditional laparoscopic techniques, robotic assistance, and more recently, the single-site umbilical technique.

Benign and malignant conditions confined to the uterus are usually treated with a simple hysterectomy using any of the methods mentioned above. More advanced malignant conditions are usually treated with a radical hysterectomy in which parametrial and/or vaginal dissection and removal may be involved. In rarer cases, exenterative procedures to remove the bladder or colon may be required if malignant extension to these organs is found. In some centres, robotic radical hysterectomies have been more commonly employed to treat gynaecological malignancies. The rate of urogenital fistula associated with simple abdominal hysterectomy for benign disease is often described as being of the order of 1 in 1000. In a national study from Sweden the rate of women undergoing any fistula surgery was reported as 0.26% in women having had a hysterectomy compared to 0.0007% in those not exposed to hysterectomy, with the 'number needed to harm' being estimated at 5700.[14] From Finland the rate of vesicovaginal fistula was reported to be 1 in 1250 after all hysterectomies, 1 in 455 after laparoscopic, 1 in 1000 after total abdominal, and 1 in 5000 after vaginal hysterectomy.[15] The publicly available tables from the national hospital database in England give similar figures of 1 in 600 after total abdominal hysterectomy, and 1 in 5000 after vaginal hysterectomy.[16, 17] More detailed longitudinal analysis of patient-level information from the same dataset suggests a rate of 1 in 788 for all types of hysterectomy, 1 in 540 for abdominal hysterectomy for benign disease, 1 in 896 following vaginal hysterectomy for benign disease (excluding prolapse), and 1 in 3861 following vaginal hysterectomy for prolapse.[18]

Naturally, caesarean hysterectomy is a recognised cause of fistula,[19]and, with the increase in the number of caesarean deliveries there have been more fistulae related to obstetricsurgical trauma. [2]

The degree of bladder injury appears to be a major factor in iatrogenic fistula formation. In one study, 1,317 benign hysterectomies were reviewed (46% abdominal, 48% vaginal, and 6% laparoscopically assisted vaginal) with reference to risk factors for VVF following intraoperative injury to the urinary tract. In all, 34 cystotomies occurred with 4 (11.7%) developing a VVF. Patients who developed a VVF were more likely to have a large cystotomy and these individuals trended toward greater tobacco use, larger uterine size, and more operative blood loss. [20] Another study involving 3,076 vaginal hysterectomies with or without additional gynaecological procedures, one ureteral injuryand 54 bladder lacerations were noted yielding a total of 4 VVF. The bladder lacerations occurred during the hysterectomy portion of the surgery in 61% of cases and during the additional procedures in 39%. [21](see **Table 1**)

VVFs associated with hysterectomy may require ureteral reimplantation in as many as one-third of the cases. [22]Ureteric trauma should be considered in any hysterectomy or operative obstetric procedure regardless of the difficulty but certainly in more difficult cases.[23] Iatrogenic ureteric injury may occur after less common procedures such as ureteroscopy, lumbar sympathectomy, abdominal trauma, and iliac vessel ligation.[24]

Altered intraabdominal anatomy such as that due to previoussurgery, extensive endometriosis and pelvic inflammatory disease have previously been thought to lead to an altered operative field increasing the risk for genitourinary injury; recent evidence from a cohort of over 300,000 women having hysterecomy for a variety of indications suggests that this may not be the case. [18]

The overall rate of ureteric injury from 4998 procedures in these studies was 1.5%; the overall sensitivity was 96.1%, specificity 99.5%, positive predictive value (PPV) 74%, and negative predictive value 99.9%. The modest PPV related to 21 cases in one study where cystoscopic examination revealed abnormal (sluggish or absent) flow of indigo–carmine dye through one or both ureteric

Table 1. Categories of Prevention Strategies: The Haddon Matrix

Author	Date	Total procedures		Cystotomies		Fistulae	
			N	*n*	%	*n*	%
Mathevet et al	2001	Vaginal hysterectomy	3076	54	1.8%	4	7%
Hadley et al	1994	Vaginal surgery		12		0	0%
Mehra et al	1996	Laparoscopic hysterectomy	300	3	1.0%	2	67%
Doung et al	2011	Hysterectomy	5698	102	1.8%	6	6%
			9074	171	1.9%	12	7%
			Confidence interval		1%		30%

orifices, but subsequent findings failed to confirm injury. For every 200 cystoscopies undertaken at gynaecological surgery therefore one might expect to diagnose three otherwise unsuspected ureteric injuries but at the expense of one false positive 'injury' that would ultimately be shown to be normal.

Visco et al. using a decision analysis model concluded that the cost-effectiveness of routine intraoperative cystoscopy depends on the rate of ureteric injury; if the rate exceeds 1.5% for abdominal hysterectomy and 2% for vaginal or laparoscopically-assisted vaginal hysterectomy, then routine cystoscopy is cost-effective. These data would suggest that whilst the routine cystoscopy might be considered clinically and cost-effective at the time of prolapse and incontinence surgery, its place at hysterectomy is less clear.

2. ONCOLOGICAL FISTULA

This section considers, where the literature permits, the epidemiology of fistula relating to malignant disease and its treatment by surgery, radiotherapy and chemotherapy. The literature relating to fistula of oncological aetiology is limited both in quantity and quality. Seventy-six papers of possible relevance were identified, of which only 52 contained any relevant material. Only one randomised trial was directly identified from the literature searches,[25] although one non-systematic review of relevance,[26] and two systematic reviews were found;[27, 28] each of the latter contained only one further randomised trial. One national cohort study, and one non-randomised cohort study, are included,[18, 29] but all other identified material comprised case series or case reports, and represent level 3or lower evidence. Two cases of duplicate publication (i.e. the same paper in two journals) were found.

In the oncological context, fistulae may occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.

Traditionally, malignancies involving the uterus, cervix, vagina, or ovaries are often treated with hysterectomy, bilateral oophorectomy, and pelvic lymph node dissection. In many cases, a radical hysterectomy is performed in which the uterus, cervix, and upper vagina are removed. It is generally accepted that the more advanced the cancer, the more radical the surgical dissection will necessarily be. With cervical and uterine carcinoma, oophorectomy is performed when indicated. Pelvic lymphadenectomy is done when invasive carcinoma is suspected or diagnosed. In one study, 536 women underwent a radical hysterectomy for invasive cervical cancer. More advanced stage of disease, obesity, diabetes, and postoperative surgical infection were predisposing factors to urinary tract complications. In this study, ureteral injury occurred in 1.32%, bladder injury in 1.49% with VVF forming in 2.61% and ureterovaginal fistula in 2.43% of cases, respectively. [30] In a similar report, 1,092 women with cervical cancer underwent a radical hysterectomy with obligatory pelvic lymphadenectomy. A VVF occurred in 0.3% and a ureterovaginal fistula occurred in 1.4%. [31] The rate of GU injury likely varies between centres. For example, in one report of 479 women undergoing different methods of radical hysterectomy for cervical cancer over a 15 year period, 52 (10.8 per cent) had urological complications (17 bladder and ureter injuries, 35 fistulae and strictures). [32] In contrast, one institution reported that , with modifications and careful dissection, ureteric and bladder injury have almost been eliminated.[33]

In two recently published case series, one of fistulae specifically associated with gynaecological cancers,[26] and one of urogenital fistula from all causes,[17] those relating directly to primary cancer were uncommon, (2/20=10%)[26] and (2/348=0.6% - 2/66=3% of the oncological cases in this series),[17] respectively. Fistulae associated with cancer surgery (3/20=15% and 30/348=8.6% - 30/66=45% of the oncological cases in this series) or radiotherapy (15/20=75% and 34/348=9.8% - 34/66=52% of the oncological cases in this series) made up a much larger proportion of both series.

Immune-deficiency may be a further contributory factor, and enterovesical fistula has previously been reported in association with non-Hodgkin's lymphoma in HIV-AIDS,[34] and vesicovaginal fistula has been seen in association with classical Hodgkin's affecting the vagina in a long-term pessary user.[35]

3. CANCER SURGERY

It is likely that all operations carried out in the pelvis can be complicated by genital tract fistula in some circumstances.[17] Operations carried out with the intention of curing malignant disease will inevitably carry a higher risk of subsequent fistula formation, as compared to those undertaken with less radical intent.

Following radical hysterectomy for cervical cancer (Wertheim-Meigs procedure] the rate of fistula formation reported from case series is between 0.6% and 4.4%.[30, 36-41]It should be noted that these data are very heterogeneous, some reporting all types of fistula together, i.e. intestinogenital plus urogenital fistula, and some reporting these separately; some report all urogenital fistulae together, and some separating vesicovaginal and ureterovaginal. Where they are reported separately, the rates of vesicovaginal and ureterovaginal fistula appear to be of the same magnitude with both being reported in between 0.9% and 2.5%. of cases [30, 42, 43] The data from UK

cited above suggests a urogenital fistula rate of 1 in 95 following radical abdominal hysterectomy in women with malignant disease as compared to 1 in 540 for total (simple) abdominal hysterectomy for benign disease, and 1 in 2041 for vaginal hysterectomy for all benign disease (including prolapse).[18] Overall, the rate of urogenital fistula appears to be approximately 9 times higher following radical hysterectomy in women with malignant disease as compared to that following simple hysterectomy (abdominal or vaginal) in women with benign conditions.[18]

The risk of visceral injury or subsequent fistula formation following radical hysterectomy undertaken in pregnancy, or immediately following Caesarean section isnot obviously increased over those carried out electively in non-pregnant individuals; Monk &Montz described inadvertent cystotomy followed by vesicovaginal fistula in one of 21 women operated on during or immediately after pregnancy.[44]

Several modifications to the conventional Wertheim-Meig's procedure of radical hysterectomy have been described in an effort to reduce the associated morbidity. The Miami modification includes vaginal reconstruction and closure using bladder and rectosigmoid serosa, retroperitoneal drainage through abdominal suction catheters, and suspension of the denuded ureters with the ipsilateral obliterated hypogastric artery. One prospective study of 978 women treated by this procedure reported a urinary fistula rate of 1.4% compared to 4.4% from a literature survey following the conventional procedure.[36] The Ohkawa procedure involves peritoneal sheathing of the ureters; Blythe et al. undertook a non-randomised comparison with retroperitoneal suction drainage, and found the conventional method to be associated with fewer ureteric complications (0/34 vs. 4/26 (15.4%)).[45] Similarly, Bostofte&Serup found no benefit in operative or postoperative morbidity following the application of the Okabayashi procedure for radical hysterectomy.[32]

Given the increased risk associated with radical surgery for malignancy, it is intuitive that the risks would increase with the stage of disease and with the extent of the surgery undertaken. There are few published reports of fistula following exenterative surgery. One study noted a 16% vesicovaginal fistula rate in 19 women following exenteration for vulvar carcinoma;[46] while another describes a 15% bowel fistula rate and an 8% urinary fistula rate from a series of 75 exenterations for recurrent cervical cancer.[47] In contrast, Ungar et al. describe only one ureterovaginal fistula and one pouch–vaginal fistula in 212 women undergoing exenteration out of a total of 2540 women treated for cervix cancer in one centre over a 13 year period (0.9%).[48]

Harkki-Siren et al. found the rate of vesicovaginal fistula to be over twice as high following laparoscopic hysterectomy compared to abdominal hysterectomy, and the rate of ureteric injury to be some 35 times higher.[15] The introduction of laparoscopic surgery within oncology is seen to have considerable advantages in terms of patient recovery; the risk of operative injury to bowel and the urinary tract, and subsequent fistula formation may however remain a concern in such cases. Although some studies, both case series and non-randomised cohorts, describe similar rates of injury to those described following open radical surgery,[29, 42, 43, 49, 50] others have reported injury or fistula rates several times higher following laparoscopic radical hysterectomy.[37, 51] A single non-randomised cohort study found that the risks of both injury to the urinary tract and of subsequent fistula formation were higher following laparoscopically-assisted radical hysterectomy as compared to that following laparoscopically-assisted radical trachelectomy (Dargent's operation).[29]

The risk of urinary tract injury from minor surgical interventions is in general low, although the use of repeat procedures may confer a significant increase in risk. Vesicovaginal fistula has been reported following repeated use of CO2 laser for vaporisation of vaginal condylomata,[52] and following cone biopsy of the cervix.[53] In one personal series of 370 urogenital fistulae, 4 were associated with large loop excision of the transformation zone (LLETZ) of cervix, 3 of which followed a second LLETZ procedure (Hilton, personal communication).

Rarely, localised malignancies have been associated with VVF. One example is a primary mixed mullerian vaginal tumour reported in a 48-year female. [54] The mechanism for fistula formation is likely to be direct invasion into the bladder.

4. RADIATION FISTULA

Pelvic irradiation can be delivered by external beam as well as locally (intracavitary/brachytherapy). Fistula formation appears to be slightly higher for postoperative external radiation (1.9%) compared to intravaginal brachytherapy (0.8%). [55] It does not appear that pre-treatment factors accurately predict those who will develop fistula related to radiotherapy. [56]

The literature in this area is particularly heterogeneous in nature, with wide variation in (and some lack of clarity over) the tumour type and stage being treated, the form of radiation and the site and dose delivered. In a series of urogenital fistulae from the UK, 34/348 or 9.8% were associated with previous radiotherapy; of those related to gynaecological cancer, 34/66 or 52% had undergone radiotherapy.[17] In a further series of cases specifically related to gynaecological malignancy, 15/20 or 75% had undergone previousradiotherapy.[26] In both series most cases followed radiation used

for the treatment of cervical cancer, although, 5/34 or 15% followed treatment of endometrial cancer, and 1/34 or 3% followed treatment of a multifocal gynaecological cancer in one series. [17] Amongst a series of 216 radiation-induced fistulae, the time to diagnosis of the fistula was made between 3 months and 10 years (mean 21 months) following radiation.[57] In other series fistulae have been reported to develop or present up to 30 years after the 'causative' influence.[17, 58](**Figure 1a** and **1b**)

The incidence of any deleterious clinical impact on the gastrointestinal and urinary tracts following radiation varies in the literature between 1% and 12%,[28, 59-65] with fistula rates of 1% to 5%.[26, 66]. In a retrospective review of 2096 patients treated for cervical cancer over a 10-year period using unspecified regimen/s of radiotherapy, 38 patients (1.8%) were found to have developed fistulae, all of whom had stage IIIa/b or IV disease at presentation.[62] Of these cases, approximately 3/4 involved the rectum, with 1/3 being combined rectovaginal and vesicovaginal fistulae; 1/4 were vesicovaginal only.[62]

Following a clearly defined regimen of external beam radiation plus brachytherapy for the treatment of primary squamous cell carcinoma of vagina in 91 women, de Crevoisier et al. reported 10.0% grade 2-3 urinary tract toxicity (using the Franco-Italian glossary)[67] and 12.1% grade 2-3 gastrointestinal toxicity.[60] Unsurprisingly, they found anterior tumour location to be correlated with increased risk of bladder toxicity and decreased rectal toxicity. Two women in this series developed rectovaginal fistulae (2%), and one ureterovaginal fistula (1%).[60]

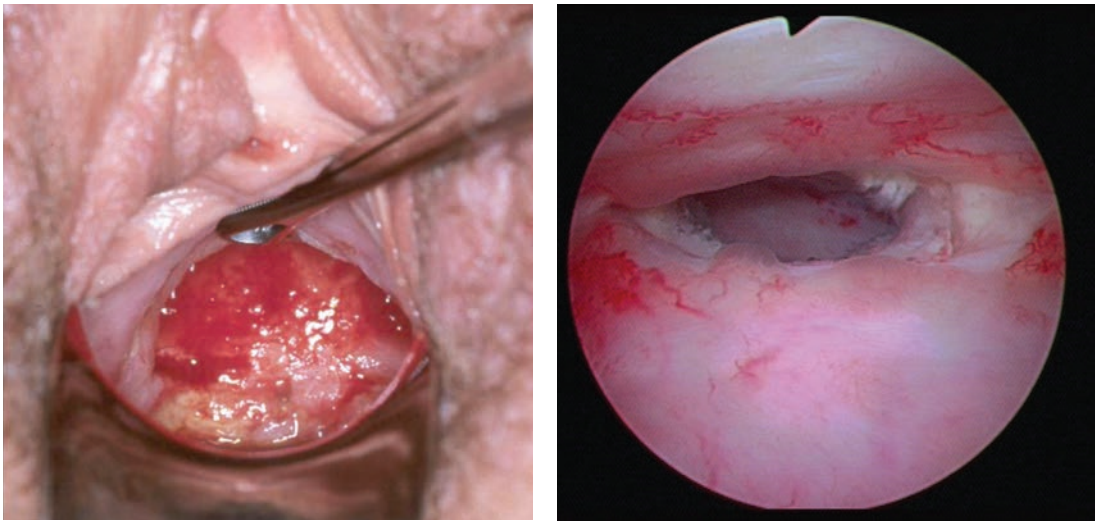

Figure 1a. Left: Acute radiation fistula; Right: fistula 20 years after radiotherapy, both for cervixcarcinoma

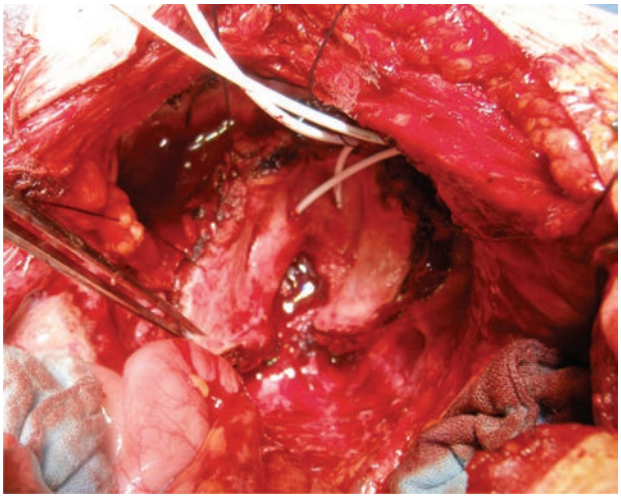

Figure 1b.Supratrigonal vesico-perineal radiation fistula in a small contracted bladder that occurred 22 years after cobalt irradiation for a gynaecological tumour.

In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynaecological cancers in one centre over a 22 year period, 133 (1.2%) developed urological complications of which 35 (0.3%) developed fistulae.[64]

In a series of 28 women treated by brachytherapy for recurrent corpus or cervix cancer, four patients developed chronic morbidities related to treatment. Three fistulae were reported in two patients (7.1%): one combined rectovaginal and vesicovaginal fistula and one ureterointestinal fistula; a further patient developed a ureteric stricture and small bowel obstruction requiring resection.[65]

These data tend to suggest a higher rate of fistula formation following the application of radiotherapy in locally recurrent disease than in primary disease. From a small series of urological complications following radiotherapy for gynaecological cancers, 14 had developed vesicovaginal fistula; of these 4 (29%) had evidence of tumour recurrence.[63] In the series reported by Jones at al. 326/1161 (28%) developed urological complications over a 20 year period; 46 developed fistulae (4%), of whom 33 (72%) had evidence of active malignant disease.[39]

When a fistula occurs after radiotherapy, it is considered good clinical practice to exclude tumour recurrence before attempting a fistula closure.

5. CHEMOTHERAPY

There are few reports of fistula formation in association with the use of chemotherapy. One case report described a patient who developed a vesicovaginal fistula having undergone abdominal hysterectomy for atypical endometrial hyperplasia whilst taking tamoxifen following a previousmodified radical mastectomy. Surgical repair of the fistula was initially unsuccessful, although after discontinuing the tamoxifen and continued bladder drainage, healing occurred.[68] It was hypothesised that the impaired healing was a result of the administration of the hormone therapy.

6. COMBINATION THERAPIES

Adjuvant or neoadjuvant therapies are used to increase the efficacy of the primary treatment, compared to its use in isolation. It might be anticipated that this would also increase the range and magnitude of adverse effects.

In a case control study examining the urinary tract complications of radical hysterectomy only a single vesicovaginal fistula was seen in 50 patients (2%) – in a patient receiving preoperative irradiation (45-50 Gy).[69] A small case series found 2/20 or a 20% rate of urinary fistulae following preoperative irradiation and radical hysterectomy in a heterogeneous group of 'high risk' cervix cancers.[70] A further case series described the impact of combined external whole pelvic irradiation (50 Gy) and intravaginal cone boost (20-26 Gy) following radical hysterectomy in 108 women. The overall rate of fistula formation was 3.7%, 2.2% following 'prophylactic' radiation, and 10.5% in 'salvage' cases where recurrent disease was present.[71]

Modarress et al. reported a randomised comparison of preoperative combined chemoradiation (cisplatin plus external beam therapy) and neoadjuvant chemotherapy (cisplatin plus vincristine) followed by radical hysterectomy in stage IB-IIB bulky cervical cancer.[25]Four patients developed hydronephrosis (3 in the chemoradiation group – 13.3%) and two vesicovaginal fistula (both in the chemoradiation group – 6.7%).[25] Two further case series reported 2/36 or a 5.6% rate of fistulae following preoperative chemoradiation (cisplatin plus brachytherapy) followed by radical hysterectomy,[72] and 4/46 or 8.7% rate of fistulae following the use of neoadjuvant and postoperative chemotherapy using irinotecan, cisplatin and nedaplatin.[73]

III. URETERIC FISTULA

A large prospective case series from Finland found an incidence of ureteric injury associated with hysterectomy for benign pathology of 0.2% [10/5279] with the lowest rate associated with vaginal hysterectomy and no difference between open and laparoscopic abdominal hysterectomy.[74] The incidence of immediate and delayed ureteric injury during radical hysterectomy was found to be 1.3% [7/536] and 2.4% [13/536] respectively in a series from Serbia; injuries appeared more common after prolonged surgery and in patients with diabetes, obesity or wound infection. [75] A registry study from the United States found an overall incidence of ureteric injury during radical hysterectomy of 0.8%.[76] Case series from referral centres in India, Pakistan, and Egypt showed that the proportion of urinary tract injuries resulting from obstetric or gynaecological surgical trauma that primarily affected the ureter varied from 1% to 23%.[77-80]

IV. FISTULA INVOLVING THE GI TRACT

The literature relating to non-obstetric fistula involving the gastro-intestinal tract is sparse and of poor quality. Although literature searching identified 78 papers of possible relevance, less than half of these contained any useful material; no randomised trials or truly systematic reviews were identified. One case controlled study is included, but all other identified material comprised case series or single case reports, and is considered to represent level 3- evidence.

It should be recognised that, whilst in most papers the term 'enterovesical' is used to describe fistulae between small bowel and bladder, and 'colo/recto-vesical/vaginal' to describe those between

large bowel and bladder/vagina, in some reports 'enterovesical' appears to be employed generically to include all fistulae involving the gastrointestinal tract. In this chapter, the term 'intestinovesical' will be used in circumstances where the generic term is clearly more appropriate.

Whilst occasionally reported congenitally,[81] the most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn's disease, and malignant disease or its treatment. There are few data on the incidence of fistula formation in these conditions, although published estimates are in the range 2-6% in Crohn's disease,[82-84] and 20% in diverticular disease.[85]

Intestinal fistulae in Crohn's disease most typically involve the small bowel, although communication with urinary tract and large bowel are also found; involvement of the bladder was reported in 27% and of the colon in 14% in one series.[86] Two large series examining the urological complications in association with Crohn's disease reported that whilst a majority of patients were female, the most serious complications were seen in males; most significantly, 13/14 or 93% of the ileo-vesical fistulae (described in these series were in men.[82, 87]

Whilst clearly diverticular disease involves the large bowel primarily in all cases, diverticular fistulae have been reported to communicate withthe bladder in 65% of cases, the vagina or uterus in 28% and small bowel in 7%.[85] Diverticular disease is the most common cause of colovesical fistula in most reports, accounting for up to 75% of cases,[88-95] with colon cancer, bladder cancer, radiotherapy and Crohn's disease accounting for the remainder.

Although there are no direct comparisons between racial groups, the distribution of these causes may vary between populations. Malignancy and/or previousradiotherapy account for 53-93% of cases of colovesical fistula reported from China,[96, 97] presumably reflecting the previously low prevalence of inflammatory bowel disease.[98]

Previoushysterectomy appears to be a significant factor in the incidence of fistula associated with diverticular disease.[99] In a national case controlled study from Sweden, involving a total of 783,245 women over a 30 year period,the risk of undergoing fistula surgery increased four-fold in hysterectomised women without diverticulitis (hazard ratio (HR) 4.0 (95% confidence interval (CI) 3.5 to 4.7)), seven-fold in women with diverticulitis without hysterectomy (HR 7.6 (95% CI 4.8 to 12.1)) and 25-fold in hysterectomised women with diverticulitis (HR 25.2 (95% CI 15.5 to 41.2)).[100] Another study described previous hysterectomy in 50% of colovesical and 83% of colovaginal fistulae associated with diverticular disease.[85]

Evidence statements epidemiology

Urogenital fistula are more frequent in women who have undergone hysterectomy	2
The risk of injury to the bowel or urinary tract and of subsequent fistula formation is higher in women with malignant disease undergoing radical surgery than in women with benign disease undergoing simple surgical procedures	2
Several modifications to conventional radical hysterectomy have been described, although they have not consistently been shown to mitigate the risk of urinary fistula postoperatively.	3
Data on exenterative surgery are inconsistent, although the risk of fistula formation may be higher following exenteration for recurrent disease as compared to that following radical hysterectomy for the primary treatment of malignancy	3
The rate of visceral injury and fistula formation is inconsistently reported following laparoscopically assisted radical hysterectomy, but may be somewhat higher than following open surgery	3
Local ablative treatments applied in gynaecological oncology, whilst apparently relatively low risk as single treatments, may carry considerable risk for fistula formation when repeated.	3
The rate of fistula formation following radiotherapy for gynaecological cancer appears to be of the same order as that following surgical treatment	4
The risk of fistula formation following radiotherapy for locally recurrent malignancy is higher than following its use in primary disease	2
The use of neoadjuvant or adjuvant therapies is likely to be associated with a greater risk of fistula development than the primary treatment alone	2
The most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn's disease, malignancy and radiotherapy.	2
The causative factors may vary in different populations, with malignancy being more commonly reported in association with enterovesical fistula in China than in other countries	3

Recommendations

The development of fistula following radiotherapy for primary treatment should trigger a search for evidence of tumour recurrence	D

V. DIAGNOSIS OF FISTULA

1. CLINICAL DIAGNOSIS

Leakage of stool, urine, or possibly both is the hallmark sign of a fistula.The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula. [101]In one study, 36% of VVF presented within 1 week of a laparoscopic hysterectomy and 50% in the second week. Most of the patients after trans-abdominal hysterectomies had leakage in the second week (90%). [102] As discussed above, more extensive dissection is a factor when lower urinary tract injury results in a fistula. However, other than a frank injury such as ureteric transection, not all injuries result in the formation of a fistula. With laparoscopic or abdominal dissection, ureteral injury may occur anywhere along the retroperitoneal ureter usually below the pelvic brim. Since the injury may not be recognised during surgery, post-operative pain is a key symptom. The cause of vesicovaginal fistulae after hysterectomy varies with the extent of surgery and the amount of damage that has occurred. In an attempt to determine causative factors of post-operative fistulae, the records of 12 patients who had developeda vesicovaginal fistula after TAH were compared with 12 consecutive TAH patients without fistula formation. Most of the patients who developed VVF had excessive postoperative abdominal pain, distension or paralytic ileus, or both. Haematuria, symptoms of irritability of the bladder, prolonged postoperative fever, and increased white blood cell count were also noted more often in the fistula group. In contrast, the postoperative course wasusually uncomplicated in the non-fistula group. The clinical course observed in many of the patients with vesicovaginal fistulas suggests that the patient has an unrecognized or recognized injury to the bladder resulting in urinary extravasation. [103] It may be possible to abort the development of many vesicovaginal fistulae by early recognition and treatment of an unsuspected bladder injury. It is suggested that patients with severe abdominal pain, distension, paralytic ileus, haematuria or symptoms of severe irritability of the bladder after abdominal hysterectomy should be investigated early for a possible genitourinary injury.

Another possible etiology of VVF in the setting of laparoscopic procedures is trocar insertion injury. To prevent this the bladder should be emptiedby intermittent or continuous bladder drainage prior to inserting the abdominal and pelvic trocars. During the laparoscopic procedure, gaseous distention of the urinary drainage bag may become evident indicating a hole in the bladder.This intraoperative sign however, has not been associated with fistula formation.[104]

The diagnosis of VVF usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection (office evaluation or exam under anaesthesia) may confirm the presence of a fistula however it may not reveal the extent, location, or course of the fistula. Some fistulae are not readily visible. This is particularly true with iatrogenic fistula in which the fistula may be high in the vagina and may involve the ureter, bladder, or both. Therefore, most physicians rely on adjunctive tools for the diagnosis of VVF. This may include imaging studies in combination with other modalities such as cystoscopy. A simple approach in the office setting to confirm that a fistula is present is to fill the bladder retrograde with a coloured fluid. This could bea milky fluid such as baby formula or vital dye-tinted water or saline (methylene blue, indigo carmine). Direct visualisation of dye extravasation or placement of a tampon into the vagina to identify staining may facilitate the diagnosis of a VVF. (**Figure 2**) A double-dye test

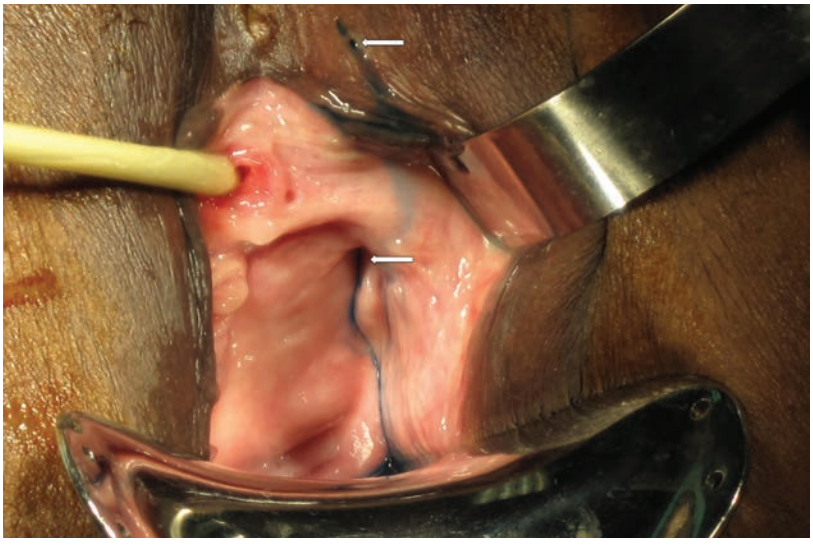

Figure 2. Methylene blue introduced intravesically, demonstrating complex vesico-vagino-vulval fistula following pelvic fracture (arrows indicate external openings)

to differentiate between an ureterovaginal and VVF may be useful in some cases. The patient is given phenazopyridine orally which will stain the urine orange while the bladder is filled with blue fluid. Blue tinting of the tampon leads to the presumptive diagnosis of a VVF while orange staining is suspicious for an ureterovaginal fistula. [105]

a) The role of cystoscopy in preventing and diagnosing VVF

A number of studies have investigated the role of routine cystoscopy in avoiding/detecting urinary tract injury at pelvic surgery; Indraratna et al. have recently reviewed these.[106]

Gilmour et al. undertook a systematic review of urinary tract injuries at benign gynaecological surgery including all studies of >500 patients reported between 1966 and 1998. [107] The overall rate of ureteric injury from 17 studies where cystoscopy was not undertaken (mostly hysterectomy) was 168⁄107,068=0.16%. In 10 studies where cystoscopy was undertaken routinely (mainly colposuspension or pelvic floor reconstruction), the rate of ureteric injury was 20/3235=0.62%. The corresponding rates of bladder injury were 0.26% (without cystoscopy) and 1.04% (with cystoscopy). Although the rates of detected urinary tract injury were approximately four-fold higher in those studies where cystoscopy was undertaken as a routine, it should be noted that none of these studies was randomised, and routine cystoscopy was undertaken predominantly during those procedures with intuitively the highest risk of injury. Summary statistics for available studies evaluating the place of routine cystoscopy (with or without intravenous indigo-carmine) at gynaecological surgery are given in **Table 2**.

Cystourethroscopy may provide direct visualisation of the fistula. In several series using cystoscopy (mostly with IV indigo-carmine) the sensitivity and specificity in detecting ureteric injury intra-operatively were >95%. Depending upon availability, radiologic studies (cystography, urography, intravenous urography, and CT urography) may be useful. Ultrasonography and colour Doppler have been used by some, although their use in routine practice remains to be established. [108][109]

Urine may extravasate externally or internally. Creatinine levels in the urinte are higher than serum levels. Therefore, in the setting of a suspected fisula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared to serum levels. [110]

b) Imaging

An unstructured review by Narayanan et al. suggested that magnetic resonance imaging, particular with T2 weighting, provided optimal diagnostic information regardingfistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative.[111] These newer modalities were considered to be superior to other X-ray contrast techniques and ultrasound.

2. DIAGNOSIS OF GI FISTULA

Pneumaturia, dysuria and/or recurrent UTI's are symptoms of a colovesical fistula but may be due to other causes as well.Accepting the limitations of small case series in this regard, a number of studies have investigated the value of a range of investigative techniques in the detection and evaluation of enterovesical or colovesical fistulae.[90, 92, 93, 97, 112-116]Since in each study the authors have presented only results on patients known to have fistulae, sensitivity (true positive/true positive + false negative) may be estimated, however, specificity (true negative/true negative + false positive), positive predictive value, (true positive/true positive + false positive) and negative predictive value (true negative/true negative + false negative) cannot (see **Table 3**). No test was shown to have consistent reliability; excluding those investigations for which only a single report was identified, CT (53%), cystoscopy (48%), and in the case of colovesical fistula, barium enema (38%) were perhaps the most useful; intravenous urography and sigmoidoscopy or colonoscopy appear to have limited utility in the diagnosis of GI fistula.

3. RECOMMENDATIONS

CT and cystoscopy appear more consistent in the confirmation and location of possible intestino-vesical fistulae, than other investigations	C
Level 3 evidence indicates that the routine use of cystoscopy with dye testing at gynaecological surgery has high sensitivity, specificity and negative predictive value in the detection of ureteric injury, although false positive tests do occur. The clinical and cost-effectiveness of routine cystoscopy remains to be established	C

VI. MANAGEMENT OF VESICO-VAGINAL FISTULA

The literature relating to surgical fistula is extensive, but of limited quality. 356 papers of possible relevance were identified, of which only 173 contained any relevant material. Three systematic reviews were identified (albeit one only as a protocol),[117-119] although none contained information of direct relevance. Six randomised trials were identified including one on causation,[120] one on prevention of urinary tract injury at surgery,[121] two on antibiotic prophylaxis at the time of reparative surgery,[122, 123], and two on surgical techniques applied to obstetric fistulae.[124, 125] There was also one quasi-randomised study of relevance.[126] Four non-randomised cohort studies,[127-130] and one cost-effectiveness study,[131] were also identified. All other identified material comprised case series [99] and individual case reports or procedure descriptions [52], and represent level 3or 4 evidence. Three examples of duplicate publication were identified.

1. CONSERVATIVE MANAGEMENT

a) Immediate management by catheterisation or defunctionalizing

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. Normal continence mechanisms, however, involve the physiological contraction and intermittent relaxation of urethral and anal sphincters. As a result, although completely spontaneous closure of genital tract fistulae does occur, it is the exception rather than the rule. Bypassing the sphincter mechanisms, or diverting flow around the fistula, for example by urinary catheterisation, percutaneous nephrostomy or defunctionalizing colostomy, may however encourage closure. Bazi reported a non-systematic review of papers including information on the spontaneous fistula closure of vesicovaginal fistulae; whilst the data quality of all was poor, he identified 30 studies from which 12 could be included; these included cases that were almost exclusively of surgical aetiology; it should be noted that in 9 of these 12 studies the sample size was less than 5 patients.[132] Few studies described catheter drainage in large fistulae, although it seemed that

Table 4. Data from studies including rates of spontaneous closure of surgical vesico-vaginal fistulae. n.b. table includes studies considered by Bazi,(132) but only those of known surgical aetiology.

		Confidence interval		23%

those of less than 1cm diameter were most likely to heal spontaneously. The time between the insult and institution of drainage in cases of non-surgical closure varied widely, although in most cases this was less than 3 weeks. Similarly, the duration of catheterisation prior to the initiation of conservative treatment was deemed to have been unsuccessful varied considerably, making true estimates of the effectiveness of this approach impossible; generally this varied between 10 days and 3 months.[132] Reported success rates varied between 0% and 100% (although 5 series had a sample size of 1!), although in several series it was difficult to determine how many women had attempted conservative management.[132] In large series of obstetric fistulae where a consistent approach to conservative management has been applied, spontaneous healing has been reported in up to 28% of cases.[133-135] In one series of urogenital fistulae of varying aetiologies, spontaneous closure was seen in 19/238 or 8.0% of surgical cases, 4/38 or 10.5% of obstetric cases, 1/36 or 2.8% of miscellaneous (largely traumatic cases) and 0/34 or 0.0% of radiotherapy related cases.[17] It is likely that in this, and many other reported series, data are an underestimate of the value of this approach to management,[17] nevertheless, combining available data (see **Table 4**) gives an overall spontaneous closure rate from 348 surgical fistulae treated by initial catheterisation of 13% ± 23%.[8, 17, 21, 136-145]. Patients with ongoing, continuous vaginal leakage despite a functioning indwelling catheter are unlikely to have resolution of the VVF without additional measures such as surgery. Such patients should be spared prolonged catheter drainage and proceed with more definitive repair as soon as medically appropriate.Small epithelialized fistulas may benefit from minimally invasive cystoscopic electrocoagulation of the fistula tract, followed by prolonged catheter drainage. In patients with fistulae less than 3.5mm in diameter, 11/15 had successful fistula tract ablation with cauterization and catheter drainage in a study by Stovsky et al.[146] In general, conservative measures are successful in small fistulas only, usually less than 2-3mm in diameter.

b) Pharmacotherapies to assist fistula closure

Several case reports describe successful fistula closure following the induction of amenorrhoea by oestrogen, oestrogen/progesterone combinations, or luteinising hormone releasing hormone analogues,[147] in the management of vesicovaginal,[148] and more frequently, uretero- or vesicouterine fistula following caesarean section.[149-153] The overall closure rate in these studies is 88%±16%. Spontaneous closure of vesico-uterine fistula has also been reported on a number of occasions,[150, 154] with a rate of 41/786 or 5% calculated in one review.[150] Whilst comparison across studies is obviously highly problematic (especially where many are single case reports, with success rates of 0% or 100%), it seems highly likely that the rate of closure following hormone treatment [14/16] is significantly higher than that of spontaneous closure [41/786] ($p<0.0005$ – Fisher's exact test).

In quasi-randomised controlled study (alternate allocation) in patients with continuing urinary leakage following ureteric or pelvi-calyceal surgery, the use of intranasal desmopressin was shown to significantly reduce the duration of leakage compared to 'watchful waiting'.[126] The use of such treatment should be avoided in patients with complicating factors such as infection.

It should be recognised that some fistulae may be associated with minimal symptoms, and even if persistent these may not require surgical treatment. Small distal urethro-vaginal fistulae, utero-vesical fistulae with menouria, colo-vesical fistulae associated with diverticular disease, and some low recto-vaginal fistulae may fall into this category.

c) Palliation and skin care

During the waiting period between diagnosis and repair, incontinence pads should be provided in generous quantities so that patients can continue to function socially to some extent as well as avoid skin complications related to chronic urinary leakage. Urinary fistula patients usually leak considerably larger quantities of urine than those with urethral incontinence from whatever cause, and this needs to be recognised in their provision of supplies.

The vulvar skin may be at considerable risk from urinary or faecal dermatitis,[155, 156] particularly if there is additional radiation change in the skin;[157, 158] liberal use of silicone barrier cream should be encouraged. Steroid therapy has been advocated in the past as a means of reducing tissue oedema and fibrosis, although these benefits are refuted and there may be a risk of compromise to subsequent healing. Some authors have recommended local oestrogen, and whilst empirically one might expect benefit in post-menopausal women,[159, 160] or those obstetric fistula patients with prolonged amenorrhoea,[161, 162] the evidence for this is limited.

d) Nutrition

To maximise the prospects for postoperative healing it is essential, that the general health of the patient should be optimised. This is most relevant to obstetric fistula patients, where social ostracism and the effects of prolonged sepsis, may commonly result in malnutrition and anaemia.[163-168] Where there is severe inflammatory bowel disease the question of an elemental diet or even total parenteral nutrition may need to be considered.[96, 99, 169-172] Nutritional support may also be important in patients with malignant or radiotherapy induced fistulae,[173] or in those with complications following diversion surgery.[172, 174, 175]

e) Physiotherapy

Obstetric fistulae are commonly associated with lower limb weakness, foot drop and limb contracture. In a group of 479 patients studied prospectively 27% had signs of peroneal nerve weakness at presentation and a further 38%, whilst having no current signs, gave a history of relevant symptoms.[176] Early involvement of the physiotherapist in preoperative management and rehabilitation of such patients is essential.[177] Although nerve injury is rarely seen in association with fistulae of other (non-obstetric) aetiologies, the value of physiotherapist support in the preoperative management and rehabilitation of patients with complex fistulae or with intercurrent pathologies should not be under-emphasised.[172]

f) Antimicrobial therapy

Active infection in the genital or urinary tracts should be treated prior to attempted surgical repair. In tropical countries the treatment of systemic infections such as malaria, typhoid, tuberculosis and parasitic infections are not uncommon and should be rigorously pursued and treatment undertaken before elective surgery. One randomised trial reported no difference in outcome between single dose IV gentamycin and continued postoperative use of amoxicillin, chloramphenicol or cotrimoxazolein obstetric fistula patients (although re-analysis suggests that a difference favouring peri-operative gentamycin may be present).[122] A further placebo controlled trial of ampicillin found no evidence of benefit from prophylactic antibiotics in terms of fistula closure or residual incontinence following repair, although the use of postoperative antibiotics was reduced.[178] A recent review of obstetric fistula practices has called for further trials in this aspect of fistula management.[179] Opinions differ on the desirability of prophylactic antibiotic coverage for surgery in the developed world, some avoiding their use other than in the treatment of specific infection, and some advocating broad-spectrum treatment in all cases. A systematic review found only weak evidence that antibiotic prophylaxis (compared to giving antibiotics when clinically indicated) reduced the rate of bacteriuria, pyuria and symptomatic urinary tract infection in female patients undergoing abdominal surgery who had a urethral catheter for at least 24 hours; this limited evidence related to women receiving antibiotics during the first three postoperative days or from postoperative day two until catheter removal.[180]

g) Bowel preparation

Although many surgeons continue to employ mechanical or stimulant laxative bowel preparation prior to recto-vaginal fistula repair,[181] and may even suggest alternative approaches to surgery where this has not been possible,[94] a recent systematic review that included 18 trials (5805 participants), found no evidence that patients benefit from mechanical bowel preparation, nor the use of rectal enemas, and concluded that bowel cleansing can be safely omitted prior to colonic surgery, without increasing the risk of perioperative complications.[117]

h) Counselling

Surgical (non-obstetric) fistula patients are usually previously healthy individuals, who entered hospital

for what was expected to be a routine procedure, and they end up with symptoms infinitely worse than their initial complaint. In contrast, obstetric fistula patients in the developing world are often social outcasts. In both situations therefore these women are invariably devastated by their situation; significant impact on their mental health has been objectively confirmed.[182, 183] It is vital that they understand the nature of the problem, why it has arisen, and the plan for management at all stages. In the setting of an iatrogenic fistula, there may be considerable medico-legal consequences. Confident but realistic counselling by the surgeon is essential and the involvement of nursing staff or counsellors with experience of fistula patients is also highly desirable. The support given by previously treated sufferers can also be of immense value in maintaining patient morale, especially where a delay prior to definitive treatment is required.[184]

2. SURGICAL MANAGEMENT

Whilst most commonly occurring after hysterectomy, virtually any operation undertaken in the pelvis may be complicated by the development of urogenital fistula.[17] In the series from UK recently published by Hilton, 238/348 or 68% were of surgical aetiology, 172 (72% of surgical cases and 49% of the series) followed excision of uterus and/or cervix.[17] It should be borne in mind also that so-called 'minimally invasive' procedures may result in fistula formation, including mid-urethral tape procedures,[119] and peri-urethral injections.[185]Minimally invasive procedures are not without risk as ureterovaginal fistula has been reported following a robotically-assisted procedure.[186]

a) Timing of surgery

The most appropriate timing for repair of vesicovaginal fistulae remains one of the more contentious issues in this area. The debate continues between the advocates of early intervention, in order to minimise the distress to the patient from continuing urinary leakage, vs. those in favour of delaying intervention until local inflammatory change has resolved, necrotic tissues have sloughed, and the patient's recovery from the causative event completed, so as to optimise results.

There is no consensus in the literature as to the definition of 'early' in this context, with different studies either failing to specify at all, or giving a broad range of definition. Although some studies have used the terms 'immediate',[187] 'less than two weeks',[188] or 'less than 30 days',[145] most reports have considered either less than 6 weeks,[189-191] or less than 3 months,[130, 188, 192, 193] as their definition of early intervention. Although relatively few studies have reported their outcomes for both early and late approaches to management, overall the results do not appear to be significantly different (see **Table 5**). The overall results for early management are estimated at 91%±6% and for later management (where provided) 90%±27% (p=1.00; Fisher's Exact test).

b) Outcomes from treatment and follow-up

Comparing the outcomes of treatment between different reports and different methods is made difficult by the inconsistent and relatively inefficient outcome measures used. These have ranged from the apparent achievement of a water-tight repair based on dye-testing in the operating theatre, to patient reported symptoms at the time of discharge from hospital. Follow-up in obstetric fistula patients is inevitably difficult in many developing world centres, but even amongst surgical or radiotherapy cases in the developed world, relatively few reports describe examination findings or symptoms at later postoperative review. Long-term outcomes and quality of life measures haveonly rarely been reported.[194, 195]

Table 5. Data from studies examining outcome from vesicovaginal fistula repair using an 'early' approach to management; where comparative data from alternative timings are available these are included.

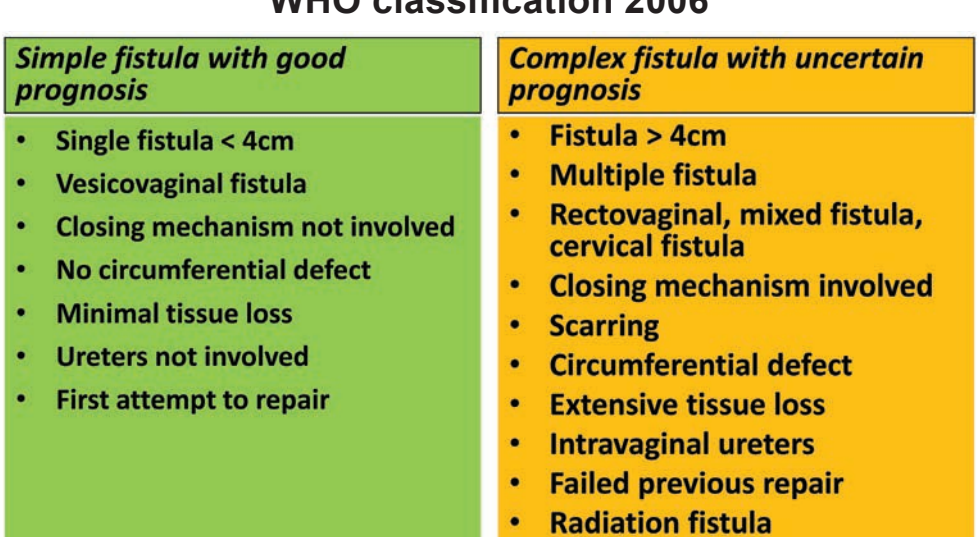

Figure 3. Adapted WHO classification of fistula. Although this classification was developed for obstetric fistula initially, it could be relevant for iatrogenic fistula as well. (400)

c) Surgical approaches

Despite the fact that there is no universally agreed upon classification of iatrogenic fistula, it is probable that there is a relationship between the complexity of the fistula and the outcome of the fistula repair.

The WHO published a classification on obstetric fistula in 2006 that divided fistula in simple or complex fistula. We adapted that classification by adding the radiation fistula to the complex fistula group. (**Figure 3**)

1. Vaginal Procedures

There are two main types of closure technique applied to the repair of urinary fistulae, the classical saucerization technique described by Sims,[196] and subsequently modified as a partial colpocleisis by Latzko,[142] and the more commonly used dissection and repair in layers or 'flap-splitting' technique (variously attributed to Hayward, Collis & Lawson Tait).[197] Individual surgeons inevitably employ these techniques somewhat variably, and in different situations, and there are no data comparing their outcomes.

The conventional dissection and repair in layers is entirely appropriate for the majority of post-surgical fistulae, although modifications may be necessary in specific circumstances. In juxta-cervical fistulae in the anterior fornix, vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilisation of the bladder from the cervix, and the repair should usually be undertaken in such a manner (usually transversely) to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulae, particularly those following hysterectomy, can again usually be managed vaginally. The vault is incised transversely and mobilisation of the fistula is often aided by deliberate opening of the Pouch of Douglas.[198] The peritoneal opening does not require to be closed separately, but is incorporated into the vaginal closure.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by ChassarMoir[199] or Hamlin & Nicholson.[200] A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if any prospect for continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but may also provide additional bladder neck support and improve continence by reducing scarring between bladder neck and vagina. These are indeed technically demanding procedures and outcomes of such complex repairs using robust measures as regards continence or sexual function are lacking.

With very large fistulae extending from bladder neck to vault, the extensive dissection required may produce considerable bleeding. The main surgical difficulty is to avoid injuring the ureters. They are usually situated close to the supero-lateral angles of the fistula, and if they can be identified endoscopically, they should be catheterised. Straight ureteric catheters passed transurethrally, or double pigtail catheters may both be useful in directing the intramural portion of the ureters internally; nevertheless great care must be taken during dissection. In such cases where the ureters cannot be visualized cystoscopically, interventional radiological techniques may be utilized to place antegrade ureteral stents from a percutaneous nephrostomy access tract.

2. Abdominal procedures

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina; most typically this might be following hysterectomy in nulliparous women, in endometriosis, or in those who have not delivered vaginally. Other indications for transabdominal repair are the need for simultaneous augmentation cystoplasty, or in the setting of a ureteric injury requiring reimplantation or simultaneous VVF and ureterovaginal fistula.

A transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack. The ureters should be catheterised under direct vision either endoscopically prior to skin incision, or following opening of the bladder. The technique of closure is similar to that of the transvaginal flap-splitting repair except that for purposes of haemostasis the bladder mucosa is usually closed with a continuous suture.

A simple transperitoneal repair is relatively uncommonly employed (although this technique does seem to be favoured by some using the laparoscopic approach – see below), although a combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. A midline incision is made in the vault of the bladder; this is extended downwards in a racquet shape around the fistula. The fistulous track is excised and the vaginal or cervical defect closed in a single layer. The bladder is then closed in two layers.

There are no randomised studies comparing abdominal and vaginal approaches; given that those surgeons undertaking both routes for repair would usually see specific indications for the two such a comparison is most unlikely ever to be seen as feasible, ethical or appropriate. Nine non-randomised cohort studies reporting results from both abdominal and vaginal procedures were identified in the current review.[9, 17, 128, 191, 201-205] In all, these series included 388 vaginal repairs and 345 abdominal repairs with overall closure rates at first operation of 89% and 87% respectively (p=0.367; Fisher's exact test). The same reports included 255 transvesical repairs with a 93% cure rate, and 399 transperitoneal repairs with an 89% success rate (p=0.130; Fisher's exact test) (see **Table 6**).

With respect to attempted repair of a previously failed VVF surgery, the law of diminishing returns appears to be as evident in these types of procedures as in many other forms of surgery. Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previously unsuccessful procedures. In a series of 2484 largely obstetric fistulae, the success rate fell from 81% for first procedures to 65% for those requiring 2 or more procedures.[206] Series of surgical cases are rarely large enough for this effect to be evident, although the recent series published by Hilton found successful fistula closure was significantly more likely in the women who had not had attempts at closure before referral (98.2%) than in those who had one or more previous unsuccessful procedures (88.2%) (p=0.003; Fisher's exact test).[17]

There is only a single randomised trial comparing aspects of surgical technique; Shaker et al. report an RCT comparing trimming of the fistula edge with no trimming.[125] Although there was no statistical difference in success rates between the two groups, in those cases where repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas those where there was no trimming were more likely to be smaller upon recurrence(see **Figure 4**).[125]

3. Laparoscopic

Laparoscopic repair of a VVF was first reported by Nezat et al., in 1994.[207] Fifteen series were identified in the current review,[187, 207-220] (plus an additional series in which 2 laparoscopic procedures were undertaken amongst a small series of vaginal and open abdominal operations).[205] All reported series are quite small (1-25 cases, median 6 cases), and in total only 119 patients were included, with an overall cure rate of 92% (confidence interval 4%) (See **Table 7**). It is not clear from these series whether they include all fistula repairs undertaken in the reporting centres, or whether they were selected in some way; if the latter, it is not clear what selection criteria were used. It is possible that there may be both selection and reporting biases that make it difficult to fully evaluate laparoscopic procedures against alternative surgical approaches.

4. Robotic

The first report of a robotically-assisted repair of vesico-vaginal fistula was from Melamud et al. in 2005.[221] Since that time four additional reports have been identified,[222-225] including a total of 17 cases (see **Table 7**). The reported cure rate is 100% in all series, although the same comments as above, in relation to possible selection and reporting biases, apply equally here. At this stage, whilst one could state that fistula repair with robotic-assistance appears to be feasible, it is not possible to indicate what its place or potential advantagesare over alternative approaches.

5. Fibrin glue

The use of fibrin glue in urological indications was reviewed by Shekarriz and Stoller;[226] they identified nine reports (eight in human subjects) of the use of fibrin glue in fistula repair, including a total of 16 patients.[227-234] A further six more recent reports were identified in the current review, where fibrin glue was used either by endoscopic injection or direct application, making a total of now 53 patients with fistu-

lae of various aetiologies.[124, 229, 235-239] Several of these publications were individual case reports, although there was also one randomised trial comparing fibrin glue (20 patients) with a Martius graft (20 patients) in obstetric fistula patients.[124] All of the case reports described successful repair (1/1=100% cure); the RCT reported 13/20=65% cure; the overall success rate therefore for the 53 reported patients was 77.4% (confidence interval 7.3%) (See **Table 8**). In one case successful closure of a radiation induced fistula was reported from the combined use of bovine collagen and fibrin glue.[229] Overall, the indications for, and optimal patient selection for this approach are not defined.

6. Endoscopic repair

Mackay described a technique for transurethral endoscopic suture repair of vesico-vaginal fistula in 1997.[240]; there have been three further papers using a similar technique on between one and four patients (total 10 cases).[202, 240-242] Although in three of these series the reported cure rate was 100%, overall, fistula closure was found in 80% (confidence interval 24%).

c) Adjuvant Techniques in the Repair of VVF: Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery.[243-247]Most commonly, such flaps are utilized in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistula, large fistula, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high level evidence for the use of such flaps in any of these situations. Furthermore, there is no high level evidence that the use of such flaps improves outcomes in the setting of an uncomplicated VVF.

For those VVF repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap can easily be mobilized. From a transabdominal approach, greater omentum can be used as an interposition flap.

A variety of other flaps including gracilis muscle flaps, labial myocutaneous flaps, seromuscularintestinal flaps, and rectus abdominis flapsas well as free grafts of bladder mucosa have been utilized as adjunctive measures in the repair of complex VVF.[248-255]

3. POST-OPERATIVE MANAGEMENT.

a) Catheter type

No studies were identified comparing different catheter types or duration of drainage following fistula repair. Most reports do not describe their catheterisation practices in any detail; in those that do, the majority have employed urethral catheterisation, with a small number preferring suprapubic drainage or a combination of both. The reason for catheterisation is to ensure free urine drainage until such time as the repair is soundly healed; for this reason some have advocated both suprapubic and urethral drainage, arguing that whilst one catheter might easily become blocked, two are unlikely to do so simultaneously.[17]

b) Duration

There appears to be no obvious consensus over the duration of catheterisation recommended following fistula repair of various types and aetiologies. In a retrospective study of obstetric fistula patients in Ethiopia, approximately equal numbers of patients were catheterised for 10, 12 or 14 days. Patients were not randomised, and there were differences between the groups in terms of the extent of urethral involvement, fistula size, and degree of vaginal scarring, with the more extensively damaged patients being catheterised for longer. Despite this, there was no significant difference in outcome in terms of the rate of repair breakdown, and the authors therefore suggested that postoperative catheterisation for 10 days may be sufficient in the management of less complicated obstetric vesico-vaginal fistulae.[256]

			53	41	77.4%
			Confidence interval		7.3%

In a recent review of practices amongst obstetric fistula surgeons, Arrowsmith reported a considerable range of practice. For 'simple' fistulae, the average duration of bladder drainage used was 12 days (range 5-21 days); for 'large' fistula the average was 17 days (range 0-30 days); and for 'difficult' fistulae, the average was 21 days (range 14-42 days).[179]

Studies of non-obstetric fistula management are no more consistent in their description of duration of catheterisation. Most report periods of between seven and 21 days drainage; most typically 10-14 days for surgical fistulae and 14-21 days for radiotherapy-associated fistulae. There is no more than level 3/4 evidence to support any particular practice in these aspects of fistula management.

The summary of the surgical management of VVF can be found in **Figure 5-7**.

Conclusions & recommendations

Spontaneous closure of surgical fistulae does occur, although it is not possible to establish the rate with any certainty; if a vesicovaginal fistula is diagnosed within six weeks of surgery, indwelling catheterisation can be considered for a period of up to 9 weeks (i.e. up to 12 weeks after the causative event)	C
Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling and support prior to and following fistula repair	D
Perioperative antibiotic prophylaxis should follow local policies	D
There is no benefit from mechanical or laxative bowel preparation prior to colonic surgery; it is reasonable that this recommendation be extrapolated to apply to fistula surgery	B
There is no proven benefit to delayed repair of vesicovaginal fistula; the timing of repair should be tailored to the individual patient and surgeon requirements, but can be undertaken as soon as any oedema, inflammation, tissue necrosis, infection are resolved	B
There are no high quality data to indicate greater cure rates for any one technique as compared to others; level 3 evidence indicates similar success rates for vaginal and abdominal, and for transvesical and transperitoneal approaches	C
Surgeons involved in fistula surgery should have appropriate training, skills, and experience to select an appropriate procedure for each patient	D
The majority of vesico-vaginal and all urethro-vaginal fistulae can be repaired vaginally, regardless of aetiology	C
Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal approach is necessary	D
A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting	C

Surgical fistulae

Immediate management
- If a vesico-vaginal fistula is diagnosed within (*three to*) six weeks of surgery, indwelling catheterisation should be considered for a period of up to (*six to*) 9 weeks (*i.e.* up to 12 weeks after the causative event
- Retrograde, ureteroscopically-assisted or antegrade ureteric stenting should be considered for immediate management for all uretero-vaginal fistulae

Timing of surgery
The timing of VVF repair should be tailored to the individual patient requirements, and can be undertaken as soon as any local oedema, inflammation, necrosis & infection resolved

Bowel preparation
No benefit from mechanical or laxative bowel preparation prior to colonic surgery; this can be extrapolated to include fistula surgery

Antibiotic prophylaxis
Perioperative antibiotic prophylaxis should follow local policies

Counselling & support
- Realistic counselling by the surgeon, nursing staff and/ or counsellors with experience of fistula patients is highly desirable
- Support from previously treated patients is appreciated and very valuable

Surgical approach
- Surgeons involved in fistula surgery should have appropriate training, skills, experience and versatility to select an appropriate procedure for any patient
- Both vaginal and abdominal approaches have an established role in fistula repair
- The majority of VVFs and all urethro-vaginal fistulae can be repaired vaginally, regardless of aetiology
- Where concurrent ureteric re-implantation or augmentation cystoplasty are required, and abdominal approach is essential
- A variety of interposition grafts are described for use in either abdominal or vaginal procedures, although there is no high level evidence to support their use
- Conventional and robotically-assisted laparoscopic approaches have both been shown to be feasible in selected cases; the place of these techniques is not yet clear

Postoperative drainage
A period of continuous bladder drainage is crucial to successful fistula repair
- 10-14 days for simple and/or surgical
- 14-21 days for complex and/or radiation

4. MANAGEMENT OF RADIATION FISTULA

The literature relating to the management of radiotherapy-associated fistula is again limited in quantity and quality. Forty-nine papers of possible relevance were identified, of which only 35 contained any relevant material. Seven systematic reviews were identified, although none contained information of direct relevance. No randomised trials and only four non-randomised cohort studies of relevance were identified. All other identified material comprised case series or individual case reports or procedure descriptions, and represent level 3or 4- evidence.

Injury to the gastrointestinal or urinary tracts may arise following therapeutic radiation, with the incidence of complications increasing when the dose exceeds 50 Gy. The obliterative endarteritis associated with ionizing radiation in therapeutic dosages may proceed over many years and may result in fistula formation long after the primary malignancy has been treated. [17, 58] The associated devascularisation in the adjacent tissues means that conventional surgical repair has a high likelihood of failure, and may also result in re-presentation with several fistulae over a period of many years. In those cases where abdominal repair surgery or urinary diversions are undertaken, a high risk of GI anastomotic leak and progressive sepsis has been reported perhaps related either to inadequate resection of irradiated bowel or to damage to other organs at operation.[59] All these factors often make the management of post-radiation fistulae more challenging than that of post-surgical or even obstetric fistulae. Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer.[203, 257, 258] Spontaneous healing seems rarely if ever to occur,[17, 40] and only one case report was identified, of a radiation fistula presenting 22 years after initial treatment, in which healing occurred following cauterisation (for biopsy) and prolonged catheter drainage.[259]

a) Diversion procedures

Because of the wide field abnormality surrounding many radiotherapy-associated fistulae, several authors have suggested that urinary and/or faecal diversion should be seen as the treatment of choice in such cases.[39, 62, 63, 203] Others have employed a routine policy of preliminary urinary and faecal diversion, with later undiversion in selected cases.[260] In a non-randomised cohort of recto-urethral fistula repairs, Vanni et al. reported 100% closure at first operation in 35 non-irradiated cases, compared to 84% in 39 irradiated cases.[260] Additionally, 97% of the non-irradiated cases subsequently underwent 'undiversion', whereas 31% of the irradiated cases required permanent faecal diversion due to a non-compliant rectum or severe sphincter dysfunction.[260]

Some authors have emphasised the place of repair in carefully selected cases of radiotherapy-associated fistulae.[17] Of 36 radiation/malignant fistulae in the series reported by Hilton, although 11 declined surgery or died before treatment, and 6 underwent primary diversion, of the 19 (53%) who underwent repair, 18 (95%) were closed at first operation.[17] Finally, some seem to take the view that diversion has little or no place in the management of radiation-induced vesicovaginal fistula in particular.[57] Of 216 radiation-induced fistula managed over a 47 year period by Pushkar et al., 210 underwent a vaginal and 6 an abdominal repair procedure (although it should be noted that this is a retrospective case series, and whilst not stated in the paper, it is possible that other patients not included in this review actually underwent diversion).[57] It should be noted, however, that with this almost exclusive use of the vaginal repair procedure, whilst a cumulative closure rate of 80% was eventually achieved after 4 or more operations, only 48% were closed after first repair, 40% were closed following a second operation, 52% following a third operation, and 35% following a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favoured over ileum as a conduit in this context, to avoid the risk of employing irradiated bowel and distal ureter.[261-263] Whilst these benefits seem clear, it should be noted that high perioperative morbidity (37%) and re-operation rates (20%) have been reported from this procedure.[262]

As an alternative to the latter operation, where both urinary and faecal diversion are proposed, Hampson et al. described the technique of left colic urinary diversion with distal transverse end colostomy.[264] This technique allows a shorter operation time, and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active following such procedures, the residual bladder or rectal wall may be used to augment the vagina.[265] Where vesicovaginal fistula co-exists with significant bladder contracture following surgery or radiation, an abdominal (transperitoneal) repair might be considered, along with simultaneous ileocystoplasty,[266, 267] or colocystoplasty. [268] Fistula repair concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaeys et al.[269] Whilst one might anticipate a very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

b) Repair techniques

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of 'flap-splitting' or dissection and repair in layers (variously attributed to Hayward, Collis & Lawson Tait),[197] and partial colpocleisis,[142] have been the most widely advocated in radiation-associated fistulae. Where patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect.[270] In a non-randomised cohort study, Hilton reported anatomical closure by colpocleisis in 94.7% of radiation-associated cases, compared to 96.1%

from a range of repair procedures in fistulae of surgical aetiology.[17]

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colo- or entero-vesical and colo- or entero-vaginal fistulas.[271, 272] Although the results have generally been good, with the avoidance of a permanent urinary or faecal stoma, Levenback et al. reported poorer results than following resection of the affected bowel, largely related to bleeding from the isolated segment, and bacterial infection.[272]

c) Interposition grafts

Several techniques have been described to reinforce fistula repair in different sites depending on the type of repair undertaken. These include the Martius bulbocavernosus muscle and labial fat graft, a gracilis muscle or myocutaneous graft, omental pedicle grafts, and peritoneal flaps. Whilst there is no high level evidence to support the use of these techniques, the interposed tissue has been presumed to help by creating an additional layer in the repair, to fill in 'dead space' and reduce the risk of haematoma formation beneath the repair, to bring in a new blood supply into the area, and to reduce scarring. For each of these hypotheses, interposition grafts might be considered to have their greatest benefit in the repair of radiation-associated fistulae.

At abdominal repair of vesicovaginal or recto-vaginal fistulae, the use of a pedicled omental graft has been widely advocated.[245, 273] The omentum is dissected from the greater curve of the stomach and rotated down into the pelvis on either the right or left gastro-epiploic arteries; this may be used at any transperitoneal procedure, but has its greatest potential advantage in radiation-associated fistulae.

The role of interposition flaps in trans-abdominal repair procedures was reviewed by Evans et al.[247] They reported 37 patients with fistulae of largely surgical aetiology, of whom 12 of 12 treated employing an omental or peritoneal interposition flap were cured, compared to 16 of 25 managed without interposition (64%); this finding was consistent for fistulae of both benign and malignant aetiology. Although their cases were not randomised, and the authors acknowledge that their overall cure rate (75%) was rather lower than many series, nevertheless, they concluded that an interposition flap should be recommended, when a trans-abdominal repair is undertaken, particularly when the repair is performed by a less experienced surgeon.

Although widely employed in the context of obstetric fistula repair in the past, there is no high level evidence to support the use of the Martius graft in this context and there seems to be a general move away from it amongst obstetric fistula surgeons. One small non-randomised cohort study reported benefit in patients with multiple or recurrent fistulae, based on a univariate analysis,[243] another reported no advantage to the experienced obstetric fistula surgeon.[127] In the series of fistulae of all aetiologies from UK reported by Hilton, the fistula closure rate was not significantly different between those procedures where an interposition graft (omental or labial) was (92.0%) or was not (96.1%) used in the repair ($p=0.264$; Fisher ' s Exact test).[17]

In the situation of vaginal repair of radiation-associated fistula Pushkar et al. strongly advocate the use of the labial fat graft interposed at fistula repair;[57] Hilton advocates its use to fill 'dead space' in the lower vagina at complete colpocleisis.[17, 270] (**figure 8**)With the former technique closure at first operation was 48%,[57] with the latter 95% closure at first operation is described.[17]

Labial skin grafts have also been employed in the repair of radiation-associated fistulae, either as an interposition, or replacement for sloughed or indurated vaginal skin. Labia minora flaps, with the outer surface de-epithelialized,[274] and labia majora flaps,[275, 276] have both been described in this context.

Muscle and myocutaneous grafts have also been employed as interposition in fistula repair. These tend to be very bulky grafts, and are perhaps best used therefore in circumstances of extreme tissue loss. The technique of rectus abdominis flap interposition was described in one series of 10 patients, although none of their cases were radiotherapy related.[277]Viennas et al. reported one case of a radiation-induced vesicovaginal fistula repair by this technique.[252] Gracilis muscle along with selective use of a buccal mucosal overlay graft has been used in recto-urethral fistulae, with 84% cure in radiation-associated cases.[260]

d) Other management approaches

In patients with intractable urinary incontinence from radiation-associated fistula, percutaneous nephrostomy or ureterostomy might be considered.[63] This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate. Several methods have been described, including the insertion of coils,[278] coils with gelatin sponge,[279, 280]clips,[281] nylon plugs with injection of polidocanol,[282] Isobutyl-2-cyanoacrylate,[283] and balloons.[283-286] These were reviewed by Avritscher et al. with success rates ranging from 50% to 100% for the different methods, and with an overall success of 77% in 150 cases from nine papers reviewed.[287]

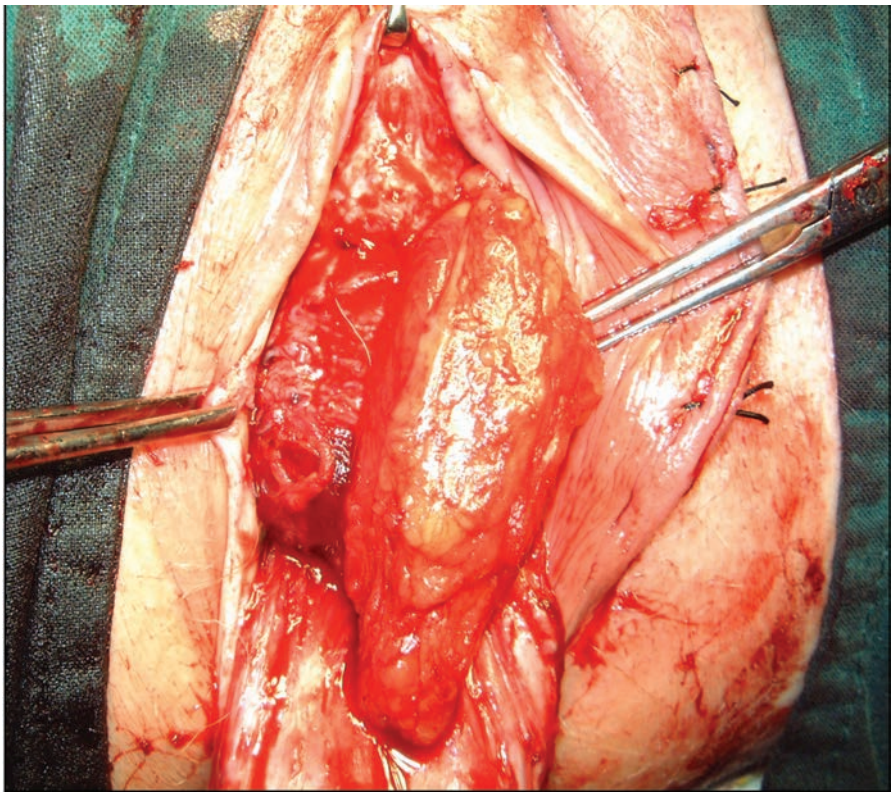

Figure 8. Martius labial fat graft passed subcutaneously to overlie fistula repair (combined with complete colpocleisis)

Recommendations Radiation Fistula

Whilst diversion is used more widely in radiation-associated fistulae of all types as compared to non-radiated fistulae, there is low level evidence that repair procedures can achieve successful fistula closure and continence in appropriately selected cases	C
Where urinary and/or faecal diversions are required, attempts should be made to avoid using irradiated tissues wherever possible, and to minimise the potential for anastomotic complications	C
There is low level evidence to support the use of interposition grafts when repair of radiation-associated fistula is undertaken	C
In patients with intractable urinary incontinence from radiation-associated fistula, where life expectancy is very short, ureteric occlusion might be considered; there is insufficient evidence to recommend any particular technique	D

VII. MANAGEMENT OF GI FISTULA

1. LITERATURE REVIEW

The literature relating to the management of urinary fistula involving the gastro-intestinal tract is limited in quantity and quality. Forty-six papers of possible relevance were identified, of which 39 contained any relevant material. One systematic review was identified, albeit of only indirect relevance, and with no mention of fistula.[117] A single non-systematic review of the management of internal fistulae in Crohn's disease was identified;[288] this included only a single randomised trial,[289] although this did not include patients with urinary fistulae. No further randomised trials or cohort studies of relevance were identified, either from within the review, or independently. One decision analysis model,[290] 26 case series and 10 individual case reports or procedure descriptions were found, including a total of 852 patients.

2. NON-SURGICAL MANAGEMENT

In the context of colo-vesical fistulae associated with diverticular disease, a surgical approach is most commonly advocated. One non-randomised cohort of 30 patients included six who did not undergo surgery, four of whom remained well for periods of up to 14 years; of the 24 who underwent surgical treatment, five (21%) died in the postoperative period.[291]

Ileo-vesical fistula in Crohn's disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents; in a non-systematic review of the management of internal fistulae in Crohn's disease, Levy &Tremaine describe the drugs that have been reported to close internal fistulas partially or completely including azathioprine, 6-mercaptopurine, mycophenolatemofetil, cyclosporine A, tacrolimus, and infliximab.[288]

One case series of 500 patients with Crohn's disease included 17 with entero-vesical fistulas; all received sulfasalazine, and most were treated with corticosteroids and antibiotics intermittently, and eight in addition received 6-mercaptopurine. Although it is not clear that their fistulae closed completely, six continued on medical treatment alone for several years.[84]

Present et al. reported a placebo controlled randomised trial of the tumour necrosis factor α (TNFα) neutralising agent infliximab, a murine/human chimeric monoclonal antibody that binds both the soluble subunit and the membrane-bound precursor of TNFα, in patients with externally draining fistulae associated with Crohn's disease.[289] Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5mg infliximab. This latter study did not include intestino-vesical fistulae, although a case of successful use of infliximab in an ileo-vesical fistula has been reported.[169]

3. SURGICAL MANAGEMENT

The most frequently advocated surgical approach to colo-vesical fistula in diverticular disease has been sigmoid resection with primary colorectal anastomosis, and closure of the bladder. Dissection of the fistula track followed by closure of the bladder and bowel, with interposition of omentum, but without resection was described in three patients by Lewis & Abercrombie.[292]This approach should perhaps be reserved for cases with minimal diverticular disease in otherwise healthy bowel, where, were it not for the presence of the fistula, there would be no indication for colonic surgery.

One series of 74 patients described a technique in which only visible or palpable full-thickness defects in the bladder were repaired; otherwise the bladder was not repaired, but simply drained by indwelling catheter for one week following sigmoid colectomy (in diverticular disease) or small bowel resection (in Crohn's disease).[91] At median 6 month follow-up there was a single recurrence of a colo-cutaneous/vesico-cutaneous fistula, but no recurrence of the colovesical fistulae. Other authors have similarly advocated leaving the bladder unrepaired in patients with Crohn's ileo-vesical fistulae, to heal by secondary intention with catheter drainage alone.[87, 293]

The main contention in the management of intestino-vesical fistulae has been over the feasibility and role of a one-stage management with resection of the affected bowel segment, primary anastomosis, and closure of the bladder, as compared to a two- or three-stage approach.

The authors of many case series have advocated a one-stage approach in the majority of cases, but have indicated that this should be limited to those patients whose nutritional state is good, and where there is no evidence of severe inflammation, radiation injury, advanced malignancy, intestinal obstruction, major medical problem, or advanced age.[90, 93, 94, 96, 294, 295] More recent series have tended to imply a greater advocacy of the one-stage approach; Garcea et al. in a series of 90 patients with colo-vesical fistula reported primary anastomosis in 61/65=94% of cases where left colon resection was undertaken.[92] Balaguera et al. argue against diverting colostomy or Hartmann's procedure as being unnecessary, and possibly bringing additional morbidity.[296] Several reports have described a laparoscopic approach to one-stage treatment of colo-vesical fistulae, including a total of 30 patients.[95, 171, 297, 298] The overall conversion rate was seen to be higher for fistulae involving the duodenum, vagina and sigmoid colon, than those involving the bladder (10%), although a low threshold for conversion to open surgery was advocated in one series.[95]

In addition to the above criteria, it is intuitive that the more complex a fistula track, the more relevant a phased approach to treatment becomes. Shackley et al. described a series of 10 patients with highly complex fistulae involving between 3 and 6 separate organs/surfaces.[172] They advocate a three-stage multidisciplinary management package, involving: [1] an acute stage involving proximal defunctioning and distal drainage of both the gastrointestinal and urinary tracts to isolate the fistula, together with the eradication of sepsis; [2] a recovery stage consisting of total parenteral nutrition, organ support, radiological planning of surgical reconstruction and intensive nursing; [3] joint urological and gastrointestinal reconstructive surgery, when the patient was stable, nutritionally replenished, and sepsis was controlled. Whilst the mean time to reconstruction was 5 [1-20] months, the fistulae were treated successfully in all patients, with functional restoration in four, and/or diversion of the gastrointestinal and urological tracts in six.[172]

4. RECOMMENDATIONS

There is limited evidence to support a non-surgical or conservative surgical approach in colo-vesical fistulae where there are minimal symptoms or evidence of limited bowel involvement	C
There is only limited low level evidence to support a non-surgical approach in colo-vesical fistula associated with diverticular disease; nevertheless, in the frail elderly, or in patients who have limited symptoms of urinary infection or urinary diarrhoea it is reasonable to consider a trial of conservative management	D
There is evidence that infliximab is efficacious in the treatment of external fistulae, but only very limited low level evidence of efficacy in urinary fistulae in association with Crohn's disease	B/D
A one-stage approach to surgery for intestino-vesical fistulae is appropriate in many cases, but should be limited to those patients whose nutritional state is good, and where there is no evidence of additional intra-abdominal pathology (e.g. severe inflammation, radiation injury, advanced malignancy, intestinal obstruction) or major co-morbidity	B
A laparoscopic approach to one-stage management has been shown to be feasible, although there is no high level evidence to allow comparison of outcomes with open surgery	D

VIII. MANAGEMENT OF URETERIC FISTULA

1. GENERAL PRINCIPLES

The relevant clinical principles are related to prevention, diagnosis, management, and after care. [299] Patients at higher risk of ureteric injury such as those undergoing complicated childbirth, radical or repeated pelvic surgery, or surgery following pelvic radiotherapy require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognise injury promptly when it occurs. Immediate repair of any intraoperative injury should be performed observing the principles of debridement, adequate blood supply and tension free anastomosis with internal drainage using stents.[300] Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvi-calyceal system. Fluid should be sent for creatinine determination to differentiate serous from urinary leak. Repair of such cases should be undertaken by an experienced team and may consist of conservative management with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< 3 months) or delayed (> 6 months) surgical repair when required.[301] Surgery should again adhere to the standard principles of tissue repair and safe anastomosis. Functional and anatomical imaging should be used to follow up patients after repair to guard against late deterioration in function of the affected renal unit. These general aspects of care of patients with trauma to the upper tract and subsequent fistula formation are covered in standard textbooks of urology and guideline documents. [300, 301] This review will concentrate on developments in the past six years.

2. EVIDENCE QUALITY

A total of 127 abstracts were screened which were categorised as being not relevant [26], cases reports without useful information [63] and for possible inclusion [38]. After review of full text, 27 were selected for the review and 11 rejected due to duplicate information (n=7) and no relevance (n=4). Four further possible papers were identified from the reference lists of included articles of which two were included in the review. The selected papers [29] included one poor quality randomised trial [302], one poor quality quasi-randomised trial [303], one high-quality population case control study[3], one registry study[76], one systematic review[304], one cost analysis[305], 14 cases series, 8 case reports, and one unstructured review.

3. EVIDENCE SUMMARY

a) Management of Specific Fistula

1. Urinary leak after renal preservation surgery

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days post-operatively, in 4% [45/1118] of patients undergoing partial nephrectomy.[306] This was associated with larger tumours, higher blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic versus open). The majority resolved without intervention but 30% required ureteric stent insertion or percutaneous drainage. A poor quality quasi-randomised study involving 16 patients with persistent leakage after pelvi-calyceal surgery despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared to control.[303]

2. Urinary leak after renal transplantation

A case series from Brazil observed a fistula rate of 2.9% [31/1046]presenting at a mean of 28 [1-131] days following transplantation predominantly due to distal ureteric necrosis and with most cases requiring open repair.[307] Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and two deaths from sepsis. A case se-

ries from China observed fistula development in 3.5% [43/1223] of patients presenting at a mean (range) of 6 [3-20] days following transplantation again primarily due to necrosis of the distal transplanted ureter. [308] Open intervention with re-implantation of the ureter into the bladder or native ureter was required in 34 patients, with one other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series form Serbia found a fistula rate following renal transplantation of 2.2% [5/224] and all required open repair.[309]

3. Uro-enteral fistula following percutaneous renal surgery

Case reports of ureterocolic fistulae occurring after renal cryotherapy, and gunshot trauma all resolved with insertion of ureteric stent.[310, 311] This is in line with previous accounts of this complication following percutaneous nephrolithotomy.[312]

4. Uretero-arterial fistula

A systematic literature review found reports of 139 cases of uretero-arterial fistula published between 1899 and 2008.[304] All patients presented with haematuria with 25% also having other urinary symptoms or back pain. Virtually all cases had a relevant past surgical history particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The great majority affected the iliac segment and pre-operative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent case series of 20 patients also showed a high mortality of 10 – 20% but did not find any difference in outcome between open or endovascular graft insertion techniques.[313]

5. Ureterovaginal fistula

Ureterovaginal fistula occurring in the early postoperative phase predominantly after hysterectomy is the most frequent presentation to urologists of upper urinary tract fistula. A randomised study involving 3,141 women undergoing open or laparoscopic gynaecological surgery lasting > 30 min found that the incidence of ureteric injury after prophylactic insertion of ureteric stents (1.2 % [19/1583]) was similar to control (1.1% (17/1558]).[302] A previous cost analysis from the United States perspective suggested stenting was only worthwhile if the risk of injury was > 3.2%.[305] If injury does occur, many cases, even those with bilateral injury, can be managed by endoscopic techniques. [314](**Figure 9)**

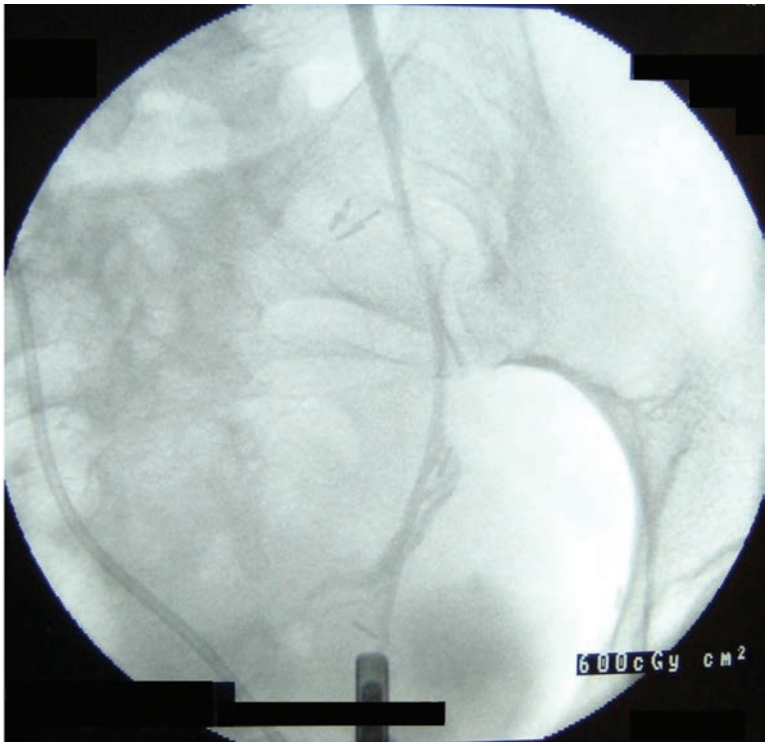

Figure 9. Conservative management of bilateral lower ureteric injury. Retrograde ureterogram showing successful cannulation of left ureter by guide wire and successful placement of right ureteric stent.

The use of ureteric stenting in patients with ureterovaginal fistulae was reported in 11 studies, including 126 patients in total;[315-325] this resulted in closure in 63 cases altogether. Success rates were between 6% and 100%, although the overall closure rate across all series is calculated at 50% ± 18% (see **Table 9**).

Where retrograde stenting proves impossible, percutaneous nephrostomy and antegrade stenting might be considered if there is some degree of pelvicalyceal dilatation. Ureteroscopy may also be helpful,[320, 324] and a technique for combined antegrade and retrograde ureteroscopic cannulation has been reported.[317] In one report all cases of uretero-vaginal fistula were managed by temporary diversion using a percutaneous nephrostomy followed by delayed repair 4-6 weeks later,[156] and a similar approach was taken in the management of one uretero-uterine fistula.[326]

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if the relevant skills and facilities are available.[327-329] A recent case report has suggested that open repair through the vagina is possible if abdominal access is problematic.[330]

6. Ureteric fistula associated the terminal phase of pelvic malignancy

Urinary leakage is very distressing for people dying of advanced pelvic malignancy but palliation by open diversion may be associated with a high rate of complications. Recent case series have described the technique of occlusion of the distal ureter with coils or other devices using an antegrade approach combined with chronic urinary diversion using nephrostomy tubes.[331-333]Natarajan et al reported successful management of five patients with two requiring repeat embolization but all achieving good palliation until death without adverse effects.[331]Shindel et al reported on 29 patients with bothersome urinary fistula despite chronic nephrostomy drainage, and poor performance status.[332] In all cases palliation of the urinary leakage was achieved. The majority of patients [23/29] died of their underlying cancer at a mean of 8 months after the procedure. Three patients with benign disease subsequently underwent definitive surgical diversion with the remaining 2 lost to follow up. Coil migration was seen in one patient without serious consequence and there were no other complications specific to the embolization. Kim et al used the technique to temporally palliate five women with ureterovaginal fistula prior to delayed definitive repair.[333]

Table 9: Data from studies including rates of closure of uretero-vaginal fistulae with ureteric stenting.

Authors	Date	*N*	Spontaneous closure	%
Andrioli et al	1984	10	5	50%
Lang	1984	10	9	90%
Lingeman et al	1985	4	4	100%
Dowling et al	1986	23	11	48%
Mandal et al	1990	31	2	6%
Barton et al	1992	5	4	80%
Koonings et al	1992	1	1	100%
Campbell et al	1993	14	6	43%
Baeghler et al	1997	1	1	100%
Narang et al	2007	3	2	67%
Ustinoz et al	2008	24	18	75%
		126	63	50%
		Confidence interval		18%

The algorithm for uretero-vaginal fistula can be found in **Figure 10**

Evidence table

Prophylactic ureteric stent insertion does not reduce risk of ureteric injury during gynaecological surgery	2
The use of desmopressin may hasten resolution of urinary leak after pelvi-calyceal surgery	3
Uretero-arterial fistula is associated with a high mortality rate	3
Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase	4

4. RECOMMENDATIONS

Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and repairing the ureter	D
Ureteric stents are not required as prophylaxis against injury during routine gynaecological surgery, while their role in more extensive surgery remains to be established	B
Ureteric injury or fistula may be suspected in patients following pelvic surgery if a fluid leak or pelvi-calyceal dilatation occurs postoperatively	D
Uretero-arterial fistula may be suspected in patients presenting with haematuria with a history of relevant pelvic surgery and indwelling ureteric stent	D
Elevated levels of creatinine in drainage fluid following pelvic surgery are suggestive of a urinary tract injury	D
Most upper urinary tract fistula should be initially managed by conservative or endoluminal techniques where such expertise and facilities exist	B
Persistent ureterovaginal fistula should be repaired by an abdominal approach using open, laparoscopic or robotic techniques according to availability and competence	D
For patients with ureteric fistula associated with advanced pelvic cancer and poor performance status, palliation by nephrostomy tudediversion and endoluminal distal ureteric occlusion is an option	C

IX. MANAGEMENT OF URETHRO-VAGINAL FISTULA

1. INTRODUCTION

Urethrovaginal fistulas are a rather rare complication of some surgical and medical conditions or treatments. Most of the literature consists of small retrospective series or case reports. There are no randomized prospective trials.

2. AETIOLOGY

Excluding obstetric aetiologies,In the developing world, urethrovaginal fistula may occur as a result of obstructed labor with or without associated VVF. In industrialized countries urethrovaginal fistula in adults mostly have an iatrogenic aetiology. (See **Table 10**)

In feminizing genital reconstructions in children with ambiguous genitalia and surgical repairs of cloacal malformations, urethrovaginal fistula can occur as early or late complications. [334][335, 336][337, 338] Also in transsexual adults undergoing female to male reconstruction, urethrovaginal fistulae have been reported. [339]

In the surgical treatment of stress incontinence in women with bulking agents [340, 341] or synthetic slings several cases of urethrovaginal fistula have been reported.[342-345] [119] (see **Figure 11**) Even conservative treatment of prolapse with pessaries can lead to the formation of fistula, if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described.[18, 346](see **Figure 12**).

Trauma – including inappropriate catheterisation- and foreign bodies are obvious causes of fistula. [347-353]

Urethral diverticula and their surgical repair may also lead to urethrovaginal fistula.[354-356]

Urethrovaginal fistula have also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum. [357, 358]

Irradiation complications can also result in the formation of urethrovaginal fistula.[359]

3. DIAGNOSIS

Clinical vaginal examination is often sufficient to diagnose the presence of an urethrovaginal fistula. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistula. In cases of difficult diagnosis, voiding cystourethrography (VCUG) or ultrasound can be useful. [360] Double balloon urethrography is the classic examination to show urethral diverticulum and urethrovaginal fistula, but 3D MRI or CT scan is becoming utilized more widely.. [361-363]

4. SURGICAL REPAIR

Several techniques for urethrovaginal fistula closure have been described. A vaginal approach is mostly used. Surgical correction intends to create a continent urethra that permits volitional, painless, and unobstructed passage of urine. Depending on the size, localisation and aetiology of the fistula and the amount of tissue loss urethral reconstruction techniques may be necessary to restore the urethra and to achieve post-operative continence. [347]

a) Vaginal approach

Goodwin described in his series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal

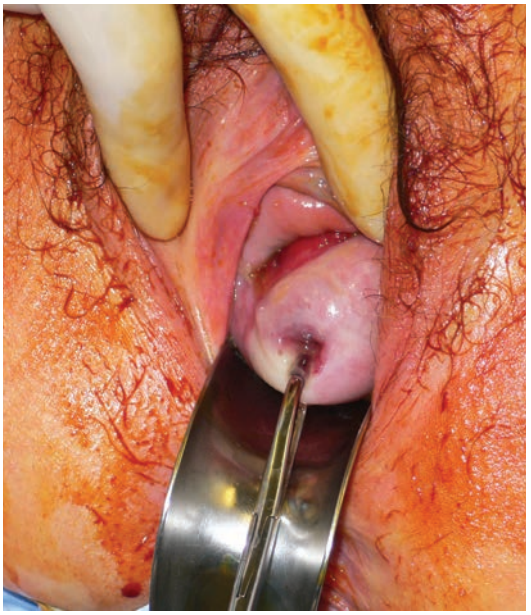

Figure 12. Fistula in anterior vaginal fornix following use of shelf pessary for utero-vaginal prolapse.

approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time, had less blood loss and a shorter hospitalisation time.[364]

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: identifying the fistula, creation of a dissection plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall. Primary closure rates of 53%-95.4% have been described (see **Table 11**). Pushkar et al. described a series of 71 women, treated for urethrovaginal fistula. 90.1% of fistula were closed at the first vaginal intervention. Additionally 7.4% were closed during a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation ororurethrotomy.[365]

Advancement flaps of vaginal wall can be used to cover the urethral suture line. In some cases more advanced methods are used to close or to protect the urethral closure.

In cases of difficult dissection and visualisation, urethral sectioning has been advocated. [366] This technique is also being used in the repair of complex urethral diverticula.[367] Fistulae that are located in the distal third of the urethra may also be marsupialized without compromising the continence mechanism.[368] Distal urethrovaginal fistula may be entirely without symptoms, and in such cases, repair is not mandated.

Blaivas advocates that vaginal flaps are usually the best option in dealing with urethral reconstruction, next to the possibility of offering anterior or posterior bladder flaps. Options for vaginal repair of fistula include primary closure, peninsula flaps, bilateral labial pedicle flaps, and labial island flaps. Outcomes are optimised by using exacting surgical principles during repair and careful postoperative management by an experienced reconstructive surgeon. [347]

1. Labial and vaginal flaps and neourethra

The simplest flap is a vaginal advancement flap. [369]

Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra. [370, 371] The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases a transpubic approach has been used. [372] The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernosus tissue can be incorporated in the pedicled flap and probably offers a better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome stress incontinence would occur postoperatively. [373, 374]

2. Martius flap

While in obstetrical fistula repair, it was not found to have any benefit in a large retrospective study in 440 women, the labial bulbocavernosus muscle / fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistula where additional bulking with well vascularised tissue is needed. [375] Rangnekar et al. report on 12 patients with urethrovaginal fistula, of whom 8 were treated with a Martius flap and 4 with a conventional repair. Only one out of the 8 had a fistula recurrence, while 3out of 4 of the conventional repairs broke down; it should be noted however that these cases were not randomised between surgical techniques.[376] Punekar et al. described 15 patients with complex and recurrent fistula, using the skin island flap modification with excellent results.[377]Radopoulus published a small series of 5 recurrent and complex urethrovaginal fistulas that all healed using a Martius flap.[378]The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomized studies.[379, 380] The indications for Martius flap in the repair of all types of fistula remain unclear.

Table 11: Closure rates of urethrovaginal fistula

Author	N patients	Success at first surgery	Success at second surgery	
Blaivas[347]	24	79%		
Goodwin[364]	24	70%	92%	
Lee [12]	50	92%	100%	
Keetel[401]	24	87.5%		
Pushkar[365]	71	90.1%	98.6%	52% incontinent
Benchekroun[402]	186	53%		Mostly obstetrical
Henriksson[403]	6	67%	100%	
Kumar[79]	43	95.4%	100%	

3. Rectus muscle flap

Rectus abdominis muscle flaps have been described by some authors. [381, 382]Transvaginal urethrovaginalfistula closure was performed followed by a pedicled rectus abdominis muscle flap interposed between the fistula closure and vaginal suture line. The muscle flap was based on the inferior epigastric vessels, and provided additional support to the urethra, bladder neck and bladder base. Urethrovaginalfistula repair with the rectus abdominis muscle flap was successful in all cases without recurrence.. Of the patients 5 (83%) were continent and able to void to completion at a mean follow-up of 23 months (range 2 to 66).

4. Other interposition material

A range of non-traditional interposition flaps and grafts have been reported by several authors. All of the publications only report on small patient numbers without long term outcomes or continence data.

Golomb et al. reported the use of a fascial patch, while adding a rectus fascia sling to a urethrovaginal fistula repair.[383] Omentum is extensively used in abdominal approaches to VVF, but Janez et al. used it during a vaginal approach in 3 patients with good results.[384]

The gracilis muscle can be used as well, although the experience is limited. The graciloplasty was described by Ingelman-Sundberg in 1947 and has been adapted by other surgeons in the treatment of fistula. The number of patients reported is low as is the quality of the evidence. [385-387]

Non-autologous material has been used as well. Lowman et al. described the use of porcine dermis interposition and a synthetic sling in an irradiated patient. Other biodegradable materials have been used, although the quality of available data is lowand is insufficient to advocate their use. [388] [389] Non-vascularized tissue grafts should be used with caution in such cases as the aetiology of the initial tissue damage resulting in fistula is often ischemic.

b) Posterior approach

In cases of high fistula with difficult vaginal access, a perineal pararectal approach has been described. Some variations exist in the incisions and dissection planes. The anterior sagittal transrectal approach (ASTRA technique) and the posterior sagittal pararectal approach only have been reported in small observational series. [390, 391][392-394]

c) Abdominal approach

Female urethral injuries may cause serious morbidity with loss of the entire urethra in some cases. Ahmed et al. reported the results of construction of a neourethra by the flipped anterior bladder-tube technique in five girls aged 3-18 years (mean 8 years). All had pelvic fractures. Three patients came with a suprapubic cystostomy, one was totally incontinent, and another had an urethrovaginal fistula. Three had an associated vaginal injury. All five patients underwent construction of a neourethra using a flipped anterior bladder-wall tube (FABWT) and have been followed for 18-80 months (mean 44 months). All patients were continent in the daytime and three were voiding spontaneously without the need for catheterization. Two were managed by clean intermittent catheterization (CIC), one per urethram and other via a continent abdominal stoma (Mitrofanoff). [395]

A retropubicretrourethral technique has been described by Koriatim[396] This approach allows a urethrovesical flap tube to be fashioned to form a continent neourethra. Urodynamic studies showed that the proximal vesical and distal urethral components of the neourethra contribute to sphincteric function. For larger fistula an enwrapping technique has been described as well.[397]

5. COMPLICATIONS

Little information can be found on complications after urethrovaginal fistula repair. A short report on 4 cases by Tehan et al. describes a disappointing experience in the transvaginal repair of these fistulas. These authors advocate a suprapubic bladder flap or bladder tube technique to achieve a functioning urethra. Complications following surgical repair have been fistula recurrence, urethral shortening and retraction, persistent reflux, bladder calculi, and bladder cancer [398].

6. FOLLOW UP

In most series of urogenital fistula repair, follow-up is of very short duration. Dolan et al. investigated urinary and sexual symptoms and quality of life in a group of 31 women 50 months (median) after successful repair of urogenital fistula using the Bristol Female Lower Urinary Tract Symptom questionnaire. [399] All women had undergone urodynamic investigation prior to their repair surgery, and only36% had normal findings. Almost all women reported one or more symptoms, and for 65%, these caused at least ‘a bit of a problem’, although 87% said that their urinary symptoms had little or no impact on their quality of life. Symptoms were similar in urethrovaginal and vesicovaginal fistulae and were not significantly associated with prior functional abnormality.

7. RECOMMENDATIONS

Urethrovaginal fistula are preferably treated by a vaginal approach	C
A variety of autologous tissue interposition techniques have been described, but their value remains uncertain	C
Urethrovaginal fistula repair may be complicated by stress incontinence, urethral stricture and urethral shortening necessitating long-term follow-up	C

CONTENTS

I. INTRODUCTION

1. EVIDENCE ACQUISITION
2. DEFINITION

II. HISTORY/ NOMENCLATURE/ TAXONOMY

1. HISTORICAL NOTES
2. NOMENCLATURE AND TAXONOMY

III. EPIDEMIOLOGY

1. EARLY EPIDEMIOLOGICAL STUDIES:
2. PATIENT SELF REPORT SURVEYS:
3. PHYSICIAN DIAGNOSES STUDIES
4. SYMPTOM BASED SURVEYS
5. INCIDENCE:
6. OTHER CONSIDERATIONS

IV. ETIOLOGY

1. MAST CELL ACTIVATION
2. INCREASED PERMEABILITY OF THE UROTHELIUM DUE TO UROTHELIAL DYSFUNCTION/GAG-LAYER DEFECTS
3. INHIBITION OF UROTHELIAL BLADDER CELL PROLIFERATION
4. AUTOIMMUNE MECHANISMS
5. INFECTION
6. NEUROBIOLOGY/PELVIC CROSS-TALK
7. TOXIC AGENTS
8. HYPOXIA
9. THE ROLE OF GENETICS IN BPS
10 . CONCLUSIONS:

V. PATHOLOGY

VI. DIAGNOSIS

1. HISTORY
2. PHYSICAL EXAMINATION
3. PAIN MAPPING
4. LABORATORY TESTING
5. URODYNAMICS
6. POTASSIUM TESTING
7. CYSTOSCOPY AND HYDRODISTENSION
8. MORPHOLOGY
9. BIOMARKERS
10 . CONFUSABLE DISEASES

VII. CLASSIFICATION

VIII. CONSERVATIVE TREATMENT (TABLE 4)

1. BEHAVIORAL MODIFICATION
2. PHYSICAL THERAPY
3. STRESS REDUCTION
4.DIETARY MANIPULATION

IX. ORAL THERAPY (TABLE 5)

1. ANALGESICS
2. ANTIDEPRESSANTS
3. ANTIHISTAMINES
4. IMMUNOSUPPRESSANT
5. SODIUM PENTOSANPOLYSULFATE
6. OTHER ORAL MEDICATIONS THAT HAVE BEEN USED FOR BPS

X. INTRAVESICAL / INTRAMURAL THERAPY (TABLE 5)

1.DMSO (DIMETHYL SULFOXIDE)
2. HEPARIN
3. HYALURONIC ACID
4. CHONDROITIN SULFATE
5. PENTOSAN POLYSUFATE
6. VANILLOIDS (CAPSAICIN, RESINIFERATOXIN)
7. BACILLUS CALMETTE-GUERIN (BCG)
8. OXYBUTYNIN
9. LIDOCAINE
10. BOTULINUM TOXIN (INTRAMURAL)

XI. NEUROMODULATION

XII. PAIN EVALUATION AND TREATMENT

1. EVALUATION OF PAIN:
2. PHARMACOLOGIC MANAGEMENT OF CHRONIC PELVIC PAIN

XIII. SURGICAL THERAPY

1. HYDRODISTENTION
2. TRANSURETHRAL RESECTION
3. CYSTOLYSIS – PERIPHERAL DENERVATION
4. SYMPATHETIC DENERVATION
5. PARASYMPATHETIC DENERVATION
6. BOWEL SURGERY
7. URINARY DIVERSION WITH OR WITHOUT TOTAL CYSTECTOMY AND URETHRECTOMY

XIV. CLINICAL SYMPTOM SCALES

XV. OUTCOME ASSESSMENT

1. THE PROBLEM
2. THE PLACEBO ISSUE
3. OUTCOME INTERPRETATION
4. IMMPACT RECOMMENDATIONS

XVI. PRINCIPLES OF MANAGEMENT

1. HARMONIZATION

XVII. RECOMMENDATIONS OF INTERNATIONAL CONSULTATION ON INCONTINENCE:

1.HISTORY / INITIAL ASSESSMENT
2.INITIAL TREATMENT
3.SECONDARY ASSESSMENT
4.REFRACTORY BPS

XVIII. FUTURE DIRECTIONS IN RESEARCH

I. INTRODUCTION

1. EVIDENCE ACQUISITION

The unrestricted, fully exploded Medical Subject Heading (MeSH) “interstitial cystitis” (including all related terms as “painful bladder syndrome”, bladder pain syndrome”, or different terms such as “chronic interstitial cystitis”, etc.) were used to thoroughly search the PubMed database (http://www.ncbi.nim.nih.gov/pubmed) of the United States National Library of Medicine of the National Institutes of Health from the years 2009-2011. Three hundred forty-nine publications in English or with English abstracts were reviewed.

Abstracts if available and titles of the 349 hits were reviewed, focusing on (but not limited to) clinical trials, randomized controlled trials, meta-analyses, scientific guidelines, and core clinical journals. The literature update ths achieved was added to the pre-existing database, covering the time period before and during 2008 (generated for the 2008 International Consultation on Incontinence[1]) that was established according to the same protocol.

Rating of the level of evidence and grade of recommendation was performed according to the Oxford Scale. The committee believes that the Oxford system for categorizing levels of evidence is primarily relevant only for the sections on treatment which follow. While the committee’s opinions will be expressed, where applicable, regarding evidence and conclusions for other areas, including diagnosis, aetiology, and pathophysiology, use of the Oxford system in this context is more open to interpretation.

2. DEFINITION

Bladder Pain Syndrome (BPS) is a clinical diagnosis that relies on symptoms of pain in the bladder and or pelvis and other urinary symptoms like urgency and frequency. Based on the evolving consensus that BPS probably is strongly related to other pain syndromes like Irritable Bowel Syndrome, Fibromyalgia and Chronic Fatigue Syndrome, the European Society for the Study of Bladder Pain Syndrome (ESSIC) published a comprehensive paper on definition and diagnosis of BPS.[2]

BPS was defined as chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded. Further documentation and classification of BPS might be performed according to findings at cystoscopy with hydrodistension and morphological findings in bladder biopsies. (see **Table 2** in section I.1) The presence of other organ symptoms as well as cognitive, behavioural, emotional, and sexual symptoms should be addressed.
