Four trials had approximately the same amount of HP contact in drug and PFMT groups [125, 130, 142, 191]; in one, this was not clear [130]. Wells [1991] assessed treatment effect after four weeks in the drug group, and six months in the PFMT group. Kafri [2007] provided 5 sessions for the PFMT group, but not for the drug group. Arruda [2008] provided two sessions per week with physiotherapist for the PFMT group and visits every 4 weeks for the drug group.

(e) PFMT versus surgery: Only one trial, published in 1986, has compared PFMT to surgery [197]. The surgical technique was based on the type of defect identified: Burch colposuspension for anterior suspension defects and vaginal repair for posterior bladder descent. Women with both defects had a combined Burch and vaginal repair procedure. No details on the PFMT parameters were provided; women had five or more group sessions with a physiotherapist.

1. Quality of Data

(a) PFMT versus VC: Adequate allocation concealment was reported by five: [107, 122, 134, 140, 180]. Three indicated that outcome assessors were blinded [134, 140, 183]; only some of the outcome assessments were blinded in two [107, 122]. Sample sizes ranged from fewer than 40 women [107, 134, 140, 169, 175, 179, 180, 182, 183], 50 [181] to 79 per group [122]. There were dropouts in both the PFMT and VC groups in all trials except Gameiro’s (2010) [181] where no details were provided or in Cammu’s (1998), in which all of the dropouts were from the VC group. Dropout rates were higher in the VC groups for several [169, 175, 179, 180, 183]; conversely, they were higher in the PFMT group for others [107, 122, 134, 140, 182]. Only one trial reported any follow-up beyond the post-treatment evaluation, and this, at 6 and 12 months post treatment [181].

(b) PFMT versus ESTim: Of the eight trials, three reported adequate random allocation concealment and blinding of outcome assessors; samples sizes ranged from 10 to 20 and 35 women per group. Four trials appeared to have no dropouts [130, 132, 184, 187]. Others reported 5% [186], 10% [140], 12% [134, 188], 13% [166] and 19% [169]. All women were assessed post treatment; follow up was at nine months and one year [130] and four years [184].

(c) PFMT versus BT: Adequate random allocation concealment was reported in one trial [190]; outcome assessors were blinded in two [128, 190]. Samples sizes ranged from 15 to 20 women [128], 43 to PFMT and 41 to BT [190] to 70 women per group. Dropouts were approximately 4% for Wyman (1998) and 12% for Yoon (2003) and 8% for Sherburn (2011). All women were assessed post treatment, and Wyman (1998) followed-up three months later (i.e. six months after treatment began).

(d) PFMT versus drug therapy: Random allocation was concealed in two of the eight trials [125, 196]. Outcome assessors were blinded in two [125, 142]. Five trials randomised 25 or fewer participants per group [130, 131, 188, 191, 193]; one randomised approximately 50 per group [125]. The two largest randomised about 80 [192] or 85 women per group [142]. Dropout rates were: 0% [130], 14% [142], 15.9% [193], 16% [191], 16.9% [196], 25% [192] and 36% [125]. Drop out rates were not reported in two [131, 193]. Most trials assessed outcomes immediately post-treatment and three had longer follow up of nine months [130], one year [188], and 21-month [193] although in this last trial most participants had discontinued drug therapy after active intervention.

(e) PFMT versus surgery: It was not clear if allocation was adequately concealed, or if the outcome assessors were blinded. Approximately 25 women were in each comparison group with no dropouts at four months (post treatment assessment). There was further long-term follow-up at one year, then four to eight years [197].

2. Results

(a) PFMT versus VC: The comparative results in seven of the 11 studies were inconsistent. For cure,
one trial favoured PFMT [134]. Six favoured neither PFMT nor VCs [107, 122, 140, 179, 182, 183]. Pooled data from these eight trials showed statistically significant heterogeneity.

For cure/improvement, pooled data in six of the 11 trials showed no statistically significant differences. In four, PFMT was better than VCs in terms of daily leakage episodes. And, two others [140,181] no significant differences in terms of incontinence-specific quality of life measures (I-QoL) and the number of incontinence episodes were found.

Three reported adverse effects associated with cones such as the inability to use them, pain, vaginitis, bleeding, a sense of unpleasantness [134,180] or inconvenience [183].

(b) PFMT versus EStim: Pooled data from three trials of women with SUI found self-reported cure was more likely with PFMT [134, 184, 187], although only one found a statistically significant difference when data from the trials was considered individually [134]. It was not clear if the cure data reported by Hofbauer (1990) were derived from a symptom scale or a voiding diary; these data were therefore excluded. Pooled data from three trials in women with also found self-reported cure/improvement was more likely in PFMT women [134,184,185]; again only Be (1999) found a statistically significant difference when trial data were considered individually. At 6 months, QOL (as measured with I-QoL Questionnaire) increased significantly both in the PFMT group 28.4% and in the EStim group 32.4% but there was no significant difference between the groups [140]. Leakage episodes and quality of life (Social Activity Index) were not statistically significant in one study [134]. At nine months post treatment, Henalla (1989) found that three out of 17 PFMT women and one out of eight in the EStim group reported recurrent symptoms. Side effects related to EStim included vaginal irritation and/or bleeding [134,184,187].

Spruijt [2003] [186] recruited women with SUI, UUI or MUI and Wang (2004) [166] women with UUI. Neither found a statistically significant difference between the groups for self-reported cure/improvement although Wang indicated women in the PFMT group had statistically significantly fewer leakage episodes per day. EStim produced “physical and emotional stress” in the elderly women in the Spruijt trial. On the KHQ there were no statistically significant differences in general health perception, incontinence impact, role limitation, physical limitation, social limitation, and personal relationship, but the EStim group had statistically significant better scores for emotions, sleep/energy and severity measures. In the Arruda (188) study [188], 52% and 76% of the women randomised to the EStim and PFMT groups, respectively, claimed to be satisfied after 12 weeks of the study treatment period. Further, there was a significant decrease in the urge-incontinence episodes, the daily number of urinary pads. However, there was no significant difference in any of these measures between the groups.

(c) PFMT versus BT: Wyman [1998] [189] recruited women with SUI, UUI or MUI. While more women in the PFMT group reported symptomatic improvement or fewer leakage episodes the difference was not statistically significant post-treatment or three months later. Sherburn recruited women with SUI. Women in the PFMT group reported significantly lower amounts of leakage on the stress test , improved symptoms and bother and greater perception of change after 5 months than the BT group (Sherburn, 2011). No adverse event data were reported in either trial. Yoon (2003) [128] did not report any data for the outcomes of interest.

Two older trials that compared an adrenergic agonist and PFMT in women with SUI or MUI were previously reported in ICI 2009. No significant differences between groups were reported [129,191].

Duloxetine had a significantly greater impact in decreasing incontinence episodes than PFMT (57% versus 35% median decrease between drug and PFMT respectively) [125]. However post-treatment data collection began immediately after treatment initiation, before the effects of PFMT could be expected to occur. There were no significant differences between the treatments with respect to Incontinence Quality of Life (I-QoL).

In the three trials that compared PFMT to oxybutynin, PFMT groups had similar or better outcomes on most parameters. In the largest of these, a comparison of PFMT and oxybutynin in older women with DO or DO with urodynamic SUI reported data for the outcomes of interest [129,131]. Of those that responded to a follow-up questionnaire at nine months, three out of 17 PFMT women and three women using oestrogens reported recurrent symptoms. Adverse events were not reported in either trial.

One trial reported that the PFMT group had better outcomes for voiding frequency, but not for incontinence episodes [193]. Follow-up at 21 months showed that the PFMT group maintained or improved their voiding frequency, whereas the drug group regressed to baseline levels. However, most participants had discontinued the drug. Similarly, another trial reported that subjective symptom improvement was almost identical in the PFMT and
drug groups (77%, 76%, respectively) [188]. Changes in incontinence episode frequency favored the PFMT group, but were not significantly different.

(e) PFMT versus surgery: At four months PFMT women with urodynamic SUI were less likely to report cure than women who had surgery, although there was no statistically significant difference in the proportions reporting cure/improvement. At 12 months, 10/24 from the PFMT group were satisfied with initial therapy, versus 19/26 randomised to surgery. Long-term data (four to eight years) were not presented by group allocation. Adverse events were associated with surgery: new UUI, retropubic or pelvic pain, or dyspareunia [197].

3. Summary

In the 11 trials that compared PFMT with VCs in women with SUI, no consistent pattern emerged in the data. Further, data on self-reported cure in eight of the trials were inconsistent and there was no difference in the pooled data from six trials for self-reported cure/improvement. Notably, there were in fact fewer daily leakage episodes with PFMT in the pooled data from three trials (Level of Evidence: 1).

PFMT with EStim in women with SUI was compared in six trials. Pooled data demonstrated that self-reported cure and cure/improvement were more likely in PFMT than in EStim groups (Level of Evidence: 1). It is worth noting that only one trial individually demonstrated a statistically significant difference in these outcomes and there was more health professional contact in the PFMT arm. There were no statistically significant differences between PFMT and EStim groups for leakage episodes or quality of life, based on a single trial on MUI (Level of Evidence: 2). In the one trial that recruited women with SUI, UUI or MUI self-reported cure/improvement rates were not statistically significantly different (Level of Evidence: 2). Self-reported cure and cure/improvement rates and satisfaction were not statistically significantly different in the 2 trials in women with UUI, although PFMT women had fewer leakage episodes per day, and women in the EStim group had better quality of life in three of the nine domains measured on the KHQ (166). (Level of Evidence: 2). Some women reported adverse events attributable to ES.

PFMT and BT was reported in three but only two included data of interest. In women with SUI, symptomatic improvement, leakage episodes and quality of life were statistically significantly better in the PFMT group (Level of Evidence: 2). In contrast the study that recruited women with SUI, UUI and MUI did not find statistically significant differences between the groups (Level of Evidence: 2).

There is insufficient evidence to determine if PFMT is better than vaginal oestrogens. Neither trial that compared an adrenergic agonist with PFMT in women with SUI or MUI found a difference in self-reported cure/improvement and adrenergic side effects were bothersome (Level of Evidence: 2). One trial of PFMT versus oxybutynin in women with DO or DO with urodynamic SUI found women doing PFMT were more likely to report improvement and have fewer leakage episodes per day after treatment (Level of Evidence: 2). Many women taking oxybutynin reported drug-related side effects. One trial compared a serotonin-norepinedphrine uptake inhibitor (duloxetine) with PFMT and while women who took the drug had fewer leakage episodes, there was no difference in terms of quality of life between the two groups and drug side effects were sufficient to discontinue treatment in some women. (Level of Evidence: 2).

Based on one trial it seemed self-reported cure was more likely after surgery than PFMT for women with urodynamic SUI, but no statistically significant difference in the proportion of women reporting cure/improvement (Level of Evidence: 2). There was insufficient detail about the PFMT programme to make a judgment about how effective it might have been.

4. Recommendations

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B).
- PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B).
- PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug (Grade of Recommendation: C).
- PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive (Grade of Recommendation: C).

For women with SUI or MUI:

- PFMT is better than VC as first line conservative therapy (Grade of Recommendation: B).

For women with UUI or MUI:

- PFMT, and BT are effective first line conservative therapy (Grade of Recommendation: B).
- PFMT is better than oxybutynin as first line therapy (Grade of Recommendation: B).

For women with UUI:

- PFMT, and BT are effective first line conservative therapy (Grade of Recommendation: B).

Larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. In planning comparisons researchers should consider carefully the potential impact of dif-
different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies. A comparison of surgery and PFMT might be least useful, because PFMT is usually first-line therapy with surgery reserved for those in whom PFMT was unsuccessful or is not the treatment of choice.

d) Does the addition of PFMT to other treatments add benefit?

In this section, the effects of PFMT combined with therapy A versus therapy A alone, are compared to address the additive benefit of PFMT. Nine RCTs were found, and three were excluded: no useable data [198]; men and women and the data were not reported separately [199] and a combination BT/PFMT programme [200].

(a) PFMT/VC versus VC: Two trials, in women with urodynamic SUI [201] or SUI [107], compared combined PFMT/VC versus VC. In both arms of each study the recommended VC regime was twice daily for 15 minutes, with cone weight progressing from 20g to 70g [201] or 100g [107]. Both PFMT programmes asked women to do 100 PFM contractions per day with 10 contractions 10 times a day [201], or a combination of fast and slow contractions [107]. Treatment duration was 12 weeks in both arms of both studies.

(b) PFMT/ESstim versus ESstim: No new trials have been published on the topic since the last review. In women with urodynamic SUI, ESstim (10 minutes, three times weekly, sufficient intensity to provoke a visible contraction to which the patient added their own PFM contraction, extravaginal and lumbar electrodes) was compared to PFMT/ES (daily PFMT home programme (not specified) and a twice weekly exercise class plus the same ES programme) [132]. Treatment duration was six weeks in both arms.

(c) PFMT/BT versus BT: No new studies were found. In women with urodynamic SUI, or urodynamic SUI with DO, Wyman (1998) compared BT (progressive voiding schedule, advice on urge inhibition techniques such as affirmations, distraction and relaxation) to PFMT/BT (twice daily PFMT, maximum of 10 fast contraction with three second holds and 40 sustained contractions with 10 second holds in addition to bladder training as above). The combined PFMT/BT group began with BT and added PFMT in the 3rd week of the intervention. Women in both groups received the same preliminary education programme and treatment duration was 12 weeks in both arms [189].

(d) PFMT/drug versus drug: Two previously reported trials compared PFMT/drug (beta(2)-adrenergic agonist (clenbuterol); duloxetine) [125,191].

Two new trials compared PFMT/drug to drug alone in women with UUI [202,203]. One was a two-stage, multi-site RCTI [203]. In Stage 1, women received tolterodine (4 mg/day) versus tolterodine plus PFMT with urge suppression strategies (behavioural training) for 4 visits over 10 weeks. Stage 2 involved drug discontinuation. PFMT included 3 sessions of 15 exercises daily, starting at 2-seconds duration and progressed to 10 seconds. The other trial [202] was a single-site study of individually-titrated, extended-release oxybutynin (initiated at 5 mg/day and escalated as tolerated to a maximum of 30mg/day) with proactive management of side effects versus oxybutynin plus PFMT with urge suppression strategies for 4 visits across approximately 8 weeks. PFMT was also 3 sessions of 15 exercises daily, starting at an individualized duration and progressed to a maximum of 10 seconds.

1. Quality of data

(a) PFMT/VC versus VC: Adequate allocation concealment and some outcome assessment was blind in one [107]. Neither of these was clearly reported in the study by another [201]. Sample sizes were approximately 20 women in each comparison group. Dropouts ranged from 63% of the women in the PFM/VC group compared to 41% in the VC group [107] to 30% of the PFM/VC group versus 9% in the VC only group [201].

(b) PFMT/ES versus ES: It was not clear if random allocation concealment was adequate or whether assessors were blind [132]. There were only 11 women in each comparison group. There did not appear to be any dropouts.

(c) PFMT/BT versus BT: In one, it was not clear if random allocation concealment was adequate; outcome assessors were not blinded [189]. There were 68 women in the BT group and 67 in combination therapy with fewer than 10% dropouts after 12 weeks of treatment. Further follow-up was reported at six months and approximately three years after study entry.

(d) PFMT/drug versus drug: Although adequate allocation concealment and blinded assessors where used in three trials [125,202,203] it was not clear in another [191]. Sample sizes varied from 18 women in the drug group and 23 in the combination therapy group [191] with 27% and 17% dropouts respectively, principally because of drug-related side effects. In another, approximately 50 women with SUI were assigned to each group, 30% of whom dropped out of both treatment groups. Burgio (2008) randomised 307 women with urge-predominant UI and had a drop out rate of 8.8% at the end of active treatment (10 weeks). Burgio (2010) randomised 64 women with urge-predominant UI before being stopped for futility and had a drop out rate of 9.4%.

2. Results

(a) PFMT/VC versus VC: In this comparison, neither of the two trials identified any statistically significant differences between the groups (for patient reported cure, improvement as measured by a Visual Analogue Scale or pad test) and all of the confidence intervals were wide [107,201].
A higher proportion of women in the combined therapy group had a successful outcome, defined as at least 70% reduction in frequency of UI episodes [203]. The combined therapy group also had greater subjective improvement, greater patient satisfaction and greater reductions in symptom distress on validated questionnaires. In another study [202], the groups were so similar on an interim analysis and power calculation that recruitment was stopped early for futility. With the individualized, escalating dose titration and proactive management of side-effects, the drug alone group achieved an 88.5% reduction of incontinence episodes, leaving little room for added benefit.

3. SUMMARY

There were few trials addressing the effect of adding PFMT to another therapy, and only five of the eight studies reported useful data. There appears to be no benefit of adding PFMT to VC or duloxetine respectively in women with SUI [107,125] (Level of Evidence: 2). There may be benefit to adding PFMT to BT for women with urodynamic SUI or SUI.

(b) PFMTES versus ES: Although Hofbauer (1990) [132] reported cure/improvement, it was not clear whether this was based on data from a symptom scale or a urinary diary. There were no data reported for the other outcomes of interest.

(c) PFMT/BT versus BT: No statistically significant difference was found in one early study [189] between combination versus single therapy in the number of women reporting they were much better or in the number of leakage episodes per day; however more in the combination group reported they were much better at six months post treatment. With regard to quality of life the combination therapy group had statistically significantly better scores on UDI and IIQ after treatment, but there was no statistically significant difference in either measure six months after treatment had begun. Approximately three years later, a similar number in each group had sought further treatment for UI (19 of 48 BT, 18 of 48 PFMT/BT). Of the women who had not sought further treatment, fewer were free of leakage episodes in the BT group (four of 22 in BT group versus eight of 16 in the combination group). Adverse events are not mentioned.

(d) PFMT/drug versus drug: Ghoniem [2005] [125] reported that the combined treatment was not significantly different from the drug-only-treatment in terms of frequency of incontinence episodes, quality of life (IQOL) and Patient Global Impression of Improvement Scale. Ishiko (2000) [191] did not report data for any of the primary outcomes of interest; 10/13 in the drug group, and 17/19 in the combination therapy group had no leakage episodes per week post treatment, and some reported drug-related side effects sufficient enough to withdraw from treatment.

4. RECOMMENDATIONS

For women with SUI or MUI a combination of PFMT/BT may be better than BT alone in the short-term (Grade of Recommendation: C), and a combination of PFMT/drug may be better than drug alone. If a woman is taking duloxetine or using VC, it may not help to add PFMT (Grade of Recommendation: C). However, these recommendations are based on single trials of variable quality and larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. Further, these studies examine the effects of combining therapies as an initial approach. Less is known about the effects of combining therapies in a stepped fashion when women do not achieve the desired outcomes with a single therapy.

5. OTHER LUTS

Seven trials included above reported data for other LUTS, e.g. frequency, nocturia, bladder pain but no new trials were added to this section for the update.

The effect of a PFMT programme on frequency, nocturia and urgency in women with MUI improved self report of symptom bother both frequency and nocturia significantly more in the PFMT group, while urgency persisted [204].

Three trials investigating different type of PFMT programs reported whether women had nocturia [147,150,152,153]. There were few data and some missing, making it difficult to observe a difference between PFMT programs.

A secondary analysis looked at the effect of PFMT versus drug therapy on nocturia in older women with UUI or MUI [142]. The PFMT group reduced nocturia by a median of 0.5 episodes per night; this was significantly more effective than drug treatment.

One trial addressed PFMT versus EStim on urgency symptoms and nocturia in women with DO. There was a significant decrease in urge incontinence episodes in both groups, but no difference between groups. Further, there was a reduction in nocturia frequencies in the EStim group [188].

Finally, one new trial [202] studied the effect of drug therapy alone and combined with PFMT on urgency and 24-voiding frequency in women with urgency – predominant incontinence. Urgency decreased significantly although there was no difference between the two groups.
6. FACTORS AFFECTING OUTCOME

Apart from differences in effect attributed to PFMT or comparison interventions, other factors may affect outcomes. Of particular interest is the effect of older age; this and other factors are considered here.

**a) Age**

Firstly we looked for trials included above that specifically recruited older woman; there were six. The average age of women in these trials was between 60 and 70 years [120,141,142,192], or over 70 years [186,190] compared with a mean age of 40 to 55 in most other included studies. It was not possible to compare the data from older women with data from younger women for the following comparisons: PFMT versus EStim [186], PFMT versus drug [142,192] and PFMT versus BT [190].

For three comparisons (PFMT versus no treatment [141], PFMT versus placebo/sham/control [120,142], BF assisted PFMT versus PFMT alone [141], there were no clear differences in the size or direction of effect when the data from the trials in older women were compared with data from other trials. The recommendations arising from these comparisons appear to apply to older women. Namely, that PFMT should be offered, as first-line therapy, to all women with SUI, UUI, or MUI.

Secondly, the methods of included trials were checked for use of regression or other methods to investigate association between baseline characteristics (specifically age) and outcome. The literature search also located some papers that reported secondary analysis of data from the included trials. Papers that reported an association between age and outcome, but did not describe the methods of testing association are not discussed here. Two reports detailed the testing of independent associations between patient characteristics (including age) and outcome [126,205]. In one data was used from PFMT groups in three RCTs [120,121,142]. The individual trials restricted entry to women 55 years and older [120,142] or 40 years and over [121]. In multivariate analysis, age was not a significant predictor of reduction in leakage episodes for PFMT women with SUI, UUI or MUI. In another trial, Hay Smith (2006) investigated the associations between leakage on paper towel test and patient characteristics using data from a trial that compared two approaches to PFMT for Women with SUI [126]. Older age was associated with more leakage in univariate models, but was not significant in multivariate analysis.

One further trial [189] used correlation methods, and one [206] categorised women as successes or failures, to investigate the association between age and outcome. In a secondary analysis [207] of the trial by Wyman [198] there were no statistically significant correlations between age and reduction in leakage episodes or change in PFM activity after PFMT or BT in women with SUI, UUI or MUI. Bø (1992) characterised participants in the intensive PFMT group as treatment responders or non-responders. Treatment responders were statistically significantly older than borderline responders; there were no non-responders.

Considering the number of included trials, there were few that restricted entry to older women and/or investigated the association between age and treatment outcome. Only two studies have used the most appropriate methods to test independent associations. More research is needed to investigate the association between age and treatment outcome. Neither study using multivariate models found an association between age and outcome, nor was there a reported correlation in another. The two studies that categorised women as treatment successes or failures had conflicting results.

**SUMMARY**

There is no good evidence to date to suggest that ‘healthy’ older women with UI do benefit less from PFMT compared to younger women.

**b) Other**

Aside from age, other factors have the potential to mediate treatment outcome, e.g. baseline UI severity, duration of symptoms and co-morbid conditions. All reports were checked for the methods used to address association between baseline characteristics and treatment outcome. Some appeared to be based on researcher observation; these data are not discussed here. Seven reports of interest were found [118,126,141,171,192,205-208]. A wide range of patient characteristics were considered in these papers; it is not clear whether it is more important to know which baseline characteristics might be predictors of outcome, or which ones might not. To eliminate long lists of non-significant associations, a pragmatic choice was made to report only significant associations although this creates a false impression of some consistent associations. None of the variables discussed here has demonstrated a consistent association with outcome, and all are worthy of further investigation.

Two reports addressed independent associations between patient characteristics and outcome [126,205]. Burgio (2003) used data from PFMT groups in three RCTs [120,121,142]. In multivariate analysis of data from PFMT women with UUI or urge predominant MUI, a 75% reduction in leakage episodes was more likely if women did not use protection (e.g. pads) prior to treatment. Continence (100% reduction in leakage episodes) was more likely if women had fewer Incontinence episodes at baseline and had a lower educational level, but less likely if they had prior UI surgery. For PFMT women with SUI or stress predominant MUI a 75% reduction in leakage episodes was less likely if women had previously been evaluated for UI or had
more than 10 leakage episodes per week pre-treatment. Hay-Smith (2003) investigated the associations between patient characteristics and two outcomes (leakage on paper towel test, self-reported improvement) using data from a trial that compared two approaches to PFMT for Women with SUI. In multivariate models increasing parity was associated with less improvement in leakage symptoms and more risk of leakage on a paper towel test. Shorter symptom duration and higher body mass index were both associated with more improvement in symptoms. Leakage once or more per day was associated with greater risk of leakage on a paper towel test; the reverse was true for women with a history of constipation.

There was no statistically significant correlation between any of the baseline characteristics listed and the two outcomes (reduction in leakage episodes or change in PFM activity) in a secondary analysis [207].

Treatment responders had statistically significantly longer symptom duration, higher body mass index, stronger PFM, and were more motivated (clinician judgment) than borderline responders; there were no non-responders [206].

Two studies examined PFM characteristics as possible predictors of successful response to PFMT [118, 208]. Yoo [2011] reported on biofeedback assisted PFMT. In multivariable regression, the only factor predictive of successful treatment response was change in mean amplitude of tonic contraction after the 8th treatment session. Dumoulin [2010] studied PFM function variables measured by dynamometer in women with postpartum SUI. Treatment success (20-minute pad test volume < 2g) was associated with lower pre-treatment passive force and greater pre-treatment PFM endurance.

Few studies investigated the association between patient characteristics and treatment outcome and no consistent pattern emerged from the available data. Even fewer studies used appropriate methods. More research is needed to test for independent associations between patient characteristics and outcome. Given the few data available, and the methodological limitations of some papers, any patient characteristic described above that was associated with outcome should be considered as a possible rather than established prognostic factor.

**Summary**

It is not clear if there are any reliable predictors of PFMT outcome. Too few trials have appropriately investigated the association between patient characteristics and outcome to be sure.

### III. WEIGHTED VAGINAL CONES (VCS)

Weighted vaginal cones (VCs) were developed as a method for testing PFM function and to provide progressive muscular overload during PFM strengthening exercises [182,209]. In theory, when a cone is inserted into the vagina, the sensation of 'losing the cone' provides strong sensory feedback that prompts the PFMs to contract to prevent the cone from slipping out. Women start in a standing position with a weighted cone held inside the vagina for at least one minute, incrementally adding time and increased cone weight whilst standing or walking. The goal is to walk around for 20 minutes without losing the cone; the gradual increase in cone weight maintains muscle overload over the course of the exercise programme.

There are various cone weights and sizes (Figure 1). However, the effectiveness of the VC training method is unclear. Of note is that the PFM contraction is not the only reason the cone is retained and because orientation of the vagina is not completely vertical, some women can retain the cone without actually contracting the pelvic floor. Radiology has also demonstrated that the cones can rest in a transverse position [210,211]. Depending on the axis of the vagina, women need to produce different force intensities to retain the cone. Thus, using VCs as a measure of PFM function does not appear to be a valid method. Finally, some women may find it impossible to insert the cones due to a narrowed vaginal opening or, conversely, to retain it due to an enlarged vaginal opening, prolapse, or an insufficient PFM contraction, one incapable of holding even the lightest cone.

This section examines the evidence for VCs in the prevention and treatment of UI in women. Questions addressed:

- Are VCs better than no treatment, placebo or control for the prevention of UI?
- Are VCs better than no treatment, placebo or control for the treatment of UI?
- Are VCs as effective as other treatments for the treatment of UI?
- Are VCs combined with PFMT better than PFMT alone for the treatment of UI?

### 1. PREVENTION

No trials investigating either the primary or secondary prevention effects of training with VCs for women with UI were found. The literature search revealed two reviews on the prevention of UI [159,212]. Of these, only Hay-Smith (2002) considered VC prevention trials; however, none of the trials measured the effect on UI, only PFM activity. Because no continence-related outcomes were measured, these trials are not reviewed here. Further, the most recent Cochrane review of VCs did not address prevention [213], and our search did not reveal any new RCTs on VCs as a preventive treatment.
2. TREATMENT

The literature search revealed one systematic review that specifically addressed the effects of VCs in the treatment of UI in women [213]. One new trial [181], the review and three RCTs from ICI 2009 form the basis of this subsection [122,140,181,183].

a) Are VCs better than no treatment, placebo or control treatments?

Four RCTs compared VCs with control treatments for women with UI [107,122,134,140]. Details of the VC programmes for each trial are presented in Table 3.

1. Quality

Of data

All four reported adequate allocation concealment, randomisation and blinding of outcome assessors. Dropout rates were 3% [122], 12% [134], 14% [140], and 40% [107]. In one, the VC group experienced more dropouts (42%) than the control group (22%) [107]. In another, participants in the VC group reported abdominal pain, vaginitis or bleeding and 14 reported problems with self-motivation and difficulty in using the cones [134]. Williams did not report any side effects for either treatment group other than the fact that 2.5% of the women in each of the trial arms reported urinary tract infections (UTI). Wilson [1998] and Castro [2008] did not report any side effects in either group.

2. Results

Women in the VC groups were more likely to report they were cured than the controls (RR 1.98, 95% CI 1.21 to 3.23). The pooled data for self-reported improvement/cure from two trials [122,134] showed statistically significant heterogeneity. Individually, one trial favoured the VC group [134] while the other favoured neither group [122]. VC participants scored better than the controls on the Leakage Index but showed no statistical differences on the Social Activity Index [134]. Further, Castro (2008) [140] reported better incontinence-related QOL in VC participants as compared to the controls on the IQoL questionnaire.

3. SUMMARY

The evidence from these four RCTs suggests that VCs are better than control treatments for subjective reporting of cure or cure/improvement and QoL impact in the treatment of SUI (Level of Evidence: 1). However, VC treatment may be inappropriate in some cases due to potential reported side effects.

4. RECOMMENDATIONS

For women with SUI, VCs with supervised training sessions by a trained health professional can be offered as a first-line conservative therapy to those who can and are prepared to use them (Grade of Recommendation: B); VCs may be inappropriate in some cases due to inability to insert or retain the cone or because of side effects and discomfort. Trained health professional assessment is recommended (Grade of Recommendation: D).

b) Are VCs as effective as other treatments?

VCs have been compared with PFMT and EStim, but not with other therapies such as drug treatment, BT or surgery.

(a) VCs versus PFMT

This comparison has been addressed in Section B2.3c. The details of the VC and PFMT programmes for each trial are presented in Table 4.

(b) VCs versus EStim

Five trials compared VCs with EStim [134, 140, 201, 214, 215]. The details of the VC and EStim programmes for each trial are presented in Table 5.

1. Quality of data

(a) VCs versus PFMT: See Section B2.3c.

(b) VCs versus EStim

Among the five trials, two [134,140] reported adequate randomisation, allocation concealment and blinding of outcome assessors; blinding was unclear in the other three [201,214,215]. Dropout rates were higher in the VC groups for [201,214,215] but higher in the EStim groups for three [134,140,201].

2. Results

(a) VCs versus PFMT See Section BII4c.

(b) VCs versus EStim

There was no statistically significant difference between VCs and EStim in the pooled data between two trials [134,140] in terms of self-reported cure or in the pooled data [134,215] for cure/improvement.

Footnotes: VCs = vaginal cones, EStim = Electrical stimulation
No differences were reported on the I-QoL questionnaire or in the number of leakage episodes on a 7-day bladder diary evaluation (mean and standard deviations: cones 1.5 ± 1.8 vs. EStim 2.3 ± 5.5) [140]. Ba [1999] also found no differences in daily leakage episodes on a 7-day bladder diary.

Discomfort or side effects between EStim and VC are reported to be similar [140, 214]. One study described women who were unable to use the VCs because of vaginal size [215] and another reported tenderness and bleeding, discomfort or motivational and other difficulties in using the EStim [134]. In the VC group, one participant reported abdominal pain, two vaginitis and one bleeding; 14 reported motivational problems and difficulty using the cones.

### 3. SUMMARY

Overall, the pooled data for VCs and EStim demonstrated no statistically significant differences between the groups in terms of a self-reported cure, a cure/improvement, incontinence-specific QOL measures or the number of leakage episodes (Level of Evidence: 1). Additionally, both the VC and EStim groups reported adverse events.

### 4. RECOMMENDATIONS

VCs and EStim seem equally effective in the treatment of SUI and MUI, but the side effects and discomfort caused by the VCs and EStim limit their utility in clinical practice (Grade of Recommendation: B).

c) Are VCs combined with PFMT better than PFMT alone?

Two trials compared a combined PFMT/VCs to PFMT alone (107, 216) Details of the PFMT/VCs and PFMT are presented in Table 6. None of the outcomes used in the two trials overlapped.

#### 1. QUALITY OF DATA

Allocation concealment was clear in one and some outcomes had blinded assessors [107, 216], but neither of these variables was clearly reported the other [216].

#### 2. RESULTS

No statistically significant differences were detected for either cure or cure/improvement after 12 weeks in either study. Dropout rates in both trials were higher in the combined PFMT/VCs group.

#### 3. SUMMARY

The limited available evidence suggested no benefit from adding VCs to PFMT for women with SUI (Level of Evidence: 2).

#### 4. RECOMMENDATIONS

If this combined intervention proves to be of interest to women, then more research is needed to confirm or refute the advantages of adding VCs to PFMT.

### 3. OTHER LOWER URINARY SYMPTOMS (LUTS)

Two trials included in the VC section reported data on other LUTS: urgency and nocturia [122], nocturia [181]. In the Williams [2006] study, there were no differences between VC, control and PFMT group after intervention for urgency or nocturia. Gameiro [2010] however, noted a significant reduction in nocturia after treatment in both VC and PFMT groups, but no significant difference between groups.

### 4. FACTORS AFFECTING OUTCOME

None of the trials above addressed the effect of age or other factors on the outcome of VC training. Nonetheless, it is worth noting that in the 22 trials included in this section, on average, 24% of the women being treated with VCs (range 0 to 63%) withdrew or dropped out. Although few trials examined the causes of attrition, among those that reported causal factors low compliance, motivational problems, unpleasantness, aesthetic dislike, discomfort, and bleeding were indicated although no one reason predominated.

### IV. ELECTRICAL STIMULATION (ESTIM)

The literature concerning EStim in the management of UI remains difficult to interpret, due to the lack of a well-substantiated biological rationale underpinning the use of EStim [217]. However, the theoretical basis of stimulation interventions is emerging with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. The mechanisms of action may vary depending on the cause(s) of UI and the structure(s) being targeted e.g. PFM or detrusor, peripheral or central nervous system. In general, the aim of EStim for women with SUI appears to be to improve the function of the PFM, while for women with UUI the objective seems to be to inhibit detrusor overactivity (DO).

EStim is provided by clinic-based mains powered machines or portable battery powered stimulators (Figure 2) with a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 3). Without a clear biological rationale it is difficult to make rationale choices about different ways of delivering EStim. Additional confusion is created by the relatively rapid developments in the area of EStim, and a wide variety of stimulation devices and protocols have been developed even for the same condition. For example, in the last 30 years or so women with SUI have been treated with a wide variety of EStim ranging from general anaesthetic for 20 minutes [168], to six months of low intensity stimulation at 10 Hz using a vaginal electrode [1, 218].

Finally, the nomenclature used to describe EStim remains inconsistent. EStim has not only been described based on the type of current being used...
1145

(e.g. faradic, interferential), but also on the structures targeted (e.g. neuromuscular), the current intensity (e.g. low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g. neuromodulation). In the absence of agreement of how best to classify EStim, no attempts were made to classify different types of EStim.

This section presents the evidence for the use of EStim in the prevention and treatment of UI in women. Questions addressed are:

- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?
- What is the effect of EStim on other LUTS?
- What factors might affect the outcome of EStim in the treatment of UI?

Eligible interventions were non-invasive EStim without implanted electrodes. (Magnetic stimulation is described in Section B.5.0.) Other criteria for inclusion were (1) randomised or quasi-randomised (lternate allocation) trial design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women (within 12 months of childbirth). Trial data reported in conference abstracts as well as full-text papers were included. EStim compared with PFMT and vaginal cones are covered in previous sections (sections B.2 and B.3). This section focuses on EStim compared with other conservative treatments or no active treatment.

Figure 2: EStim machine
The primary outcomes were cure rates (the number of women cured), and improvement rates (the number of women improved, including cure). There was considerable variability in the way these outcomes were measured. Women’s self-report was given priority but for studies in which it was not reported, the rate based on diaries was used as a proxy; where diary data were also not reported, the rate based on pad tests or any other definitions chosen by the trialists was used [219]. Data on health-related quality of life and adverse effects were also extracted. Data at the end of the prescribed treatment phase, or at the first outcome measurement, if later, were used in the analysis. Any treatment effects shown are likely to reflect maximum effect of each intervention. Data from further follow-ups were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a predominant symptom of SUI (as defined by trialists), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trialists), (3) other studies of UI in which neither stress- or urge-UI represented a predominant symptom in the study population, and (4) studies of OAB or DO in which it was unclear whether all participants had UI.

Single estimates with 95% confidence intervals (CI) were derived for each study comparison using odds ratios (OR) for dichotomous variables or mean difference (MD) for continuous variables. Summary estimates were calculated using random effects models if there was more than one study reporting the same outcome (meta-analysis).

‘Risk of bias’ in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group [220]. Risk of bias regarding blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

**Description of intervention in included studies of EStim**

A total of 33 trials were eligible. The electrical stimulation parameters and protocols in this section are summarised in Table 7. Some approaches to treatment are now rare, such as the use of faradic current or external electrodes. There was considerable variation in the intervention protocol. Although the biological rationale and purpose of EStim might be different depending on diagnosis, there was no consistency in the EStim protocols used for women with SUI, UUI, MUI, or DO.

In addition, there were three trials that recruited both men and women. These include comparing: EStim (transcutaneous electrical nerve stimulation) with oxybutynin for 13 men and 30 women with idiopathic DO [221]; EStim with sham EStim for 29 men and 39 women with UI due to either idiopathic or neurogenic DO [222]; and EStim and MStim for 15 men and 17 women with UI due to either idiopathic or neurogenic DO [223]. These trials did not differentiate the effects of treatment by gender or by diagnosis and therefore did not contribute to the analysis.

1. PREVENTION

No published trials were found that investigated either the primary or secondary prevention of UI or LUTS.

2. TREATMENT

a) Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?

Seventeen studies compared EStim with no active treatment. Characteristics of studies comparing EStim with no active treatment are presented in Table 8. No active treatment consisted of sham EStim in the majority (11 of 17) of the studies. In others, the ‘no active treatment’ groups received no treatment [130,224], placebo drugs [225], non-active control intervention such as instruction in the use of an anti-incontinence device [134] or motivational phone calls [140].

One study [226] was a three-arm trial: two of the arms using EStim with either sacral or suprapubic electrodes were combined (N = 32) and compared with the sham ES arm (N = 16). The trial by Brubaker and colleagues [227] included women with SUI or DO with women with SUI comprising the majority of the study sample. Data from this trial therefore contributed to the analysis for SUI.

1. QUALITY OF DATA (RISK OF BIAS)

Three studies [134,225,228] reported adequate methods of allocation concealment, namely opaque (and sealed) envelopes with third party involvement in the allocation procedure. Allocation concealment was assessed as suboptimal in two [168,224] that used opaque or sealed envelopes but with no indication of third party involvement. The remainder did not describe methods used for allocation concealment. Trial results were reported for everyone who entered the trial in three studies [132,224,229] but this was not done in the others.

2. RESULTS

(a) SUI or predominant SUI. Pooled data suggest that cure rates were on average higher for EStim compared with no active treatment but the difference was not statistically significant [132,134,140,178,227,228,230]. Improvement rates were statistically significantly higher for EStim compared with no active treatment [134] [130,132,134,178,227,228,230] although there was some evidence of statistical heterogeneity for the improvement rate (I-squared = 59%).

Adverse effects appeared uncommon. One study reported tenderness and bleeding in 10 of 32 participants using the active EStim device, of which seven withdrew from treatment due to adverse effects [134]. Another study reported that 14 of 35 participants using the active EStim device and seven of 17 participants using the sham device experienced vaginal irritation, pain or infection [230].

Quality of life was reported using diverse measures in three studies. Two of these studies reported statistically significant differences favouring EStim compared with no active treatment: the first [134] used the Social Activity Index, and the second [140] used the I-QoL questionnaire. However, the third study [198] found no significant differences between the groups based on either the Urogenital Distress Inventory or the IIQ.

(b) UUI or predominant UUI. One small study in which all participants had MUI with UUI as a predominant pattern found no significant difference between the groups in cure rates [231] although the confidence interval was wide. Improvement rates were significantly higher for EStim compared with no active treatment based on another small study in which all participants had UUI alone [232]. However, these differences are not informative, because the confidence interval is very wide and the OR is clinically implausible. No information was available on adverse effects and quality of life.

(c) SUI, UUI or MUI. One study [168] that provided information on cure and improvement found no difference between the groups. No information was available on adverse effects and quality of life.

(d) DO (wet or dry). Cure and improvement rates were reported only in one study [225]. There was a statistically significant difference in the improvement rate in favour of the EStim group compared with no active treatment but no difference was found for the cure rate. Caution is required, as the OR is clinically implausible and may be a statistical artefact. Two studies with data on quality of life outcomes reported inconsistent results [224,225]. One study using the KHQ (total score) reported a statistically significant difference favouring EStim compared with no active treatment [225], whereas the other study using the IIQ found no significant difference between the groups [224]. No information was available on adverse effects.

3. SUMMARY

Included studies were generally assessed as having a high risk of bias. EStim might be more effective than no treatment in improving (not necessarily curing) symptoms in women with SUI, UUI or DO, although this may not result in cure (Level of Evidence: 2). Information on quality of life was sparsely reported and the limited data that were available were not consistent. Adverse effects appear uncommon but some women experienced discomfort with the treatment device. Few data were available on long-term performance.

4. RECOMMENDATIONS

EStim might be better than no treatment in improving symptoms (Grade of Recommendation: B). However, the recommendation should be viewed with caution until the findings are supported or refuted in

Footnote: * abstract only; **Source of outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy. † Publication in Danish with English abstract. English translation of the main text was not available at the time of writing. ‡ Part of 4-arm trial which randomised 83 women with OAB. The number in each arm was not reported; Estim = electrical stimulation, OAB= overactive bladder, DI = detrusor instability, SUI = stress urinary incontinence, UUI = urge urinary incontinence, MUI mixte urinary incontinence, NR = not reported
b) Is one type of EStim better than another in the treatment of UI?

Four studies compared one approach to EStim versus another; two in women with SUI [171,218] and two in women with DO and sensory urge [226,233]. The characteristics of studies comparing one type of Electrical stimulation with another are presented in Table 9. No study focusing on UUI or predominant UUI was identified.

1. QUALITY OF DATA (RISK OF BIAS)

Allocation concealment was inadequate in one study that used consecutive (alternative) assignment (quasi-randomisation) [171]. Allocation concealment was also suboptimal in another study in which sealed consecutively numbered envelopes were used but it was unclear if they were opaque and whether a third party was involved in the allocation procedure [218]. The other two studies did not mention allocation concealment [226,233]. In Lobel (1998) data were reported only for those who completed the trial (37 of 43 randomised). It was unclear in the other three studies if trial results were reported for everyone who entered the trial.

2. RESULTS

(a) SUI. Two studies assessed different variants of EStim performed as an adjunct to PFMT and biofeedback. The first compared faradism with interferential therapy: no difference was found between the groups in improvement rates, both after the supervised treatment phase and at six months after the end of the supervised phase [171]. The second study compared maximal EStim with low intensity EStim with higher improvement rates for maximum EStim either at the end of supervised phase or at 6 months after the supervised phase [218]. No information was available on cure rates, adverse effects or quality of life.

(b) DO (wet or dry). Data were available from one study comparing two groups receiving EStim either once or twice a week (for 10 weeks) [233]. The most common adverse effects reported were discomfort and leg tremor during treatment, and UTI, although it was unclear in which group these adverse effects occurred. No difference was found between the groups on a quality of life questionnaire (not specified). No information was available on cure and improvement rates.

3. SUMMARY

Included studies were generally assessed as having a high risk of bias. There were four small trials comparing different EStim protocols; the clinical heterogeneity between studies meant it was not appropriate to pool the data. Based on a single trial for women with SUI, maximal clinic-based stimulation may be more effective than low-intensity home-based stimulation in improving symptoms, although no data were available on cure rates, quality of life and adverse effects (Level of Evidence: 2). The other studies did not find clinically important differences between stimulation groups; the studies were small and may have been underpowered. Further comparisons of EStim protocols are needed.

4. RECOMMENDATIONS

For women with SUI maximal clinic-based EStim might be better than daily low-intensity home-based EStim in improving symptoms (Grade of Recommendation: B). There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.

c) Is EStim better than other treatments for UI?

EStim has been compared with PFMT, VC, magnetic stimulation (MStim), and drugs. The comparisons of EStim versus PFMT, and EStim versus VC, have been addressed in Sections B.2.3c and B.3.2b, respectively. For the comparison of EStim and MStim, one trial by Yamanishi and colleagues included both men and women with UI due to either idiopathic or urogenital DO [223]. Because data were not reported separately for women with idiopathic DO it is not clear from this trial whether there was any difference in the effect of MStim compared with EStim.

The remainder of this section focuses on studies that compared EStim with medications: vaginal oestrogen (Premarin) for women with SUI [130]; propantheline bromide 7.5 to 45 mg (variable dose) two to three times per day for women with UI due to DO (assumed to be predominant UUI) [187]; oxybutynin 5 mg twice [188,201] or 2.5 mg three times per day [225] and tolterodine 2 mg twice per day [204]. Four studies recruited women with DO [201] or OAB [204,225], or both DO and OAB [188] where some but not all had UI. (See Table 10.)

1. QUALITY OF DATA (RISK OF BIAS)

Methods used for allocation concealment were adequate in one [225] but unclear in the other five. Trial results were reported for everyone who entered the trial in one study [187] but this was not done in four [130,188,201] and unclear in one [204].

2. RESULTS

(a) SUI. In one small study of 25 women, 32% in the EStim group and 13% in the oestrogen group reported improvement and the difference was statistically significant [130]. At 9 month follow-up, one of the eight women in the EStim group and all three in the oestrogen group who had reported improvement post-treatment had recurrent symptoms. There was no report of adverse effects. No information was available on cure rates or quality of life.

† Publication in Chinese with English abstract. English translation of the main text was not available at the time of writing.
(b) Predominant UUI. Based on one older small study that recruited women with UI due to DO (UI was assumed to be the predominant symptom), there was no evidence of a difference between ESTim and propantheline bromide both in terms of cure and improvement [187]. No data were available for adverse effects or quality of life.

(c) DO (wet or dry). In three studies with data on cure or improvement, there was no evidence of a difference in cure or improvement between ESTim and oxybutynin [225], or between ESTim and tolterodine [188]. In two of these studies cure and improvement were defined in terms of resolution or reduction of urgency symptoms rather than UUI [188,225] whereas the outcomes were not defined in the other [204]. Follow-up data based on one study found that treatment effects persisted over time (one year) in four of the 11 (36%) participants in the ESTim group and 10 of the 17 (59%) participants in the oxybutynin group who had reported improvement in the initial treatment phase (three months) but the difference between the groups was not statistically significant [188].

More women with DO who received drugs, experienced adverse effects than those who did not. The most commonly reported adverse effect in both oxybutynin or tolterodine treatment group was a high percentage of dry mouth [188,204] which was “intolerable” [225] or “unacceptable” [201] in a smaller number. Other drug side effects were constipation, indigestion, nausea, headache, dizziness and blurred vision. There was no report of adverse effects or adverse effects resulting in treatment withdrawal in the ESTim group. Quality of life outcomes were reported only in one study using the KHQ (total score) [225]. The study reported a statistically significant difference in favour of ESTim over oxybutynin; no further data was provided.

3. Summary

Included studies were generally assessed as having a high risk of bias. With small numbers per comparison group available, there is insufficient evidence to determine if ESTim is better than vaginal oestrogens in women with UUI, propantheline bromide in women with UII, or oxybutynin and tolterodine for DO (Level of Evidence: 2).

4. Recommendation

Based on current evidence medical treatments appear to be no more effective than ESTim (Grade of Recommendation: B). This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

d) Does the addition of ESTim to other treatments add any benefit in the treatment of UI?

A total of 12 studies assessed the effect of ESTim as an adjunct to another treatment, compared with the other treatment alone (Table 11). Of these, 10 [121,132,135,173,177,234-238] combined ESTim with PFMT (ESTim + PFMT vs. PFMT), while the other two studies [171, 218] combined ESTim with PFMT and biofeedback (ESTim + PFMT + BF vs. PFMT + BF).

Two studies were three-arm trials that included both PFMT and PFMT plus sham ESTim as two of the study arms [135,236]. These arms were classified as being equivalent to PFMT and combined in the analysis. In two other three-arm trials two of the study arms involving ESTim were also combined [107,218]. In one, ESTim arms included faradism and interferential therapy [218]; in another, maximal and low intensity ESTim were included [171].

1. Quality of data (risk of bias)

Allocation concealment was inadequate in two studies that used consecutive (alternative) assignment (quasi-randomisation) [171,236]. Allocation concealment was also suboptimal in another two in which sealed consecutively numbered envelopes were used but it was unclear whether they were opaque and whether a third party was involved in the allocation procedure [218,237]. The remainder (66%) did not mention allocation concealment. In six (50%) studies, results were reported for everyone who entered the trial [121,132,173,235,237,238], but this was not done in one [234] and unclear in three others [135,171,218].

2. Results

A. ESTim + PFMT vs. PFMT

(a) SUI or predominant SUI. Pooled data found no evidence of a difference between the groups in terms of cure [121,132,177,234,235] or improvement [121,132,177]. Adverse effects were reported in one study [121]; the group randomised to ESTim with PFMT recorded four occurrences (6%) of vaginal irritation due to application of ESTim devices, compared with none in the PFMT only group. Quality of life was also reported only in one study [121]; the results based on the IIEQ found no difference between the groups (no further data was provided).

(b) SUI, UII and MUI. Data available from one study found no significant difference between the groups for either cure or improvement [237]. One small study using the KHQ reported that quality of life was on average better after ESTim compared with no ESTim during the treatment and at three-month follow-up [173]. The differences reached statistical significance at three-month follow-up. No adverse effects were reported.

B. ESTim + PFMT with biofeedback vs. PFMT with biofeedback

SUI. Pooled data from two studies found no difference between the groups in terms of the improvement rate [171,218]. Improvement rates at six

Foot note: **Source of outcome: women’s self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy. Estim = electrical stimulation, SUI = stress urinary incontinence, MUI = mixed urinary incontinence, UUI urge urinary incontinence, NR = not reported
months after the end of the initial treatment phase did not differ between the groups in either study. No data were available on cure rates, adverse effects and quality of life.

3. SUMMARY

For comparisons of EStim with PFMT versus PFMT alone, there was no evidence of a difference between the groups in women with SUI or MUI (in which SUI was the predominant symptom) (Level of Evidence: 2). There was also no evidence to suggest that the addition of EStim to a BF-assisted PFMT was more effective than BF-assisted PFMT in women with SUI (Level of Evidence: 2). A few women experienced side effects with EStim. There is no evidence to draw any conclusion about the effect of adding EStim to PFMT for women with UUI.

4. RECOMMENDATIONS

The addition of EStim to PFMT or BF-assisted PFMT programmes does not appear to add benefit (Grade of Recommendation:B); this hypothesis needs to be investigated further with high quality trials if it is a clinical/research question of interest to women.

3. OTHER LUTS

No trials were identified that analysed the effect of EStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcomes of EStim. Regarding age, there was no clear indication from the included trials that EStim could not be tolerated by elderly. On this basis there is no reason to exclude older women from studies of EStim, or not to offer EStim as part of a conservative management programme, except where recognised contraindications such as a cardiac pacemaker are present. However, it should be noted that this section considered the effect of EStim from studies recruiting independent, community dwelling women; the frail elderly are considered in the chapter on the elderly.

Of note, in a prospective cohort of 3,198 women treated with home-managed EStim in Norway during 1992-1994, there was no association between self-reported improvement and age [239]. In the same cohort, success rates defined by clinicians were higher in younger individuals but this effect was no longer significant after controlling for other factors.

Aside from age, other factors may have the potential to mediate treatment outcome. On the basis of trial reports to date, it appeared that there was considerable variation in EStim protocols with no consistent pattern emerging. EStim protocols are also often poorly reported, lacking detail of stimulation parameters, devices and methods of delivery. The wide range of protocols that have been tested may have impacted on the effect estimates reported in this section.

It is not clear whether one diagnostic group may benefit more than another from EStim. It has been hypothesised that, in women with SUI who cannot voluntarily contract the PFM to begin a PFMT programme, EStim might help initiate or substitute for a voluntary contraction. However, most studies focusing on the efficacy of EStim do use EStim to initiate or substitute for a voluntary PFM contraction [240]. To date, there has been no trial addressing this hypothesis.

EStim is reported to be unsuccessful in women with major descent of the vagina and prolapse of the uterus [228]. Additionally, denervated PFM muscles might not respond to EStim [241]. This means that in women with reduced or no integrity of the relevant nerve pathways EStim provides no or little chance of cure/improvement [217]. It has also been reported that treatment will fail if EStim does not increase urethral pressure profile, although age, oestrogenisation, and urethral mobility may also affect urethral pressure profile and may influence therapeutic outcome [242]. It is unfortunate that it is difficult to assess individuals easily in the clinical setting with regard to integrity of the sacral arc, and other factors, to determine the suitability of EStim as a treatment modality.

As with all conservative therapy modalities, one of the key factors to the success or failure of EStim is treatment adherence. Some authors commented on adherence or reported adherence data. However, adherence measures were highly variable, making comparison across studies difficult. Adherence to EStim was satisfactory and could be attributed to the physician motivating individuals to continue with EStim if they considered stopping prematurely [229]. ‘Excellent’ or ‘good’ adherence was observed in 45% of the study participants in one study and this did not differ between EStim and sham [234]. However, another [243] reported that the proportion of women achieving 80% adherence was lower in the active EStim group (61%) compared with the sham group (89%). Be [134] reported a 75% adherence rate, although it is not clear how this compares with the non-active control group (instruction in the use of an anti-incontinence device). Nevertheless, adherence to EStim was less than that for PFMT (93%) in the same trial, and the reasons for non-adherence to EStim were a lack of motivation and discomfort. Knight [218] reported adherence to home-based low intensity EStim (72.5%) was somewhat higher than that for clinic-based maximal intensity EStim (percentage not reported).

V. MAGNETIC STIMULATION (MSTIM)

MStim has been developed for noninvasive stimulation of both central and peripheral nervous systems [244]. MStim for the treatment of UI was reported
for the first time in 1999 by Galloway [245]. In contrast to EStim, extracorporeal magnetic innervation (more commonly called magnetic stimulation) stimulates the PFM and sacral nerve roots without insertion of an anal or vaginal probe [246]. For treatment, the individual is positioned in a chair. Within the seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit (Figure 4). A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the individual’s perineum is centred in the middle of the seat, which places the PFM and sphincters directly on the primary axis of the pulsing magnetic field (Figure 5). Because of this, all tissues of the perineum can be penetrated by the magnetic field. According to Galloway [1999] no electricity, but only magnetic flux enters the body from the device. Goldberg [2000] has suggested that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue impedance, creating a theoretical advantage in its clinical application compared to EStim as structures such as sacral roots or pudendal nerves can be magnetically stimulated without discomfort or the inconvenience of a vaginal or rectal probe. Conventional magnetic stimulators deliver, at frequencies of 10 to 50 Hz, repetitive pulses of current lasting less than 100 μsec [246] and 275 Φs [245] in duration. Size and strength of the magnetic field is determined by adjustments of this amplitude by the therapist [245].

Possible advantages of MStim are that it is performed through full clothing, needs no probes, skin preparation, or physical or electrical contact with the skin surface. On the other hand, the need for repeated clinic based treatment sessions is a potential disadvantage. In contrast to EStim, MStim lacks portability, although in 2003 [247] reported the development of a portable small electromagnetic device (Pulsegen) for home use that fit into the underwear and was designed for continuous use for up to 8 weeks. Furthermore, because both the depth and width of magnetic field penetration is proportional to coil diameter, the present technology is still best suited for stimulation of a field, rather than a narrowly focused target as the sacral roots or the pudendal nerve [246].

MStim of the sacral nerve roots and pelvic floor is said to be effective for both UUI and SUI [246], although the mechanism of action is not fully understood [248]. Some authors have suggested that in SUI stimulation of the PFM causes external sphincter contraction [249], acts as a passive PFMT exercise [250], and increases maximal urethral closure pressure [247]. In UUI, MStim might suppress DO through activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibres at the spinal reflex arc, activation of inhibitory hypogastric sympathetic neurons, or a combination of both mechanisms [251]. Stimulation of sympathetic fibres maintaining smooth muscle tone within the intrinsic urethral sphincter and modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root, are also suggested to play a role in this mechanism of action [251].

In this section the evidence is considered for the use of MStim for the prevention and treatment of UI in women. Questions addressed are:

- Is MStim effective in the prevention of UI?
- Is MStim better than no active treatment (placebo, sham, control or no treatment) for the treatment of UI?
• Is one type of MStim better than another in the treatment of UI?
• Is MStim better than other treatments in the treatment of UI?
• Does the addition of MStim to other treatments add any benefit in the treatment of UI?
• What is the effect of MStim on other LUTS?
• What factors might affect the outcome of MStim in the treatment of UI?

Description of intervention

Ten trials were identified. Characteristics of the MStim intervention in the included studies are summarised in Table 12. Two further trials that did not specify the gender of the participants were found: a cross-over trial comparing MStim plus PFMT with sham MStim plus PFMT for 56 individuals with UUI (due to DO) or SUI [252]; and a comparison of MStim with sham MStim for 87 participants with UUI (due to DO) or SUI [253]. These trials did not contribute to the analysis. Table 12 illustrates the intervention characteristics.

1. PREVENTION

No trials investigating the primary or secondary prevention effects of MStim for women with UI were found.

2. TREATMENT

a) Is MStim better than no active treatment (placebo, control or no treatment)?

Nine RCTs comparing MStim with sham for women with UI were found. Characteristics of studies comparing magnetic stimulation with no active treatment are presented in Table 13. One report by Gilling [2002] [254] was an abstract. The trial, which has not yet been fully published, appears to be related to Gilling [2001] [255] of which a full report was published in 2009 [256] (comparing MStim plus PFMT with PFMT alone), but there was insufficient information to verify this. No data were available for any of the pre-specified outcomes. Of the nine included trials, three assessed the efficacy of a magnetic stimulator developed for home use, whereas in others treatment was provided in the clinic setting [247, 257, 258].

1. QUALITY OF DATA (RISK OF BIAS)

Allocation concealment was considered to be adequate in three (33%) trials that used numbered devices of identical appearance [247, 257, 259], or involved a randomisation list in a locked drawer only accessible to a member who had no other involvement in the trial. Allocation concealment was assessed as being sub-optimal in one study [258] that used sealed envelopes but did not mention whether envelopes were opaque nor any involvement of a third party in the allocation process. Another five (56%) did not describe methods used for allocation concealment [254, 260-263]. Two studies reported data for all participants randomised [260, 261]. In three, data were reported only for those participants who completed the study [247, 259, 263]. In particular, in the study by Morris [2007] only 29 of 44 (66%) women randomised completed the study, including 10 women deemed ineligible after randomisation. The number of women lost to follow-up was not clearly reported in the other four (45%) trials [247, 254].

2. RESULTS

(a) SUI. Data on cure and improvement rates were reported in one study [Fujishiro, 2000]: on average active treatment (single session) was better than sham treatment both in terms of cure and improvement but the difference was statistically significant only for improvement. One other study that provided stimulation for three days a week for two weeks (six sessions in all) that also measured cure and improvement did not provide any data but reported no statistically significant differences [262].

Information on quality of life was provided in two studies using different measures [261,262]. One study using the KHQ did not report a total score but scores on all questionnaire items were similar between the groups either at one week or one month after the intervention [262]. The second study did not describe how quality of life was ascertained but reported that mean scores did not differ significantly between the groups [261]. No adverse effects were observed in one of these studies [261].

(b) UUI. Suzuki and colleagues (2007)[263] conducted a cross-over trial including 16 men and 23 women with UUI refractory to PFMT [263]. Participants were randomised to either 10-week active treatment, four-week no treatment and 10-week sham treatment (A-S group) or 10-week sham treatment, four-week no treatment and 10-week active treatment (S-A group). Only quality of life outcomes were reported separately for women, based on the International Consultation on Incontinence-Questionnaire: Short Form (ICIQ-SF), in which lower scores indicate better quality of life. In women in the A-S group, ICIQ-SF scores (mean, SD) decreased from baseline by 4.6 (3.9) at 10 weeks and 3.5 (3.5) at 24 weeks. The corresponding scores in women in the S-A group were 1.3 (2.9) at 10 weeks and 4.5 (4.2) points at 24 weeks. These results were interpreted by the study authors to mean that active MStim was more effective than sham MStim. There was no report of adverse effects.

(c) MUI. In one small study, active treatment resulted in statistically significantly higher improvement rates compared with sham treatment [257]. There were no adverse effects in either group. Information on cure and quality of life was not available.

(d) SUI, UUI, or MUI. One small study reported statistically significant differences in favour of active treatment for cure or improvement [247]. In

Foot notes: NR = not reported; * abstract only; **Source of outcome: women’s self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.
(e) **DO (wet or dry)**. One small study reported that improvement rates did not differ significantly between active and sham treatments [258]. No information was available regarding cure rates. Quality of life outcomes were reported in three studies using different measures [258-260]. There was no difference between the groups in terms of the I1Q or the Urogenital Distress Inventory [259] or between KHQ or the Australian Quality of Life questionnaire [258]. There was one report of statistically significant better quality of life scores for treatment than sham, although it was unclear how this was ascertained [260]. No adverse effects were noted.

### 3. Summary

Since there was little duplication of MStim interventions, or sample populations, in the nine small trials, it was not thought appropriate to combine study findings. For women with SUI a single trial showed that one session of sacral root MStim might be more effective than sham in improving symptoms (Level of Evidence: 2), but another trial suggested that six sessions of a chair-based MStim might be no better than sham (Level of Evidence: 2). For women with UUI, evidence from a small trial suggests that active MStim might result in better quality of life than sham (Level of Evidence: 2), although there is some uncertainty surrounding this. Active MStim was associated with higher cure rates than sham in a small trial with women with MUI (Level of Evidence: 2), and also higher cure and improvement rates in another small trial with women with SUI, UUI or MUI (Level of Evidence: 2) but no such difference was observed for women with DO (wet or dry) (Level of Evidence: 2). In general, adverse effects appear uncommon.

### 4. Recommendations

Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence (Level of recommendation: D).

**b) Is one approach to MStim better than another?**

One study from Korea [264] compared the effect of pelvic floor MStim with BIOCON compared with stimulation via NEOCONTROL for females with SUI (Table 14). This report was published in Korean. Data were extracted only from the abstract and main data tables that were reported in English.

#### 1. Quality of Data (Risk of Bias)

Risk of bias could not be assessed, because the trial was published in the Korean language and English translation was not available at the time of writing.

#### 2. Results

Any UI. No statistical difference was found between the groups in terms of cure of UUI or cure of SUI. Quality of life scores based on the Bristol Female Urinary Tract Symptoms were also similar between the groups.

#### 3. Summary

There is insufficient evidence to determine if one type of MStim is better than another (Level of Evidence: 2). No recommendation is possible (Level of Recommendation: D).

**c) Is MStim better than other treatments?**

There was a single trial by Yamanishi and colleagues that addressed this comparison [223]. In this trial, MStim was compared with intravaginal ESTim in 17 women and 15 men with either idiopathic or neurogenic DO. As data were not reported separately by gender and by diagnosis, it is not clear whether there is any difference in effect of MStim compared to ESTim for women with idiopathic DO.

**d) Does the addition of MStim to other treatments add any benefit in the treatment of UI?**

One trial [255] was identified for this comparison. This report was initially available only as an abstract published in 2001. Subsequently, a full-text publication became available in 2009 [256], although participants were followed up for six months post-intervention and no further follow-up was reported. It should be noted that the aim of the trial was to compare active and sham MStim treatments, rather than to examine the effect of MStim as an adjunct to PFMT. Because trial participants had varying degrees of pre-existing knowledge about their condition and available treatments such as PFMT, low-intensity PFMT supervised by a uro-physiotherapist was added to both groups in order to minimise a potential bias. Characteristics of studies comparing MStim combined with another treatment with the other treatment are presented in table 15.

#### 1. Results

SUI. The trial found no statistically significant difference for any outcome between the active and sham groups at eight weeks or 6 months (cure; Incontinence Quality of Life questionnaire, KHQ) [255].

The study authors postulate that PFMT performed in each arm of the trial might have concealed any small additional benefit from MStim. This was supported by a post hoc subgroup analysis which suggested that the women with poor PFM tone at baseline (and therefore unlikely to have performed PFMT properly) did better with active treatment than sham treatment.

#### 2. Recommendation

Based on current evidence (Level of Evidence: 2) the addition of MStim to PFMT does not appear
to be beneficial (Grade of Recommendation: C). This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

### 3. OTHER LUTS

No trials were identified that analysed the effect of MStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

### 4. FACTORS AFFECTING OUTCOME

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. In one early prospective multi-centre study, factors predicting success of MStim were included [243]. Treatment success was associated with no prior hysterectomy, no prior anti-incontinence operations, UI symptoms for less than 10 years, and no use of medications known to cause UI. Brodak has suggested that detrusor response to stimulation might be better in ‘thin’ individuals (presumably due to a shorter distance between the stimulating coil and the sacral nerve roots) and at low bladder volumes [265]. Overall, little is known about the factors affecting the outcome of MStim.

### VI. SCHEDULED VOIDING REGIMENS

This section examines the evidence on use of scheduled voiding regimes in cognitively intact, non-institutionalised women with UUI, SUI, and MUI and provides recommendations for their use in clinical practice. A summary of the search strategy and inclusion/exclusion criteria for selecting studies for review is provided (See appendix). The chapters on the Frail Elderly and Neurogenic Incontinence provide detailed review of scheduled voiding regimes that are used in those with cognitive impairment, or UI secondary to central nervous system or spinal cord disease.

#### Scheduled Voiding Regimens

Bladder training is a broad term often used to describe any type of a scheduled toileting intervention. This has created conceptual confusion in interpreting research reports where few details are provided other than the statement that bladder training was used. The types of scheduled voiding regimens can be categorised as: bladder training, timed voiding, habit training, and prompted voiding [266]. Although these regimens share a common feature of a toileting schedule, they differ on the basis of adjustments to the voiding schedule, the active or passive involvement of the patient, the nature of patient education including the teaching of strategies to control urgency and prevent stress leakage, the use of reinforcement techniques, and the nature of the interactions between clinicians and patients. In practice, however, scheduled voiding regimens may share aspects of one or more of these features.

#### Bladder training

Bladder training (also referred to as bladder drill, bladder discipline, bladder re-education, and bladder retraining) involves a programme of patient education along with a scheduled voiding regimen with gradually progressive voiding intervals. Specific goals of bladder training are to correct faulty habit patterns of frequent urination (if present), improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient confidence in controlling bladder function. The underlying mechanism of how bladder training achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved

cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from better individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the “reserve capacity” of the lower urinary tract system [189,267,268]. A Cochrane review of bladder training was last updated in 2010 [269].

**Timed voiding**

Timed voiding is a fixed voiding schedule that remains unchanged over the course of treatment [266]. The goal is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity. Timed voiding has been recommended for patients who cannot participate in independent toileting [270]. It also has applicability for use in outpatient settings with incontinent women who have infrequent or irregular voiding patterns [271] and men who are independent in their voiding function [272]. A Cochrane review of timed voiding was last updated in 2009 (published 2010) [273].

**Habit training**

Habit training is a toileting schedule matched to the individual’s voiding pattern based on their voiding diary. The toileting schedule is assigned to fit a time interval that is shorter than the person’s normal voiding pattern and precedes the time period when incontinent episodes are expected. Thus, the voiding interval may be lengthened or shortened throughout the day depending on the patient’s voiding pattern with the goal to pre-empt UI. Habit training is usually implemented by caregivers, in institutional settings with cognitively and/or physically impaired adults, but it has also been tested in homebound older adults [274]. It is potentially useful for adults without cognitive or physical impairment, who have a consistent pattern of UI [271].

A Cochrane review on habit training was updated in 2009 and published in 2010 [275] following first publication in 2004. Prior to this, the last literature review was published in 1986 [266]. The Cochrane review identified three trials that described the effects of habit training combined with other treatment components compared to usual care on the frequency and severity of UI [274, 276, 277]. A fourth trial compared habit training alone with habit training and an electronic monitoring device [278]. Participants from the first three trials were primarily care-dependent women with cognitive and/or mobility impairment, and the fourth trial comprised men and women with a mean age of 83 years and thus, did not meet the criteria for this chapter. No studies were located that investigated habit retraining in independent-living women.

**Prompted voiding**

Prompted voiding refers to a caregiver education programme in combination with a scheduled voiding regimen, typically every two hours. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so [279]. It has been used primarily in institutionalized settings with cognitively and physically impaired older adults. In a 2009 Cochrane review of prompted voiding [279], nine trials were identified involving 674 elderly people, mainly women. These trials did not meet the criteria for this chapter as the samples were drawn from care home settings and comprised elderly individuals with impaired cognitive and/or functional ability.

This section will examine the evidence for the use of timed voiding and bladder training for the prevention and treatment of UI in non-institutionalised women of all ages without cognitive or mobility impairments. However, the majority of evidence available pertains to bladder training thus the effects of bladder training are the focus of this section.

Questions addressed are:

- Can scheduled voiding regimes prevent UI?
- What is the most appropriate bladder training protocol?
- Is bladder training better than no treatment, placebo or control treatments?
- Is bladder training better than other treatments?
- Can any other treatment be added to bladder training to add benefit?
- Does the addition of bladder training to other treatments add any benefit?
- What is the effect of bladder training on other LUTS?
- What factors might affect the outcome of bladder training?

This section is based on previously published systematic reviews, including Cochrane reviews, and additional searches of the literature. Studies that were excluded from prior systematic reviews, due to the inclusion criteria for the review or restriction to RCTs or quasi-RCTs, were also considered. Conference abstracts were considered where adequate information was available.

1. **PREVENTION**

No trials were identified that examined scheduled voiding regimens as a sole intervention in the prevention of UI.

2. **TREATMENT**

Three systematic reviews on bladder training were located that provided descriptive synthesis with evidence grading [269, 270, 280]. The third is a published Cochrane review that has been updated in 1999, 2004, 2007, and 2010 [269].
a) What is the most appropriate bladder training (BT) protocol?

No trials were identified that compared two or more methods of bladder training (BT). In the absence of trials comparing two or more approaches, a content analysis of the protocols used in trials investigating the effects of BT was performed. Seventeen trials on BT involving a total of 2462 women were identified. Six of the trials provided no or minimal details regarding the specific BT protocol used [128,269,281-285]. In trials that did provide some description, BT protocols were implemented in several ways.

All protocols involved some type of patient education, namely:

- Brief verbal [282,283] or written instructions [286, 287]
- Verbal, written, and audiovisual instruction [189, 268, 288]
- Introduction to an individual who successfully completed BT [284]

If specified, the education was provided by nurses [128,189,268,281,289,290], or general practitioners [291].

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant's voiding pattern or 30 minutes beyond the participant's average voiding interval [287,292].
- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens [284], after 48 hours of dryness [293], every four to five days [292], or weekly if schedule was well-tolerated [189,268].
- Goals for optimal voiding interval varied from three to four hours.
- Voiding was 'mandatory' with restriction of voiding in between assigned toileting times even if UI occurred [284], a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable [189,268,289], or self-scheduling of voiding with a target goal to reach [286].
- Voids were not scheduled (allowed) during sleeping hours [284]; none of the other protocols identified how voids were handled during sleeping hours.

In some protocols the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation [189, 268, 266, 287, 289], and pelvic floor muscle contraction [189, 281, 287]. In other studies there was encouragement to suppress urge but it was not clear what strategies were used [48, 283, 291]. Feedback techniques included self-monitoring [189, 268, 282, 285, 289], goal setting with feedback of progress [290], and positive reinforcement [189, 268, 292].

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments [48,288,289]
- Fluids allowed up to a certain level (1,500 ml) [293]
- No fluid modifications [189,268,286,291]
- Advice on constipation prevention [289].

Both in and outpatient BT programmes have been used. Early inpatient BT programmes involved five to13 days of hospitalisation to ensure strict protocol adherence [284]. Outpatient programmes are more commonly described and the amount of health professional contact had ranged from weekly visits for six weeks with fortnightly telephone calls for six additional weeks [189], to weekly visits [128,268], fortnightly visits [292], and monthly visits [293].

Overall, there is a lack of consistency in BT protocols. Based on the protocols described, a reasonable outpatient BT protocol is shown in Figure 6.

Box: Typical Bladder Training Regimen

• an initial voiding interval typically beginning at one hour during waking hours, which is increased by 15 to 30 minutes per week depending on tolerance of the schedule (such as fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the woman’s feeling of control over urgency and confidence to expand the voiding interval), until a two to three hour voiding interval is achieved. A shorter initial voiding interval, e.g. 30 minutes or less, may be necessary for women whose baseline micturition patterns reveal an average daytime voiding interval of less than one hour.

• education about normal bladder control and methods to control urgency such as distraction and relaxation techniques and PFM contraction.

• self-monitoring of voiding behaviour using diaries or logs in order to determine adherence to the schedule, enhance self-awareness, evaluate progress, and determine whether the voiding interval should be changed. FIGURE 6 from 2009

• a supervising health care professional to monitor progress, suggest adjustments to the voiding interval, and provide positive reinforcement to women undergoing BT at least weekly during the training period.

If there is no improvement after three weeks of BT, re-evaluation is warranted and other treatment...
options would be considered. Inpatient BT programmes may follow a more rigid scheduling regimen with progression of the voiding interval on a daily basis.

1. Summary

There is no trial evidence to suggest the most effective method or specific parameters of BT. For those undertaking BT it is likely that more health professional contact will be better than less, based on the developing evidence for PFMT, which like BT, requires behavioural change. The literature suggests several variables that could be investigated in future trials including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

2. Recommendations

It is not clear what the most effective BT parameters are. Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of BT parameters or approach (Grade of Recommendation: D). Clinicians should provide the most intensive BT supervision that is possible within service constraints (Grade of Recommendation: D). More research is needed to investigate which BT parameters, supervisory intensity, and adjunctive treatments are most effective. Future trials should include outcomes that matter to patients including the length and frequency of supervisory contact.

b) Is BT better than no treatment, placebo or control treatments?

BT as the sole therapy has been used in the treatment of DO, urodynamic SUI, MUI, UUI, UUI with a stable bladder, and OAB syndrome (also called urgency-frequency syndrome). Individual RCTs that met inclusion criteria and the Cochrane review [269] were used to address the question of whether BT is better than no treatment, placebo, or control treatments for UI.

Five RCTs reporting on 515 women were identified that compared the effect of BT to no treatment or control [128,268,285,289,291]. In one trial, it was not possible to identify the effect of BT alone, because results of participants in the treatment group who received BT (those with UUI or MUI) were combined with those who also received PFMT (SUI participants) [291]. However, in the Cochrane review, additional data were provided by the lead author to describe the women with DO who were randomised to BT versus control. In another trial with three consecutive treatments (self-monitoring, BT, and PFMT, with the decision for which treatments to implement based on participants' goals), it was difficult to discern the effect of BT alone as compared to a control group, because some participants had already undergone lifestyle modifications (caffeine and fluid modifications and constipation advice) and diary keeping in a prior self-monitoring condition [289]. Thus, this trial is not discussed further in this section. A recent trial by Diokno et al 2010 [288] compares group session teaching of a behavioural modification program (BMP) includes both bladder training and pelvic floor muscle training, thus it was not possible to determine the effect of BT alone in this study and it is not included in subsequent discussion.

Figure 6: Self-monitoring of voiding behaviour (Courtesy of Dr Jean Wyman, University of Minnesota, USA)
There were four older trials with analysable data: Jarvis (1980) investigated the effect of an in-patient BT programme in 60 women aged 27 to 79 years with a diagnosis of DO or coexisting SUI, whereas three [128,268,291] examined the effect of an outpatient programme. Fantl (1991) studied the effect of a six week outpatient programme in 123 women aged 55 to 90 years with urodynamic SUI, DO, or both who reported an effect of an eight week outpatient programme in 50 women aged 35 to 55 years with UI (type not identified) who had pad test weights at least 1g or more and 14 or more voids during a two day diary. Lagro-Jansen (1992) studied the effect of an outpatient programme in 18 women aged 20 to 65 years who reported UUI twice or more per month and had urodynamically confirmed DO.

1. Quality of data

In one trial random allocation concealment was inadequate [291]; in the remainder it was not clear if allocation was concealed. One used stratification based on urodynamic diagnosis of urodynamic SUI and/or DO [268]. Blinding of outcome assessors was described in only one trial [128].

Sample sizes in the four analysable trials were 18 [291], 50 [128], 60 [285], and 123 [268]. Fantl (1991) reported a power calculation although details were not described. Losses to follow up were none in one trial, although it was not clear if this was due to having no dropouts or due to lack of reporting [285]. In the other two analysable RCTs, loss to follow up was 6% [268] and 14% [128]. Dropout rates at the immediate follow-up time point seemed similar between the BT and the control groups, ranging from 8% vs. 5%, respectively [268], to 10% versus 14%, respectively [128]. No trials reported whether analyses were based on intent-to-treat principles. Follow-up periods ranged from six [268], eight [128] and 12 weeks [285,291], with an additional evaluation six months [285] and nine months [268], after initiation of treatment. Two trials noted whether there were adverse events with BT [268,285]. No trial reported on adherence.

All of these RCTs, with the exception of the one by Jarvis (1980), were considered in the Cochrane review [269]. The Cochrane reviewers based their conclusions on data available from 172 women in the other three trials.

2. Results

Three of the four RCTs reported statistically significant improvements in the BT group compared to the control group incontinent episodes [268,285,291]; the fourth did not report data on incontinent episodes [128].

Jarvis (1980) reported that 90% of the participants in the treatment group were continent and 83% were symptom free at six months (method for determination of continence and symptom status was not specified but probably self-report) compared to 23% of the control group who were both continent and symptom free. All women who were symptom free after treatment reverted to a normal cystometrogram.

Twelve percent of participants in the treatment group were continent and 75% had reduced their incontinent episodes by at least 50% or more at six weeks, measured by a seven day voiding diary, compared to 3% of controls with no incontinent episodes and 24% with at least 50% reduction in their incontinent episodes [268]. These results were maintained at six months. Women with DO and those with urodynamic SUI with and without DO had similar improvement rates. Participants in the treatment group also significantly decreased the grams of fluid lost on a retrograde pad filling test by 54% with results maintained six months later; this was more pronounced in those who had DO with or without urodynamic stress UI. While some women did revert back to normal bladder function following BT, no relationship was found between changes in urodynamic variables and the number of incontinent episodes [294].

Lagro-Jansen [1992] reported that eight or nine patients in BT perceived improvement of UI compared to none of nine in the control group. Yoon (2003) reported that there was no difference between the BT and control groups in the amount of leaked urine at an immediate follow-up; however, it was not clear if this referred to pad test weights solely or a UI severity score. Conclusions from this trial are uninterpretable because of insufficient power.

The Cochrane review [269] noted that the few data available tend to favour BT; however, the scarcity of data implies that they should be interpreted cautiously.

3. Summary

The few trials available were small and of variable quality, there is minimal Level 1 evidence that BT may be an effective treatment for women with UUI, SUI, and MUI (Level of Evidence: 1).

4. Recommendations

BT is an appropriate first line conservative therapy for UI in women (Grade of Recommendation: A).

Additional high quality studies are needed that examine the effect of BT versus no treatment in treatment of women with UUI, SUI, and MUI.

c) Is BT better than other treatments?

To be included in this section, trials needed to compare BT alone versus another active therapy. For the comparison of BT versus PFMT see B.2.3d. The only other comparison for which trials were found was BT versus drug therapy. Individual trial reports that met inclusion criteria and the Cochrane review [269] were used as the basis of the review of BT versus drug therapy.
Three RCTs were located that compared BT to drug therapy in 322 women [281, 284, 292]. The study by Park and colleagues [281] compared a 12-week BT programme to 2mg tolterodine twice daily in women (ages unknown) with OAB (unclear if UI was present); because there were no findings reported on UI, this trial is discussed in the section on Other LUTS (B.6.3). The two trials included in this section used a combination of flavoxate hydrochloride and imipramine [284], or used immediate-release oxybutynin chloride [292].

1. QUALITY OF DATA

One trial reported adequate random allocation concealment [292]. Sample sizes were 50 [284] and 79 [292]. Neither trial reported a power calculation;

Follow up periods varied from four [284], six [292], and 12 weeks [284], and six months [292]. Both RCTs evaluated drug tolerability and adverse events. Dropouts were none in one trial; however, it is not clear whether this was a reporting issue [284]. In the other trial loss to follow up was 7% [292]. Neither trial identified whether intent-to-treat principles were followed. The conclusions of the Cochrane review [269] were based on the same trials.

2. RESULTS

One RCT published in 1981 suggested that BT may be superior to drug therapy in women with DO [284]. Inpatient BT was compared to outpatient treatment of 200mg of flavoxate hydrochloride (three times a day) and 25mg of imipramine (three times per day) in 50 women aged 17 to 78 years with DO, and concluded that BT was more effective. In the BT group, significantly more patients (84%) became continent and symptom free (76%) assessed by self-report, as compared to the drug group where 56% became continent and 48% were symptom free at four weeks. Patients who were symptom free at four weeks were able to maintain their outcomes at 12 weeks and more in the BT group perceived at four weeks were able to maintain their outcomes free at four weeks. Patients who were symptom free at four weeks were observed in 93% and 62% of patients with DO, 67% and 75% of those with low compliance bladder, and 60% and 81% of those with urgency-frequency syndrome in those randomised to oxybutynin and BT respectively. The relapse rate at six months was higher for the drug group. In the analysis by the Cochrane Group (2010) participants' perception of cure was not statistically significant at the end of the treatment phase but favoured BT six months after the treatment ended. Perceptions of improvement were also higher in the BT group at the end of the treatment phase but this difference was not statistically significant. Adverse events included dry mouth, constipation, nausea and tachycardia in patients who received drug therapy, with none in those who received BT.

3. SUMMARY

It is not clear whether BT is more effective than drug therapy for women with DO or UUI (Level of Evidence: 1). This is consistent with the findings of the Cochrane review [269], which concluded that there was not enough evidence to determine whether first line therapy should be BT or anticholinergic drugs.

4. RECOMMENDATIONS

In a choice between BT and anticholinergic drug for women with DO or UUI, either may be effective (Grade of Recommendation: B). BT may be preferred by some clinicians and women because it does not produce the side effects and adverse events associated with drug therapy (Grade of Recommendation: D).

d) Can any other treatment be added to BT to add benefit?

To be included, trials needed to investigate the effects of BT versus BT plus therapy A to address the additive benefit of therapy A. Trials addressing the additional benefit of three other treatments were found: caffeine reduction, PFMT, and drug therapy. The trial addressing the added benefit of caffeine reduction [48] is considered in the section on Lifestyle Interventions (A.1.2d), and the trial addressing the added benefit of PFMT [189] is considered in the section on PFMT (A.1.3e). The trials addressing the added benefit of drug therapy are considered below.

One RCT was found that compared BT alone versus BT with tolterodine (2mg, twice daily) in women with OAB [281]. However, incontinence status of the participants was unknown, and details regarding the study methodology were limited (abstract only). Therefore this trial was not considered further in this section.

A further three RCTs compared BT with placebo drug versus BT with drug therapy in patients with DO. One of these used terodoline (a drug that was withdrawn from the market) [283]. Therefore, this trial was not considered further in this section. In the other two trials the drugs used were imipramine [293] and immediate release oxybutynin [282].

Castleden [1986] studied 34 patients with DO (28 women aged 30 to 91 years and six men). Szonyi [1995] recruited 60 patients aged 70 years and over (56 women, four men). While it is possible that the placebo drug could augment BT, and both these trials included a small number of men in addition to women (and data for women were not reported
separately), a pragmatic decision was made to review these two trials in this section.

1. Quality of Data

Adequate random allocation concealment, or blinding was not reported in either study [282,293]. Study size was based on a power calculation in one [282]. Post-treatment follow up periods were variable. One trial evaluated participants at six weeks [282]; 16 were lost to follow up. The other did not have a clear endpoint but followed participants for one to 11 months; one participant was lost to follow-up [293].

2. Results

It was not possible to discern the treatment effects in only women in these two trials, and the findings were inconsistent. More participants became dry on BT plus imipramine 25mg or more per day (14 of 19) compared to those in the BT plus placebo group (six of 14), but the authors reported that there was no statistically significant difference in outcome between the two groups [293]. One patient in the imipramine group became confused and another complained that the drug made him feel ill. Several patients taking imipramine reported dry mouth and constipation (data not reported), but none on placebo.

No difference was found in a comparison of BT plus 2.5mg of immediate release oxybutynin (twice daily) compared to BT and placebo for reducing incontinence episodes [282]. The authors concluded, however, that the combined therapy group was superior to the BT and placebo group, because it had greater subjective benefit (86% versus 55%), and adverse events were similar in the two groups at 50%.

3. Summary

In two small trials comparing BT plus placebo drug versus BT plus drug in DO, there was a suggestion that the effect of BT might be enhanced by active drug (Level of Evidence: 2). However both trials were small, placebo controlled, conducted in gender mixed sample populations, and the outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with drug therapy.

4. Recommendations

Direct comparisons of BT versus BT with drug are needed to address the question of whether the effect of BT can be augmented by drug therapy.

e) Does the addition of BT to any other treatment add benefit?

To be included, trials needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. Trials were located that investigated the effects of PFMT alone versus PFMT plus BT, and drug therapy alone versus BT plus drug therapy. A new trial compared Solifenacin (5/10mg) alone with Solifenacin and bladder training [287]. One older study (Wyman 1998) compared BT, PFMT, and combination therapy in 204 community dwelling women aged 45 years and older with SUI and/or DO [189]. Two RCTs were identified that compared BT plus tolterodine (2mg twice daily) [281,286] to drug therapy alone. In one three arm trial [281], women with OAB were enrolled but it was unclear if UI was present. Therefore this trial was not considered further.

1. Quality of Data

(a) BT plus PFMT versus PFMT alone: In an early, three arm RCT women were ransomised to PFMT (n=69) or PFMT with BT (n=67) [189]. Outcomes were assessed after the 12 week intervention and three months later. It was not clear if random allocation was adequate or outcome assessors were blind. Study size was based on a power calculation. Losses to follow-up were six at 12 weeks, and 16 three months later.

(b) BT plus drug therapy versus drug therapy alone: Mattiasson [2003] evaluated “simplified” BT (consisting of a one page instruction sheet) in a single blind study of 501 participants (378 women and 123 men) aged 18 years and over with OAB with or without UUI. Allocation concealment, blinding of assessors, and a prior power calculation were not described. Post-treatment follow-up was 12 weeks, and then 24 weeks. Seven participants were lost to follow-up: five in drug therapy and two in combination therapy. Analyses were based on intent-to-treat principles. However, because of reporting issues, it was not possible to discern the effect of treatment in women alone. In 2010, Mattiasson compared solifenacin alone with solifenacin and bladder training in a prospective, parallel group, open label study of 643 men and women with OAB, it was not possible to identify the treatment effect in women alone (85% of sample were women).

2. Results

(a) BT plus PFMT versus PFMT alone: Post-treatment the combination therapy group had significantly fewer incontinence episodes compared to PFMT alone. More women in the combination therapy group than PFMT group reported cure (31% versus 13% respectively), or 50% improvement or more (70% versus 50%). The combination therapy group also reported greater perception of improvement and more satisfaction with treatment than PFMT alone. However, three months later between group differences were not statistically significantly different for cure (27% versus 20%), improvement (59% versus 56%), perception of improvement, or satisfaction with treatment.

(b) BT plus drug therapy versus drug therapy alone: Mattiasson (2003) reported no difference between participants who received brief written BT instructions plus tolterodine versus tolterodine alone with
respect to reducing incontinent episodes (median reduction 87% vs. 81%, respectively). Data were combined for men and women and most data were not presented separately for those who had UI versus those who did not. Mattiasson [2010] reported solifenacin was effective in improving OAB at 8 weeks reducing mean number of micturitions by 2.09, when BT was added there was a further significant improvement reducing episodes by 2.78. Again this study did not present data which enabled analysis of men and women separately.

3. SUMMARY

A single trial found that combining BT with PFMT improves short-term outcomes compared to PFMT alone, but the added benefit did not persist three months later.

There is no evidence for an added benefit of combining brief written BT instructions with tolterodine (2mg twice daily) compared to tolterodine alone for urge incontinence (Level of Evidence: 2), although this trial included men and women and it is not known if one gender did better than the other with respect to outcome. The use of BT with solifenacin (5/10mg) adds benefit to symptom reduction at 8 weeks compared to solifenacin alone, mainly to symptoms of frequency (Level of Evidence 2 – NOTE: This evidence related to men and women).

4. RECOMMENDATIONS

The current evidence is conflicting for the addition of written information on bladder training for women taking an antimuscarinic drug. One trial states no clinical benefit in adding brief written instruction in BT (Grade of Recommendation: B), whilst another suggests no significant improvements to urgency and urge incontinence but significant improvements in frequency (Grade of recommendation: B). More research is needed using an appropriately supervised BT programme (see B.6.2a) combined with anticholinergic or antimuscarinic drug therapies versus drug alone.

f) Timed voiding

A 2010 Cochrane review on timed voiding for management of UI in adults was recently published [273]. Otaśzkiewicz (2010) considered randomised and quasi-randomised trials only and identified two trials that compared timed voiding combined with additional interventions (including medications) to usual care. Both trials were conducted in nursing facilities and most participants were elderly women with cognitive impairment, therefore neither study recruited participants that met the criteria of interest for this chapter.

Two non-randomised studies that were not included in the Cochrane review reported findings related to the effects of timed voiding in women with UUI, stable bladders with UUI, and MUI [194,295]. Klarkov [1986] reported a consecutive series of 20 women aged 27 to 75 years with a double-blind crossover to compare timed voiding plus anticholinergic drug therapy (terodoline) to timed voiding plus placebo. As terodoline has been withdrawn from the market, this study is not considered further.

1. QUALITY OF DATA

A 1984 case series report involved 20 women aged 24 to 94 years in women with a mild degree of UI, irregular voiding patterns, and normal urodynamic parameters (UI type not clearly reported) [295]. The voiding schedule consisted of a two hour voiding interval. Follow-up periods ranged from six weeks to eight months after treatment [295].

2. RESULTS

A 79% success rate (not objectively quantified) was reported in the case series. Fifteen patients became totally continent, one had less leakage, three (with neurogenic diseases) remained unchanged, and one patient was lost to follow-up.

3. SUMMARY

There are no RCTs, or high quality observational studies, providing evidence on the effects of timed voiding for UI in women. Based upon the data from one small uncontrolled study, it seems a two hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function (Level of Evidence: 3).

4. RECOMMENDATIONS

Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (Grade of Recommendation: C). It may also be helpful as an adjunct to other treatment.

3. OTHER LUTS

One trial recruited participants with OAB but the continence status was unclear [281]. BT was compared to tolterodine (2mg, twice daily) or combined BT and tolterodine in women with OAB [281]; this study was reported as a conference abstract. Tolterodine/BT group had greater reductions in diurnal micturition (32.6%), nocturnal micturition (63.2%), urgency scores (63.2%), and bladder symptom improvement rates (69.3%) than those in BT alone or tolterodine alone. However, only the bladder symptom improvement scores were statistically significantly better in the combination therapy group. Thus, it is not clear if BT alone, tolterodine alone, or the combination, is better for LUTS other than UI in women with OAB symptoms.

The most common LUTS, aside from UI, are urgency, daytime (or diurnal) frequency and nocturia. Some trials that contributed to the sections above reported data specifically for these symptoms.
(a) Urgency: Jarvis [1981] compared BT and drug therapy (flavoxate and imipramine), and 16% versus 44% of participants reported they continued to experience urgency post-treatment. Mattiasson [2003] compared BT with tolterodine versus tolterodine alone and patient rating of urgency was somewhat less in the combination therapy group.

(b) Daytime (diurnal) frequency: Data on frequency are more commonly collected that data on urgency. Three trials reported diurnal frequency in comparisons of BT with no treatment. Jarvis [1980] reported a small controlled trial of inpatient bladder drill for DO [285]. After BT 17% in the treatment group and 77% in the control group continued to have symptoms of diurnal frequency. Fantl [1991], in subgroup analyses, found a significant reduction in diurnal frequency in participants with urodynamic SUI who had a baseline diurnal micturition frequency of at least 61 per week, and also in participants with DO with or without urodynamic SUI who had at least 57 diurnal micturitions per week [268]. Finally, Yoon [2003] reported that the BT group significantly reduced diurnal micturitions, whereas the control group deteriorated slightly [128].

Three trials compared BT with drug therapy. Jarvis [1981] reported that 24% of the BT group continued to experience frequency as compared to 48% of the drug group (flavoxate and imipramine) [284]. Columbo [1995] found that diurnal frequency was resolved in 18 (56%) of 32 patients taking oxybutynin versus 20 (69%) of 29 BT patients [292]. Kim SW et al [2008] found improvement in daytime frequency in 15 (65%) cases using bladder training alone and 21 (84%) using BT and propiverine combined.

Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found that there was a greater reduction in diurnal micturition frequencies in participants taking oxybutynin alongside BT compared to those on placebo and BT. Similarly, in a trial of BT plus drug versus drug alone Mattiasson (2003) found that “simplified” BT significantly augmented the effect of tolterodine compared to drug alone for voiding frequency (33% versus 25% improvement, respectively; p<0.001).

(c) Nocturia: Three trials reported data on nocturia in comparisons of BT with no treatment. Jarvis [1980] reported a small controlled trial of inpatient bladder drill for DO. After bladder training, there were 11% in the treatment group and 80% in the control group who continued to have symptoms of nocturnal frequency [285]. Fantl [1991] also found significant reductions in nocturnal frequency [268]. In subgroup analyses, nocturnal micturitions were only significantly decreased in women with urodynamic SUI alone, who experienced at least five episodes of nocturia per week, and not in those who had DO. Yoon [2003] reported that the BT group significantly reduced nocturnal micturitions, whereas the control group deteriorated slightly [128].

Two trials compared BT with drug therapy. Jarvis [1981] reported that the 19% of the BT group continued to experience nocturia compared to 68% of the drug group (flavoxate and imipramine) [284]. Columbo [1995] found that nocturia disappeared in three (27%) of 11 patients taking oxybutynin and 11 (61%) of 18 BT patients [292]. Another trial compared BT plus placebo versus BT plus drug [282]. Szonyi [1995] found no difference in nocturnal micturition frequencies.

1. SUMMARY

Scheduled voiding regimens have been implemented in many forms and with a variety of intensities, ranging from strict in-patient regimens to simple instruction sheets. Most research has examined BT, and most of these trials have recruited women with symptoms of UUI or OAB. It is therefore disappointing that there is so little data about LUTS other than UI. The indications so far are that BT is effective for reducing UI, as well as frequency of micturition. The scant research comparing BT to drug therapy is inconsistent with some evidence for the superiority of each. It is not yet clear whether drug therapy can enhance BT, or whether BT can enhance UI outcomes from drug therapy, although it appears that reductions in frequency of micturition may be greater with the addition of BT.

4. FACTORS AFFECTING OUTCOME

a) Age

With the exception of two RCTs [128, 291] all trials included older women in their study populations. Three specifically recruited elderly women aged 65 to 70 years and over [282, 283, 293]; and two recruited women aged 55 years and over [268, 289]. In conducting analyses of factors predicting success, two trials reported that age was not a factor in treatment outcome [189, 289].

b) Other

Few trials on BT examined other predictors of treatment response. Several discussed the effect of diagnosis on treatment outcome; two reported that urodynamic diagnosis did not have an effect on treatment outcome as measured by incontinent episodes and the IIQ [189, 268]. These RCTs included women with urodynamic SUI, DO, or both diagnoses. BT also led to more clinical cures in one small drug trial. BT in women with sensory urgency (81%) and low compliance bladders (75%) produced better outcomes than in those on oxybutynin immediate release (60%, 67%, respectively); however, oxybutynin led to greater cure rates in patients with DO (93% versus 62%).

VII. COMPLEMENTARY AND ALTERNATIVE MEDICINES

There is minimal evidence that complementary and alternative medicines (CAMs) may influence physiologic function and/or health outcomes. CAMs include
those therapies that are not part of the traditional biomedical model, such as meditation, imagery, hypnosis, acupuncture and naturopathic and herbal remedies. While some consider biofeedback (BF) part of complementary therapy, we have included BF in this chapter as an adjunct to physical therapies.

A search of AMED (Allied and Complementary Medicine) using the key words randomised controlled trials, and urinary incontinence, retrieved 32 records in 2012. One reported a randomised controlled trial investigating the effect of hand acupuncture for female SUI on 52 women randomly assigned to either experimental hand acupuncture or control, assessment was made at 12 weeks and 37% less incontinence was reported in the experimental group. The reporting of this trial did not conform to traditional standards and should be treated with caution, however the undertaking of an RCT in the CAMs literature indicates a move towards the gathering of robust ‘main-stream’ evidence in this area.

There is a need for well conducted RCT’s in the area of CAMs before recommendations can be made.

VIII. SUMMARY AND RECOMMENDATIONS

1. SUMMARY

Whilst the effect of PFMT has received considerable research attention, the effect of lifestyle interventions or prevention trials have not. However even with the number of reasonable trials on conservative management of UI in women, the standards of trial conduct and reporting varied considerably and it is strongly recommended that future randomised trials account for sample size, heterogeneity, risk of bias, and followup.

2. RECOMMENDATIONS FOR PRACTICE

- While some recommendations are underpinned by good and consistent evidence of effect, there are also many recommendations that need further testing because there is insufficient Level 1 or 2 evidence. For this update, the recommendations from ICI 2009 remain. These are not based on robust research and require further study:

a) Lifestyle Intervention

- Weight loss in obese and morbidly should be considered a first line treatment to reduce UI prevalence (Grade of Recommendation: A).
- Caffeine reduction may help in improving incontinence symptoms (Grade of Recommendation: B)
- Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than 30 ml/kg a day (Grade of Recommendation: B) Moderate exercise may help in decreasing the incidence of UI; this effect may be mediated by weight control (Grade of Recommendation: C)

b) PFMT (principal recommendation)

- Supervised PFMT should be offered as first line conservative therapy to women with stress, urge, or mixed urinary incontinence (Grade of Recommendation: A)
- The most intensive PFMT programme possible should be provided (in terms of exercise dose, health professional teaching, and supervision) within service constraints; health professional taught and supervised programmes are better than self-directed programmes; more health professional contact is better than less (Grade of Recommendation: A).
- There does not appear to be a clear benefit of adding clinic (Grade of Recommendation: B) or home based BF (Grade of Recommendation: B) to a PFMT programme.

c) PFMT (other recommendation)

Pregnant women expecting their first baby:

- Intensive strengthening antepartum PFMT, with regular health professional contact to teach and supervise training, to prevent postpartum urinary incontinence (Grades of Recommendation: A) (for women continent at 18 weeks) and B (for population approaches, that is intervention offered whether women are continent or not at 20 weeks gestation)

Postnatal women, immediately after delivery:

- Individually taught PFMT programme that incorporates adherence strategies for women who had a vaginal delivery of a large baby (4000g or more) or a forceps delivery (Grade of Recommendation: C)

For postnatal women with persistent symptoms of UI three months after delivery:

- PFMT is offered as first line conservative therapy (Grade of Recommendation: A)
- The ‘best’ PFMT programmes are ‘intensive’ with regard to supervision and exercise content (Grade of Recommendation: B)

For women with SUI:

- PFMT is better than EStim as first line conservative therapy, particularly if PFMT is intensively supervised (Grade of Recommendation: B).
- PFMT is better than BT as first line conservative therapy (Grade of Recommendation: B).
• PFMT and duloxetine are both effective in first line therapy, although PFMT is better because of the side effects experienced with the drug (Grade of Recommendation: C).

• PFMT and surgery are both effective therapies, although PFMT is better as first line therapy because it is less invasive (Grade of Recommendation: C).

For women with SUI or MUI:
• PFMT is better than VC as first line conservative therapy (Grade of Recommendation: B).

For women with UUI or MUI:
• PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).
• PFMT is better than oxybutynin as first line therapy (Grade of Recommendation: B).

For women with UUI:
• PFMT and BT are effective first line conservative therapy (Grade of Recommendation: B).

Vaginal cones:
• For women with SUI, VCs with supervised training sessions by a trained health professional can a first-line therapy to women able and prepared to use them (Grade of Recommendation: B); some women cannot insert or retain the the cone or have side effects and discomfort. Trained health professional assessment is recommended (Grade of Recommendation: D).

Electrical stimulation (ESstim)
While the usefulness of EStim in practice might be limited because some women cannot use it (due to contraindications), have difficulty using it, or dislike it:

• EStim might be better than no treatment in improving symptoms (Grade of Recommendation: B).
• EStim may be equal to other medical treatments (Grade of Recommendation: B).
• EStim plus PFMT or BF-assisted PFMT programmes does not appear to add benefit (Grade of Recommendation: B)

Magnetic stimulation (MStim)
• Of the MStim protocols investigated to date, it seems that both sacral root MStim and home-based MStim, are worthy of further investigation in women with UI. No recommendation is possible based on current evidence (Level of recommendation: D).

Bladder training (BT)
With regard to Grade A recommendations for BT:
• BT is an appropriate first line treatment for UI in women (Unchanged).

Grade B recommendations (all unchanged from ICI 2009):
• Either BT or antimuscarinic drug may be effective, although BT may be preferred by some because it does not produce side effects and adverse events associated with drug therapy.
• There may be no benefit in adding brief written instruction in BT to drug therapy for incontinence but it may improve episodes of frequency.
• A combination of PFMT/BT may be better than PFMT alone in the short-term for women with symptoms of SUI or MUI.

There are two Grade D recommendations (unchanged from C( 2009):
• Clinicians and researchers should refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach.
• Health Professionals should provide the most intensive BT supervision that is possible within service constraints.

Timed voiding (unchanged)
• Timed voiding with a two hour voiding interval may be beneficial as a sole intervention for women with mild UI infrequent voiding patterns (Grade of Recommendation: C).

IX. FUTURE RESEARCH DIRECTIONS
Conservative management of incontinence is ripe for future research directions. Research that is urgently needed, in the opinion of the committee members, is highlighted with the use of italics. There are a few recommendations that apply to all further studies:
• All future trials must be designed, implemented and reported in ways that maximise their usefulness in practice; this includes being well powered, with longer term follow up, with evaluation of cost-effectiveness and planned secondary analysis of trial data to investigate factors affecting outcome. Readers are referred to the revised CONSORT statement for guidance (http://www.consort-statement.org/)

a) Lifestyle Intervention:
• Given the high prevalence of both UI and obesity in women, the dual issues of weight loss and prevention of weight gain (and exercise) should receive high research priority.
Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

Further research is needed to define the role of straining in the pathogenesis of UI.

Studies to establish whether heavy exertion is an etiologic factor in the pathogenesis of UI and whether changing exertions can alleviate established UI.

Prospective studies on the effect of smoking cessation on the prevention or resolution of UI.

Separate investigations of the impact of lifestyle interventions on nocturia, diurnal frequency, urgency and UUI to delineate whether certain interventions preferentially affect different areas of OAB.

### b) Pelvic floor muscle training (PFMT)

In antenatal and postnatal women, trials are needed to investigate the effects of:

- Antepartum PFMT on preventing postpartum UI in multiparous women.
- Postpartum PFMT programme (suitable exercise dose and supervision) in the long term (five plus years).
- Periodic refresher sessions after an initial supervised postpartum PFMT programme, in the long term (five plus years).

In all women, trials are needed to investigate:

- The effect of different supervisory intensity in PFMT program. In addition to clinical effectiveness, this is an important question because of resource implications, both financial and human, for health-service delivery.
- Whether clinic BF may benefit certain women, such as those with a weak PFM or with difficulty contracting the PFM in isolation.
- Whether the addition of bladder training or medication adds benefit to PFMT.

### c) Vaginal cones (VC)

If the combination of VC with PFMT is an intervention of interest for women then this combination of therapies could be explored further. VC could be used as an overload progression to active PFM strengthening exercises. Thus, a VC programme could be offered to women with a demonstrated minimum PFM strength level and could be aimed at either additional strength training by pulling on the cone for three series of eight to 12 contractions daily, or endurance training, using a low-load over a sustained period of time.

### d) Electrical stimulation (EStim) and magnetic stimulation (MStim)

- Studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.
- Comparisons of EStim with other treatments such as PFMT, vaginal cones, and bladder training are more important than comparison of EStim with sham.
- EStim as an adjunct to treatments that seem to be effective such as PFMT, vaginal cones, and bladder training.
- MStim protocols, both sacral root MStim and home-based MStim, are worthy of further investigation. Well powered RCT are needed to study the clinical effect of Mstim in different diagnostic group.

### e) Scheduled voiding regimes, especially bladder training (BT)

- BT variables to be investigated include the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.
- BT versus another active treatment such as PFMT or drug therapy.
- The potential benefits of combining BT and anticholinergic/antimuscarinic drug need further investigation, including comparisons of BT plus drug versus drug alone, and BT plus drug versus BT alone, or BT vs no treatment.
- Habit training in women with a consistent pattern of UI who are ambulatory and cognitively intact.

### B. PELVIC ORGAN PROLAPSE (POP)

Pelvic organ prolapse is characterised by a variety of pelvic floor symptoms. Treatment depends on the severity of the prolapse and its symptoms, and the woman’s general health. Conservative treatment is generally considered for those with a mild degree of prolapse, those who wish to have more children, the frail or those unwilling to undergo surgery. Conservative treatment is defined here as lifestyle interventions, physical therapies and pessaries.

The aims of conservative treatment in the management of POP include:

- to prevent the prolapse becoming worse;
- to help decrease the frequency or severity of symptoms caused by prolapse (pelvic heaviness, vaginal symptoms, backache, urinary, bowel and sexual symptoms);
- to avert or delay the need for surgery.

In this section the evidence is applied for the use of conservative treatments in the management of
POP, utilising information from two Cochrane systematic reviews [296,297], and literature identified via a search strategy summarised in Appendix 2.

I. LIFESTYLE INTERVENTIONS

Lifestyle interventions include weight loss, reducing exacerbating activities (e.g. lifting, coughing) and treating constipation and are intended to avoid exacerbation of the prolapse by decreasing intra-abdominal pressure. The extent to which any of these lifestyle interventions are effective in managing prolapse is largely unknown [195].

1. PREVENTION

a) Quality of data

No new intervention studies were identified in this update, however further observational studies have been published and these are reported here and summarised in Table 16. In ICI 4th edition, no literature was found relating to the effects of lifestyle change interventions for the prevention of POP. Observational studies were identified that examined the association between factors such as occupation (involving heavy lifting/strenuous physical activity), bodyweight and constipation, and POP.

(a) Association between POP and occupation:

Three new studies investigated the association between occupation and prolapse.

Miedel [298] undertook an assessment of non-obstetric risk factors, including heavy lifting at work, in a population-based, cross-sectional study derived from a sample of 5489 Stockholm women, 30 to 79 years old, who answered a validated questionnaire for the identification of symptomatic prolapse. 69% responded and of those, women who had symptomatic prolapse (n=454) and randomly selected controls (n=405) were given a detailed questionnaire regarding their risk factors, including current or previous occupations that involved heavy lifting (up to 10 kg daily, more than 10 kg) or exposure to vibrations, and participation in low- and high-impact exercise. Only women with intact uteri and no history of surgery for prolapse or incontinence were included (n=273 cases, n=285 controls). Odds ratios and confidence intervals were estimated from multiple logistic regression analysis.

Slieker-ten Hove undertook a cross-sectional study of all female residents between 45 and 85 years old in one Dutch city (n=2979), the results of which were reported in four articles [299-302]. Women received a validated questionnaire via which they were classified as symptomatic (if they reported feeling and/ or seeing a vaginal bulge) or non-symptomatic. A response rate of 63% was achieved. Finally 1224 women were included in the analysis (n=142 symptomatic; n=1082 asymptomatic). Multiple logistic regression was used to estimate the odds ratios and confidence intervals for the potential risk factors including current and past heavy physical work [299].

Braekken [303] carried out a one-to-one age and parity matched case-control study (n=49 women with prolapse >=stage II with or without symptoms, and n=49 controls with prolapse stage 0 or I) with recruitment via community gynaecologists and newspaper advertisements. Women had clinical examination, pelvic floor muscle (PFM) function assessment (strength, endurance and vaginal resting pressure in cmH2O) and completed questionnaires including risk factor assessment. The study primarily looked at the association between PFM function and POP, but also measured occupational heavy lifting and BMI as potential risk factors for POP. Heavy occupational work was defined by a positive response to three questions: self-report of physically heavy occupational work; >20 heavy lifts per week; >50% of working time in standing position. One or two positive responses was classified as moderate occupational work. Multivariate logistic regression was used to estimate odds ratios for risk factors.

(b) Association between POP and bodyweight:

Four new studies have addressed the relationship between obesity and prolapse [298, 303-305].

Whitcomb [2009] published a secondary analysis of the data from 1155 obese women from the Kaiser Permanente Continence-Associated Risk Epidemiology Study. Prolapse was identified from responses to a question regarding the sensation of a bulge or something falling out of the vagina. Women were asked to report bother on a visual analogue scale. Multivariable logistic regression was used to assess severity of obesity (obese, severely obese, morbidly obese) as a risk factor for various pelvic floor disorders including prolapse. Models were adjusted for age, parity and mode of delivery.

Washington [2010] reported on a cross-sectional study of all women with pelvic floor disorders (n=971) attending a tertiary urogynaecology centre over one year. Data on POP-Q, PFDI-20, and PFIQ-7 were gathered. Women with POP-Q >=stage II were classed as having prolapse; women with BMI>=30 were classed as obese. In addition, two studies [298,306] (described above) assessed body mass index as one of several risk factors for prolapse.

(c) Association between POP and bowel function:

Four new studies, one relating to irritable bowel and prolapse [307] and three looking more generally at defecatory problems [298,301,308] were found.

Wang [2010] analysed data from the Reproductive Risks for Incontinence Study addressing the relationship between irritable bowel syndrome and pelvic

Foot notes: N/A non applicable; PFM= Pelvic floor muscle, PFMT = pelvic floor muscle training.
floor disorders, and the effects of such symptoms on quality of life. RRISK is a racially-diverse cohort of women aged between 40 and 69 years (n=2109). Data were collected by self-administered questionnaires and interviews. IBS status was determined by asking a single question regarding whether a woman had ever been told by a medical doctor that she had IBS. Prolapse was identified by asking about feeling or seeing a bulge or protrusion. Multivariate logistic regression was used to assess factors associated with having IBS including prolapse.

Saks [2010] in a cross-sectional study examined whether there was an association between obstructive defaecatory symptoms and prolapse. Women presenting with prolapse of grade 2 or greater (Baden-Walker system) of any compartment (anterior, posterior, apical) to one tertiary urogynaecology service completed a questionnaire (PFDI-20) that reported pelvic floor symptoms. A multivariate regression analysis was performed, adjusting for confounding variables, the dependent variable being presence of obstructive bowel symptoms (defined as at least moderate bother with one or more of: splinting, straining, incomplete emptying).

Both Miedel [2009] and Slieker-ten Hove [2009] assessed the presence of constipation (<3 bowel movements per week), hard stools and difficult evacuation as risk factors for symptomatic prolapse and changes in POP-Q stage.

(d) Association between POP and nutrition:

Previously one study of women in rural Gambia had been published on the association between prolapse severity and anaemia [309]. A new study by Badalian [310] addressed the association between Vitamin D deficiency and pelvic floor disorders. The authors hypothesised that there is a plausible link between vitamin D deficiency and poor muscle strength since vitamin D receptors are found in human muscle tissue. Over three thousand women aged 20 years or above from the US National Health and Nutrition Examination Study 2005-2006 were selected by probability sampling. Analysis was based on the 1881 non-pregnant women who participated, and who had data for both vitamin D levels and pelvic floor symptoms. Prolapse was identified from a positive response to a single question regarding whether a woman had ever been told by a medical doctor that she had IBS. Prolapse was identified by asking about feeling or seeing a bulge or protrusion. Multivariate logistic regression was used to assess factors associated with having IBS including prolapse.

Slieker-ten Hove [299] found that current heavy physical work was an independently significant risk factor for symptomatic prolapse; 24.5% of cases versus 18.9% of controls were currently engaged in heavy work. The odds ratio was 1.48 (95% confidence interval 0.98-2.23) and the population attributable risk (PAR) was 8.5%. Other independent risk factors were having POP symptoms during pregnancy and mother having prolapse. Past heavy work was not a significant risk factor.

Braekken [2009] also reported that heavy occupational work, compared to moderate or light occupational work, was associated with greater risk of prolapse >= stage II. BMI and pelvic floor muscle function variables were also significantly associated with risk of prolapse as described in later sections.

Previously the majority of studies (5 out of 6) reported a positive association between occupations associated with lifting and the presence of prolapse. The additional three studies were supportive of an association between current heavy occupational lifting and prolapse, however the odds ratio in one study was only marginally significant.

(b) Association between POP and bodyweight:

Morbidly obese women had significantly increased odds of having prolapse (reported bulge) compared to obese women (Whitcomb, 2009). The odds for severely obese women compared to obese women were not significantly increased. The visual analogue scores for bother with prolapse did not differ significantly between obesity groups. There may be a trend towards increasing prevalence of prolapse with increasing severity of obesity. However this was not reflected in the bother reported.

In the Washington [2010] study of 971 women, 721 met the inclusion criteria and had sufficient data...
to be included in the analysis. Mean age was 56.5 years (SD 16.2) and 65.2% were post-menopausal. 35.8% were obese and 62.2% non-obese. The mean BMI was 35.8 (SD 5.4). Stage II prolapse was present in 52% of women. No difference in presence of prolapse of stage II or greater was found between obese and non-obese women and similarly for stage 3 or greater prolapse: obese 16.2% vs non-obese 18.4%. Being obese was however associated with more pelvic floor symptom distress: the mean score on the PFDI-20 was significantly higher for obese women compared to non-obese women, due to higher mean scores on subscales for colorectal-anal distress and urinary distress. There was no significant difference between obese and non-obese women in the prolapse-specific subscale of the PFDI-20. The analysis performed was unadjusted, but it was reported that there were no significant differences in age, parity, race, prior pelvic surgery or co-morbidities between the obese and non-obese group.

Miedel [2009] found that although age, parity, and family history of prolapse were the dominating risk factors for symptomatic prolapse, increased BMI was also an independent significant risk factor in the final fully adjusted model (p=0.038). Compared to women of normal weight (BMI 19 to 25), overweight (BMI 26 to 30) and obese women (BMI >30) had increased odds of symptomatic prolapse (OR 1.88 95% CI 1.15 to 3.08 and OR 2.07 95% CI 0.95 to 4.50, respectively).

Braekken [2009] reported that having a BMI of >25 (compared to <=25) was significantly associated with having prolapse >= stage II (OR 5.0, 95% CI 1.1 to 23.0).

In ICI 4th edition the majority of studies (4 out of 6) indicated an association between being overweight and having prolapse. There are now four additional studies to draw on. Each study supported the previous finding.

(c) Association between POP and bowel function:

Symptomatic prolapse in the last 12 months was associated with having inflammatory bowel symptoms (IBS) after adjusting for age, race, medical history, urinary urgency and urinary incontinence: 5% in the no IBS group had symptomatic prolapse compared to 12% in the IBS group. Bother due to prolapse was also significantly associated with IBS. The authors suggest that women with IBS have cycles of constipation which makes them prone to having a weak pelvic floor and prolapse [Wang, 2010].

In the study by Saks [2010], 311 women met the inclusion criteria: mean age 60.5 years (SD 12.5), BMI 27.1 (SD 5.5), and parity 2.6 (SD 1.3). Most women were white (69%) and post-menopausal (79%). Apical prolapse was the most common type (86%), followed by anterior (77%) and posterior (23%). Most had prolapse involving more than one compartment. Nine bowel symptoms were examined and in all cases the prevalence of the symptom was not associated with grade of prolapse. Some obstructive symptoms (splinting, straining, anal incontinence, bulging of rectal tissue) were associated with the presence of a posterior prolapse, but none were associated with the grade of posterior prolapse. In a multivariate regression analysis adjusting for age, BMI and presence of apical or anterior prolapse it was confirmed that women with posterior wall prolapse were more likely to report obstructive bowel symptoms than those who did not have posterior wall prolapse (OR 3.46, 95% CI 1.69 to 7.01). Grade of prolapse (either overall or specifically for the posterior wall) was not significantly associated with obstructive bowel symptoms. The authors concluded that obstructive bowel symptoms often co-exist with posterior vaginal wall prolapse but probably do not cause the symptoms.

Miedel [2009] found all bowel variables were significantly associated with risk of symptomatic prolapse in an age- and parity-adjusted model. In the final multivariable logistic model, one variable remained significant: lack of a normal bowel habit was associated with a two-fold risk of symptomatic prolapse (OR 2.13, 95% CI 1.37 to 3.31).

Slieker-ten Hove [2009] found, in an unadjusted analysis, no significant association between constipation and POP-Q stage, nor straining to defaecate and POP-Q stage.

Previously the evidence was inconclusive with regards to the relationship between constipation and prolapse. There tended to be positive associations with symptoms of prolapse but not anatomical prolapse measures (e.g. POP-Q). Four new studies add some information in this area. The conclusions from these are similar however: significant associations with prolapse symptoms, but no significant associations with prolapse stage.

(d) Association between POP and nutrition:

In the ICI 4th Edition, only one study was found that suggested anaemia was associated with increased odds of having prolapse. A new study by Badalian (2010), looking at the effects on prolapse of vitamin D, found in a univariate analysis that women reporting bulge had higher levels of vitamin D: in women over 50 years old 8.6% reported bulge in the >=30 ng/mL group compared to 3.3% in the <30 ng/mL group. However the model findings suggested that vitamin D level was not associated with vaginal bulge (prolapse): a vitamin D level of 30 ng/mL or more (normal) compared to lower levels had an odds ratio for prolapse of 1.66 (95% CI 0.61 to 4.49). The authors suggest that the small numbers of women reporting prolapse may have been an underestimate due to self-reporting. A significant association between low level of vitamin D and presence of urinary incontinence was reported.
c) Summary

Overall there are still no prospective studies of lifestyle interventions to prevent prolapse.

Some new observational studies were located adding to our knowledge of potentially helpful ways to modify lifestyle risk factors. There is now further evidence that occupations involving heavy lifting/hard physical labour or being overweight may play a role in the development of POP (Level of Evidence: 3).

Constipation is a modifiable risk factor which perhaps has potential to impact on development of prolapse symptoms. However, evidence regarding the association between constipation or straining at stool and prolapse remains conflicting. New studies were reasonably sized and adjusted for covariates.

No further studies on anaemia were found. A study of vitamin D found no association with self-reported bulge.

2. TREATMENT

Previously no studies had been identified that evaluated the effectiveness of lifestyle interventions in the treatment of women with POP. Currently this is still the case.

II. PHYSICAL THERAPIES

The primary physical therapy for POP is PFMT, with or without other adjuncts. PFMT may include PFM assessment and education, PFMT exercise instruction, and PFM bracing against increased intra-abdominal pressure, for example when coughing and sneezing (termed "The Knack" [145]). Adjuncts (such as biofeedback) or other physical therapies (such as neuromuscular EStim) may be used. These therapies aim to improve PFM strength, endurance, coordination and function.

The promotion of PFMT for prolapse varies between treatment centres with some providing only a patient information leaflet and others giving individual instruction from a physiotherapist [311]. Research shows that verbal teaching of pelvic floor exercises alone is insufficient [312]. It is suggested that 15% of women are incorrectly 'bearing down' when trying to carry out these exercises. In women with prolapse, this could further add to the strain on the area and worsen the condition.

A Cochrane systematic review has indicated that PFMT should be offered as first-line conservative management for urinary stress, urge and mixed incontinence [126]. However, its role in managing prolapse is less well-established [313]. The importance of clarifying the place of PFMT in the prevention and management of prolapse has been highlighted [314,315].

1. PREVENTION

a) Quality of data

No studies have been identified to date that evaluate the role of PFMT in prevention of POP. This lack of evidence was noted by Harvey (2003) in a systematic review of PFMT during and after pregnancy [212].

However, one trial is now underway [http://clinicaltrials.gov/ct2/show/NCT01171846]. Four hundred women originally enrolled in a longitudinal follow-up of post-natal incontinence (including a subgroup involved in a trial of post-natal PFMT), who have not sought treatment for prolapse, have been randomised to receive either a programme of PFMT (individualised physiotherapy appointments, maintenance via Pilates-based classes and annual one-to-one check-ups) or a prolapse prevention advice leaflet. Women are being followed up at 2 years. This trial is due to report in late 2013.

In addition, three more cross-sectional studies have examined the relationship between pelvic floor muscle function and prolapse.

Braekken [2009] conducted a case-control study, in which they examined the association between PFM function and POP, but also measured occupational heavy lifting and BMI as risk factors for POP as reported above.

Moen [2009] [316] undertook an observational study in women presenting with pelvic floor disorders. Women were questioned about their performance of pelvic floor muscle exercises and then were examined to measure pelvic floor muscle contraction strength (Oxford grading scale). Prolapse stage was also recorded. Univariate analysis was performed to assess associations between prolapse stage and muscle strength.

Slieker-ten Hove, as described above, performed a cross-sectional study of women aged 45-85 (n=2979) in one town in the Netherlands [302]. Women completed a validated questionnaire and indicated if they would consent to a vaginal examination. A random sample of consenting women were examined to assess prolapse stage (POP-Q) and pelvic floor muscle function (voluntary muscle contraction and effective involuntary muscle contraction during coughing, relaxation and straining were scored by visual inspection and digital palpation). The chi squared test for trend or ANOVA was used in an unadjusted analysis to assess associations between prolapse stage and pelvic floor muscle variables.

b) Results

In one study [303] weaker pelvic floor muscles, poorer endurance and lower vaginal resting pressure were each significantly associated with greater risk of prolapse >=stage II. There was a significant interaction between muscle strength and vaginal...
resting pressure: weak pelvic floor muscles and low vaginal resting pressure giving a higher odds ratio than other combinations. The authors concluded that women with poor PFM function were more likely to experience POP compared with women with good PFM function, and that this supports the hypothesis that PFMT may be important in the prevention and treatment of POP.

In another study [316] of 325 women with a mean age of 57.8 years, 48.9% (159) had prolapse (stage II, III or IV) and 23.4% (76) were able to perform a contraction with strength rated 3, 4 or 5 on the Oxford scale. Pelvic floor muscle contraction strength was significantly lower in women with prolapse >=II compared to women with stage 0 or I prolapse (1.52 versus 1.87, p=0.007).

Slieker-ten Hove [2010] achieved a 62.7% response rate with 1140 women both completing the questionnaire and consenting to a vaginal examination. Of these 1140 women, 800 were randomly selected and 649 then underwent vaginal examination. Fifty four (8.3%) had prolapse. Higher stages of prolapse compared to lower stages were associated with less ability to attain levator closure. Higher stages of prolapse were also associated with lack of effective involuntary contraction during coughing, but better ability to perform proper straining technique. There was no association between stage of prolapse and voluntary muscle contraction strength or endurance. The authors suggest tentatively that strong pelvic floor muscles alone do not prevent the development of prolapse.

c) Summary

Previously one study had reported women with stage II prolapse were better able to elevate their pelvic floor than those with stage III or IV, and hypothesised that poor PFMs may contribute to the development of prolapse. Now additionally three other studies have examined the association between pelvic floor muscle function and prolapse. Two studies had large sample sizes but unadjusted analyses; the third study was smaller but used an adjusted analysis. Two studies suggested the strength of voluntary pelvic floor muscle contractions was negatively associated with prolapse stage, whilst the third did not, but instead found an association between higher stages of prolapse and lack of an effective involuntary contraction.

Currently, there is no evidence from intervention studies regarding the role of PFMT or other physical therapies in the prevention of POP; better PFM function may be associated with less risk of prolapse (Level of Evidence: 3).

2. TREATMENT

a) Quality of data

An evidence-base is now emerging regarding the role of PFMT in the treatment of prolapse, both as a treatment in itself and as an adjunct to surgery. A Cochrane review specifically addressing this question was first published in 2004 and its second update was published in November 2011 [296].

(a) PFMT alone:

Six trials now exist in this area (Table 17), three of which were included in the 4th edition. The three new trials are reported in detail below.

Braekken [2010] undertook a single-centre trial where they randomised 109 women (59 PFMT, 50 control), the results of which were reported in two articles [306,317]. Women had stage I, II or III prolapse of any type (determined by POP-Q), and 63% were reporting symptoms of prolapse. Randomisation was stated as stratified by severity of prolapse. The intervention group women were instructed in PFMT for 6 months (weekly physiotherapy appointments for three months then fortnightly appointments) with home exercise (3 sets of 8-12 close to maximal contractions daily). Both groups were given lifestyle advice and taught “the Knack”. Prolapse stage, prolapse, bladder and bowel symptoms, pelvic floor muscle manometry and ultrasound measurements were taken at 6 months.

The risk of bias was judged to be low. A statistician generated and stored the allocation envelopes. The participant opened the opaque sealed envelope herself. Random permuted blocks were not used which resulted in unequal group sizes. There was a significant difference at baseline between the randomised groups in the prevalence of prolapse symptoms (43/59 PFMT group, 26/50 control group). Pelvic floor ultrasounds were taken and assessed blinded to women's group in the trial, but pelvic floor assessments were not blinded. Dropouts were adequately reported and the rate was low (2%).

Stupp [2011] randomised women with untreated stage II anterior or posterior prolapse attending a urogynaecology service in Sao Paulo, Brazil [318]. POP symptoms were the women’s main clinical presentation. The PFMT group (n=21) received 6 appointments over 14 weeks with a specialist women’s health physiotherapist at weeks 0, 1, 2, 6, 10 and 14. The first 3 sessions aimed to achieve sensory awareness. A 12-week home exercise program was prescribed and women were encouraged to perform 3 sets of exercises daily. One set was 8-12 MVCs, held for 6-10 secs, double rest times between contractions, followed by 3-5 fast contractions in a row. Fortnightly the same physiotherapist phoned the woman. A standardised lifestyle advice sheet was given to both groups containing global stretching exercises and advice on weight loss, fluid intake, constipation, and avoidance of heavy lifting. No detail was provided of who delivered the intervention e.g. how many physiotherapists. Control group (n=16) received instructions on performing a PFM contraction without a protocol, and a lifestyle advice

</table>

Foot notes: MVC = maximum voluntary contraction, PFMT = pelvic floor muscle training, PFME = pelvic floor muscle exercises,
were: pelvic floor muscle function (strength – Oxford grading, endurance – PERFECT assessment); electrical activity (sEMG); symptom severity. It was stated that compliance in the PFM group was 100% and in the control group 76.2%. 91% in the PFM group adhered to the home exercise programme.

Risk of bias in this study was potentially high: no detail of the randomisation process was given, nor blinding of the outcomes measures, other than POP-Q.

A multicentre trial of PFMT for stage I, II or III prolapse which randomised 477 women has recently been completed [296]. This was a parallel group randomised controlled trial. Women in the intervention group were randomised to PFMT, delivered by a physiotherapist at 5 appointments over 16 weeks, and lifestyle advice. Women in the control group received a Lifestyle Advice Sheet by post only. Women had their prolapse assessed by a gynaecologist (POP-Q system) at baseline and (blinded) 6 months, and completed postal questionnaires at baseline (prior to randomisation) and 6 and 12 months. The primary outcome was prolapse symptom severity (Pelvic Organ Prolapse Symptom Score – POP-SS) at 12 months. Other key outcomes were prolapse severity (POP-Q), women’s perceived change in prolapse, uptake of further treatment and cost-effectiveness. Analysis was by intention-to-treat.

The risk of bias was judged to be low. Randomisation was by computer allocation using a remote randomisation service, and groups were comparable at baseline. Outcomes were measured mainly via questionnaire thus avoiding measurement bias. Gynaecologists were blinded to women’s trial group when undertaking the follow-up POP-Q assessments. Questionnaire response rates were high at 6 month follow-up (84% intervention; 86% control), but lower at 12 months (67% intervention; 65% control). Rates of attendance for 6-month prolapse assessment and POP-Q were good (81% intervention; 82% control). Compliance with the intervention was high: 80% of women attended 4 or 5 physiotherapy sessions. Compliance beyond the hymen (80% versus 80%). The authors stated that compliance in the PFM group was 100% and in the control group 76.2%. 91% in the PFM group adhered to the home exercise programme.

(b) PFMT and surgery:

No new evidence to report.

(c) PFMT and pessary:

A feasibility study (the PEPPY study) looking at the possible effects of PFMT with a vaginal pessary in situ has been completed but full results have not yet been published.

(d) Ongoing trials:

There is currently one ongoing RCT (of PFMT as an adjunct to vault prolapse surgery – OPTIMAL) under the direction of the NIH-sponsored Pelvic Floor Disorders Network [319]. This trial compares two methods of suspending the vaginal vault in women undergoing vaginal surgery for POP and additional will randomise half of the participants to adjunctive post-operative PFM exercises and behavioural therapy and half to routine care. The analysis will assess whether such adjunct therapy improves both anatomic and symptomatic outcomes two years after surgery. The study is expected to be complete by 2012 (the OPTIMAL trial, ClinicalTrials.gov Identifier: NCT00597935).

A further feasibility study of pre- and post-operative PFMT for women undergoing prolapse repair is underway (the SUPER study: ISRCTN 08203457). This study aims to recruit 30 participants over 3 sites. Participants are randomised to either the intervention group (n=15) or the control group (n=15). Prior to surgery all patients who have agreed to take part are seen by a physiotherapist to complete baseline outcome measures. Those in the intervention group are also seen once pre-operatively by another physiotherapist to be taught pelvic floor muscle exercises. After 6 weeks those in the intervention group are seen for a total of 5 visits over a 16 week period for further instruction in pelvic floor muscle exercises and advice. Both groups complete outcome measures at 6 and 12 months post-surgery.

(b) Results

(a) PFMT alone:

In the Braekken trial [306,317], in women with prolapse symptoms at baseline (69/109), those in the PFMT group compared to the control group were significantly more likely to have reduced symptom frequency (74% vs 31%) and bother (67% vs 42%). Fewer women in the PFMT group than the control group had no improvement in POP-Q stage (81% versus 92%). In contrast, no significant difference was noted in the subgroup of women with prolapse beyond the hymen (80% versus 80%). The authors also used ultrasound to measure the position of the bladder and rectum within the pelvis, and the dimensions of the muscles and hiatal area, to indicate the severity of prolapse. They found the change in resting position in standing of the bladder and rectum, compared to baseline, were significantly greater (both were higher) in the intervention group than the control group; and changes in measures of the muscles and hiatal area were also significantly different in favour of the intervention group. Manometry (unblinded) was used to measure contraction strength and endurance and found improvement in strength and endurance were significantly greater in the intervention group compared to the control group. Braekken also reported better urinary outcomes for women in the intervention group in their trial.

Stupp [2011] showed that the intervention group had significantly greater anatomic improvements in anterior and posterior vaginal wall prolapse than did the
control group, and a decrease in symptoms [318]. In addition, the intervention group had greater improvements in muscle strength, endurance, and electromyography parameters compared to the control group.

Hagen [2011] found prolapse symptoms were reduced significantly more in the intervention group compared to the control group at 6 months and 12 months. Change in prolapse stage from baseline to 6-month follow-up showed a marginally significant difference between trial groups: 20% in the intervention group had an improved stage versus 12% in the control group. The majority of women in both groups had no change in their prolapse stage. By 12 months, a significantly greater proportion of control women (55%) reported they had received further treatment for prolapse compared to the intervention women (30%). Control women were significantly more likely than intervention women to report subsequent referral to physiotherapy. Rates for receiving other treatments were similar. When analysis of the primary outcome measure was adjusted for additional treatment received, the estimate of the effect of PFMT at 12 months was greater and comparable with that at 6 months.

ICI 4th edition reported on three trials of PFMT versus control for prolapse that found a positive effect, however two of the trials were small (<25 per arm) and the remaining trial had serious methodological limitations. Results from an additional three trials are now available [296,306,317,318] indicating a benefit on both anatomical and symptom measures of prolapse. Stupp (2011) was a pilot study; the remaining two trials were rigorously conducted trials with large sample sizes which provide level 1 evidence of the effectiveness of PFMT for women with stage I to III prolapse.

c) Summary

Based on previous studies and new evidence from two rigorously conducted trials and a smaller pilot trial, we conclude that PFMT can improve the symptoms of prolapse and the anatomical defects. (Level of Evidence: 1)

No further evidence is available regarding the role of PFMT as an adjunct to surgery and thus conclusions are unchanged: pre- and post-operative PFMT may help to improve quality of life and urinary symptoms in women undergoing surgery for POP, but the findings regarding its effects on PFM strength are contradictory. The evidence available however is based on two small trials, one of which included women undergoing surgery for UI and/or prolapse. (Level of Evidence: 2)

d) Recommendations

PFMT can improve prolapse symptoms and severity (Grade of Recommendation: A).

Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C). Larger trials are needed, and prolapse-specific measures should be primary outcomes in such trials.

Future studies of PFMT for POP should aim to reach a consensus on the optimal intervention programme prescribed and might also consider comparisons of individualised training with group training.

III. PESSARIES

Pessaries offer a non-surgical option for the treatment of urinary incontinence and pelvic organ prolapse (POP). Pessary use dates back prior to the days of Hippocrates, and innumerable varieties such as half a pomegranate, a linen tampon soaked with astringent vinegar or a piece of beef have been used. It was only in the 16th century that a device was made specifically to be used as a pessary, as opposed to using naturally occurring objects. Since the 20th century, considerable refinements have occurred and modern pessaries are made from a variety of materials including rubber, clear plastic, soft plastic with metal reinforcements and silicone [320].

A range of vaginal pessaries (Figure 7) exist which can be broadly divided into two types: support and space-filling pessaries. Support pessaries lie along the vaginal axis, with the posterior component sitting in the posterior fornix and the anterior component coming to rest just under the symphysis pubis, thus providing a supportive shelf for the descending pelvic organs [321]. As there is no evidence to support the use of a specific type of pessary, choice is based on experience and trial and error. It is generally accepted that the ring pessary should be tried first because of ease of insertion and removal, and if this fails, other pessaries can be used [322]. Clemons [323,324] found that the ring pessary was successful in grades II and III prolapse, but for higher grades, a Gellhorn pessary was more effective. By contrast, a randomised crossover trial of the ring versus the Gellhorn pessary, did not demonstrate any difference in effectiveness between the two types of pessaries [325].

While it is not possible to establish a global perspective of the full extent of pessary use, a survey of the members of the American Urogynecologic Society showed that 75% of members used pessaries as first-line therapy for POP. Ninety two percent of physicians believed that pessaries relieve symptoms associated with POP, while 48% felt that pessaries also had therapeutic benefit in addition to relieving symptoms. No clear consensus emerged regarding the type of pessary or their indications for use [326]. Similarly there are no clear prevailing removal regimes [Cundiff, 2000]. In the United Kingdom, a recent postal survey demonstrated that 87% of consultants use vaginal pessaries for management of POP [327]. Many physicians receive little or no
training in the use of pessaries [328] and have limited experience with pessary selection and fitting.

Likely candidates for vaginal pessaries are those with co-morbid medical conditions, those who still wish to bear children, as interim relief prior to surgery and for those who prefer non-surgical treatment [314]. Kapoor (2009) demonstrated that when pessaries are offered to patients with symptomatic pelvic organ prolapse, nearly two thirds of women choose a pessary rather than surgery as initial management [329]. Furthermore, a case-control study comparing women who chose pessaries to those who underwent surgery one year after their respective treatment found no difference in prolapse symptoms, bladder, bowel or sexual dysfunction between groups [330]. Thus, although traditionally thought of as treatment only for women deemed unfit for surgery or infirm, pessaries should be considered a viable treatment option for the majority of women in the initial management of POP. Other indications include vaginal laxity, neonatal prolapse mainly seen in association with neural tube defects such as spina bifida and prolapse during pregnancy [322].

Factors that predict the type of treatment chosen for POP have been evaluated in various studies. Powers [2004] [331] noted that patients who refused a pessary were significantly younger and had a higher incidence of urodynamic stress urinary incontinence (SUI). More patients with stage III prolapse refused while more patients with stage IV accepted pessary trial. Heit [2003] [332] found that the probability of choosing a pessary over surgery increased as age increased and decreased as the prolapse severity increased. Clemons 2004 [324] evaluated characteristics that were predictive for pessary usage for up to one year. Age greater than 65 years at the time of pessary insertion and more severe prolapse (Stage III-IV) were more predictive for pessary discontinuation. Brincat [2004] [333] found that women who were sexually active and those with POP were more likely to continue wearing a pessary than women with urinary incontinence. In keeping with this, Ko [2011] [334] found that substantially older women or menopausal women opted for a pessary rather than surgery, and significantly more sexually active women preferred surgery.

Evidence of the effectiveness of pessary use for prolapse can be obtained from a large number of observational studies (prospective and retrospective) and two RCTs (Table 18 and Table 19).

1. QUALITY OF DATA

(a) Randomised controlled studies:

One new randomised intervention was found [335] in which the Colpexin Sphere was compared to PFMT in women with stage I and II pelvic organ prolapse on improving pelvic floor muscle strength and reducing symptoms. The device is a spherical

Figure 7: Range of pessaries (Courtesy of Mediplus Ltd, UK)
intravaginal device, similar to a pessary, which is placed above the levator musculature and requires active PFM contractions to keep it in place. Its purpose is to reduce the prolapse while facilitating PFM strengthening. Group 1 used Colpexin Sphere with PFMT and the other group did PFMT only for a 16 week period. Outcomes were evaluated at baseline and at 16 weeks for comparison of pelvic floor muscle strength. A total of 50 women were enrolled and 48 women completed the full 16 week assessment which consisted of Colpexin pull through test and a digital test. All assessments were performed by only one investigator who was blinded to the group assigned. The small sample size and the short period of treatment are limitations. In addition, the authors did not report a power calculation. The participants were stratified into two groups by using computer-generated random numbers. Participants within each stratum were randomised by using opaque sealed envelopes to one of two study groups.

No other new randomised controlled trials were found on the use of a pessary compared to another device or treatment protocol. Cundiff [325] conducted the largest multi-centre crossover trial, comparing a ring with support and a gelhorn pessary for the treatment of symptomatic stage II or greater symptomatic prolapse. There were no significant differences between groups in baseline characteristics. Participants were fitted with one of the pessaries for three months, and with the second for a further three months. During each three-month period, data were collected at one, six and twelve weeks from women who had a successful fit. Outcomes were measured at enrolment and three and 12 months, and included objective assessment using POP-Q and subjective assessment using Pelvic Floor Impact Questionnaire (PFIQ), and a sexual function questionnaire. Random allocation was by computer-generated random numbers using permuted blocks of variable size. Opaque, sealed envelopes were used to store the random allocation. Participants and clinicians were not blind to the allocation, but data were coded such that analysis was conducted blind.

**b) Prospective observational cohort studies**

Wu [1997] [336] conducted a prospective study of 110 women with symptomatic POP to evaluate a protocol for pessary treatment. After initial fitting, they were seen at two weeks for re-examination and thereafter at 3-6 month intervals. Handa (2002) [337] described the course of POP amongst 56 women who used a supportive vaginal pessary for at least one year.

In 100 women with prolapse, Clemons [2004] [323], analysed the factors that contributed to successful pessary use. Two publications resulted: one on the symptoms and patient satisfaction at two months on 73 out of the original 100 study women who had a successful pessary fit and the other on the continu-ration with pessary at one year of the sub-group who were satisfied users [324].

Lukban [2006] [338] described a study of the effectiveness and safety of the Colpexin Sphere device in women (n=39) with prolapse beyond the hymenal ring; all women had grade three or greater prolapse of at least one vaginal compartment (69% cystocele, 44% rectocele, 31% enterocoele, 8% vault prolapse, 21% uterine prolapse). Women were instructed to use the Colpexin Sphere only whilst in bed for the first week, and to use continuously thereafter, and were taught PFM exercises to be performed twice daily (PFMT and knee squeezes). The intervention period was 16 weeks. Outcome measures included prolapse stage (modified Baden and Walker classification system), PFM assessment (Brink Scale score), and a Pull Test to measure PFM tone and strength (a tensiometer is used to measure the force required to remove a 35mm sphere from above the levator plate). The small sample size, lack of control group and short follow-up were limitations of the study.

Using the Sheffield Pelvic Organ Prolapse quality of life questionnaire, Fernando [2006] [339] addressed the effectiveness of pessaries in alleviating symptoms associated with POP in a prospective study of 203 consecutive women attending a specialist urogynaecology unit four months after pessary insertion. Abdool [2011] [330] evaluated and compared the effectiveness of pessaries and surgery in patients with pelvic organ prolapse in 554 women one year after treatment. Of these 359 were treated with a vaginal pessary and 195 had surgery. Lone [2011] [340] prospectively evaluated the use of pessaries in 246 women over a 5 year period and identified complication rates and reasons for discontinuing use over the 5 year period. There was an overlap of patients in these studies as they are from one institute. Kuhn [2009] [341] used the same Sheffield Pelvic Organ Prolapse quality of life questionnaire and Female Sexual Function Index questionnaire to evaluate quality of life and pelvic organ and sexual function before and during pessary use in 73 women of whom 31 were sexually active.

Komesu [2007] [342] compared pelvic floor symptom changes in 36 who continued pessary use to 28 who discontinued using the Pelvic Floor Distress Inventory-20 (PFDI-20) before and after pessary use. In the same group of women, they further explored whether patient determined goal achievement was associated with pessary continuation.

Barber [343] undertook a study to evaluate the responsiveness PFDI and PFIQ in women with pop undergoing surgical and non-surgical management. The pessary group consisted of 42 women with stage II or greater prolapse enrolled in an multicentre randomised trial comparing two different pessaries and 64 women with Stage III or greater prolapse who underwent vaginal reconstructive surgery. All subjects completed the questionnaires at baseline and again
either three months (pessary group) or six months (surgery group) after initiation of treatment.

Jones [344] evaluated 90 women who had a pessary inserted for POP at baseline and 3 months after pessary use. Pelvic Floor symptoms were assessed using PDFI scores. In addition they assessed the change in genital hiatus measurements. Logistic regression analysis was used to assess baseline characteristics predictive of continued pessary use.

Patel [345] sought to evaluate whether use of a vaginal pessary would change body image, bother symptoms, and quality of life in women with pelvic organ prolapse. Seventy five women presenting for pessary insertion completed the short forms of Pelvic Floor Distress Inventory-20, Pelvic Floor Impact Questionnaire, and Body Image Scale. After successful pessary insertion and use for at least 3 months, 54 subjects repeated the surveys.

(c) Retrospective studies:

There are several retrospective studies on pessary benefits and outcomes but these are limited by the retrospective study design [334,346-351]. Thus we have chosen not to evaluate them in this review as there are several prospective cohort studies that allow a better assessment of effect.

2. OUTCOME

a) Patient reported outcomes

As can be seen in Table 18, follow-up periods evaluating patient reported quality of life varied from three to 12 months. In most studies a recognised measure of prolapse was used i.e. POP-Q examination, to objectively assess and evaluate the prolapse. One study [342] included patients with prolapse and/or incontinence. Various types of pessaries were used. Validated questionnaires to assess patient related outcome were used in eight studies. Commonly used questionnaires were the Sheffield POP symptom questionnaire, and the Pelvic Floor Distress Inventory (PFDI) and Pelvic Floor Impact Questionnaire (PFIQ). Other questionnaires used were Female Sexual Function Index, Body Image Scale and Kings Health Questionnaire.

A direct comparison between studies is difficult as different outcome measures have been used. When pessary insertion was successful, there appears to be a significant improvement in prolapse symptoms. Cundiff [2007] found significant and clinically significant improvements in majority of the PFDI scales and many PDIQ scales with both pessaries but no difference between the ring or gelhorn pessary. Two prospective studies [343,344] found a significant improvement in the urinary and prolapse scales of the PFDI but not in the colorectal scale 3 months after insertion of pessary compared to baseline. Others [342,345] demonstrated a significant improvement of the PFDI-20 scale 3 months after pessary use.

However data on the questionnaire that measures impact i.e. PFIQ varies as Barber (2006) demonstrated no significant changes in the 3 scales while Patel (2010) showed significant decrease in PFIQ scores and prolapse/vaginal subscale of the PFIQ. Fernando (2006) and Abdool (2011) administered the Sheffield Pelvic Organ Prolapse Quality of Life questionnaire (SPS-Q) at before, 4 months and one year after pessary insertion. Two hundred and three patients from the previous study (Fernando) were included in the later paper (Abdool). A significant improvement was seen in prolapse symptoms, bladder and bowel function as seen in Table 18. Contrary to Fernando’s study, Abdool did not demonstrate improvement in bowel evacuation at one year probably as this was only marginally significant (p=0.045) at 4 months.

Women who were sexually active and wore a pessary showed significant improvement in satisfaction of sexual activity at 4 months [339] and at 12 months [330]. Kuhn [341] found a significant improvements in desire, orgasm, lubrication and satisfaction after pessary use. This suggests that a vaginal pessary does not negatively interfere with sexual activity but may even improve sexual function. However, sexual activity is only possible with a ring pessary in situ [330,339]. The other pessaries need to be removed prior to sexual intercourse.

Self-perception of body image is reduced in women with advanced POP [352]. A significant decrease in body image scale scores has been reported indicating an improvement in women's perception of themselves in addition to improvement in PFDI-20 and PFIQ scores at 3 months [345]. However, majority of subjects in this study had stage 3 prolapse, so it is possible that improvements might not be the same for women with less advanced prolapse (i.e., stage 2) and those with urinary incontinence alone.

Two studies [330,343] compared patient related outcome after pessary and surgery use. Abdool demonstrated a significant improvement in prolapse, urinary, bowel and sexual function in both treatment arms but no difference between the two groups. However, Barber (2006) found that subjects in the surgery group had significantly greater improvement in each of the scales of the PFDI and the prolapse and urinary scales of the PFIQ than did the pessary group.

The placebo effect of treatment for prolapse needs further exploration. Komesu [2007] found an improvement in the PFDI-20 total, bladder and prolapse scores in women who discontinued and those who continued pessary use although this was more modest [342]. This could be because of placebo effect or because of conservative interventions such as dietary change and pelvic floor exercises. In the same group they further studied the association between patient determined goal achievement and pessary continuation. Goals commonly listed were
bladder (36%), activity (20%), and general health (13%) and prolapse related (11%). Although goals were found to be variable, women who continued pessary use were more likely to meet one to two goals. Women who attained self-determined goals were more likely to continue pessary use.

1. Success Rates

There is no agreement in the literature on what is considered successful fitting of a pessary. Some consider success if a pessary was perceived comfortable by a patient when retained during valsala and voiding at the initial visit, while others consider it success if a patient continued to use the pessary until the following visit to the doctor. Therefore, the rates of successful fitting vary between 89% to 8% with the follow-up time to define success ranging from initial fit to 7 years. (Table 19). Five studies [333,342,347,349,351] included patients with prolapse and/or incontinence.

Higher success rates for specific types of prolapse (83% for uterine prolapse and 82% for cystocele) are recorded [349]. Comparison of success rates by pessary type was difficult due to use of differing protocols for pessary selection within studies (Table 19). Wu [1997] [336] used ring pessaries in 96% of women who were successfully fitted. Similarly, ring pessaries were the primary choice of treatment in other studies [337,339,353]. The fitting protocol used by Mutone [348] specified the ring pessary with support diaphragm in the first instance. Of women who had a successful pessary fitting, ring pessaries were used more often in women with stage II (100%) and stage III (71%) prolapse whereas Gellhorn pessaries were used more often with stage IV (64%) prolapsed [353]. Hanson [2006] found significantly greater success with the ring, ring with support and Gellhorn pessaries than other type of pessaries (p<0.05), however only 54% of women in this study had prolapse (the remainder had UI).

Parameters reported as associated with a successful pessary fitting were often contradictory. Hanson [2006], Clemmons [2004], and Mutone [2005] reported that patient age was not significantly related to the success of pessary fitting whereas Wu [1997] and Friedman [2010] reported that women who were fitted successfully tended to be older. Mutone [2005] found that women classed as obese were significantly less likely to have a successful fit, whereas Maito [2006] [347] indicated that weight was not a predictor of successful pessary fit.

Clemmons 2004 [353] reported no effect on fitting success of previous surgical intervention while others found a significant relationship between unsuccessful fit and previous hysterectomy or prolapse repair [346-348]. Wu [1997] reported that a history of pelvic surgery reduced the probability of a successful pessary fitting from 79% to 67%, although this result was not significant (p=0.2). Hanson [2006] found a higher fitting success rate in women with previous abdominal genitourinary surgery (71%) compared to those with a history of genitourinary surgery via the vaginal route (60%). Fernando [2006] found 75% retained the pessary at two weeks, and that failure to retain was associated both with increasing parity and hysterectomy in a multivariate logistic regression analysis; site and type of prolapse did not affect success.

Current hormone use did not predict greater likelihood of fitting success [336,353] whereas use of local oestrogen (with or without systemic HRT) was felt to play an important role in successful pessary fitting [349]. Sexually active women were more likely to continue wearing a pessary for a longer period of time [333,343].

Women with SUI before pessary fitting are reported to have a significantly lower success rate in two trials [336,346] but not in one [324]. Maito [2006] found no significant difference in success rates between women with SUI (94%), POP (89%), or both (81%).

Increasing severity of prolapse did not affect the success of pessary fit [336, 348, 353]. Neither was large genital hiatus [324,348,350], severe vaginal atrophy nor a foreshortened vagina affected success nor was the location of the prolapsed an issue [348]. However, a shorter vaginal length and wider vaginal introitus were associated with an unsuccessful fitting [324,350]. On the other hand, Maito [2006] [347] found mild posterior prolapse to be a significant predictor of successful fit. Clearly, differing techniques, follow up, support and skills affect how well pessaries are tolerated and maintained.

Comparison of long term pessary usage rates was difficult due to differing follow-up periods used in the studies reported. Maito [2006] reported continued pessary use of on average six months (range one to 17 months); discontinuation of pessary use was significantly associated with severe posterior prolapse after adjustment for age. Wu [1997] found that 66% of those who used a pessary for more than one month were still users after 12 months and 53% were still users after 36 months. Lone [2011] prospectively evaluated 246 women who opted to use a vaginal pessary (ring, cube, gellhorn, donut) [340]. One hundred and eighty seven (76%) successfully retained the pessary four weeks after pessary insertion. Over a five year period, 19% of the 187 women were lost too follow-up. Of the 151 women included in the analysis, 13.9% discontinued use at some point after four weeks, whereas 86.1% used the pessary successfully over 5 years. The authors concluded that if the treatment for pessary is successful at four weeks, most women will continue to use the pessary over 5 years without a concomitant increase in complications.

Reasons for failure range from expulsion to complications such as vaginal discharge, erosion, de novo SUI, pain, voiding difficulty and constipation (Table 19).
2. Complications

Minor complications after pessary insertion range from vaginal discharge, erosion, de novo SUI, bleeding pain and constipation as can be seen in Table 19. Sarma [2009] [351] reported a complication rate of 56% after pessary use. Rarely major complications may occur. Neglected pessaries present with more serious complications namely fistula formation and peritonitis. Erosion into the bowel or bladder and dense adhesions to other pelvic structures has been reported. Unusual complications of cervical entrapment, small bowel incarceration, and hydronephrosis [354] have been reported.

3. Pelvic Floor Muscle Strength

In a randomised study on the use of Colpexin Sphere [335] a statistically significant improvement in pelvic floor muscle strength was noted as compared with baseline values and at 16 weeks was shown in both groups, with mean difference pull test contraction values of 2.25 + 3.28 N (P < 0.05) in the study group and 1.38 + 2.17 N (P < 0.05) in the control group. There was no statistically significant difference in improving pelvic floor muscle strength between the study and the control groups. The authors concluded that even though Colpexin Sphere plus pelvic floor exercise improved pelvic floor muscle strength, the improvement was not statistically different from exercise alone.

4. Financial implications:

Hullfish [355], developed a Markov decision analysis model to assess and compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy pelvic organ prolapse e.g. expectant management, use of a pessary and surgery obtaining months of quality-adjusted life over one year. Sensitivity analysis was conducted to determine whether the results depended on specific estimates of patient utilities for pessary use, probabilities for complications and other events and estimated costs. Only two treatments i.e. initial pessary use and vaginal reconstructive surgery were found to be efficient choices. Pessary use (including patients that eventually transitioned to surgery) achieved 10.4 quality-adjusted months at a cost of $10,000 per patient, while vaginal reconstructive surgery obtained 11.4 quality adjusted months at a cost of $15,000 per patient. The authors concluded that research is needed to standardise POP outcomes and complication, so that healthcare providers best utilise cost information in balancing the risks and benefits of their treatment decisions.

IV. SUMMARY AND RECOMMENDATIONS

There is growing attention being paid to the effectiveness of conservative interventions for the condition. There are encouraging signs of more rigorous research in this area, with the publication of 4 RCTs [296,306,318,335] in this field since the 4th ICI and 3 more trials awaited.

C.4.1 Recommendations for practice

There is limited Level 1 and Level 2 evidence on which to base recommendations for practice, and most recommendations are, in effect, hypotheses that need further testing in RCTs.

Pelvic floor muscle training (PFMT)

- PFMT can help improve prolapse symptoms and severity (Grade of Recommendation: A) (New).
- Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse (Grade of Recommendation: C) (Unchanged).

Pessaries

- In a choice between the Gellhorn pessary and a ring with support, either may improve prolapse symptoms and reduce their impact (Grade of Recommendation: B).

2. FUTURE RESEARCH DIRECTIONS

a) Lifestyle interventions

- Studies are needed to fully investigate the association between occupation/heavy lifting, bodyweight, constipation and POP. These studies should ensure that:
  - Occupation, physical activity, bowel function and diet are assessed rigorously, using instruments with sound psychometric properties.
  - Potential confounding variables are considered.
  - Attempts are made to overcome some of the obstacles in research in this area such as recall bias inherent in assessing lifetime occupational history, or healthy worker bias which is a problem when attempting to compare POP in women currently employed in heavy labour type jobs versus others.
- Only when the links between various lifestyle factors and POP have been more clearly established can good RCTs be set up to investigate the effects that changes in these lifestyle factors can have on preventing POP.
- Anaemia is a treatable condition, either through diet or medication, and further research on its role in prevention of prolapse is warranted.

b) Pelvic floor muscle training (PFMT)

- Studies are needed to fully investigate the role of physical therapies in the prevention of POP. Such studies should:

Foot notes: N/A = not applicable; N/R = not reported; *Includes patients with incontinence and/or prolapse; ** women who discontinued pessary usage after two weeks and within the first two 2 months; ***Predictors identified at one year
Consider the exact nature and timing of any physical therapies.

Ensure that the effects of lifestyle factors and other potential confounding variables are taken into account.

- Further trials are needed to add to the evidence regarding:
  - The effectiveness of PFMT for different stages and types of prolapse.
  - The role of PFMT as an adjunct to prolapse surgery.

- There are no trials that address the following comparisons of interest:
  - Low versus high intensity supervision of PFMT
  - Individual versus group PFMT.
  - PFMT versus surgery.
  - PFMT versus pessary.

### c) Pessaries

- There remains a pressing need for well-designed RCTs to examine the effects of using the wide variety of different pessaries in the treatment of POP. Such studies need to:
  - Address optimal pessary effectiveness, including the symptomatic and therapeutic benefits of pessaries as well as the indications for use, pessary fit, replacement and care.
  - Adopt consistent protocols regarding choice of pessary.
  - Allow sufficient follow-up periods.

- Randomisation may not be appropriate but efforts should be made to match the characteristics of the treatment groups being compared. Comparisons of interest are:
  - Pessaries versus surgery.
  - Pessaries versus physical therapies.
  - Pessary in conjunction with PFMT.

The assessment and measurement of POP and the assessment of prolapse symptoms need to be made in a standardised fashion using a validated outcome measure (such as the POP-Q examination). The choice of a single validated symptom tool is problematic at the present time.

### C. URINARY INCONTINENCE IN MEN

UI in men remains under-reported and under-studied in comparison to studies including women. The report from the 4th ICI indicated that the prevalence of UI and LUTS in men ranged from eight to 23% depending on the method of data collection, population accessed, and location [1,356]. As for previous consultations, despite the prevalence of UI and LUTS in older men, the only aspect which continues to receive systematic consideration with respect to conservative management are post-prostatectomy urinary symptoms. Thus, the major focus of this section is UI after prostatectomy for benign or malignant disease. All prostatectomy types and approaches were considered including radical prostatectomy (open radical retropubic or perineal, laparoscopic, and robotic) or endoscopic procedures (such as transurethral prostatic resection, high intensity microwave therapy).

The PMFT, EStim and MStim interventions in the current review were reorganized to reflect the evolving evidence and emerging directions of research on post-prostatectomy urinary incontinence. Studies of EStim and MStim in men post prostatectomy all included PFMT as an intervention as well, so these were combined under PFMT. EStim and MStim studies of non prostatectomy related incontinence or other LUTS were kept in separate sections. As preoperative studies may represent the only truly preventative studies, and studies that only included incontinent men the true treatment studies, the categories of prevention and treatment were changed in the PFMT section. Instead, studies in these sections have been grouped into three types: preoperative interventions, mixed pre and post operatives studies of all men undergoing prostatectomy and studies of post operative interventions for men with established incontinence. Studies in the pre and post operative study category are heterogenous in timing of recruitment and intervention, an ongoing concern in this research area.

#### Aetiology of UI after prostatectomy

For purposes of the current review, the reader is directed to the report from the 3rd and 4th ICI (1,356) in which the aetiology of UI after prostatectomy is covered in detail (see report from Committee 13: Surgery for urinary incontinence in men). In brief, risk factors which have been repeatedly identified for UI after radical prostatectomy and transurethral resection of prostate (TURP) are abnormalities of detrusor contractility [357] and age [358]. Other related factors include neurovascular injury during surgery, previous TURP [359], preoperative radiotherapy, trauma, spinal cord lesion, new obstruction such as prostatic regrowth, bladder neck contracture, urethral stricture, Parkinson’s disease [360,361], dementia, and medications [356].

#### Treatment

The primary conservative treatment for UI after prostatectomy remains physical therapies with or without some form of Biofeedback (BF). PFMT, along with...
anal EStim, BF or transcutaneous electrical nerve stimulation (TENS), MStim, and even pharmaceuticals have all been utilised and reported as modestly successful in some trials and not in others.

A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed. No other types of study design were considered. The report of the 4th ICI (1) identified 14 relevant RCTs on conservative management of UI post radical prostatectomy (n= 12) or TURP (n=2) [362-375]. For this review, nine new published trials [376-384], and seven abstracts [385-391] were found, 14 in men undergoing radical prostatectomy, two in men undergoing TURP. One was excluded as it was a study in progress [388], and one [386] was found to be the same study as one of the published trials [384]. Thus, 14 trials were added to the current evidence base for a total of 32 RCTs on some aspect of continence treatment after radical prostatectomy and four on treatment after TURP. Table 20 provides summary information on the trials.

### I. LIFESTYLE INTERVENTIONS

Lifestyle recommendations such as smoking cessation, healthy eating, appropriate body weight, avoiding excessive caffeine or alcohol are all part of a primary care approach and are intended to be preventative in the onset of obesity, cardiovascular disease, diabetes. Whether these factors have a direct impact on continence is suggested but not known. To date, no trials have addressed the topic of lifestyle interventions alone for men with UI. Nevertheless, in practice, it seems reasonable to offer advice on healthy lifestyle choices that may reduce or delay the onset of continence problems.

### II. PELVIC FLOOR MUSCLE TRAINING (PFMT)

The quality of trials included in this update of PFMT has improved from earlier ICI reports although heterogeneity and varying outcome measures continue to affect the ability to compare trial findings.

#### 1. PREOPERATIVE RP PFMT

Trials in this section compared preoperative interventions. Two new studies were identified as focusing on preoperative PFMT [385,389].

Delmasastro [2010] report a trial in which men undergoing radical prostatectomy were randomised preoperatively to PFMT plus proprioceptive training (n=60) vs PFMT alone (n=57). The authors present a novel argument that proprioceptive training of the agonist and antagonist muscle activity may affect acute adaptive responsiveness, enhancing the effectiveness of PFMT in men undergoing radical prostatectomy. Outcomes were measured at baseline (preop) and 4.8, and 24 weeks post surgery; Although the authors report significant differences in outcomes favouring the intervention group (PFMT plus proprioceptive training) the report of the study was available in abstract form only, and details of the randomization technique and data were not available. This study represents an innovative theoretical perspective, but further investigation and testing is needed to establish efficacy of the treatment approach.

Tobia [2008] (article translated from Spanish) randomised 38 men to to preoperative kinetic pelvic exercises (n=19) or no preoperative treatment (n=19). Using DRE and perimenter plus 'low to medium frequency EStim', participants undertook 'kinesthetic exercises', practiced daily at home 7-10 times. No further details of the intervention were provided such as the number of times the participants visited the therapist, how participants were randomised, assessors blinded. Nor was continence defined. The authors reported no difference between groups in continence at 14, 30 or 60 days post catheter removal.

#### 2. PREOPERATIVE AND/OR POSTOPERATIVE RP PFMT, POST RP CONTINENCE STATUS NOT ESTABLISHED PRIOR TO INTERVENTION

Trials in this section addressed the effect of PFMT initiated preoperatively and/or postoperatively but before post op continence/incontinence was established. In these studies, men were recruited preoperatively or immediately postoperatively and the investigators compared a treatment group that received the intervention preoperatively and/or postoperatively RP to a group receiving an intervention only post operatively. Post operative interventions were often described as usual care. Nine trials from the previous review [210,362,369,370,372,375,392-394] and one new study [382] are included for a total of 10 trials in this category. One study in abstract form [388] was not included as it described a study in progress with no findings presented.

##### a) Preoperative PFMT instruction with postoperative home PFMT versus control

No new trials were added to this section. Three were all addressed in the ICI 2009 chapter [1,362,392,393]. Two utilised preoperative BF assisted instruction in PFMT followed by postoperative self-PFMT at home, compared to postoperative verbal instruction [362] or usual postoperative exercise advice [392]. The other study (abstract only), assigned participants to PFMT plus BF (method/type not described) or PFMT alone plus home exercises. Primary outcomes were pads or bladder diary.

#### 1. QUALITY OF DATA

Of the three trials in this subsection, only one [392] reported adequate random allocation concealment. With regard to blinding of outcome assessment, Bales [2000] attempted to control for bias in outcome

- **Post Op**: Post-operative
assessment by having a nurse not directly involved in the study interview the subjects. It is not clear whether he/she was blinded to allocation group. Burgio [2006] had outcomes assessors blinded to group assignment and described dropouts.

2. Results

Burgio [2006] reported a statistically significant difference in favour of PFMT in time to regain continence and proportion of men with severe or continual leakage measured by voiding diary at six months, PFMT (59%) versus controls (78%); additional data provided by the authors on the 24 hour pad test did not indicate a difference between groups. Bales [2000] found no significant group difference on participant report of number of pads used or time to return to continence. Lilli [2006] did not find a difference between participants who received BF in addition to PFMT at any of the time points; at six months, 71% and 67% respectively dry and no use of pads. In the Lilli trial both groups received intervention and it is not clear how intensive the pre-operative PFMT instruction was.

D.2.2b Pre-operative PFMT instruction followed by supervised post-operative PFMT versus post-operative PFMT

One new trial was added to this subsection, making a total of four studies included [369,370,372,382]. Centemero [2010] randomised 118 men more than four weeks preoperatively, with the treatment group receiving twice weekly BF (anal probe) intensive PFMT with a physical therapist plus home exercise and repeated the twice weekly sessions for four weeks post operatively with home exercise until dry. The control group received only post operative PFMT. Outcomes were self report of leakage on bladder diary and provocative (stress) pad test. As reported in ICI 2009 [1], one trial compared active pre- and post-operative PFMT programme to no PFMT instruction [372] and two others pre- and post-operative instruction versus post-operative instruction [369,370]. Participants in one trial [372] had two pre-operative and four post-operative sessions of anal probe BF plus post-operative home PFMT using an exercise ball, or no intervention (similar to Burgio (2006) above). Continence was assessed by pads report and continence questionnaires at six, 12, 16, 20, 28 and 52 weeks post surgery. Sueppel [2001] randomised 16 men (no dropouts) to two pre-operative and five post-operative sessions of anal probe BF or five post-operative sessions plus home PFMT. Continence and quality of life were assessed by AUA symptom score and quality of life questionnaire, pad count, 45 minute standardised pad test, and a leakage questionnaire at six weeks and one year post surgery. In another [369] all participants had one session of pre-operative instruction using BF and verbal coaching and were then randomised to intervention or control groups. The intervention group (n=26) practised PFMT daily with a home BF unit (anal probe) from week 3 to 12 after surgery, whereas the control group (n=24) only followed written instructions. Both groups completed questionnaires, pad counts, and 24 hour pad tests at two, five and 12 weeks post-operatively.

Quality of data

Centemero [2010] had surgeons blinded to group allocation and reported no dropouts. Sueppel [2001] indicated incomplete data but did not describe dropouts. Two did not provide any information [372].

Results

Treatment group was more likely to be continent at one and three months post operatively measured by leakage recorded on a bladder diary (44%, 59% vs 20%, 37%) and on pad test (25%, 17% vs 34%, 32% > 150 gm) [382]. More men were continent in the pre and post treatment group at 12 weeks but there was no statistically significant difference at any other time point to 12 months [372]. Sueppel [2001] reported that at one year the pre and post treatment group had less leakage on a standardised 45 minute pad test compared to the postoperative group (mean 2.8g (range 0.0-13.0g) versus 33.3g (range 0 to 194g) and Mathewson-Chapman [1997] found no statistically significant differences between groups at any of the time points.

c) Post-operative PFMT immediately after catheter removal (no pre-operative instruction)

No new trials were found comparing post operative PFMT immediately post catheter removal. Three previously reported trials in ICI 2009 commenced post-operative PFMT immediately after catheter removal [210, 375, 394]. A total of 524 men were randomised to PFMT programme or no formal instruction. Filocamo [2005], weekly 45 minute PFMT guided by a physiotherapist or one PFMT training session then home exercises [210] or PFMT with verbal and written instructions intensive postoperative physiotherapy for three days, a post-discharge rehabilitation programme for three weeks, and a three month home PFMT programme with twice daily with EStim or PFMT with EStim and BF [375]. Outcomes in the studies varied from ICS Male Questionnaire (ICS MaleQ), pad count, and pad test (one and 24 hours), self-report of no pads, and PFMT strength.

1. Quality of data

In one study, surgeons were blinded to group allocation [210]. Another had data analysed by a professional statistician [375]. Dropouts were described by two [210] and number of dropouts was provided by one [375] but reasons were not described. ITT analysis was described by two [394].

2. Results

One trial [394] favoured treatment at three and 6 months for self-reported ‘completely dry’. Differences between treatment and control were 96% versus 65%
at six months and at one year 99% and 88% (not significant). There were no significant differences between groups on 24 hour pad test (Filocamo, personal communication). Overgård (2008) reported no difference between groups for proportion dry (no pads) or 24 hour pad test at three months; however, at 12 months, the proportion of continent men was statistically significantly greater in the treatment group (33/36; 96%) versus the control (28/39; 72%). PFM strength and 24 hour pad test results did not differ between groups at any of the time points. Of note is that 20 participants in the treatment group did not receive face to face instruction due to distance from facility but rather followed detailed instructions provided on a DVD. Wille (2003) found more men in the PFMT/EStim group reported recovery compared to PFMT alone, but the difference was not statistically significantly different (OR 0.48, 95% CI 0.21 to 1.09).

3. Summary

A total of 10 trials were found applying a variety of pre- or post-operative PFMT based interventions (or a combination of both). Any differences between experimental and control groups were modest and short term; differences did not appear to be sustained up to 12 months post surgery. A particular challenge in evaluating the trials was that participant reported outcomes in three of the studies [210, 392, 394] all indicate some level of improvement in the treatment groups; however, there were no clear differences in pad test results in any of the trials. Because all the studies reviewed were generally small, varied in design, and had different outcome measures, it is difficult to interpret them as a whole. Whilst the evidence that therapist delivered PFMT with or without BF before or after surgery improves continence recovery after radical prostatectomy remains inconsistent, there is some suggestion that men who undergo some sort of conservative management including PFMT will achieve continence in a shorter time frame than non-treated men but that this difference is not significant at 12 months post surgery (Level of Evidence: 2).

Further discussion is needed on the outcomes of most importance. It is possible that the emphasis on quantitative outcomes is not meaningful to participants; men appear to find therapy personally helpful and value the direction provided by a therapist.

4. Recommendations

Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful (Grade of Recommendation: B); whether this is in the form of ‘hands on’ therapy of verbal instruction and support remains unclear. Studies comparing the effectiveness of pre- versus post-operative PFMT, and the number of sessions required, are needed so that practitioners may advise men about pre-operative preparation and budget conscious health boards can make informed decisions on programme funding. In designing such studies, the natural history of UI after radical prostatectomy must be taken into account because the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

3. Postoperative RP PFMT for Incontinent Men

a) PFMT with Digital Rectal Feedback (DRE) after Radical Prostatectomy

Two additional trials were identified for this update [376,379] resulting in a total of five trials as Dubbelman [2004] is considered a duplicate [367, 368, 376, 379, 395, 396] in which PFMT was taught using digital rectal feedback (DRE) in at least one arm.

In the largest RCT to date, 411 men who had undergone open or laparoscopic RP and who reported incontinence 6 weeks after surgery were randomised to lifestyle information leaflet or leaflet plus 4 sessions of PFMT with a continence physiotherapist or nurse and home exercises (2,376). PFMT regime was three maximum strength contractions with 10 second break between each lying, sitting and standing twice daily plus submaximal contractions when walking. DRE was used to assess strength of contraction during training sessions. Dubbelman [2010] randomised 79 men who were incontinent one week after catheter removal to physiotherapist guided PFMT using DRE to to written material only. Treatment group received nine 30 minute sessions plus daily home exercises and written material provided one day prior to surgery; the control group received only the written material. This trial appears to be the same as the 2004 report by the authors which was a poster at the ICS [395].

Joseph [2000] randomised a mixed group of 10 men (four radical retropubic prostatectomy and six radical perineal prostatectomy) to weekly verbal teaching plus DRE or BF assisted PFMT over a four week period. Manassero [2007] randomised 107 (94 completed) men to urologist taught PFMT using DRE (unclear how often) plus daily home exercises for up to a year; the control group did not receive any instruction. Participants were assessed at one, three, six and 12 months with a home pad test, VAS and DRE. In Moore [1999] 63 men (58 completed) were randomised to one of three groups: control (written materials only and no therapist contact), PFMT using DRE, or PFMT augmented with EStim via anal probe. Both treatment groups met with the therapist twice a week for up to 12 weeks.

1. Quality of Data

Three trials [368, 376, 379] reported adequate random allocation concealment. Data were collected by blinded assessors in two [379,396]. In another, data were collected and outcomes as-
sessed by the primary investigator who had a direct involvement in the trial, although treatment was provided by a therapist blinded to the control group outcomes [368]. Three trials described reasons for dropout [368, 376, 396] but only Glazener [2011] indicated how withdrawals/dropouts were dealt with in the analysis and provided intention to treat analysis. Dubbelman [2010] conducted a power analysis for sample size, but fell short of recruiting the target number.

There was considerable variation in the type and intensity of interventions, follow-up ranged from six and a half months to 12 months, and primary outcomes varied from pad test, pad count or subject report.

2. RESULTS

Between them, the five trials, considering Dubbelman [2004] as a duplicate, had over 600 participants with complete data. Four of the five studies did not find statistically significant differences between the groups. Outcomes included one and 24 hour pad tests, voiding diary or quality of life (IIQ-7). No differences were reported between groups at 1, 4, 8, 12 and 26 weeks on one and 24 hour pad test as well as no difference in time to continence [379]; between treatment and control groups in participant reports of any incontinence or severe incontinence at 12 months [376]; or in pad test between PFMT and PFMT with EStim groups [368]. In a small study of 10 participants no differences between treatment and control groups were found [367].

One research group reported a difference between groups [396]. There was a statistically significant difference in proportion of continent subjects (<2g on 24 hour pad test) in the PFMT group at three, six and 12 months (54%, 33%, 17% compared to 78%, 60%, and 53% for the controls), with 9/54 versus 21/40 continent at 12 months.

3. SUMMARY

The most recent and largest trials [376, 379, 396], which compared PFMT taught by DRE or no instruction used different approaches to defining and measuring continence and showed conflicting results. Whereas Mannasero [2007] reported a statistically significant difference in the proportion of continent men (based on 24 hour pad test) in the treatment group at three, six and 12 months the other two found no differences in continence status between groups based on participant report using standardized questionnaires or 24 hour pad test respectively [376, 379]. In the three other smaller and earlier trials, in which the control groups had written or verbal instruction on PFMT, there were no statistically significant differences between groups on pad test. (Level of Evidence: 2). Clinical heterogeneity meant that it was difficult to consider the findings from the studies as a whole.

4. RECOMMENDATIONS

Some instruction in PFMT may be helpful; it remains unclear on the objective benefit of the PFMT. Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction (Grade of Recommendation: B) is not clear. Further well designed studies using standardized outcome measures and participant input are needed to test this hypothesis.

b) PFMT with BF after radical prostatectomy

No new trials were found under this category although reference Ribeiro [2008] [397] was a conference abstract and is replaced by Ribeiro [2010] [398]. Thus to date, there are six trials evaluating PFMT with BF compared to a non active or alternate treatment commencing after radical prostatectomy [365, 366, 371, 374, 397-399].

Three compared PFMT with BF versus no treatment, placebo treatment, or usual care [366,374,398] and three compared PFMT with BF versus verbal instruction and home PFMT [365,371,399]. Continence was measured variously by 1 hour, 24, and 48 hour pad test.

1. QUALITY OF DATA

Two trials appeared to have adequate random allocation and concealment [374,398], although in the latter treatment was provided by the primary investigator who was aware of group assignment. In another [399], therapists were blinded to the results of the control group; pads were weighed by a person unaware of group assignment; data was entered by a data manager. Van Kampen (2000) had pad weights done directly by the individual at home. Dropouts were accounted for and described fully in two [374,399], partially in one [371]. There was a high dropout rate in Franke (2000) and these data were not accounted for in the analysis. There were no reported dropouts two others [365,398], ITT analysis was described by three [365,374,399].

Continence evaluation was different for each study as well as timing of recruitment and intervention, content of intervention and control treatments. Outcomes varied widely; percentage of participants pad free [366]; one hour pad test [365]; 24 hour pad test (<2g=continent) [374,398]; <8g=continent [399]; and pad test not described [371]. Follow up ranged from 12 weeks to one year.

2. RESULTS

Three trials compared PFMT and BF to a control condition [366,374,398]. At 12 weeks, Ribeiro [2010] reported statistically significant difference in 24 pad tests (51g, SD 119 versus 197g, SD 269, p=0.026), but there was no statistically significant difference at six months post surgery. In another study [374] at 8 weeks, there was a statistically significant difference in mean urine loss (30g treatment; 82g control). By 12 weeks this difference
was no longer statistically significant but the proportion of treatment group participants reporting continence compared to control (88% versus 56%) was statistically significant; no differences were found beyond three months. One other trial reported no difference between groups on 24 hour pad test or pad-free rates but sample was small and dropout rate nearly 50% [366].

None of the three trials that utilised PFMT and BF versus verbal or written instruction on home PFMT showed statistically significant differences between the groups. Outcomes were measured using one hour pad test or number of pads [365], 24 hour pad test, International Prostate Symptom Score (IPSS), or subjective report of continence at eight, 12, 16, 18, or 52 weeks [399], and pad test at 12 weeks [371].

3. Summary

Health professional instruction in PFMT with BF when compared with control conditions seemed to reduce the amount of leakage in the early weeks of recovery (up to three months). However, comparisons of PFMT with clinic BF versus PFMT at home did not find similar differences. Based on the current evidence the addition of EStim or BF does not appear to improve continence outcomes over and above PFMT. (Level of Evidence: 2). However, BF may be less difficult for the therapist than DRE.

It seems men who participate in PFMT compared to no active treatment might have less leakage in the first three months postoperatively. To the individual, this early improvement may be important in activity, well-being, and socialising. Such concepts require further investigation.

4. Recommendations

The use of BF in clinic, over and above home PFMT, is currently a therapist/individual decision based on economics and preference. (Grade of Recommendation: B).

c) PFMT plus or minus BF with EStim or MStim after radical prostatectomy

The most notable addition to the evidence base in this section is five new trials which combined EStim with PFMT for men incontinent post radical prostatectomy [378, 380, 383, 384, 387] with four of these including BF as part of the intervention. These five trials were added to two RCTs previously included in the EStim section [400]. Opsomer [1994] compared intensive PFMT plus EStim (once a week) plus BF versus simple PFMT in 43 men. As it was not possible to differentiate the effects of additive EStim (method not described) from adjunctive BF this study was not further considered for this section.

Two studies [400] previously reported and one new [378] reported comparisons of PFMT to PFMT plus EStim and recruited men with severe post prostatectomy UI one week after catheter removal (more than 200 gm of urine lost daily on pad test). In the Yamanishi trial, men were randomised into active EStim group (n=26) or sham EStim (n=30) by computerized random assessment through a connection to the stimulation device. All men had PFMT by nurses (verbal and written information) and were coached to continue this though the study period. Active EStim was 50 Hz with a 300 µsecond pulse duration, 5 seconds on/5 seconds off duty cycle and maximum output of 70 mA. Men receiving sham EStim received limited stimulation at 3 mA with a 2 seconds on/13 seconds off duty cycle. Treatment continued until the incontinence was cured or the 12 month study period ended.

Moore [1999] compared standard treatment (verbal and written instructions about PFMT) versus intensive PFMT, versus intensive PFMT plus rectal EStim in 63 men with UI median of 8 weeks (range 4-241) post radical prostatectomy. EStim was provided by a surface anal electrode, with intensity to induce visual lifting of the levator ani. Stimulation parameters were 50Hz, biphasic pulse shape with one second burst, a one second pulse width and one second pulse trains. All therapy was performed by one experienced physiotherapist. Hoffmann [2004] compared percutaneous EStim plus PFMT versus anal EStim plus PFMT versus PFMT alone in men with post-prostatectomy incontinence; this trial allocated 60 men per group, the intervention was for four weeks, and each individual was followed up for three months. PFMT consisted of a “specialized program” of “continence training”, lifestyle changes, osteopathy and “Feldenkrais Lehre” three times/week in the clinic and three times/day at home, with a daily maintenance home programme after finishing the therapy. In comparing PFMT with BF plus EStim, three trials [383,384,387] included men one to four weeks after catheter removal and one [380] enrolled men at least one year after surgery. Mariotti [2009] compared PFMT with BF plus EStim to a control group which received only verbal and written information from a urologist. Randomisation occurred one week after catheter removal, and severity of incontinence among participants at enrolment varied from 20-1500 gm of urine lost on 24 hour pad test. Men in the intervention group received 12 treatment sessions (twice weekly for 6 weeks) of PFMT with BF and EStim from a single clinician. EStim was delivered by anal surface electrode at 30 Hz for 10 minutes and 50 Hz for the following 10 minutes, 300 µsecond pulse duration and a maximum output of 24 mA. BF was via perineal and abdominal surface electrodes. The frequency details of home PFMT were not provided. Marchiori [2010] randomised 332 men one month after catheter removal to intensive PFMT with BF plus EStim or a control group that received only verbal and written instruction and home exercises. This study was available only as an abstract, and the intervention was not fully described.
Three studies had adequate concealment of randomisation [380] or whole body vibration daily at 20 Hz on a vibration plate (Fitvibe MedicalR) plus exercises (not described). Each group was in contact with the therapist over a 3-4 week period and had home exercises prescribed (protocols not described). Outcomes were testosterone, blood sugar, IPSS, pad count, and pad test. This trial was translated from German for this review.

Goode [2011] recruited 208 men with post radical prostatectomy incontinence persisting at least one year after surgery (range 1-17 years) and conducted a three group comparison of behaviour therapy BT that included PFMT, bladder control techniques and fluid management, BT/PFMT plus EStim and control (delayed treatment) [380]. Four visits two weeks apart to teach PFMT were provided for instruction from physician investigators or nurse practitioners. Anal palpation was used during instruction. The second group (BT plus) received BT with added in office anal palpation was used during instruction. The second group (BT plus) received BT with added in-office anal palpation and had home exercises prescribed (protocols not described). Each group was in contact with the therapist over a 3-4 week period and had home exercises prescribed (protocols not described). Outcomes were testosterone, blood sugar, IPSS, pad count, and pad test. This trial was translated from German for this review.

In a three arm trial [401] electrical stimulation (ES
tim), magnetic stimulation (MStim) and verbal/written instruction in PFMT were compared in 36 men with post RP incontinence. Home EStim comprised 15 minutes of twice daily stimulation for one month, at maximum tolerable level of intensity. For MStim, treatment sessions were 20 minutes, twice a week for two months, with stimulating intensity gradually increased up to the tolerable level. PFMT consisted of PFM exercises in supine position with instructions how to contract the anal muscles selectively. Verbal and written instructions for home practice were given to the men. Participants were followed up for six months.

1. Quality of data

Blinding, dropouts and continence evaluation

Three studies had adequate concealment of randomisation [368,378,380]; one included a power calculation, and adherence to protocol was monitored using patient-recorded diaries. Five participants dropped out, three in PFMT/EStim and two in the PFMT group. In one participant dropout was related to the use of EStim (rectal pain) [368]. Goode (2011) included a power calculation and stratified participants by site, incontinence type and severity. Randomization was conducted via a computer generated random assignment schedule. Sealed envelopes with group assignments were opened sequent-

tially at the time of randomization. There were 23/70 dropouts in the BT group, 30/70 dropout in the BT plus EStim plus BF group and 4/68 in the group that received no intervention. Dropouts were explained and analysis was by intention to treat. Interventions were not concealed as physician investigators were involved in delivery of interventions. Yamanishi [2010] used a computer generated random assignment that connected to the EStim devices, thereby blinding participants, physicians and staff to assignment. Dropouts included 4/26 in the active EStim group and 5/30 in the sham EStim group.

Randomisation details were not provided in two trials [384,401]. In the Mariotti trial , intervention was directed by the lead author, therefore there was no blinding of the researcher to the intervention group. A power analysis was performed to determine sample size. All participants completed the study. Another [400] did not make clear if allocation was concealed or if observers were blinded. Dropouts were 22/60 in the anal EStim/PFMT group, 4/60 in the percutaneous EStim/PFMT group and 0/60 in the PFMT group. Marchiori [2010] data was available only in abstract form and details of randomization and blinding are not described. In the Yokoyama trial, the number of treatments, duration and intensity seemed to be different between groups.

2. Results

In comparisons of PFMT +/- EStim, 9/60 men in the anal EStim/PFMT group reported recovery, versus 11/60 in the percutaneous EStim/PFMT group; data were not reported for the PFMT only group [400]. For comparisons of PFMT to PFMT plus EStim and BF, Goode [2011] found that both treatment groups (BT/PFMT and BT/PFMT plus EStim and BF) reported a statistically significant reduction in incontinence episodes at 8 weeks compared to the control group as recorded on bladder diaries. Both treatment groups maintained improvement at six and twelve months, although there were no statistically significant differences between treatment groups. No comparison to the control group was made after 8 weeks.

Pad test results were not consistent. Using a 24 hour pad test [368] one reported a decrease of urine loss favouring PFMT over EStim/PFMT; another found that at three months 77% in EStim/PFMT group were continent versus 65% in the PFMT group, with 82% and 77% continent respectively after 12 months [375]. None of these differences at any of the time points were statistically significant. Yamamishi [2010] reported more men in the active EStim group were continent (less than 8 gm urine lost on 24 hour pad test) at 1, 3 and 6 months than those in the sham EStim group (4%, 16%, 44% versus 36%, 63%, 81% respectively), although there was no difference at 12 months (86% continent in both groups).

For comparisons of PFMT plus EStim and BF, men in the treatment group who received PFMT plus EStim
and BF had a shorter mean time to continence (urine loss less than 2 gm on 24 hour pad test) than those in the control group (8 weeks versus 13.88 weeks) [384]. At six months, 3.3% of the intervention group and 33.3% of the control group were still incontinent, at 12 months there was no difference between the groups. A shorter time to continence favouring intervention group receiving PFMT with EStim and BF (44 days intervention group vs 76 days control group), was reported with all participants continence (2 mini pads or less per day) at 12 months [384]. At six months, 3.3% of the intervention group and 33.3% of the control group were still incontinent, at 12 months there was no difference between the groups. A shorter time to continence favouring intervention group receiving PFMT with EStim and BF (44 days intervention group vs 76 days control group), was reported with all participants continence (2 mini pads or less per day) at 12 months [384].

EStim was associated with adverse events. Discomfort [378,400], urethral stricture [378], or bladder neck contractures [368]. Whether the EStim caused the strictures or contractures is debatable.

Yokoyama (2004) reported that at one month, urine loss on 24 hour pad test was 72g, 83g and 175g (FES, ExMI, and control groups respectively) [381]. At six months was mean loss was less than 10g in all groups. No complications were noted in any of the groups. The authors concluded that both MStim and EStim offered earlier continence compared with PFMT after radical prostatectomy.

Zellner [2011] (translated from German) reported no difference between control and the PFMT/BF/EStim groups based on IPSS, pad test, and pad count but the whole body vibration group (FitVibe medicalTM) had a statistically significant decrease in pad test results from 41g pre therapy to 11g post relative to the other two groups. Whole body vibration was not described in detail.

3. SUMMARY

Seven RCTs investigated the addition of EStim to PFMT plus or minus BF for men with post-prostatectomy incontinence. Data suggested no further benefit of EStim when added to PFMT over PFMT alone, although EStim may help achieve continence earlier in men with severe incontinence post prostatectomy; the numbers in each trial were relatively small. (Level of Evidence: 2)

4. RECOMMENDATIONS

For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme (Grade of Recommendation: B).

d) PFMT compared to other interventions after radical prostatectomy

Two new trials were identified that combined PFMT postoperatively with other novel interventions in men with post prostatectomy incontinence [390,391]. Park [2011] compared PFMT to an overall 12 week exercise program plus PFMT in 49 men over 65 years after RP, reporting that the exercise (treatment) group had an earlier return to continence on pad test and self report. Zhang [2008] randomised 29 men to PFMT + BF plus six biweekly meetings of a support group (n=14) or to a control group which had only the PFMT +BF. The treatment group reported less UI on VAS rating scale (3.2 vs 4.7), less pad use (50% vs 84.6%), and had better adherence to the PFMT regime. Both trials were available only in abstract form, and details on baseline incontinence, randomisation, blinding and data were not provided.

4. PREOPERATIVE TURP PFMT

Little study has been dedicated to UI after TURP. In fact, the issue has been largely ignored, perhaps because the incidence of UI after TURP is reported to be very low.

5. PREOPERATIVE AND/OR POSTOPERATIVE TURP PFMT

In previous consultations, two trials were potentially eligible for inclusion [367], but the latter trial was grouped with studies of PFMT after radical prostatectomy because the 11 participants comprised one following TURP and 10 following radical prostatectomy. One new trial on TURP pre and post operatively was added [381].

Men undergoing TURP were randomised preoperatively to a treatment group (n=26) which involved preoperative PFMT of 1 hour individual and a 3 hour group session along with home exercises compared to control group (n=23) which received verbal information only post operatively. Outcome was symptoms as measured by the Danish Prostate Score. Three day bladder diaries and a pad test were also identified as measurements in the study but data from these were not included in the published report, therefore the effect on incontinence is not clear. An earlier trial included men booked for TURP [373]. At the baseline preoperative visit, PFM strength, tone and grading were established with a DRE. There were weekly follow up sessions for four weeks post TURP. It was unclear what information, if any, the control group received.

Quality of data

It was unclear if random allocation was concealed or outcome assessment blinded, and the proportion of dropouts was not stated.

Results

While there were statistically significant differences in UI and post micturition dribble as measured by voiding diary and IPSS, there was no statistically significant difference at four weeks.

Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if PFMT reduces
UI following TURP. More systematic investigation of the the natural history of UI after TURP is probably needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

6. POSTOPERATIVE TURP PFMT FOR INCONTINENT MEN

Only one study was identified which included men incontinent after TURP. Glazener [376] randomised 442 men post TURP who reported incontinence 6 weeks after surgery. All men received a lifestyle information leaflet; those assigned to the invention group had four:1:1 sessions with specialist continence physiotherapist or nurse. PFMT regime was three maximum strength contractions with 10 second break between each practiced lying, sitting, and standing twice daily plus submaximal contractions when walking plus home exercises. DRE was used to assess strength of contraction during training sessions.

The 4rd ICI identified two RCTs on conservative management of PMD [364,402] and no further trials were found for the past two updates. No trials were found on prevention of PMD and it is unlikely that such studies would be undertaken because of the longitudinal nature of such an exploration.

a) PFMT for post micturition dribble (PMD)

Two RCTs totalling 85 participants who had not undergone prostatectomy have been reported in which PFMT and/or urethral milking were compared to verbal instruction and lifestyle changes [364,402]. In one men were assigned: daily PFMT, urethral milking, or lifestyle changes using four hour pad test at five, nine, and 13 weeks. In another study on erectile dysfunction [403], over 65% of participants also complained of PMD and were randomised to PFMT using BF (5 weekly treatments plus home exercises) or lifestyle advice. Outcome was patient report using a standardised questionnaire administered by an interviewer unaware of group assignment.

1. Quality of data

It was not clear if allocation was adequately concealed in either study. In both studies data collection was done by the researchers but data analysis was done by a separate party.

2. Results

Paterson [1997] found both PFMT and urethral milking were equally effective and better than lifestyle changes. Dorey [2004] found that the PFMT group not only reported a significant improvement in erectile function measured by International Index of Erectile Function (p=0.001) but also a significant improvement in PMD measured by standardised questionnaire (67% improved in treatment group compared to 7% of controls; p<0.002).

3. Summary

Based on two small studies, it seems that PFMT and urethral milking might both be effective in the control of the annoying symptom of PMD (Level of Evidence: 2).

4. Recommendations

Men can be offered instruction to do a strong PFM contraction immediately after voiding, or urethral massage to empty the urethra, to improve symptoms of PMD (Grade of Recommendation: C).

8. FACTORS AFFECTING OUTCOME

Based on the current evidence, it appears that time from surgery to implementation of exercises does affect outcome and that by three months after surgery less improvement is noted. Future trials could consider analysis to evaluate the effect of length of time from prostatectomy surgery, co-morbid conditions, prior pelvic surgery, and medications (including smoking and alcohol use) on treatment outcome.

III. ELECTRICAL STIMULATION (ESTIM)

ESlim (ESlim) is reported to be effective in the treatment of UUI but no better than PFMT alone for men with SUI [242,404,405].

Symptoms of DO and UUI can be associated with neurogenic disorders and to bladder outlet obstruction such as benign prostatic hyperplasia; in some men the cause is unknown. It is believed that ESlim for UUI acts through reflex inhibition of pelvic efferents or activation of hypogastric efferents through stimulation of the afferent input in the sacral route [223,405].

SUI is rare unless iatrogenic with radical prostatectomy, pelvic surgery or radiation, or TURP [368,406-408]. DO, poor compliance and decreased contractility may also be factors related to post-prostatectomy incontinence [368, 409]. For male SUI, ESlim could be used to enhance sensory response to contraction of the PFMs in the same way as female SUI [410,411]. As a stand alone therapy it is unclear whether ESlim enhances continence recovery [375,412]. It has been postulated that continence is regained more rapidly [413] and the duration of the application of ESlim is reduced when PFMT is augmented with ESlim [413,414]. ESlim is also believed to be more effective in participants who are initially unable to identify and contract the correct PFMs [415]. Interestingly, it is generally agreed amongst those using
EStim that it should be avoided for those with carcinoma of the bladder for fear that EStim may increase abnormal cell activity [403]. Although there are no data to confirm or refute this, many physiotherapists are unwilling to use EStim for individuals with cancer and, therefore, post radical prostatectomy. Further research is needed to clarify this risk.

This section will examine evidence for the use of EStim for the prevention and treatment of UI in men. Questions addressed are:

• What is the most appropriate EStim protocol?
• Can EStim prevent UI?
• Is EStim better than no treatment, placebo or control treatments for UI?
• Is EStim better than other treatments?
• Does the addition of EStim to other treatments add any benefit?
• What is the effect of EStim on LUTS other than UI?
• What factors might affect the outcome of EStim?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see Appendix 2). No other types of study design were considered. Since the 3rd ICI only one new RCT [400] was identified and included in this chapter. A previous relevant Cochrane systematic [412] was updated and contributed to this section [416].

1. PREVENTION OF UI

There have been no studies on the effect of EStim for prevention of non postprostatectomy UUI or SUI in men.

2. TREATMENT OF UI

In the 4th ICI, one systematic review was identified [412], along with nine RCTs [221-223,368,371,375,400,401,404]. An abstract of a trial [417] reported data for men, but the separate effects of EStim could not be assessed and the study was excluded.

a) Is EStim better than no treatment, placebo or control treatments?

No new studies were identified that compared EStim with no treatment or a control. Two earlier placebo controlled trials both included men and women. One included 29 men and 39 women with UUI [222,404] and the other 30 women and five men with SUI [404]. In the latter trial, four men had post-prostatectomy incontinence and one had sphincter deficiency due to sacral cord tumour.

1. Quality of data

Both trials blinded participants and doctors to treatment allocation [222,404]. For EStim in UUI, three participants (8%) in the active group and one (3%) in the sham group dropped out, and two in each group discontinued the treatment due to adverse events (5.4% and 6.5% respectively). For EStim in SUI, two of 35 participants (6%) dropped out and none had adverse events.

2. Results

(a) Men with UUI: The authors reported statistically significant differences in cure (22% active and 4% sham) and improvement rates (81% active and 35% sham) between the groups; data were not differentiated for men and women [222].

(b) Men with SUI: None of the participants in the sham group were cured or improved. One man in the active EStim group was cured and a second was improved; five men participated in the study but it was not clear how many were allocated to sham and how many to active EStim.

3. Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if EStim, as a stand alone treatment for male UUI or SUI, is better than no treatment, placebo or control treatments.

b) Is one approach to EStim better than another?

EStim protocols for men are similar to those for women and like protocols in women vary widely. Intermittent, short-term stimulation (or maximal EStim) using a portable stimulation device at home or in clinic is most common [368,375,401]. Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region. For the treatment of SUI (and post-prostatectomy incontinence) EStim may be combined with PFMT or monotherapy. Usually a rectal electrode is used, and the stimulation artificially stimulates the pudendal nerve and its branches to cause direct reflex responses of the urethral and periurethral striated muscles [368,400,401].

Frequencies of 14Hz have been used for UUI [400], while 20Hz [401], 27Hz [375] and 50Hz [368] have been used for SUI. Pulse form is mostly biphasic; pulse width varies and includes 300 microseconds [401], 250 milliseconds [400][401], one [368] and five seconds [375]. Duration of the stimulation varies as well, from 15 minutes [375] to 30 minutes [368], and from twice daily [375] to twice weekly [368]. Duration of treatment has ranged from one month [401], to three months [375].

1. Summary

So far, no studies comparing EStim protocols have been identified. The most appropriate EStim protocol for different types of symptoms is unknown. EStim protocols for men have been developed from studies in women. The variability in the findings of
the trials included in the remainder of this section may in part be due to differences in the effectiveness of the wide range of protocols that have been tested. There are many differences in clinical application that have not yet been investigated. Some populations or subgroups of men may benefit from ESlim more than others, but this observation has not yet been investigated.

c) Is ESlim better than other treatments?

No new trials were found comparing ESlim with other treatments making a total of two comparing ESlim with MStim [223] or medication [221] in men and women with UI. One evaluated ESlim with MStim for inhibition of DO in a urodynamic study of 32 participants (15 males, 17 females) [223]. The other compared ESlim (TENS) with medication (oxybutynin) for UI in 43 participants (13 men, 30 women) with DO [221]. Results were not reported by gender. Oxybutynin was started at a dose of 2.5mg orally twice daily and titrated to 5mg orally three times daily by day seven. Dual channel TENS with two self-adhesive pads connected to the stimulator and applied bilaterally over the perianal region (S2 to S3 dermatome) was used. Stimulation parameters were set at a frequency of 20Hz and a pulse width of 0.2msecs on a continuous mode. TENS duration was up to six hours daily.

1. Quality of data

Random allocation concealment was adequate; results were not reported by gender [222]; another did not provide information about randomisation procedure, random allocation concealment, blinding of observers, or drop-outs [221].

2. Results

In the urodynamic study of ESlim versus MStim in men with DO, bladder capacity at first desire to void and maximum cystometric capacity increased significantly in both groups compared to baseline; the increase in maximum cystometric capacity was statistically significantly greater in the MStim (106%, SD 130) than the ESlim group (16%, SD 34).

ESlim and medication improved subjective parameters but only oxybutynin showed statistically significant improvements in objective urodynamic parameters such as bladder volume at first desire to void and at first overactive detrusor contraction [221].

3. Summary

There were few men in either of the two trials comparing ESlim and MStim, the single trial comparing ESlim with verbal/written instruction in PFMT, or single crossover trial comparing ESlim with oxybutynin. In the absence of sufficient data it is not known if ESlim is better than MStim or written/verbal instruction in PFMT or oxybutynin for UI in men.

d) Does the addition of ESlim to other treatments add benefit?

Four RCTs have been identified investigating the addition of ESlim to other treatments for men with post-prostatectomy incontinence [368,371,375,400] and are discussed under the PFMT section on post-prostatectomy incontinence. No studies of ESlim being added to other treatments for UI in men and women were identified.

3. OTHER LUTS

No studies were identified which addressed this comparison in men.

4. FACTORS AFFECTING OUTCOME

a) Age

There are no comparisons of the effects of ESlim for UI between younger and older men. While many ESlim studies include participants over 50 years most studies don’t include those over about 80 years [418]. In the studies of ESlim for post-prostatectomy incontinence in this chapter the mean age of men is about 66 years. Although post-prostatectomy studies have included older men it may be unwise to extrapolate the effects of ESlim in older men with UI to older men with UI, because in the former UI is usually as a result of sphincter incompetence whereas in the latter the symptoms are those of an OAB.

b) Other

Many other factors, such as types of electrodes, intensity, frequency and duration of stimulation, electrode positioning, the number of treatment sessions, diagnosis and underlying cause, participant selection, and treatment adherence are plausible factors affecting outcome. Little is known about the effect of any of these and there are no trials investigating these factors in males.

IV. MAGNETIC STIMULATION (MSTIM)

Background information about extra corporeal magnetic innervation, more commonly called magnetic stimulation (MStim), has been given in the section on MStim for women (see B5). MStim has also been used in men; it is unclear whether the mode of action and effects of MStim are similar in men and women. In men, MStim is used to treat UI after radical prostatectomy [401,419] and for the inhibition of DO [223].

The questions to be addressed are the same as those for women (see B5). Since the 4th ICI no further RCTs were found. Suzuki [2007] compared the effect of MStim versus sham MStim for UI in 39 individuals (23 females and 16 males). The study was not included in the review below because both groups also received PFMT, and data were not reported separately for men and women [263].
1. **PREVENTION OF UI**

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

2. **TREATMENT OF UI**

Three treatment RCTs were identified; two published articles [223,401] and one abstract of an ongoing study without data [419]. The first trial [223] included both men and women with UI; because the effects of MStim might be different between sexes (due to differences in the underlying aetiology of symptoms) this study has only contributed to the analysis where the researchers’ differentiated the effects of treatment in men and women.

a) **Is MStim better than no treatment, placebo or control treatment?**

No studies were found addressing this question.

b) **Is one approach to MStim better than another?**

No studies were found addressing this question.

c) **Is MStim better than other treatments?**

Two studies were identified [223]. Both compared MStim with EStim; the latter also compared MStim and PFMT. Readers are referred to section D.3.2c for a description of these studies, findings, and summary.

3. **OTHER LUTS**

No studies were found.

4. **FACTORS AFFECTING OUTCOME**

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. The relationship between age (or any other factor, such as treatment parameters, treatment adherence, or diagnosis) and the outcome of MStim has yet to be determined.

V. **SCHEDULED VOIDING REGIMENS**

Scheduled voiding regimens include bladder training, timed voiding, habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to indicate that scheduled voiding regimens, especially bladder training and timed voiding, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to the literature on their use in women.

1. **PREVENTION OF UI**

No trials investigating the preventive effects of scheduled voiding regimens for men with UI were found.

2. **TREATMENT OF UI**

Since the 4th ICI in 2009, there have been no new reports of bladder training that have included men. Of the five that have included men, most had only a small number of men in the sample [48,282,283,286,293]. Two observational studies, but no RCTs, were found regarding timed voiding. No studies were located that addressed habit training or prompted voiding in men.

a) **Bladder training**

A total of five RCTs involving 142 men met the criteria for inclusion in this review. All trials (previously described in section B6) had predominantly female participants; one RCT compared bladder training (BT) to BT plus caffeine reduction (seven men, 86 women) [48]; and three RCTs compared BT plus placebo drug versus anticholinergic drug therapy (six men, 28 women [293]; four men, 30 women [283]; two men, 58 women [282]). The largest RCT compared drug therapy alone (tolterodine) to drug therapy plus BT (123 men, 378 women) [286]. A sixth study was located that compared BT supplemented with drug therapy after three months, but it was excluded from review because the full length report was in Japanese and an English translation was not available [420].

As none of the trials reported outcome data separately for men, and with the proportion of male participants being so small (3%, [282]; 8%, [48]; 12%, [283]; 8%, [293]; 25%, [286]), there is insufficient evidence available to comment on the effectiveness of BT in men.

b) **Timed voiding**

No new trials were found on timed voiding. There are two clinical series that investigated timed voiding in men only [272,421]. In the first, timed voiding was initiated in incontinent men in a geriatric hospital [421] and in the other men with persistent post-prostatectomy incontinence [272]. Outcomes were measured by a two week voiding diary kept at baseline and during two weeks of timed voiding by patients diagnosed with SUI, UUI, and/or continual leakage.

1. **Quality of data**

Both studies used a clinical series design and patients in both subsequently received other treatment if they were not adequately improved. In the Sobbein study, nurses checked the patients’ clothing for wetness at each two-hour voiding interval and recorded the results. Data in the Burgio study were based on bladder diaries completed by the patients. Reasons for drop-out [421] and non-adherence [272] were provided.

2. **Results**

In one study an 85% improvement rate in UI was reported [421]. In the second, the two hour timed voiding schedule was used with only 12 out of 20 men, because they were either already on a voiding schedule, unwilling to go on a voiding schedule, or were noncompliant [272]. In five men with SUI,
there was a 29% decrease of incontinent episodes; in three men with UUI, two improved and one dramatically regressed producing a 33% increase in incontinent episodes. In four patients with continual leakage, there was no reduction in percentage of wet intervals.

3. **Summary**

With limited Level 3 evidence (and no higher order evidence), there is insufficient evidence available to comment on the effectiveness of TV in men.

3. **OTHER LUTS**

No studies were identified in men.

4. **FACTORS AFFECTING OUTCOME**

**a) Age**

No new trials were found addressing outcome. The five RCTs involving bladder training included older men, as well as women. Three specifically recruited adults aged over 65 years [282, 283, 293]. The largest trial recruited men with a median age of 62 years. There was no subgroup analysis related to age and gender effects, so it is not possible to draw conclusions regarding the effect of BT in older men [286]. Voiding regimens are of particular interest for the elderly, but some are effective in younger patients with UI [266].

**b) Other**

No studies were identified on other factors affecting outcome of BT or prompted voiding in men.

Individuals who appear to benefit most from scheduled voiding regimens are highly motivated without cognitive deficits. Men and women with SUI and UUI have benefited, whereas patients with severe sphincter damage (e.g. after radical prostatectomy) generally do not [Hadley, 1986].

4. **COMPLEMENTARY AND ALTERNATIVE MEDICINES**

Therapies include acupuncture, relaxation, meditation, imagery, hypnosis, naturopathic and herbal remedies, but only trials of acupuncture therapy have been found in men with UI. Therefore, only acupuncture will be considered in the remainder of this section.

Acupuncture is a traditional Chinese modality and has been used for the treatment of urinary disturbances. Acupuncture has been reported to relieve OAB symptoms including UI due to spinal cord injury [422], and idiopathic DO or MUI [423,424].

1. **PREVENTION OF UI**

No studies were identified on the preventative role of complementary therapies in men.

2. **TREATMENT UI**

Acupuncture may improve urodynamic parameters such as sphincter function [425,426] or bladder capacity in men with UUI (Honjo, 2000; Kitakoji, 1995). It is a form of somatic sensory stimulation [Bergstrom, 2000]. The mechanism by which acupuncture inhibits DO remains unclear, but suppression of the spinal and supraspinal reflexes that lead to detrusor contractions is considered one of the most important mechanisms [427,428] or release of endorphins [Bergstrom, 2000]. There has been no report on the effects of acupuncture for male SUI or post-prostatectomy incontinence.

**a) What is the most effective acupuncture protocol?**

Acupuncture has been carried out with disposable stainless steel needles (0.3mm in diameter, 60mm in length) inserted into the bilateral BL-33 points on the skin of the third posterior sacral foramina [422,423,429] or several other points (BL-31,32, 21, 23, SP-6, KI-3, LI-11,CV-1,2,4,5 ) [430], and usually performed once or twice weekly [422-424,429,431]. Acupuncture protocols vary and there is no apparent consensus between investigators. It is not known if any acupuncture protocol is more effective than another.

**b) Acupuncture versus no treatment, sham acupuncture or any other treatment**

No new studies were identified. Only one RCT has been identified including both men and women [432], but there is no study exclusively for men. In a randomised, placebo-controlled, single-blind study among 20 elderly patients (three males, 17 females) Ellis (1990) showed that the frequency of voiding at night was reduced after acupuncture. Uncontrolled studies suggest improved symptoms post acupuncture [422,423].

The evidence of the effectiveness of acupuncture for men with UI is limited by the lacked of controlled studies. To date, the studies are small, objective measures of UI are not included and long-term follow-up is lacking. Uncontrolled studies suggest that RCTs of acupuncture in the treatment of UI in men are warranted.

3. **OTHER LUTS**

No new trials were found in this category. In the one trial in men with sensory urgency after TURP [431] a significant improvement was reported by acupuncture reflexotherapy (ESTim of somatic and auricular points) in terms of IPSS, QOL scores, decrease of daytime frequency and nocturia, but no improvements with the use of placebo or oxybutynin.

4. **FACTORS AFFECTING OUTCOME**

Aside from Ellis [1990], reported above, who specifically recruited elderly participants there is a lack of...
evidence about the effect of any prognostic factor for the outcome of complementary therapies in men.

VII. SUMMARY

Despite the prevalence of UI and LUTS in older men, the only group that has received much attention in research is men following radical prostatectomy. Overall, the effect of conservative treatment (lifestyle interventions, physical therapies, schedule voiding regimes, complementary therapies) for men has received much less research attention compared to women.

1. RECOMMENDATIONS FOR PRACTICE

There is generally insufficient Level 1 or 2 evidence on which to base recommendations for practice, and most recommendations are, in effect hypotheses, that need further testing in research.

Lifestyle interventions

• It seems reasonable for health professionals to offer men advice on healthy lifestyle choices that may reduce or delay the onset co-morbid conditions that are risk factors for incontinence (Grade of Recommendation: D) (Unchanged).

Pelvic floor muscle training (PFMT)

• Some preoperative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful (Grade of Recommendation: B) (Unchanged).

• It is not clear whether PFMT taught by digital rectal examination (DRE) offers any benefit over and above verbal or written instruction in PFMT (Grade of Recommendation: B) (Unchanged).

• The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference (Grade of Recommendation: B) (Unchanged).

• Use of a strong pelvic floor muscle contraction immediately after voiding, or urethral massage to empty the urethra, can improve symptoms of post micturition dribble (Grade of Recommendation: C) (Unchanged).

EStim (EStim)

• For men with post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme (Grade of Recommendation: B) (Unchanged).

2. FUTURE RESEARCH DIRECTIONS

There is much scope for research on the effects of conservative therapies for UI and LUTS in men. Research that is urgently needed, in the opinion of committee members, is highlighted with the use of italics. There are a few recommendations that apply to all future studies in men, namely:

• All future intervention studies must be designed to allow standardised and comprehensive reporting of results based on the ICS and CONSORT recommendations.

• The natural history of UI after radical prostatectomy must be taken into account in study design as the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.

• More research is needed to find out what are the most important outcomes for men with UI, so such measures can be incorporated as the primary outcome measures in further trials.

• Data are needed to establish the cost, and cost effectiveness, of conservative therapies in men with UI.

• Surgical approaches with laparoscopy or robotics offer promising improvements in visualisation for nerve-sparing procedures; further research should address continence and erectile function after these newer surgical procedures.

a) Lifestyle interventions

• To date, no trials have addressed the topic of lifestyle interventions for men with UI.

• The effects of interventions such as weight and caffeine reduction, both of which show some evidence of benefit in women, are priorities for future research.

b) Pelvic floor muscle training (PFMT)

• Further studies to test the hypothesis that preoperative proprioceptive training plus PFMT is more effective than PFMT alone to prevent UI in men undergoing radical prostatectomy.

• A comparison of preoperative versus postoperative PFMT verbal and written feedback to reduce prevalence and severity of UI following radical prostatectomy is needed.

• Methods of PFMT instruction and supervision require further investigation. Two areas of research interest are:

  o Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction.

  o The effect of group exercise. Because of the peer support that men may receive from participating in a group [433] this might be useful after radical prostatectomy; three reported that support in the post operative period may be important to healthy recovery [368,371,391].
• More systematic investigation of the natural history of UI after TURP is needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

• The relationship between age, or any other factor, and the outcome of PFMT for UI in men has yet to be determined.

c) Electrical stimulation (EStim) and magnetic stimulation (MStim)

• It is not known if pre or postoperative EStim or MStim has a role in reducing UI after radical prostatectomy.

• RCTs in larger samples, with long-term follow up, are needed to investigate all aspects of the effectiveness of EStim and MStim as a treatment for UI in men, including:
  
  o Either type of stimulation versus no treatment, sham stimulation or other control conditions.
  
  o Comparisons of both EStim and MStim protocols.
  
  o EStim versus MStim.
  
  o Either type of stimulation versus medication.
  
  o Whether the addition of either type of stimulation to other treatments adds benefit, in particular the addition of stimulation to PFMT.

• The effect of age, and other factors, on outcome of stimulation. Elderly men may have more co-morbid conditions than young men and a more pragmatic approach to inclusion in EStim studies is needed.

d) Scheduled voiding regimens

In the absence of trials exclusively in men, or trials that report data separately for men and women, there is a pressing need for high quality RCTs with an appropriate sample size and long-term follow up to address the effects of BT, Timed voiding, habit training and prompted voiding in men suffering from UI.
APPENDIX 1

TERMINOLOGY

Pelvic Floor Muscle Therapy (PFMT): any programme of repetitious, voluntary PFM contractions taught by a healthcare professional. It is the PFM, not pelvic muscles in general, which are the target of the intervention. This broad definition accommodates variations in the PFMT end-goal, type of supervision (e.g. individual or group sessions) and the exercise programme (e.g. variations in frequency, intensity, number of contractions and duration of training). It may include the use of PFM contractions for urge suppression and to prevent stress leakage, under the term “the knack”.

PFMT is used in preference to other previously-used terms such as Kegel’s Exercises, pelvic floor exercises and PFM exercises. The term ‘Kegel’s Exercises’ is no longer appropriate because it refers to Kegel’s original exercise programme of 500 contractions per day (58). Current PFM programmes are very different from the one originally prescribed by Kegel (1948).

“Training” is also viewed as a more appropriate word than “exercise”. The term “exercise” is commonly interpreted as one training episode or a single muscle action, whereas, “training” encompasses repeated exercises over a sustained period of time.

APPENDIX 2

REVIEW OF THE LITERATURE/SEARCH TERMS

A systematic search of studies up to the end of August 2011 was conducted. Only papers published in English or in a language for which a translator could be found were included. Relevant systematic reviews and reports of RCTs and quasi-RCTs were included. Therefore, only Level 1 evidence is considered in this section and recommendations are based on the findings of existing up-to-date systematic reviews and more recent RCTs.

Several Cochrane reviews were critical to the rigour of the present chapter: UI prevention (96,170); management of urinary continence in women (97,126,213); management of urinary incontinence in men (412,416); management of pelvic organ prolapse (296,297); habit training and timed voiding (273,275); and bladder training (269). Pre-specified outcomes of interest were urinary continence (for prevention studies), urinary continence, patient symptoms, quality-of-life measures and pad tests (for treatment studies).

Data for SUI were taken from a recent UK Health Technology Assessment (HTA) on non-surgical interventions for stress urinary incontinence in women (219). This was supplemented with additional studies for SUI completed after publication of this HTA, and studies for UUI and other LUTS, located through additional literature searching conducted in the Cochrane Incontinence Group Specialised Register as part of an ongoing Cochrane review. The same methods used in the HTA for data collection and analysis for SUI were applied to the studies on UUI and LUTS.

Criteria for inclusion were (1) randomised or quasi-randomised (alternate allocation) trial study design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women. Retrospective data was not included. ‘Risk of bias’ in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group (220). Risk of bias due to blinding to the allocated intervention should be considered to be high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

The Consort Statement Checklist was used to determine the quality each study (434). Empirical evidence indicates that two elements of trial quality, allocation concealment and double blinding, are important for estimating treatment effect with precision. Trials with inadequate or unclear concealment of allocation appear to overestimate treatment effect by about 30% and trials that are not double-blinded overestimate effect by about 15% (435). Therefore, trials that reported adequate allocation concealment have been noted. Although it is often difficult or impossible to blind patients to PFMT, trials that reported blinding of the outcome assessment have also been noted. Readers may wish to consider these factors in their interpretation of the data.

The search terms may be seen at http://hdl.handle.net/10402/era.26262. (Click on the “download” link, top right.)

I. INTRODUCTION

Surgery for male incontinence is an important aspect of treatment with the changing demographics of society and the continuing large numbers of men undergoing surgery and other treatments for prostate cancer.

Basic evaluation of the patient is similar to other areas of incontinence and includes primarily a clinical approach with history, pad testing, frequency-volume chart or bladder diary, and physical examination. Since most of the surgeries apply to patients with incontinence after other operations or trauma, other investigations such as radiographic imaging of the lower urinary tract, cystoscopy, and urodynamic studies may provide important information for the treating clinician.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment is indicated following similar strategies applied in post-prostate cancer treatment incontinence i.e. slings and artificial urinary sphincter (AUS).

Radical prostatectomy for prostate cancer is performed far more frequently now than 15 to 20 years ago, with nearly two-thirds of surgical cases being performed via the robotic-assisted laparoscopic approach in the United States [1]. Approximately 5-25% of patients will experience incontinence that fails to improve with conservative management, and a substantial minority will ultimately undergo surgical treatment [2]. The AUS has provided a satisfactory result in most cases, regardless of the degree of urinary incontinence, with a positive impact on quality of life. Sling procedures have emerged as an efficacious treatment in the majority of men with mild to moderate stress urinary incontinence, however, they have not proven predictably successful in men with higher degrees of incontinence. Injectable agents have not shown durable long-term results. Volume adjustable balloons have been limited in their utility due to a high complication rate. Newer techniques involving adjustable urethral slings have demonstrated efficacy similar to that of non-adjustable slings, with the potential advantage of postoperative alterations in sling tensioning (tightening) but a higher complication rate.

Stratification of treatment based on the degree of stress incontinence is now feasible. Men with milder degrees of incontinence and normal bladder function are candidates for either artificial urinary sphincter placement or sling surgery, each with similar success rates. Sling surgery appears to have a lower risk of surgical complications in this population. Patient preference may be for a sling versus a mechanical device [3]. On the other hand, with more severe incontinence, AUS surgery has a more predictable success profile than does sling surgery.

Incontinence following radiation therapy, cryosurgery, high-intensity focused ultrasound, other pelvic operations and trauma is a particularly challenging problem because of tissue damage inside and outside the lower urinary tract. In such instances, periurethral bulking, sling procedures, and inflatable periurethral balloons have generally proven inefficacious and worsening of incontinence may happen after such surgery. The AUS is the most successful surgical procedure in this setting, but is associated with a higher rate of complications compared to implantation following surgery in the absence of adjuvant cancer therapy. With tissue damage beyond the urinary sphincter, other surgical approaches may be necessary. Patients with unresolved problems from pediatric age and with associated incontinence from detrusor overactivity may benefit from a variety of complex reconstructive surgical procedures. Other complicated problems encountered include urethrocutaneous fistulae, and fistulae between the prostate, bladder neck, or urethra and rectum. Surgical reconstruction, in experienced hands, often in a staged manner, is usually successful.

With decades of worldwide use of the AUS in the surgical management of male incontinence, its complications and their management are well known. Durability of the device is an important aspect that impacts on outcome and cost of treatment. A growing body of literature regarding male sling surgery, its indications, factors affecting outcome, and complications and their management,
has changed the landscape of incontinence surgery over the past 5 years.

Although the literature is replete with well-done cohort studies, there is a continuing need for prospective randomized clinical trials, especially needed for adequate comparisons among surgical techniques.

**MATERIALS AND METHODS**

The committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Third Consultation [4] for non-neurogenic male incontinence. Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the committee and included in the chapter.

The incontinence problems were classified according to their etiology, i.e. either primarily sphincter or bladder related, and are listed in Table 1. Treatment of fistulae is covered separately.

Specific recommendations are made on the basis of published results and determined by the levels of evidence. Consensus of the committee determined the recommendations, which are found at the end of the chapter. Recommendations for future research are also included.

### II. EVALUATION PRIOR TO SURGICAL THERAPY

Recommendations for evaluation prior surgery have not changed substantially from the last edition in 2009 [5]. A basic history and physical is the cornerstone of this evaluation. The history should focus on the precipitating events (surgery, trauma, etc) that led to the incontinence, the evolution over time of the leakage symptoms (has there been improvement, etc), what precipitates the leakage (straining, cough, exercise, etc – suggestive of stress urinary incontinence (SUI) or the sudden onset of urgency, the sense of needing to void immediately, particularly in the absence of any physical activity – suggestive of urgency incontinence) as well as other potential comorbidities. A general sense of the degree of bother of these symptoms, sexual function and pad use is important as well. The physical examination should note any gross urine leakage per meatus with patient straining or coughing as well as general characteristics of the lower abdomen, perineal area and penis and scrotum. Assessment of hand function is important to assess manual dexterity for manipulation of an implanted device. A brief neuro-urological examination (perineal sensation, anal tone, voluntary contraction and relaxation of the anal sphincter, bulbocavernous reflex [6]) should be performed. A urinalysis to rule out infection or signs of inflammation or hematuria should be obtained.

A frequency-volume chart [7], or bladder diary (indicating daytime and nighttime frequency of micturition, incontinence episodes, voided volumes, 24-hour urinary output, etc.) is also helpful. According to Wyman et al. [8] the 7-day diary can be considered as the gold standard for voiding diaries. Schick et al. [9] demonstrated that a 4 day frequency-volume chart gives a reliable snapshot of the patient’s situation. A pad test quantifies the severity of incontinence and may be the most objective measure of the incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis of urinary incontinence because it is the most reproducible. [10] The 1-hour pad test may be used because it is easily done and standardized, however there is no strict

parallel with the 24-hour pad test and it may underestimate the weakness of the sphincter in the later part of the day. A pad test may be helpful in quantifying leak in AUS failures.

The ICIQ-SF (short form) questionnaire (www.iciq.net) can be recommended for the assessment of the man’s incontinence, and has been used in RCTs of treatment for post prostatectomy incontinence.

Postvoid residual urine measurement is a good estimation of voiding efficiency [11,12]. These basic investigations are recommended in incontinent males prior to surgical therapy.

Blood testing (BUN, creatinine, glucose) is recommended only if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented by the frequency-volume chart [13].

Further evaluation should be adapted to the particular patient. Cystourethroscopy will verify the integrity of the urethral wall (anterior aspect of the distal sphincteric mechanism in post-TURP incontinence [14], erosion by the cuff of the artificial sphincter), and the status of the bladder (trabeculation, stone, diverticula, etc). It will allow observation of the urethral sphincter and voluntary contraction on the part of the patient, if done under local anaesthesia. The presence or absence of urethral, prostatic, or bladder neck stenosis is also necessary to ascertain prior to incontinence surgery, especially in patients who have undergone treatment for prostate cancer.

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of incontinence following artificial sphincter implantation when during the original procedure the hydraulic system was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons [15].

Figure 1 illustrates the case of a young spina bifida patient in whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Second KUB compared to previous one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is suspected [16], e.g.: following abdominoperineal resection of the rectum. Cystourethrography may be used to demonstrate a fistula, stricture or urethral diverticulum e.g., following healing of the urethral wall erosion caused by the cuff of the artificial urinary sphincter (Figure 2). Ultrasound is widely used not only to evaluate the upper urinary tract, but also to evaluate postvoid residual urine. The sensitivity of 66.7% and specificity of 96.5% when post-void residual is 100 ml or more is adequate for routine clinical use [17]. It has been shown to be cost-effective when compared to catheterization [18]. Other modalities, for example transurethral ultrasound [19] and magnetic resonance imaging of the external sphincter are still under development.

URODYNAMIC TESTING

Urodynamic studies (UDS) have traditionally been performed in men under consideration for invasive treatment in order to assess Valsalva Leak Point Pressure (VLPP), detrusor overactivity and bladder compliance. However, there are now several studies, which call into question the use of routine UDS in men with pure SUI. These studies will be commented on at the end of this section.

When performing UDS there are specific issues that must be considered. In patients with incontinence secondary to radical prostatectomy who developed bladder neck stenosis, the urethral catheter can create obstruction giving false values for Valsalva leak.
III. INCONTINENCE AFTER RADICAL PROSTATECTOMY FOR PROSTATE CANCER

1. INCIDENCE AND PREVALENCE

Urinary incontinence occurring after radical prostatectomy (RP) is a substantial problem. Despite improvements in continence preservation [59] during the 1990’s and 2000’s primarily due to a better overactivity and/or decreased compliance during bladder filling. It can be coupled with fluoroscopic imaging, video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound [39,40]. Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry [41] but at present its use is controversial [42].

Non-invasive pressure-flow urodynamic evaluation based on Doppler ultrasound seems to have potential for diagnosing bladder outlet obstruction [43]. However invasive pressure-flow studies are still the gold standard in the incontinent male to rule out bladder outlet obstruction accompanied by detrusor overactivity [44] which in turn can cause incontinence.

In most recently published studies, urodynamic testing has been done prior to surgery [45-49]. Cystoscopy is frequently done as well [48,50-54]. However, as noted above, there are some reports that question the value of urodynamics studies in predicting outcomes after surgery. Thiel et al. [55] found no evidence that patients with detrusor overactivity, early first sensation of filling, decreased compliance or low bladder capacity had worse outcomes after artificial sphincter placement in 86 men. Trigo Rocha et al. [56] also found that preoperative urodynamic findings such as detrusor overactivity, impaired detrusor contraction, low Valsalva leak pressure, bladder outlet obstruction, and mildly reduced compliance did not lead to a poor outcome after artificial sphincter implantation. Ballert et al. [57] studied the association between preoperative detrusor overactivity and postoperative outcome after male sling surgery and found no difference in the number of pads used post-operatively. Preoperative detrusor overactivity was not associated with worse postoperative outcomes. Finally, Lai et al. [58] reviewed 129 patients with post-prostatectomy incontinence, all of whom had multichannel videourodynamics, and noted that the presence of adverse preoperative urodynamic features (such as detrusor overactivity, early sensation of desire to void, reduced cystometric capacity of <200cc, low abdominal LPP <30 cm H2O, low maximum flow <10cm H2O and poor bladder contractility) did not negatively affect the continence results after AUS implantation.

The proposed evaluation of the incontinent male is summarized in Table 2.

point pressure (VLPP). Sphincter weakness can be documented by the Valsalva [20] or cough or abdominal leak point pressure [21]. Catheter size seems to have a significant influence even with a small size 7-F urethral catheter [22], and the correlation is extremely high between the test-retest leak point pressure when the same size of catheter is used [23,24]. In male patients, abdominal leak point pressure may be evaluated via a rectal catheter because a urethral catheter is much more likely to invalidate VLPP measurements than it does in female [25]. It has become evident that bladder volume influences VLPP, i.e. it decreases with bladder filling [26-28]. However, this observation is not consistent [29]. Unfortunately, there is no agreed standardization of the technique at the present time which somewhat limits its usefulness [30]. Measurement of leak point volume may also provide information on the functional capacity of the bladder [31].

Retrograde leak point pressure has been used to study incontinence following placement of an artificial sphincter [32,33]. It correlates with the lowest abdominal leak point pressure [34]. The intraoperative use of this technique has been proposed and this allows early recognition of intraoperative urethral injury and mechanical malfunction [35]. Intraoperative retrograde perfusion sphincterometry may be helpful to determine the appropriate tension on male slings [36]. Similarly, others have utilized repeated intraoperative abdominal leak point pressure (ALPP) measurements to adjust the tension for male slings [37]. Electrophysiologic studies, mainly sphincter electromyography, may be useful to document denervation of the pelvic floor when nerve injury or neuropathology is suspected [38].

Detrusor function is best evaluated by multichannel urodynamics. Its main purpose is to detect detrusor overactivity and/or decreased compliance during bladder filling. It can be coupled with fluoroscopic imaging, video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound [39,40]. Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry [41] but at present its use is controversial [42].

understanding of the pathophysiology and improvements in surgical technique, continence rates have generally plateaued over the past decade. As RP has continued to increase in popularity as a treatment for prostate cancer, especially with the advent of robotic-assisted surgery, the prevalence of post prostatectomy incontinence (PPI) has increased in developed countries, which has led to an overall increase in the number of patients affected.

Data from large multicenter studies and prostate cancer databases suggest that following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of post prostatectomy incontinence (PPI) depends on the definition of urinary incontinence and the length of follow-up. [60–62] In addition to numerous definitions of incontinence, the tools used to evaluate incontinence vary from self-administered validated and non-validated questionnaires, to interviews from a data manager, to response to the surgeon's inquiry, to insurance database inquiries regarding secondary surgical procedures. It should be noted that SUI also affects men who have not had surgery for prostate cancer, occurring at a baseline prevalence of 1.3%–4.8% [63,64]. In addition, men with prostate cancer who choose radiation therapy, androgen ablation, or even watchful waiting also develop urinary incontinence, recently reported at rates of up to 12%, 11%, and 3%, respectively [65,66]. In addition to urinary incontinence, bothersome lower urinary tract symptoms may affect patients following any treatment (or even watchful waiting) for prostate cancer.

Typically, reports of large cohorts use definitions that include “total control/perfect continence/dry”, “occasional leakage but no pad”, and “less than one pad”. Because 1/3 to 1/2 of men who do not wear pads will have occasional leakage of urine [60,67] it is important to distinguish among those men who leak enough to require pad use versus those who do not, as it has been demonstrated that health related quality of life (QOL) is strongly correlated with the level of incontinence. Wearing one pad, even if this pad is considered “a security pad”, more significantly affects the quality of life than wearing no pad at all [68,69]. In addition, not all men who leak will elect to have further treatment. Most large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery. [70–73] Several large cohort studies are listed in Table 3 [62,67,69,74–92].

Another bothersome type of incontinence occurring during orgasm in men post-prostatectomy has been termed 'climacturia' and may significantly affect the quality of men with post-prostatectomy potency [93].

2. RISK FACTORS

Reported risk factors for incontinence following radical prostatectomy include patient age at surgery, socio-economic status, preoperative continence status, obesity, pre-surgical bladder dysfunction, stage of disease, surgical technique (including nerve sparing, bladder neck preservation, and posterior reconstruction of Denonvilliers' musculofascial plate, anterior periurethral suspension sutures [94,95], prior radiation therapy, preoperative length and intraoperative preservation of the membranous urethra, prior transurethral resection of the prostate (TURP), postoperative radiation or cryotherapy, and vascular comorbidities. However, various studies have come to conflicting conclusions regarding the importance of specific risk factors. Predisposing factors contributing to incontinence after TURP have been less clearly defined, probably because the incidence is so low, (and the plethora of minimally invasive therapies is reducing the popularity of TURP surgery), making the accumulation of large prospective series of this type of incontinence difficult. However, previous external beam radiation and prior brachytherapy does predispose to post-TURP incontinence (Section VII in this chapter).

Pre-operative urinary incontinence has been reported as a risk factor for post-operative SUI. While pre-operative lower urinary tract symptoms, including
Table 3: Continence rates after radical prostatectomy according definition of continence, Definition 1: total control without any pad or leakage, Definition 2: no pad use but loses a few drops of urine, Definition 3: use no or one pad per day.

RRP: radical retropubic prostatectomy; RPP: radical perineal prostatectomy; LRP: Laparoscopic radical prostatectomy; Rx: radiotherapy; RALP: robotic assisted laparoscopic prostatectomy
urgency incontinence and “overflow incontinence” may improve with de-obstruction secondary to ex-tirpative surgery [96], pre-operative SUI does not improve following RP. Several recent cohort studies have demonstrated that pre-operative sphincteric insufficiency (demonstrated either the pre-existing clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts post-operative SUI. [97,98] Pre-operative bladder dysfunction can also contribute to post-operative incontinence. Pre-existing abnormalities of detrusor function may predispose to leakage following surgery, especially in the setting of neurogenic detrusor overactivity due to Parkinson’s disease, dementia or spinal cord injury. [99]

Advancing age as a risk factor is supported by several studies [73,96,100-106]. Steiner, et al found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older [107]. Others have found advancing age and the number of co-morbidities to have a negative impact on the recovering time for continence during the first year after radical prostatectomy [108] although the rate at one and two years did not seem to be significantly affected [109]. Mohamad and colleagues reviewed 16,524 patients who underwent RRP in public hospitals, covering 95% of all procedures in Austria between 1992 and 2003. They found that increasing age was associated with an increased risk of future AUS implantation. In those aged 45-49, 0.5% were bothered enough by PPI to merit AUS placement, while those age 70-74 were five times as likely to undergo AUS placement for PPI.[110] Similarly, Rogers et al. demonstrated that age affected post-operative continence status following laparoscopic RRP. In those ≤ 50 years old, 100% achieved 0-1 pad per day continence at 1 year, which decreased to 91% and 81% for those age 50-59 and > 60 yrs, respectively (p<0.01). [111] Nilsson et al. [112] reported that age at surgery predicted in an exponential manner the long-term risk for urinary incontinence, with an estimated relative increase of 6% per year.

In addition to age, overall well-being has also been related to the risk of PPI. For example, a recent study out of Italy demonstrated that both age and Charlson comorbidity index were independent predictors of return to urinary continence [105]. It is especially interesting to note that in this particular cohort study, there were no variables related to the prostate cancer itself that were significantly correlated with urinary continence. A large study from Sweden recently demonstrated that in addition to age as a risk factor (relative risk of 2.4 between the oldest and youngest quartiles), educational level also impacted incontinence, with low educational level, as compared with high education level, being associated with a 2.5 time risk of incontinence[112].

Obesity, especially when coupled with physical inactivity, appears to be a risk factor for PPI in men undergoing RRP. Obesity with a BMI >30 was reported as a risk factor with an incontinence rate of 25.8% versus 8.7% in BMI <30 in a series of 252 men after RRP [113]. Wolin, et al. demonstrated that greater than one year after surgery, obese men were markedly more likely to have urinary incontinence (defined as any pad use) than were non obese men, while this risk was exacerbated by sedentary lifestyle, and ameliorated by at least 1 hour of physical activity per day (preoperatively). Nonobese active men were 26% less likely to have urinary incontinence than obese inactive men. In obese men who were physically active, the relative risk of urinary incontinence was 15% less than in the inactive obese men [114].

Most large series have found no correlation between the stage of disease and incontinence rates [101,102,115-117] Loeb and colleagues specifically demonstrated excellent continence rates even in high risk (high local stage) patients. [118] However, in certain cases, the stage of disease may affect the surgical technique (i.e. nerve sparing) and incontinence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage [103]. Yang et al reported that neoadjuvant hormonal ablation was associated with a lower risk of urinary incontinence, and while patients with higher stage disease may have been more likely to receive hormonal ablation pre-operatively, it is not clear that stage of disease was an important risk factor [106].

Regarding surgical technique, the many parameters involved in continence may explain difficulties in understanding the benefit of certain technical points. Bladder neck preservation has been reported to improve continence at 1 month [119] and at 3 months [116] but no difference was found at 6 and 12 months [120,121]. Nerve sparing has no significant impact according to Steiner et al. [107] and Lepor and Kaci [76]. Recently Pick et al. reported that nerve sparing, whether unilateral or bilateral, did not affect continence rates following RALP [122]. Others did find benefit [97]. In particular, Nandipati and colleagues reported that in a cohort of 152 patients followed prospectively, bilateral nerve sparing surgery was associated with a shorter time to regain continence as well as improved long-term continence rates compared to non-nerve sparing surgery. They additionally found that increased age was a risk factor for post-prostatectomy incontinence [123]. Burkhard, et al. similarly demonstrated a positive effect of nerve-sparing surgery on post-operative continence. In a prospective cohort study of 536 patients, PPI developed in 1/75 (1.3%), 11/322 (3.4%), and 19/139 (13.7%) with attempted bilateral, attempted unilateral and without attempted nerve sparing, respectively. Attempted nerve sparing was in fact the only statistically significant factor influencing urinary continence after RRP in this cohort [124]. Two recent reports have linked pre-operative sexual function with post-operative continence. While those who are sexually active pre-operatively may be more likely to have
their cavernosal nerves spared during surgery, it appears that the pre-operative status has a significant effect on post-operative continence rather than the nerve sparing technique [119,122,125].

Within the last decade, laparoscopic and robotic-assisted laparoscopic radical prostatectomy have become standard treatments for men with prostate cancer. Over the past 4 years, the body of available data on post-operative continence has generally demonstrated no obvious differences in continence rates between open and laparoscopic/robotic approaches. Several studies have compared the techniques either prospectively in non-randomized fashion, [85,86,88-91,126,127] or via limited meta-analysis [84,128] and similar continence rates were found. Further prospective comparative studies with open surgery are needed. Currently, a multicenter prospective comparative study of robot assisted laparoscopic and retropubic open radical prostatectomy is underway, with an accrual goal of 2100 patient, with the primary objective of comparing rates of urinary incontinence at 1 year post-operatively [126].

Perineal prostatectomy is done by only a limited number of urologists but is still advocated for markedly obese patients and the continence rate was reported as similar to the retropubic route [79,90,129,130].

3. PATHOPHYSIOLOGY

Post-prostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction or a combination of both. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated [129,131]. Urodynamics demonstrated that the sphincter incompetence occurs as the sole cause in more than two thirds of patients, while isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% [132-135].

Sphincter and bladder dysfunction can coexist in at least one third of incontinent patients. Bladder dysfunction may occur de novo after prostatectomy perhaps induced by bladder denervation; may be caused by outlet obstruction, or may be related to pre-existing factors such as age. Impaired detrusor contractility, which occurs in 29% - 61% of patients (de novo in approximately 47%), and poor compliance, which occurs in 8%-39% of patients (de novo in approximately half), have traditionally been thought to resolve in the majority of patients within 8 months [135,136]. However, two recent prospective urodynamic studies have demonstrated that decreased bladder compliance can occur in up to one-third of patients following RP, and persist in 28% at 36 months, while detrusor underactivity can occur in half of the patients, and persist in 25% at 36 months [136,137]. Decreased sphincter resistance may be due to tissue scarring in some cases and reflected by a low urethral compliance, however this parameter is difficult to measure [132]. Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography, and is clinically suspected when both incontinence and decreased force of stream coexist.

The pre-operative length of the membranous urethra determined on MRI has been shown to be significantly related to time to post-operative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at one year, versus 77% with or less than this length [138]. Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence [97,139,140]. A recent elegant study of intraoperative stretched urethral length (from the urogenital diaphragm to the prostatic apex with cephalad retraction) and cut urethral length (length of preserved urethral stump) during RALP revealed that although in this cohort, MRI urethral length did not correlate well with continence, the intraoperative measurements correlated significantly with time to continence [141]. Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence as well as the extrinsic component responsible for active continence may be involved as has been demonstrated in a urodynamic alpha blockade test [142]. This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Post-operative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory functions [143,144]. In clinical practice, urodynamic evaluation of a urethral weakness may be assessed by resistance to antegrade leakage (ALPP or VLPP), retrograde leakage, or profilometric measurement (MUCP) [145]. However no such parameters have been correlated to outcomes of treatments for the correction of post-prostatectomy incontinence.

The state of a patient's pelvic floor may also influence continence or return to continence after RP. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the post operative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal [146,147]. Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. Another study showed that providing patients with instructions for pelvic floor muscle exercise alone was equivalent to biofeedback or electrical stimulation [148]. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months [149]. On the other hand, a recent trial from Brazil did demonstrate significant difference in 12-month continence rates, quality of life, and lower urinary tract symptoms in general when randomizing patients to biofeedback-
pelvic floor muscle training versus verbal instructions alone [150]. Studies in which physiotherapy was used as a treatment modality for established incontinence have shown more variable results [151-154]. A recent randomized trial of formal one-to-one pelvic-floor muscle training versus advice alone for incontinent men 6 weeks after RP failed to demonstrate any difference in continence rates at 12 months. Nor did the physiotherapy improve SUI after TURP [155].

No medical treatment is available to cure postprostatectomy incontinence. Duloxetine at 60 mg per day could improve mild or moderate incontinence but half of the patients had some side effects and 25% stopped the treatment because of adverse effects in two short non-randomized series. This treatment is not approved in many countries and could be only a treatment option to improve symptoms in selected patients informed of side effects [156].

4. SURGICAL AND MINIMALLY INVASIVE TREATMENTS

a) Urethral Bulking Agents

Urethral bulking is a minimally invasive treatment proposed for post prostatectomy incontinence, and theoretically works by adding bulk and increasing coaptation at the level of the bladder neck and distal sphincter. It can be done in an office or outpatient setting in a retrograde or antegrade fashion. Several different agents have been used for urethral bulking in men including bovine collagen (Contigen®), silicone macroparticles (Macroplastique®), ethylene vinyl alcohol copolymer (Tegress®), Dextranomer hyaluronic acid (Deflux®), and carbon-coated zirconium beads (Durasphere®). All agents share the similar problems including the need for multiple injections, deterioration of effect over time, and very low cure rates.

For collagen, “success rates” for post-prostatectomy incontinence ranged from 36-69%, with 4-20% of patients reporting being dry [157-164]. Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections were required to achieve modest rates of subjective improvement. There was no advantage of delivery technique (retrograde vs. antegrade). Several authors identified factors which negatively affect results include extensive scarring or stricture formation, previous radiation, and high grade stress incontinence and low ALPP [158,160,161,164]. One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% ‘social continence’ versus 62.5%) [161]. It appears that collagen injection did not adversely affect outcomes of artificial sphincter implantation and did not increase the complication rate [165]. Nor did collagen injection adversely affect the outcome of the bone-anchored male sling (BAMS). [166,167] The cost efficacy of injections remains to be determined. Collagen is no longer available as an injectable agent.

Other bulking agents such as polymethylsiloxane (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1,3,6, and 12 months respectively [168]. They also noted that a urethral closure pressure of at least 30 cmH2O was essential for success. Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving short-term continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was limited to 3 months.[169] In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the majority had SUI following BPH surgery, with more than1/3 of the cohort suffering from SUI following RRP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52]

With regard to the newer (not FDA approved for male SUI) injectable bulking agents, dextranomer hyaluronic acid has been reported in men with PPI and in men with neurogenic ISD. Four of four patients with PPI failed to improve, and 1 of 2 neurogenic patients (both with detrusor areflexia, wet between catheterizations) failed [170]. With ethylene vinyl alcohol copolymer (Tegress®) in a report by Hurtado et al., not only was the failure rate high, but also the complication rate was unacceptable. In 17 men, who averaged 1.4 injection sessions followed at a mean of 4 months, 10 had complications, with erosion of injected material in 41.1%, and with only a minority of patients achieving a 50% decrease in leakage [171]. Tegress® has been withdrawn. Carbon-coated zirconium beads have been similarly reported to be inefficacious, with a recent report of 8 men with mild to moderate incontinence receiving a relatively large average injected volume (23.8 ml), none of whom achieved subjective or objective cure [172].

There has been interest in the use of autologous muscle cells, stem cells, and fibroblasts as an injectable sphincter-restorative agent for PPI. Transurethral injection of living muscle stem cells to reconstitute the deficient urethral sphincter has been reported. Mitterberger and colleagues demonstrated a 67% continence rate at an average of 1 year follow-up in a cohort of men suffering from PPI who were treated with transurethral ultrasound.
guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies. An earlier report from the same group demonstrated that men with PPI achieved a 52% dry rate with injection of adult autologous stem cells, which was superior to a similar cohort of men treated with collagen injection. However, it must be pointed out that there was a retraction issued by the editors of The Lancet for a previous article on the treatment of female SUI with autologous cells published by the same group. The project was investigated by the AGES PharmMed, a department of the Austrian Government’s Agency for Health and Food Safety. The editors stated that in their view “the conclusions of the official investigation pinpoint so many irregularities in the conduct of their work that, taken together, the paper should be retracted from the published record.” Current research has focused on the relatively abundant adipose derived stem cells, which are believed to be easier to harvest (higher yield) than are autologous bone-marrow derived stem cells.

**b) Male Sling**

The male sling procedure is based upon the concept of urethral support and external urethral compression, and has established itself as an accepted and efficacious treatment for PPI. The male sling is actually based on the concept similar to that described by Kaufman and associates in the early 1970’s. At that time a high rate of failure, septic complications and pelvic pain as well as the advent of the mechanical artificial urinary sphincter (AUS) led to the abandonment of the Kaufman prostatectomy. Now with the higher prevalence of PPI and patient desire for less invasive surgery and a non-mechanical device the concept has been revisited. Procedures have been developed based on principles used to treat female stress urinary incontinence. These procedures rely on compression from the ventral side of the urethra rather than the circular compression caused by a natural or artificial sphincter. Therefore, most successful sling surgeries rely on a device that is placed under tension, occluding the urethra at rest, and during stress manoeuvres.

Schaeffer and Stamey described the bulbourethral sling which uses Dacron bolsters placed under the urethra, which are suspended to the anterior rectus fascia by sutures. Data on this procedure are limited to retrospective analyses from the two authors who described the procedure: it did not gain widespread popularity. In the initial report from 2 centers, 64 patients were included and 56% were “dry” and 8% “improved” at a mean follow up of 22.4 months. Almost one-third needed secondary tightening procedures and patients with radiation fared poorly. Subsequently, Clemens, et al reported a questionnaire-based study of 66 men from a single institution and 41% were cured and 51% improved but mean follow up was only 9.6 months. They also reported that the bulbourethral sling did not cause significant outlet obstruction.

The long-term efficacy of the bulbourethral sling was evaluated in 2005, where 95 patients were followed retrospectively at an average of 4 years post-operatively. With follow-up questionnaires returned by 71 patients, the authors found that patients who had undergone radiation, had worse outcomes with only 14% dry and 43% requiring 1 or 2 or fewer pads daily. Moderate to severe pain was reported by 12% of patients after 4 years. Patients who had not had radiation treatment had a cure rate of 42% and 72% used only 0-2 pads per day for mild leakage. Others have described a bulbourethral sling using a polypropylene mesh graft with or without a porcine dermis backing (presumably to reduce the risk of erosion) in two small studies of 9188 and 1653 patients cure rates range from 56-69% and failure rates from 22-25% at a mean follow up of 14 months. John described the bulbourethral composite suspension where porcine dermis is secured to the bulbospongious muscle and a 1 cm wide polypropylene sling is placed over this and passed through the retropubic space to emerge from two suprapubic incisions (similar to the tension free vaginal tape procedure in women). He reported a 69% cure and additional 6% improvement in 19 patients, with a mean follow up of 14 months. Eight intraoperative bladder perforations healed without complication.

Xu and colleagues described a bulbourethral composite suspension utilizing a suburethral polyester patch plus a narrow polypropylene tape passed from a perineal incision to a suprapubic incision. At an average of 28 months, 22 (85%) of 26 patients were successfully treated.

A common method of sling fixation involved use of bone anchors. The bone anchored male sling (BAMS) obviated the need for any suprapubic incision or suture passage and fixation. In 2001, Madjar, et al reported on 14 patients with post RP incontinence that underwent the procedure with a synthetic or cadaveric fascial sling. At a mean follow up of 12.2 months, 86% were “cured” wearing none or 1 pad. Comiter reported a 76% cure and 14% “substantially improved” rate in 21
men with post prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months 166. In a 2005 update, the same author reported that with a median of 48 months follow-up, 65% of patients remained pad free and 15% required 1 pad per day. [191] Urodynamic follow up in 22 men, revealed that the sling had no substantial effects on voiding function and no one was obstructed postoperatively [192]. Onur and colleagues reported on 46 men with a mean follow-up of 17 months (6-26) [193]. They used different materials for the sling (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis). Overall they reported 41% of patients dry and 35% improved (50% reduction in the number of pads). All patients in whom allograft or xenograft alone was used failed. A 24-month update revealed a patient satisfaction rate of 70% and a 74% improvement in leakage at a median of 24 months.194 Giberti et al195 reported that in 36 men followed for an average of 41 months, 62% were cured and 70% were satisfactorily improved. In the subset who had a synthetic sling implanted, a higher success rate was experienced, with 77% achieving cure. Complications included sling infection in 4.8%, and de novo detrusor overactivity in 7.1%. Carmel et al196 reported that at an average follow up of 36 months, in a cohort of 45 men with moderate to severe PPI, 78% were improved by pad use, 76% had dry ICS 1-hour pad tests, and 72% were satisfied or very satisfied. Infection occurred in 1 patient, and pain resolved in all patients by 12 weeks postoperatively.

However, the morbidity (infection, pubic bone osteitis, perineal pain) related to bone screws coupled with the emergence of effective alternatives has decreased the popularity of the InVance sling.

The transobturator (TO) male sling technique was introduced in 2004 [197] and has since become the most common type implanted for PPI, since the early reports of 2007. [49,197,198]. This approach relies more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than on direct compression of the urethral lumen.[199] Over the past few years, there have been several large case series reporting favorable outcomes. Cornu et al [200] followed 136 men with mild to moderate (< 5 pads per day) PPI for an average of 21 months following implantation of the TO sling. A 78% success rate (based on pad test) was achieved. Rehder et al201 reported their cohort of 118 men with mild to moderate SUI, with a 1-year success rate of 91% at 12 months. Bauer et al202 achieved a success rate of 76%, at a median of 27 months follow-up in 137 men with PPI. In contrast, Gill et al203 reported a subjective success rate of only 51% (PGI-I scale) and objective success rate of 60% (pad use) at a mean follow up of 9 months, and Cornel et al204 reported only 9% of men achieving total dryness at 1 year post-operatively, with a 46% improvement rate.

Membranous rather than bulbular placement of the sling was introduced with the Advance sling with the aim of relocating the urethra in a more proximal direction. However, the concept is controversial as patient anatomy and pathophysiologic modifications are complex. This type of sling surgery close to the membranous urethra requires a deeper dissection compared to bulb or perineal compression slings.

The I-Stop TOMS sling with four arms and a large surface over the bulbular urethra involves tensioning each corner of the sling. A prospective multicenter study [205] was recently published with 122 patients after minimum follow-up of 12 months for 84% of them, and showed a cure rate of 60% and improvement with only one pad per day in 20%. There were no erosions or acute urinary retention. Wound infection was reported in 2% and all resolved. An “inside-out” TO sling also positioned over the bulbular urethra206 was implanted in 173 men, of whom 49% were cured and an additional 35% improved at a median follow-up of 24 months [207].

In case of failure after sling surgery, no clear guidelines yet exist. Surgical options include repeat sling and balloon or artificial sphincter implant. More studies are needed to document results and predictive factors. With respect to “repeat” TO sling following previous sling failure, Soljanik et al208 reported a cohort of 35 men undergoing a second TO sling. Success rate at 6 months was 79% (46% dry, 33% improved), and was maintained at 76% at an average of 16.6 months, demonstrating that the TO sling may be an effective treatment for managing SUI after a prior failed sling surgery.

Two adjustable retropubic slings have been introduced, with the objective of overcoming potential problems of overcorrection or under correction of continence - the “Argus” [209] and the REMEEX210 slings. In a multicenter trial of the Argus sling in 48 patients211, a 73% continence rate and additional 10% improvement rate was reported after an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent incontinence as well as for urinary retention [211]. In an update reported of 47 patients after a mean follow up of 45 months, 66% were dry and 79% used < 1 pad per day [212]. Hubner’s group [213] reported similarly favorable results, with 79% of 101 men achieving dryness at an average of 2.2 years post-operatively. Thirty-nine per cent required adjustment (10% loosening, 29% tightening) at a mean of 104 days after surgery. Erosion or infection necessitated explantation in 16% at a mean of 1 year. A report from the Netherlands [214] revealed a 72% success rate for the Argus at a median follow up of 27 months. Outcome was
dependent on the degree of pre-operative incontinence, with surgical success in 92% of men with mild leakage (1-2 pads per day), 67% in men with moderate leakage (3-5 pads per day) and 67% in those with severe (> 5 pads per day) incontinence. Explantation was required in 11%, due to infection, erosion, sling rupture or pain. Bladder perforation occurred in 16%, and de novo urethral stricture requiring treatment in 12%. Dalpiaz et al. [215] reported less favorable results, with 79% of 29 patients achieving dryness and 76% satisfaction in the short term, but the dry rate and satisfaction rates deteriorated to 17% and 28% respectively at 35 months. Complications occurred in >80% of cases, with a 35% explanation rate, 14% de novo urgency rate, and a single instance each of urethral stricture and ureteral injury. In a retrospective cohort study of 16 men status post AUS explantation for erosion [216], who were treated with an Argus sling or repeat AUS, men receiving the AUS had a better outcome. Of those who underwent repeat AUS implantation, 63% were cured, and an additional 25% were improved, with only 12% failing. Notably 75% of the Argus patients failed to improve. In a prospective multicenter Phase II trial of the RE-MEEX adjustable sling, 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% reporting improvement over baseline158. More recent, but smaller studies have also shown promising results. Navalon Verdejo et al217 reported that 3 of 5 men were dry at an average of 1.4 months, with the other 2 patients experiencing marked improvement. Four of 5 patients experienced recurrent SUI, which was resolved after surgical re-adjustment via the varitensor. A study with lower success rates was reported from Spain with a cohort of 14 men at an average of 18.6 months postoperatively, 42% are dry and 33% are improved218. However, bladder perforation occurred intraoperatively in 29%, sling explantation was required in 21%, urinary retention occurred in 36%, and readjustment was necessary in 83%.

The newest iteration of the male sling is the VIR-TUE® Male Sling (Coloplast, Humlebaek, Denmark) an implantable, sub-urethral, permanent, non-absorbable support sling. The sling is a synthetic suburethral mesh of knitted, monofilament polypropylene that measures 5.5 cm x 7 cm, with superior and inferior extension arms. Quadratic fixation is achieved with both transobturator and supra-pubic components198. This hybrid sling is based upon the mechanisms of action of the TO sling and the BAMS, providing a broad area of urethral compression and achieving proximal relocation of the membranous urethra. The sling has been shown to increase the retrograde leak pressure in 22 patients from 33.4 to 68.8 cm water after tensioning intraoperatively [36].

Sling results are shown in Table 4 [45,46,53,184,187-195,209-211,219-222].

1. SLING COMPLICATIONS

Due to the small size of most reported cohort series of BAMS patients, the precise complication rate is 221 not known. However, reports from the largest cohorts of patients reveal an infection rate ranging from 0-6%, and a urethral erosion rate of 0-2% [46,191,221] Bothersome scrotal pain or numbness affects 16%-72% of patients post-operatively, but has been reported to resolve in nearly all patients by 3 months.[191,195] Postoperative urinary retention was reported in 2-12% of patients. In most cases, it was self-limited and resolved in within 2 weeks [50,194,196,222,223] or rarely required loosening after one month [46].

Infection of the perineal incision/mesh occurred in 3-12%. These infections usually required removal of the implanted sling. Some superficial infections were successfully treated with antibiotics. In men with postoperative mesh infections, 76% [19/25] required surgical explantation of sling [50,191,195,196,221,223,224]. The majority of infections occurred early, however late infections at 3 months and 1 year have been reported [50,196].

Urethral erosion is a well-defined complication in the female SUI population. It has not been frequently reported with BAMS, although theoretically it may be associated with infection necessitating sling removal in some patients [46].

Abnormal postoperative pain or paresthesia is thought to be from compression or intraoperative disruption of the perineal nerves, or from healing around the newly placed bone screws. This complication is difficult to characterize because there is no standard level of pain that is considered abnormal. While some series acknowledged that the majority of patients experience mild pain for 1-3 months after surgery [221], others reported only those with severe pain that required explantation of the sling [222]. The pain generally resolves within 3 months [191,193,196,221,223] although persistent pain beyond 3 months has been reported46,50. Sling removal has been reported in two patients for persistent pain [46,50].

De novo detrusor overactivity or urinary urgency has been reported at 1-14% of patients, and can be treated with oral anticholinergics when necessary. One patient required sling explantation due to this complication [50].

There is a report of early loosening of one of the bone screws [223]. This caused recurrent incontinence and required a second operation to replace the bone screw. Bone screw dislodgement can happen as a late complication and has been reported in 3 patients [191,225].

</table>
The most common complications reported with the TO sling are perineal pain and urinary retention and studies are needed to establish the best rate between success and side effects among different slings.

Pain beyond the normal perioperative period has been reported to affect 0-20% of patients, and urinary retention has been reported in 3-21% of cases. While incision or explantation for retention is rare, the need for catheterization can persist for up to 12 weeks [200, 201, 226], with rare instances of retention lasting longer than 3 months[203]. Less commonly experienced is wound infection, with only rare sling infection or erosion requiring explantation [204, 226, 227]. Unlike the BAMS, however, there are occasional instances of worsening incontinence following TO sling placement, which likely occur if the sling is not adequately fixed in position, and allowed to migrate proximally and posterior to the urethra, thereby exerting a pulling tension that opens the dysfunctional urethral sphincter [204,228].

Reported rates of recurrent incontinence following sling surgery are generally low [46,191,194,208], and it is unclear which patients are amenable to revision surgery. In theory, the adjustable slings are designed to allow increased sling tensioning via a simple adjustment of the tensioning mechanism silicone washer adjustment for the Argus [212], and varitensor adjustment for the REMEEX [229]. But the small sizes of the cohorts, and the limited follow-up of less than 5 years prevent meaningful comparisons of male slings and to the AUS at this time.

Permanent urinary retention is uncommon with male sling surgery, and may be avoided by excluding those patients with detrusor underactivity on preoperative urodynamics.[195,230,231]. However, a recent report from Han et al. [232] found no difference in postoperative residual or urinary retention when comparing 2 groups of men after sling surgery, one with preoperative normal contractility and one with impaired contractility.

2. PREDICTORS OF SUCCESS

Several cohort studies have demonstrated that prior radiation therapy is associated with diminished efficacy of the male sling, probably due to urethral fibrosis and inadequate urethral captation.[49,187,193,195,207,233-235] Bauer et al [236] recently published their results of a cohort of men undergoing TO sling placement, all of whom had adjuvant radiotherapy following RP. They reported that success was only achieved in 50% of the cohort (cure in 25%), and that only 46% of men reported they were satisfied with the surgical outcome. With respect to the BAMS, Giberti et al. [195] recently reported a markedly lower rate of success in men who had had previous pelvic radiation, with only 15% cure in those patients. The adjustable REMEEX sling also appears to have inferior success in radiated men (60%) compared to patients without radiotherapy (90.2%) [229]. Worsening of incontinence may also occur and patients must be informed of this, especially those with mild incontinence.

The use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material.[193, 195, 221, 237]. The treatment of male SUI with a suburethral sling requires tension that can only be maintained with the use of synthetic material. Pre-treatment severity of incontinence measured by the degree of leakage also appears to influence sling results. Several reports indicate that those with more severe leakage do not achieve similar continence rates when compared to those with milder leakage. [193, 195, 221, 224]. Fischer and colleagues were able to quantify, in prospective fashion, that leakage greater than 423 gm on pre-operative pad weight predicted an inferior outcome, compared to those men with less leakage on pre-operative pad weight test. [46] In their report, 62 patients with SUI were followed prospectively. All patients were rigorously evaluated with 24-hour pad test, urodynamics and validated incontinence questionnaires. Success was determined by the Patient Global Impression of Improvement. Overall, 36/62 (58%) of surgeries were successful at a mean follow-up of 15 months. The only preoperative predictive factor was 24-hour pad weight. If pad weight was less than 423 gm, there was a 6-fold greater success rate compared to those with a pre-operative pad weight of greater than 423 gm.

Finally, previous AUS placement and explantation predicts sling failure.[192,216,221]. However, it is not clear if this is directly due to the urethral fibrosis and poor urethral coaptability, and/or if those patients simply suffer from more severe incontinence, which interferes with successful sling surgery.

3. CONCLUSION

In the intermediate term, the male sling appears to perform well. Slings have surpassed the artificial sphincter as the most common surgical treatment for PPI. The European Association of Urology Guidelines has concluded that there is limited short-term evidence that fixed slings cure PPI, that men with severe incontinence, previous radiotherapy or urethral stricture surgery have poor outcomes and no sling is superior to other slings. Adjustable slings have limited evidence of efficacy. [238] However, in the UK, the National Clinical Guidelines Centre in The Management of Lower Urinary Tract Symptoms in Men has stated that implanted compression devices and slings can be
offered to men with SUI only within the context of a randomized clinical trial [239].

The best candidates appear to be those with lower and moderate degrees of incontinence, who have neither had previous radiation nor AUS placement. With non-circumferential urethral compression, the male sling appears to have a lower risk of urethral erosion and atrophy than does the AUS in the intermediate term. In men with mild to moderate degrees of SUI, or for patients demanding a less invasive procedure or non-mechanical device, the male sling has established itself as a viable alternative to artificial sphincter. When given a choice of surgery, patients have been reported to overwhelmingly choose the male sling over an artificial urinary sphincter. Kumar et al [3] reported that in men with moderate PPI (pad weight 100 to 400 gm/24 hours) who were recommended to receive an AUS or a male sling, 92% opted for the sling. Interestingly, even when the surgeon recommended an AUS for severe leakage (> 400 gm/24 hours), 25% still opted for the sling. While intermediate and long-term data support the BAMS as a durable treatment for PPI, longer term outcomes of the TO sling, pubourethral sling, and quadratic sling are unknown. (Level of evidence 3; Grade of recommendation C)

c) Adjustable Balloons

The adjustable balloon procedure is based upon the concept of passive compression of the urethra utilizing two balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial name ACTTM (Adjustable Continence Therapy) was originally conceived and developed for female stress urinary incontinence, and subsequently was applied to male incontinence. The proACTTM device was developed and reported in 2000 [240].

The device consists of a silicone elastomer balloon attached to an injectable titanium port via a silicone tube. A balloon is implanted on either side of the urethra, either under the bladder neck for post-radical prostatectomy incontinence, or under the verumontanum for post TURP-incontinence. The ports are located subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed under general or spinal anesthesia through a short perineal incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation, and then the balloon is pushed along inside the sheath. Fluoroscopic and urethroscopic guidance are used for the procedure. Transrectal ultrasound guided implantation [241] is a possible option. An isotonic medium with sterile water and contrast medium is prepared to fill the balloons with 2 ml during the initial procedure. Then, after a period of time, approximately one month, the balloons are topped up with 1 ml of this solution at each period (maximum filling is 8 ml) until continence is achieved. The adjustment of the filling are volume limited and are carried out step by step in order to obtain a pseudo-capsule surrounding the balloons and therefore to minimize the risk of urethral erosion or migration. Results from 8 prospective studies [48, 51, 242 - 247] reported are shown in Table 5. Of 170 patients reported by Hubner [242] and Lebret [51], one-third became pad free. In other studies

</table>
70% of patients utilized 0-1 pads daily [51,242-244]. Mean procedure time of 35 minutes was reported. Along with this improvement in pad use, there were parallel improvements in I-Qot quality of life score [51,242,243]. Based upon these trials, the mean number of post-operative adjustments of the balloon was 3 to 5, with some patients requiring 6 to 8 refillings. In an interesting comparison of the BAMS and ProACT, Crivellaro et al reported their experience of 84 consecutive patients assigned non-randomly to either surgery. Results were similar with respect to success (1 pad or less) with 68% and 64% achieving social continence respectively. However, the explantation rate for the ProACT was more than double that for the BAMS (14% vs. 6%) [248]. Gregori et al [246] recently reported that previous radiotherapy and severe incontinence were associated with higher ProACT failure rates. According to the degree of incontinence, dry rates achieved in patients with mild, moderate, and severe leakage were 85%, 64% and 33%, respectively. Whereas 66% of patients overall realized dryness on a 24-hour pad test, in those patients previously irradiated, the dry rate was only 36%. They therefore considered these pre-operative factors as relative contraindications to ProACT placement. Roupret et al [247] also recently reported a lower success rate in irradiated patients, with continence rates of 46% in radiated patients versus 68% overall. The only reported risk factor for failure or adverse events was prior external beam radiotherapy. Similarly, Kocjanic et al. [245] demonstrated a continence rate of 67% in non-radiated patients, compared to 36% in radiated patients.

1. Complications

The most common peri-operative complications are urethral or bladder perforation, necessitating removal of the implant on the perforated side. However, contralateral implantation was not adversely affected, and repeat ipsilateral implantation was invariably achieved after healing of the urethral or bladder wall. Lebret et al. [51] reported a perforation rate of 10% and Hubner [48] reported a rate of 18% early in their series, but a lower urethral perforation rate in the most recent cases illustrating a relatively short learning curve for optimal balloon placement near the urethral/bladder wall. Temporary urinary retention from presumed obstruction was reported at 5% [48]; removing fluid from the balloon restored voiding.

Device explantation was related to balloon failure, infection, erosion, or migration. The explantation rate ranged from 6 to 58% [48,51,242-247], but decreased with experience [48]. Device removal is straightforward, as a deflated balloon can be explanted transperineally.

As balloon deflation and migration may occur, a long follow-up is required to appreciate this technique over the time.

2. Conclusion

The proACT™ balloon technique appears to be a feasible procedure to improve the continence in short and median term, with better results occurring with more operator experience. Similar to the male sling procedure, appropriate candidates include those with mild to moderate leakage due to intrinsic sphincter deficiency, and no previous radiation. The benefit of an adjustable system should be weighed against the need for multiple sessions of refilling the balloon, and with reported rate of peri-operative and post-operative complications. Longer follow-up is needed before definitive comparison to male sling or artificial sphincter can be made. No recommendation is possible due to variable data on complication rates (12-58%). (Level of evidence 3, Grade of recommendation D).

d) Artificial Urinary Sphincter

The artificial urinary sphincter remains the most effective long-term surgical treatment for post RP incontinence due to sphincteric insufficiency. However, due to the cost, the perceived cumbersome-ness of the device with resultant patient reluctance to have or inability to use a mechanical implant, and the fear of complications, it is not suitable for all patients. In addition, the development of less invasive techniques (as described above) potentially gives patients new options for treatment. Ultimately the choice of AUS will be based upon patient dexterity, economics, degree of incontinence, previous incontinence surgery, and expectations from surgery. Patient preference was tested in a study by Kumar et al.[3]. Based on the magnitude of their incontinence patients either had an AUS (high grade incontinence) or sling (low grade incontinence) or a choice between the two (moderated grade incontinence) recommended. Outcomes, length of experience and complications were reviewed with the patients. Of interest, all recommended to have a sling chose a sling, 75% recommended to have an AUS had an AUS while of those given a choice 92% chose a sling. This sheds some light on patient preferences in this area.

The AUS has the longest track record of success in the treatment of PPI. Two older studies have reported that about half of the patients with severe incontinence will undergo AUS implantation [249,250]. However, these studies were conducted before male slings and bulking agents became popular, and sling surgery has since surpassed the AUS in number of procedures performed annually. To this end, it is likely that the advent of the male slings has increased the rate of surgery in men with milder incontinence who may not otherwise have opted for an artificially sphincter. The success rates for AUS as defined by a continence status of zero to one pad per day range from 59% to 90% [251, 252], as shown in Table 6 [56, 251, 253 - 262]. Just as with...
reported rates of incontinence following prostate cancer surgery depend on the definition of incontinence, continence rates with the AUS can vary with the definition of continence, the method of evaluation, and the length of follow-up. The lowest rates are from patient administered questionnaires when pad free rates range from 10-72% [254, 263 - 267]. Nevertheless, high satisfaction rates of 87% to 90% are consistently reported, even without total continence [255, 259, 263].

One potential downside of the AUS is the need for periodic revisions in a number of patients. Revision and explantation rates due to mechanical failure, urethral atrophy, infection and erosion vary considerably among studies with respectively reports of 8-45% and 7-17% [267]. In a large cohort reported by Lai and colleagues [262], non-mechanical failure has decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff and mean time to reoperation was 26.2 months (mean 2-68 months). With a Kaplan-Meier analysis, the overall 5-year expected product survival was 75%. Only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years. Actuarial freedom from revision at 5 years was estimated at 50%-75%. Interestingly, there do not appear to be any urodynamic factors that predict AUS failure in men with ISD. Whereas the male sling has been shown to have inferior success rates in patients with severe leakage, the AUS has been reported to have predictable success regardless of the degree of incontinence and regardless of detrusor underactivity, detrusor overactivity, low abdominal leak point pressure, or diminished compliance [58]. And while the success of the AUS in treating incontinence is not adversely affected by preoperative detrusor overactivity, the rate of persistent overactive bladder symptoms may be high (71%), and patients must be counselled accordingly [268].

The long term efficacy of the AUS was demonstrated by Fulford et al who reported that at 10-15 year followup, 269 75% of patients with an implanted AUS either still had or died with a functioning device. Revisions include replacement of the malfunctioning part, cuff replacement, repositioning or downsizing due to urethral atrophy, a second or tandem cuff [270,271] or transcorpsolar cuff placement [272]. Transcorporal cuff placement, which involves inserting the cuff through the corporal bodies to avoid perforating the dorsal aspect of the urethra, can be particularly useful for patients with prior radiation or urethral erosion; however potency if present may be compromised. Some have advocated tandem cuffs not only as a salvage procedure, but also as a primary procedure for men with severe incontinence [273, 274]. However, O'Connor et al. reported no difference in continence outcome and a higher revision rate in patients undergoing double-cuff implant versus single-cuff after longer follow up [275].

An increased revision rate has been reported for patients who received pelvic radiation [254,27] but was not found in a recent series [252]. The results for continence for radiated patients are variable with some studies showing lower success rates [251,276] while others do not [266]. It has been recommended that such patients have a lower pressure reservoir and/or longer period of deactivation time [254].

**CONCLUSION**

The AUS remains the gold standard for the treatment of PPI secondary to sphincteric insufficiency in patients with severe incontinence, in those who
have had external beam radiation treatment and in those who have had prior AUS placement. It has the largest body of literature reporting long-term success. The long term success rates and high patient satisfaction seem to outweigh the need for periodic revisions in some patients. Intermediate term data with the male sling demonstrates that the sling is an alternative to the AUS in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility. Overall, the AUS remains the reference standard to which all other treatments must be compared. (Level of evidence 2; Grade of recommendation B)

5. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of PPI, either with benign or malignant disease. Therefore, at present guidelines as to timing of the surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. Observational studies of men following prostate cancer surgery typically demonstrate improvement in continence from the early post-operative period until the end of the first year [114]. In addition, it is common for clinical trials of nonoperative management to follow patients for up to 12 months post-operatively, usually with improvement in both the intervention and the control groups during that year of follow up [150]. In a prospective cohort study of men undergoing RRP, Lepor and Kaci [76] demonstrated continued recovery of continence up to 24 months post-operatively, from 80.6% at 3 months to 95.2% at 12 months, reaching a plateau at 98.5% at 24 months. Other cohort studies have demonstrated a plateau in continence rates at 12 months [277, 278]. Since continence may improve up to 12 months post-operatively, and possibly even until 24 months, it is generally recommended that behavioral/conservative management be utilized during the first year after prostate cancer surgery.

There have been some studies evaluating the effect of early interventional treatment for incontinence. Schneider and colleagues [279] demonstrated a beneficial effect on the earlier return to continence with early injection of periurethral bulking agent. Results were better in the subgroup of 34 patients that were injected early (mean 23 days post-operatively) compared to 10 patients treated at a mean of 26 months post-operatively. It could not be demonstrated, however, that long-term continence is improved by early injection of bulking agent. Similarly, Jones and colleagues [280] demonstrated in a comparative cohort study of RRP patients treated either with or without a simultaneous suburethral sling, that sling placement at the time of RRP resulted in an earlier return to continence. There was no difference after 24 months.

(Level of evidence 3-4; Grade of recommendation C)

IV. INCONTINENCE AFTER PROSTATECTOMY FOR BENIGN DISEASE

1. INCIDENCE AND RISK FACTORS

The incidence of urinary incontinence after prostatectomy for benign disease has been reviewed and described in the AHCPR “Benign Prostatic Hyperplasia” clinical Practice Guidelines [281]. The following percentages for stress incontinence and total incontinence, respectively, were reported:

Open surgery (retropubic or transvesical prostatectomy): 1.9% and 0.5%.

TUIP (transurethral incision of the prostate): 1.8% and 0.1%.

TURP (transurethral resection of the prostate): 2.2% and 1.0%.

These figures were based on studies reported before 1990. Several other series were published after 1990. These series were reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. A clear description of the method of follow-up and assessment of the continence status was indicated in only about one third of these studies. The incidence of incontinence after open surgery, TURP, TUIP and HoLEP is low: the reported percentages ranged between 0 and 8.4%. Since the method of assessment of the continence status and the definition of incontinence is rarely stated it is actually not possible to make a distinction between simple stress incontinence and total incontinence. There is generally no clear indication that the incidence is affected by patient age or (resected) prostatic volume. [282] However, a recent study out of Brazil did demonstrate that the rate of urinary incontinence following BPH surgery is higher in older patients. However, most of the increased incidence in incontinence was due to bladder dysfunction rather than to sphincter insufficiency. In a retrospective chart review from Wendt-Nordahl and colleagues [284], the incidence of incontinence following TURP was reported to have decrease over 17 years, from 3.3% in 399 patients operated on between 1987 and 1997, compared to 1.3% in 550 patients operated on from 1997-2004. It is not clear whether this statistically significant (p< 0.05) difference was due to improvement in surgical technique or patient characteristics. However both the earlier and later incontinence rates are consistent with those in the AHCPR and AUA guidelines reports.
In 2003, the AUA published guidelines for the management of “benign prostatic hyperplasia” [285]. The estimated frequency of incontinence following TURP was 3% (from 19 trials that included > 5000 patients). However, the Veterans Affairs Cooperative Study, reported an incontinence rate of only 1% in TURP patients, which was not different from the watchful waiting arm [286]. The AUA conducted meta-analysis of RCTs comparing TURP with TUIP or transurethral electrovaporization did not reveal any statistically significant differences in incontinence rates. [285, 287-291] The 2010 AUA updated guideline provided no additional information [292].

Over the past decade, transurethral holmium laser enucleation of the prostate (HoLEP) has become a standard treatment for BPO. Review of RCTs by the AUA as well as a meta-analyses of RCTs comparing TURP with HoLEP did not reveal any significant differences in incontinence rates [285,291,293-299]. While incontinence did not increase with age in men undergoing HOLEP with morcelation, it was noted that the overall complication rate - including bladder mucosal injury, urethral stricture disease, and bladder neck stenosis was higher in patients with prostate volumes > 50 g [300]. Moreover, it does not appear that either bipolar resection of the prostate or photovaporization of the prostate are associated with a substantially different rate of urinary incontinence than are other BPO surgeries [301]. While incontinence following PVP is comparable to that of other BPO surgeries, and more often than not improves over 12-36 months postoperatively with conservative management, the rate of post-operative dysuria is higher than that of TURP, recently reported at a rate of 10.1% [302].

In summary, the incidence of urinary incontinence after open surgery, transurethral resection of the prostate, transurethral incision of the prostate, and holmium laser enucleation of the prostate is low, and does not differ appreciably among the various techniques.

2. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of incontinence, as mentioned above in the section on post-radical prostatectomy. Therefore, at present guidelines as to the timing of surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. (Level of evidence 3-4; Grade of recommendation C)

3. SURGICAL TREATMENT OPTIONS

a) Artificial Sphincter

The literature on this subject was reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence [4, 282, 283]. Candidates for treatment with the artificial urinary sphincter (AUS) are patients with incontinence due to intrinsic sphincter deficiency that have normal bladder compliance [303]. Detrusor overactivity is not a contraindication [268]. The AUS has been placed around the bulb urethra via a perineal route or transverse scrotal routes [304] or around the bladder neck [4, 282, 283]. The above mentioned review of the results obtained with the AUS indicated that more than 70% of the men treated with the AUS for this indication are dry or almost dry after a follow-up of more than 2-3 years. However, most series on the AUS include both post-prostatectomy incontinence for benign and malignant disease [282].

In summary, the AUS is a successful surgical treatment option for post-prostatectomy incontinence. It is the most commonly performed surgery for post-prostatectomy incontinence, with the longest follow-up and therefore longest record of success. (Level of evidence 2; Grade of recommendation B)

b) Injectable Agents

Most series include post-prostatectomy incontinence after treatment for benign and malignant disease, with the majority after prostate cancer surgery. For collagen, “success rates” range from 36-69%, with 4-20% of patients reporting being dry. [157-164] Study results are inconsistent with both TURP [305] and radical prostatectomy [306] showing better outcomes.

Other bulking agents such as polydimethylsiloxane PDMS (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bulpel and co-workers treated 15 patients. They noted rapid deterioration of initial improvements with success rates of 40%, 71%, 33%, and 26% at 1,3,6, and 12 months respectively [168]. As mentioned previously in the section on post-radical prostatectomy incontinence Kylmala et al. prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively [169]. Follow-up, however, was only 3 months. In a randomized trial of AUS versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPO surgery, with less than1/3 of the cohort suffering from SUI following RP), Imamoglu and colleagues demonstrated no difference in success with AUS versus Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. [52] There has also been some initial work with sphincteric injections of muscle stem cells.[173,174]

Bulking therapy fails in up to 75% of men. Of those who are improved only a minority actually becomes
dry with short-term follow-up. Although bulking therapy may be slightly more efficacious in treating SUI following TURP compared to SUI following prostate cancer surgery, bulking is of limited value in those men with all but minimal SUI. (Level of evidence 3; Grade of recommendation C)

c) Male Sling Procedures

Since Frangenheim described his first successful urethral sling suspension for post-traumatic stress urinary incontinence in 1914, various sling materials and surgical methods have been reported [307]. Rectus fascia, as described by Frangenheim, has distinct advantages over alloplastic materials with respect to erosion and infection risks. Allograft off-the-shelf materials like lyophilized fascia lata have a higher infection risk than does autologous fascia, whereas the use of synthetic materials like polypropylene mesh or polytetrafluoroethylene slings are associated with a higher incidence of urethral erosion [308]. According to various published techniques, the sling can be placed either underneath the bladder neck, the urethral bulb or the membranous portion of the urethra. The principle of continence support is similar for all sling procedures and comprises passive compression of the urethra, which is dependent on the applied sling tension [219]. This mode of action favours sling procedures as a treatment option for intrinsic sphincter deficiency. However, the sling tension needed for restoration of continence has not been standardized, with tensioning techniques ranging from perfusion sphincterometry, to a cough test, to visual approximation, [193, 309] and therefore the success of the procedure probably depends heavily to the surgeon’s experience and the degree of sphincteric incompetence. Overcorrection with consequent urinary retention (especially in the setting of detrusor underactivity) and undercorrection with persistent or recurrent incontinence are certainly possible, which may adversely affect continence, bladder emptying, and patient satisfaction. Most series of sling surgeries deal with a preponderance of men following prostate cancer surgery. Therefore, it is difficult to draw conclusions about any differences in sling efficacy between those with SUI following BPH surgery versus those with SUI following RP due to small numbers of BPH patients most the cohort series.

V. INCONTINENCE AFTER EXTERNAL BEAM RADIOThERAPY ALONE AND IN COMBINATION WITH SURGERY FOR PROSTATE CANCER

The risk of incontinence after external beam radiotherapy (EBRT) for prostate cancer is variable and ranges from 0 to 18.8%. Lawton et al. [310] reported a risk of urinary complications of 7.7% in more than 100 patients, proportional to dose. Perez et al. [311] found incontinence in only 5 of 738 patients. Shipley et al. [312] reviewed more than 2500 cases with an incontinence rate of 0.5%. Similar incidences have been reported in more recent series. Madalinska et al. [77] reported an incidence of 6.7%. With three-dimensional conformal radiotherapy, Weil and colleagues [313] reported no incontinence in 168 consecutive patients and Hanlon et al. [314], in a series of 195 men, found that post treatment urinary symptoms were no different from a control group without cancer. With conformal radiotherapy, Sandhu et al. [315] reported a 9% incidence of stress incontinence in 110 patients. The impact of EBRT followed by prostatic boost, for a total of 66-70 Gy, was evaluated. Scalliet and coworkers [316] reported urinary incontinence in 16% of 230 patients, however, Fransson and colleagues [317] reported an increase in urinary incontinence on a patient-administered symptom bother scale 3 years after treatment in 153 men compared to pretreatment status. The increase was from a mean of 0, at the start to 2 out of 10 at 3 years. Ponholzer et al. [318] reported incontinence in 18.8% of a group of 82 men who were surveyed 4.4 year after EBRT for prostate cancer. Furthermore urinary incontinence worsened from year 2 to year 6 in a cohort of 147 men treated with 3D conformal RT. [319] Budaus et al. [320] conducted a review of radiation series published from 1999-2010 and concluded that early storage symptoms are commonly reported but long-term incontinence is not.

Pre-radiotherapy transurethral prostatectomy may be a risk factor for incontinence. Jonler et al. [321] reported an incontinence rate of 11% with pretreatment TURP. Green et al. [322] and Lee et al. [323] also reported a higher risk of incontinence with pretreatment TURP versus those without with 5.4% and 2% respectively. There are no series reported on the treatment of patients who only have incontinence after EBRT.

Salvage or adjuvant radiotherapy is frequently given after radical prostatectomy and the impact on continence is controversial. Petrovich et al. [324] reported no difference in incontinence in 2 cohorts of patients, one with and one without adjuvant radiation. In a follow-up study the same group reported no late toxicity. [325] Fontaine et al. also reported no change in continence status in 16 of 17 men after salvage radiation. [326] However, Petroski et al. reported that postoperative radiotherapy worsened continence in 26% of 129 patients followed for a median of 5 years. [327] On the other hand salvage radical prostatectomy following external beam radiotherapy has been generally reported to have a high incidence of urinary incontinence [328-330] possibly because of radioinduced fibrosis of the external sphincter. [329] Cozzarini et al. demonstrated that older age and greater radiation dose in the salvage setting and younger age and hypertension in the adjuvant setting resulted in worse urinary toxicity. [331]
1. SURGICAL TREATMENT

Results of surgical treatment of incontinence in this setting are based on retrospective clinical series. In the past the most commonly published treatment modality was the artificial urinary sphincter as therapy for sphincter damage. As discussed and referenced in the following paragraphs, the series published contain both patients who had and had not received radiotherapy and collagen injections have also been reported in case series.

There has been a higher reported revision rate for the artificial sphincter following radiotherapy (Table 7) [251, 252, 254, 262, 265, 276, 332, 333] compared to low risk patients, 38% versus 22%. Although recent reports dispute the higher rate [252, 262]. However, generally this is due to a higher incidence of erosion and infection as well as urethral atrophy, possibly secondary to radiation induced vasculitic fibrosis of the urethra.254 Radiation may also induce detrusor overactivity or poor compliance leading to urgency incontinence. Recurrence of bladder neck contracture may be more common. [262] Radiation was also identified as a co-morbidity associated with erosion [334] and infection. [335] However, good results are reported, and it is generally recommended that the cuff be inserted outside the radiated field. [336]

Collagen injection has also been reported for incontinence after radical prostatectomy and adjuvant radiation [159,163,305,337-339] or after salvage radical prostatectomy following radiotherapy [166,340] Continence results are poorer compared to those without radiation. [306] Very few patients have been reported on with the use of Macroplastique following radical prostatectomy and adjuvant radiotherapy.

The male perineal bone-anchored sling has been reported in patients following adjuvant RT. In Comité’s group with the perineal compression sling 3/21 with radiation had no adverse sequelae.166 Similarly in the series of Onur et al. radiation did not cause a worse outcome.[193] However, Schaeffer et al. reported that prior irradiation was the only identified factor that predisposed to failure. Their success rate following a single sling procedure was only 29% (2 of 7) for irradiated patients, and the corresponding rate for nonirradiated patients was 68% (39 of 57). [184] They postulated that the sling acts by compressing and elevating the urethra, thereby increasing urethral resistance to abdominal pressures. Theoretically, radiation-induced fibrosis of the urethral and periurethral tissues would make compression and elevation more difficult by reducing tissue compliance and mobility. As mentioned above, the results of AdVance slings, adjustable slings, and adjustable balloons are adversely affected by radiation.

In summary, despite the frequently reported higher incidence of complications of the artificial sphincter in post-prostatectomy patients after adjuvant radiation, it has provided acceptable treatment benefits. Injectable agents have yielded poor results. Other techniques are adversely affected by radiation. (Level of evidence 3; Grade of recommendation C)

VI. INCONTINENCE AFTER OTHER TREATMENT FOR PROSTATE CANCER AND NEOBLADDER FOR BLADDER CANCER

1. BRACHYTHERAPY

Brachytherapy is a form of radiation therapy in which radioactive materials are placed directly into the prostate gland. The incidence of incontinence following this modality is given in Table 8 [341-353] and was previously related to the treatment of post-brachytherapy retention of urine. Numerous series have reported retention to be associated with larger initial prostate volumes. [354] In a systematic review of brachytherapy series, Crook et al. [350] reported the incidence of retention to be 1-14%. Many patients require prolonged or permanent alpha blocker or TURP. The main risk factor for incontinence after brachytherapy is TURP. Hu and Wallner [347] reported on the incidence of urinary incontinence after TURP/TUIP following prostate bracytherapy for prostate cancer. Of the 10 patients who underwent the outlet relaxing procedures for refractory urinary obstruction, 7 developed some degree of permanent urinary incontinence. They surmised that the cause may be multifactorial and may include physical damage to the urinary sphincters and the radiation dose to the urethral region. Surgical therapy when required has included the artificial sphincter. [348] High dose brachytherapy that is administered over a short period of time may have reduced toxicity. [355] Urethrorectal fistula is another complication that has been reported in 1.8% of patients in a large U.S. medicare retrospective review. [348] Salvage brachytherapy leads to a higher rate of urinary tract complications. [330]

2. CRYOSURGICAL ABLATION OF THE PROSTATE

Cryosurgical ablation of the prostate is used for clinically localized prostate cancer either as primary treatment or after unsuccessful external beam radiation therapy. The frequency of the main lower urinary tract complications are listed in Table 9 [356-369]. The artificial sphincter has been mentioned as one of the treatments for incontinence. [367] Cryotherapy is an adverse factor for collagen injections. Urethrorectal fistulae can also occur in up to 5% of treated patients. Severe incontinence and fistulae that occasionally results may have to be treated with extirpative surgery and diversion. [370]

3. HIGH-INTENSITY FOCUSED ULTRASOUND (HIFU)

Transrectal high-intensity focused ultrasound is another minimally invasive treatment for prostate

*Previously radiated/not previously radiated
cancer. HIFU destroys prostate cells by coagulative necrosis of the tissue without damaging the structures intervening between the transrectal probe and the target tissue [371]. Reports of efficacy also include morbidity. In a systematic review involving 37 articles/abstracts Rebillard et al. [372] reported that stress incontinence occurs in 6-28%, urethra/bladder neck stenosis in 1-31%, and rectourethral fistula in 0-3% of treated patients. With improvements in techniques the risk of complications is decreasing [372]. In a recent sytematic review from 2000-2011, Cordeiro et al. noted that the rate of incontinence ranged from <1-34.3% [373].

4. INCONTINENCE AFTER NEOBLADDER CONSTRUCTION

The incidence of continence after neobladder construction following radical cystectomy for bladder cancer ranges from 85 to 100% during the day and 55 to 100% at night Table 10 [374-386]. Most patients achieve daytime continence after one year and nighttime continence after 2 years. Most of the published reports do not comment on specific surgical management and imipramine is mentioned as treatment only occasionally. Martins and Boyd [254] reported on 8 patients treated with the AUS for persistent sphincter weakness incontinence. Six of these underwent revisions, 3 for infection and/or erosion and 3 for inadequate cuff compression. They cautioned against the use of the AUS and suggested alternatives such as intermittent catheterization at night. However, O’Connor and colleagues [387] reported a successful outcome, after AUS, with no complications in 5/5 men with incontinence after neobladder, with a mean follow-up of 22 months and Simma-Chiang et al. [388] reported success in 11/12 men 22 months after AUS implant. The bone-anchored sling has been reported for one case [389] and the AdVance sling for 2 cases [226] Collagen has only been reported in women following neobladder construction.[390]

**In summary** there are not enough data upon which to recommend definitive surgical therapy, although the artificial sphincter is reasonable. (Level of evidence 3; Grade of recommendation C-D)

### VII. TRAUMATIC INJURIES OF THE URETHRA AND PELVIC FLOOR

Incontinence following posterior urethral injuries occurs in 0-20% of patients [391,392] and is thought to be due to the extent of injury rather than to the method of management.

The data on surgical treatment are all retrospective case series and the most commonly published surgical therapy is the AUS. The series published contain both patients with and without traumatic injuries. Perez and Webster [251] reported on 27 patients after urethral or bladder neck strictures. The revision rate was 41% and the continence rate was 85%. In a subsequent report from this centre on reoperations the patients with traumatic injuries were not discussed separately. [393] In Montague’s [253] series 22 out of 166 patients had incontinence after trauma. He did not separate the results of this group from those of the other patients. Martins and

Bladder neck reconstruction by excising the scar and narrowing the calibre was reported by Iselin and Webster [395] in 6 patients who had incontinence with an open bladder neck on cystourethrography, following urethroplasty for traumatic strictures. Bladder neck closure with a Mitrofanoff catheterizable abdominal stoma has also been reported as treatment following severe urethral or bladder trauma. [396] (Level of evidence 3; Grade of recommendation C)

For patients with severe bladder neck strictures and incontinence after prostate surgery Meulen et al. [397] and the group from Baylor [262, 398] reported on the use of a Urolume stent with a bulbar artificial sphincter. Alternative management with perineal urethroplasty and subsequent artificial sphincter placement in 6 patients was reported by Simonato et al. [399] (Level of evidence 3; Grade of recommendation C)

In summary, the AUS provides a reasonable outcome in appropriate cases. Since there are so few reports of alternative therapies the C recommendations were based primarily on expert opinion as to what is reasonable surgical therapy in very difficult cases.

VIII. CONTINUING PEDIATRIC PROBLEMS INTO ADULTHOOD: THE EXSTROPHY-EPISPADIAS COMPLEX AND OTHER CONGENITAL ANOMALIES

In exstrophy, the bladder plate at birth is smaller than a normal bladder. It is uncertain whether that which does exist is normal. It has been shown that the muscarinic cholinergic and other neurotransmitters in exstrophy detrusor muscle are the same as in controls [400, 401]. Microarray analysis shows that the bladders are developmentally immature [402]. The number of number of myelinated nerve fibers in the detrusor is reduced in new born exstrophy bladders compared to that of neonates who had died from cardiac causes (controls) [403]. It seems probable that the spectrum of neurological and morphological changes seen in exstrophy bladders beyond the neonatal period, are largely secondary to the medical management [404].

Control of the bladder outlet depends on proper function of the pelvic floor musculature and of the urethral sphincters. In exstrophy infants who have not had an osteotomy, the pelvic floor muscles have normal bulk, but abnormal orientation, especially in their relationship to the urethra. They are unable, therefore, to contribute very much to urethral continence [405]. The prostate is a flat plate of normal size, lying behind the urethra. It is not wrapped around the urethra [406]. Growth of the prostate at puberty will not improve continence.

The existence of the urethral sphincters is also uncertain. There is no histological study to show their presence or innervation. However, electromyographic studies of continent children have shown normal electrical traces [407].

Epispadias is a very rare condition. There are very few data on the bladder and sphincters for this diagnosis alone. In general the bladder is of better volume and there may be some active sphincter function in those at the better end of the spectrum.

Storage of urine in children with exstrophy depends on creating sufficient bladder outflow resistance that there is a leak point pressure great enough to stretch up the bladder volume. Voiding depends on the ability, either by detrusor or by abdominal wall contraction, to generate enough pressure to overcome a fixed outlet obstruction.

The pediatric literature often refers to patients with exstrophy having a ‘dry interval’ of so many hours. The implication of this is that the bladder has a fixed capacity beyond which the pressure becomes higher than that of the fixed outflow resistance. Providing the child recognizes this point, a visit to the lavatory will avoid incontinence. Patients in many clinical situations to avoid a ‘social or hygienic problem’ use this technique of timed voiding but it does not constitute continence as would be understood by a ‘normal’ person. It is a means of managing poor bladder control. It is rare to find literature on the long-term follow-up of patients with this complex describing ‘normal’ continence. The evidence base is level 3 at best.

1. EARLY MANAGEMENT OF EXSTROPHY AND EPISPADIAS

The early reconstruction of bladder exstrophy is clearly important but not a subject for this chapter. Only an outline will be considered as a basis for discussing problems of continuing incontinence in adolescence and adulthood. Techniques have gradually evolved over the last 100 years since the first (transiently) successful closure described by Trendelenberg in 1906 [408]. The most important development, at least in Western countries, is the concentration of cases in a small number of centers. In the United Kingdom, for example, it is estimated that 12 babies a year are born with exstrophy and all are cared for in two centers.

Broadly, there are three approaches to early reconstruction —
• Staged repair, originally described by Jeffs [409]. Here the principle is to close the bladder in the first operation. The bladder neck and epispadias repair are then done as a second stage.

• Complete primary repair of bladder exstrophy (CPRE) often attributed to Mitchell [410]. The objective is to close the bladder and bladder neck and to repair the epispadias in one operation. Although more than one operation is often needed, the important principle is to create bladder outflow resistance as early as possible. This should allow proper development of bladder volume and compliance. A subsequent bladder neck reconstruction may be needed in up to 40% of children [411].

• Single stage radical soft tissue mobilization (RSTM), usually called the Kelly operation [412]. The entire anterior pelvic contents with blood and nerve supply are mobilized from the pelvic sidewall, reconstructed and repositioned more posteriorly in the pelvis. There is no osteotomy, but the radical mobilization allows abdominal wall closure without osteotomy.

Each of these is subject to many modifications by different surgeons, which makes comparison of results difficult. Not surprisingly, there are no controlled trials. Outcomes have been described from specialist centers with good results and from generalists with, usually less good results.

At the longest follow-up available, the results of these three approaches are very difficult to determine, at least as far as bladder function is concerned. Data beyond the age of 18 are limited, especially for RSTM. Definitive reports in peer-reviewed journals of long-term outcomes from the centers that specifically champion these techniques are lacking. There are reports from other centers of small numbers of patients, but often without the use of a consistent technique.

Approximate figures are given in Table 11. Sadly, the results in the world at large are much worse. There are also differences in outcomes in relation to the condition of the kidneys, genitalia, cosmetic appearance and sexual function that are beyond the scope of this chapter.

2. LATE BLADDER FUNCTION

If the figures for continence shown in the table are maintained into adult life and ‘partial continence’ is not acceptable, no more than 70% of patients will have a native bladder and normal voiding. In reality, this figure is rather optimistic and may be as low as 7% [413].

For the children who have done well, there is some evidence that continence may not be maintained into adulthood. In a follow-up of 56 patients for a minimum of 20 years, 13 were found who were continent and voiding naturally at 10 years old. However, by 20 years old, only three were still in this situation. The remainder were augmented or on CIC or both. The patients had been operated in the 1960s and early 1970s by older techniques than are currently used [414].

Late failure has several possible causes. Possibly the most important is that the outflow resistance generated by bladder neck reconstruction is not sphincteric, but fixed. Voiding is, therefore, always against obstruction. Deterioration in bladder function would come either from detrusor failure or from overactivity. Borer et al found detrusor overactivity in six of 13 children (46%) who had had a staged repair but in none of 19 who had had CPRE [407].

Another problem was identified by Yerkes et al. [415] In an investigation of 18 children who were said by themselves and their parents to be ‘continent and voiding well’, none were, in fact, voiding normally. Apart from infections, stones and a dry

Table 11. Outcomes of childhood surgery for exstrophy with special reference to continence.  
Data are best estimates from recent literature from specialist centers. Approximations have been taken as reporting systems are not consistent between papers [412,780,781].

RSTM - Single stage radical soft tissue mobilization
interval of two hours, there were major objective bladder dysfunctions in all patients. Seventy two percent had a residual urine of at least a third of bladder capacity; 70% had a flow rate below 10ml/sec; 30% had staccato stream; and 36% voided by Credé’s maneuver.

Finally, there is the problem of the definition of continence. The disciplined life of a closely supervised child may well make a three-hour dry interval seem like continence. It fits in well with the school routine. It does not lie well with the life style of an adolescent. It quickly becomes apparent that the coffee, sodas and alcohol that soon become a part of an adolescents’s life expose the fact that they have to make far more visits to the lavatory than their peers or risk being wet. It has been shown that one of the prime desires of exstrophy adolescents is to be ‘normal’. This includes being treated as normal and having normal lavatorial habits [416]. This difference from normality may drive some young adults to seek continence surgery even though, by pediatric criteria, they had been classed as continent.

3. MANAGEMENT OF INCONTINENCE

a) Investigation

Standard investigations for incontinence are appropriate for patients with exstrophy. Urodynamic studies have been use to clarify the etiology and have clinical value in management [407,415]. Dave et al. [417] investigated 31 children one year after a modified bladder neck reconstruction. Fifteen had satisfactory continence defined as a dry interval of two hours or more, no stress incontinence and no more than two episodes of nocturnal enuresis per week. The continent children had a better bladder capacity at 162 ml compared to 113ml for those with poor continence or 55ml for the totally incontinent. End filling pressure was around 31cm H2O for the continent children versus 48 or 41cm for the other two groups. However, involuntary detrusor contractions were seen in a third of the continent group and were associated with a lower than average bladder capacity and less good compliance than the other continent children.

It has been pointed out by Hollowell et al. [418] that even in severely incontinent children who appear to drip continuously, leakage is often due to detrusor overactivity. They found that a leak point pressure (LPP) of at least 10 cmH2O was necessary to allow bladder expansion. However, in some children with a higher LPP than 10, bladder expansion did not occur because detrusor contractions were constantly emptying it.

As in other conditions of bladder abnormality, end filling pressures over 40cmH2O were associated with hydronephrosis (two thirds of patients) [417]. The role of electromyography (EMG) of the sphincters has been reported but not correlated with management or outcomes [407]. In Dave et al’s [417] patients only 12 children voided with sustained detrusor contractions and only five voided effectively. Ten children had persistent EMG activity during voiding but no other detectable neurological abnormality. Eight of them had significant residual urine volumes.

Some authors stress the importance of examination under anesthetic. In the assessment of incontinence, the volume of the bladder has some predictive value and is most accurately measured under general anesthesia. Although not statistically significant, children with a bladder capacity before bladder neck reconstruction of less than 25ml do less well than those with larger bladders [407]. Secondly, a transverse oval appearance of the bladder neck is associated with its incompetence and hence incontinence [411].

Complete objective evaluation of bladder function in this manner is particularly important in exstrophy as the description by patients and parents is unreliable [415].

b) Medical Management

The apparent normality of the detrusor muscle at least in infants born with exstrophy, suggests that standard anti-muscarinic drugs should be effective in detrusor overactivity [400]. There have been no disease specific controlled trials, least of all in adults. In children, there has been an uncontrolled trial of imipramine using both clinical and urodynamic criteria to assess response [419]. All of 17 children (mean age 7.9 years) had urodynamically proven detrusor overactivity, small poorly compliant bladders and incontinence. Imipramine 1.5 – 2.0mg/kg was given for a mean of 9.5 months. There was a 40% increase in bladder capacity and a 25% reduction in end filling pressure. Eleven of 17 children had a clinically significant improvement in continence; all of eight children with partial continence (1-2 hr dry interval by day but enuretic) became dry day and night with a dry interval of more than 2hours. Three of nine children with severe incontinence improved. Hydro nephrosis improved in three of nine patients. In an editorial comment on this paper, Gearhart stated that he used oxybutynin 0.5mg/kg in combination with imipramine, which ‘gave even better results’. No further data were given.

c) Bulking Agents For The Bladder Outflow

In patients with exstrophy who have bladder outflow weakness, there is logic in using injectable bulking agents to increase resistance. Although not mentioned in the literature on this subject, the obvious drawback is that there will be even greater fixed outflow resistance that may limit the opportunity for the action of any active sphincter.
Burki et al. [420] reported the use of polydimethylsiloxane (macroplastique™) in 34 children with exstrophy and 18 with primary epispadias. Apart from bladder neck reconstructions eight had had augmentations. In addition, 14 relied on a Mitrofanoff for self-catheterization. There was no standard technique of injection and the objective seems to have been to put in enough of the bulking agent to produce visual occlusion of the bladder neck area using 2.5 to 7.5 ml. Twenty patients had one injection and the rest had an increasing number up to seven. The follow-up assessment was entirely clinical and there were no urodynamic data. Only 17% were completely dry at a mean of 4.6 years; 33% were reported to be significantly improved. The milder the initial incontinence the better the result, however four of 36 patients who were totally wet did become totally dry. The continence rate was improved by up to four injections but only one patient became dry after more than four (he became dry after six injections). Other bulking agents have been reported including Teflon and collagen but in series of patients with different diagnoses including exstrophy and epispadias.

**d) Surgical Management**

Adults with exstrophy who have failed to become dry after initial reconstruction and the relatively conservative management of medication and bladder neck bulking have a difficult decision to make. The most elusive outcome is to create a bladder that is continent and from which there is spontaneous voiding. It will be seen that the choice to achieve this result is a second bladder neck reconstruction or insertion of an artificial sphincter. Both of these require a natural bladder of adequate capacity and which retains normal detrusor function. If the bladder is small or of high pressure, there may be some improvement when outflow resistance is increased with a successful bladder neck procedure, though, again, the data come from studies in children and may not be applicable to adults [407]. Otherwise, augmentation will be necessary. The options for augmentation, with or without a Mitrofanoff, are considered elsewhere in this chapter.

A more realistic objective if the urethra is to be used for urinary drainage would be to accept CIC for bladder emptying. If the bladder is inadequate, it can be augmented. However, this option does depend on having a urethra that can be catheterized. This may be difficult after repair of the epispadias and bladder neck initially; after a second bladder neck reconstruction, it may be more difficult.

a) Bladder neck reconstruction: In children who have had a bladder neck reconstruction and failed to become dry, the results of further reconstruction are poor. In adults, data are very limited. In a group of older children (3.2y – 15.5y) the group at the Hospital for Children, Great Ormond Street reported very modest results. There were 20 boys and ten girls most of whom had had several operations apart from the initial bladder neck reconstruction, including injection of bulking agents, augmentation and Mitrofanoff procedures and yet still remained wet. Sixty percent became dry by day (80% of girls but only 50% of boys), but only 50% by night. None could void urethrally and only five performed a re-do Young-Dees operation. Urethral catheterization was difficult in eight. The authors acknowledged that the outcomes were not good and suggested that closure of the bladder neck might be a better option [421]. In an earlier series from Johns Hopkins all of eight patients achieved a dry interval of three hours or better with a re-do Young-Dees operation but all required CIC [422]. Although these data cannot directly be extrapolated to adults, it seems likely that they are representative of patients with failure of the initial bladder neck reconstruction.

b) Artificial urinary sphincter (AUS): The patient with exstrophy has, by definition, a reconstructed bladder neck and urethra. Such structures are not well suited to the support of an AUS cuff. It is also common for incontinent patients to carry a residual urine and so, with an AUS, would need to use CIC. Even in the earliest reports of the AMS 800 AUS, the results in patients with exstrophy were poor [423]. Again, data on this procedure in adults with exstrophy are limited and often included in series of patients with different diagnoses. In one series of 112 patients without spina bifida, there were 12 with exstrophy and four with epispadias aged four to 17 years old. The AMS 880 AUS was used with 5.5 to 7.5 cm cuffs and 61–70 cm water balloons. The cuff eroded in three of 12 exstrophy patients. Only four were dry and able to void spontaneously all of the time [424]. Herndon et al reported a 20% erosion rate in patients of any diagnosis who had had a bladder neck repair [425].

e) Diversion:

It is beyond the remit of this section to consider urinary diversion for exstrophy in detail. There is a school of thought that the results of exstrophy reconstruction in the long run are so poor that early diversion should be the initial management [426]. The original diversion of choice was a ureterosigmoidostomy, however the results before antibiotics and an understanding of hyperchloremic acidosis were very poor with 50% of children dying before ten years old [427]. With modern management and the use of a de-tubularized rectal pouch, such as the Mainz II, the results are very good and continence rates of 95% day and night are reported [428, 429]. This would certainly be the
management of choice in countries with limited facilities for reconstruction [430]. Surveillance for the development of anastomotic neoplasms from the tenth year after construction is mandatory [431].

Even in exstrophy patients who are continent, very many will have had an intestinal augmentation procedure. If the urethra is continent it may be used for self catheterization. When the urethral reconstruction has failed, either because it is wet or impossible to catheterize, a supra-pubic catheterizable channel, such as a Mitrofanoff, should be formed. The wet urethra is closed at bladder neck level to allow continued seminal ejaculation. If the bladder is too small or of too high pressure, it is augmented with intestine.

In the large series from Baltimore, 91 of 704 (13%) of exstrophy children required such procedures [432]. Of the reconstructed patients, 65% had a bladder neck closure. At a mean follow-up of six years, 93% were continent.

There are no data on the use of these techniques in adults specifically with exstrophy. However, as there are no other alternatives, a reconstruction based on the bladder is the recommended option. Long-term follow-up of intestinal diversions in other situations suggests that stone formation, stomal stenosis, hyperchloremic acidosis are common. Spontaneous rupture, an acute and life-threatening complication is rare. Renal function is preserved at least to ten years [433].

A long-term problem unique to exstrophy patients with a retained bladder is the risk of cancer. At the age of 40, exstrophy patients have a 640 fold increased risk over the normal population of that age. The reported tumors are aggressive and frequently fatal. Histologically, they are a mixture of transitional, squamous and adenomatous, most commonly arising on the bladder neck [434]. To date, the reported cases have been in those whose bladder reconstructions were done in early childhood; it remains to be seen whether those with reconstructions done in the first few days of life will have the same risk. It is important to pay urgent attention to the standard symptoms suggestive of bladder cancer even in young adults with exstrophy.

If the bladder is too small to be useful, or has been removed, one of the standard supra-pubic diversions such as a colonic reservoir can be used. The Mainz II rectal reservoir is an alternative. Ileal conduit is almost never indicated. However, the risk of bladder cancer remains, even if the only remaining part is the bladder neck.

4. RECOMMENDATIONS

The published studies to date are retrospective case series with levels of evidence at best 3 with a Grade of Recommendation of C and Level of Evidence 3. The expert opinion of the Committee has resulted in the following recommendations regarding the evaluation and treatment of persisting incontinence in adulthood. (C)

- Anti-muscarinic drugs are the first option for detrusor overactivity although there are no data specifically related to exstrophy patients.
- Standard techniques for enlargement of a small or high-pressure bladder are appropriate.
- Bladder neck bulking agents may be effective but continence is unlikely to be achieved if 4 injections have failed.
- Re-do bladder neck reconstruction has a high failure rate, and is very unlikely to allow complete, spontaneous voiding. Urethral CIC may be difficult or impossible.
- AUS also has a poor outcome because of erosion, chronic retention and CIC difficulties.
- Supra-pubic continent diversion with or without augmentation and with or without bladder neck closure is the best choice for exstrophy patients with urethral failure. Rectal diversion (eg a Mainz II pouch) should be considered especially in countries with limited medical facilities.
- Patients with exstrophy-epispadias complex should be evaluated and managed in specialized centers.
- A universal definition of continence should be established.
- Persisting incontinence should be evaluated with urodynamics and its treatment should be individualized based on urodynamic findings.
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications.
- Comparative studies, including quality of life and psychological assessment, should be undertaken if possible.

IX. DETRUSOR OVERACTIVITY AND REDUCED BLADDER CAPACITY

1. REFRACTORY URGENCY INCONTINENCE AND IDIOPATHIC DETRUSOR OVERACTIVITY

The overactive bladder (OAB) syndrome refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia [435]. Detrusor overactivity (DO) indicates the urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. Idiopathic Detrusor Overactivity (IDO) exists when there is no defined cause. Neurogenic Detrusor Overactivity (NDO) is seen when there is a relevant neurological condition. Ahlberg et al found that 82% of patients initially considered idiopathic on careful searching actually had pathology potentially leading to the problem [436].
Idiopathic detrusor overactivity is a normal situation early in life. Children have urgency incontinence as a stage in acquiring bladder control. The incidence of detrusor overactivity during mid-life years (20 to 60) has been estimated as 10% [437]. In the asymptomatic elderly, detrusor overactivity once again becomes common, occurring in 50% of men over 70 [438]. In the symptomatic elderly, over 75 years old, it can reach 90% in men [439]. Detrusor overactivity may be a cause of severe storage symptoms such as frequency, nocturia, urgency and urgency incontinence. Conservative treatment of these symptoms such as bladder training and pharmacotherapy is discussed in other sections.

Magnetic stimulation has been reported as a non-invasive treatment of DO [440,441]. Bradshaw et al. demonstrated an effect on cystometry with magnetic stimulation and found an improvement in urodynamic parameters but no consistent change in OAB symptoms [442]. Almeida et al. [443] in a prospective urodynamic controlled study of 91 women with UI, found an improvement on DO only in patients with initial bladder contractions greater than 15 cm H2O. There are no other specific data available [444].

The use of intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin was extended to DO of non-neurologic origin after the suggestion that its etiology involved the enhancement of the C-fiber mediated spinal micturition reflex [445] and emerged as a minimally invasive procedure: the results are shown in Table 12 [446-453]. In spite of promising and controversial results, it is still

| Table 12. Intravesical capsaicin and resiniferatoxin for detrusor overactivity (males and females) |
|---|---|---|---|---|---|
| Author | No. | Improvement | Duration of effect | Drug and dose | Side effects |

considered experimental and more clinical studies are necessary for it to be licensed [454].

The mechanism of action is still under study. The mean bladder perception threshold is increased only in patients with clinical improvement [455]. The complexity of the mechanism is demonstrated by the presence of vanilloid receptors not only on sensory fibers but also in bladder urothelium and smooth muscle cells [452] and by ineffectiveness in treating an overactive bladder from idiopathic causes or suprapontine lesions with no vanilloid-sensitive fiber-mediated reflex [456]. It has been suggested that over expression of transient receptor potential vanilloid subfamily 1 in the bladder predicts the response [457]. A well designed double-blind placebo-controlled study revealed no difference between placebo ethanol 10% saline solution and 50 nM resiniferatoxin, nevertheless both treatments showed improvement in symptoms of women with IDO [453].

Some placebo-controlled studies either did a quasi randomization458 or did not explain how it was done [452]. Patients with increased bladder sensation without DO presented some improvement in symptoms in a small non placebo controlled series [459]. There are no recent clinical series published and at present time, the use of resiniferatoxin has been restricted to animal studies [460,461].(levels of evidence 1 – 4; Grade of recommendation D, two level 1 studies have contradictory conclusions. [452,457])

For symptoms that are refractory to conventional means, 3 interventional treatments have been reported: botulinum-A toxin detrusor injections, neuro-modulation, and bladder augmentation.

a) Botulinum toxin A injection in the bladder

The minimal invasiveness of this method makes it very attractive but long-term results in IDO are lacking Table 13 [462-478]. The effects of its use are still not fully recognized [479], with possible systemic consequences [480-482], such as generalized muscle weakness in a number of patients treated for neurogenic bladder overactivity, and the development of resistance to the drug [483-485]. The FDA conducted a safety review of botulinum toxin products and issued a report that included a "Boxed Warning" highlighting the possibility of life-threatening distant spread of the toxin, a Risk Evaluation and Mitigation Strategy (REMS) with a medication guide to help patients understand the risks and benefits, and changes to the established drug names to reinforce individual potency and lack of interchangeability of the different products and to prevent medication error [486].

Most of the initial experience comes from its use in neurogenic bladders [487-490]. In 2011, OnabotulinumtoxinA was approved by countries in North and South America and Europe for treatment of urinary incontinence in people with neurologic conditions as spinal cord injury or multiple sclerosis. Information about its use in children is scarce [491]. DasGupta et al. [492] published a systematic review on its use in children. They found 225 children in 10 peer-reviewed publications with 165 pediatric patients with neurogenic overactivity (6 studies), 21 patients with idiopathic overactivity (1 study) and 39 patients with voiding dysfunction (3 studies). Only 11 male children with idiopathic OAB were included, limiting conclusions on this subject.

A randomized study comparing the results of botulinum toxin A injections to intravesical resiniferatoxin in NDO showed superior clinical and urodynamic benefit with the use of botulinum toxin [490]. The need for reinjections seems to be overcome by the significant improvement in quality of life of these patients [493-495]. Cost-effectiveness with botulinum toxin A in patients with detrusor overactivity is becoming an important issue with its increasingly widespread use [496]. The number of BTx treatments in the UK has increased dramatically from around 50 in 2000 to 4088 in 2010, making costs an important matter to be considered [497-499]. A 3-year cumulative cost analysis of BTx versus augmentation cystoplasty favored botulinum toxin injections [500], but longer follow up may change this.

The use of botulinum toxin B (Myobloc – RimabotulinumtoxinB) is less efficient, with duration of action of about 10 weeks [501].

The optimal site of injections, including or not including the trigone, is still under debate [502]. In 2007, Kuo [474], published a study comparing the injections into the detrusor, suburothelial area, and bladder base, with the last location improving urgency but not increasing capacity. Recently Kuo did a single blind, randomized, parallel, actively controlled trial testing 100 U of OnabotulinumtoxinA with patients assigned to receive injection into one of the three following sites: bladder body, 100 U; bladder body, 75 U plus trigone, 25 U; and bladder base, 50 U and trigone, 50 U. He concluded that the injections are a safe and effective treatment for IDO regardless of the injection sites [503]. Manecksha et al [504] performed a study with 500 U of AbobotulinumtoxinA in 22 patients randomized to trigone-included or trigone-sparing detrusor injections. Benefits of trigone included injections were superior to trigone sparing injections for the treatment of refractory IDO and did not cause VUR in this study. A case series of 56 women with IDO underwent submucosa-only injection of 200 U of OnabotulinumtoxinA at 30 sites, showed success in 85.7% at 2 months and 54.3% at 12 months [505]. Initial results of bladder instillation of 300 units of OnabotulinumtoxinA and 50 mL of 50% DMSO in aqueous solution in women with IDO, showed safety and some efficacy that merit further research [506].

Many studies on idiopathic overactive bladder have been done in women [468, 469]. Data are still lacking on dose, concentration, site(s), numbers of injections, long-term efficacy and side effects. Attempts

to determine whether poor responders could be predicted from preoperative urodynamic parameters showed only a very high maximal detrusor pressure over 110 cm H2O as an unfavorable predictor when using 200 units [476]. Studies in women suggest a longer duration of action than its mere motor-nerve blocking potency can explain [469]. Therefore, a dual mechanism of action has been proposed: in addition to binding to cholinergic terminals, it might also affect afferent nerve transmission, thereby decreasing urgency [507, 508]. Kuo evaluated retrospectively the effects had significantly greater long-term success than its mere motor-nerve blocking potency can explain [469]. Therefore, a dual mechanism of action has been proposed: in addition to binding to cholinergic terminals, it might also affect afferent nerve transmission, thereby decreasing urgency [507, 508]. There are two commonly marketed forms of botulinum toxin-A: Botox (Allergan Pharmaceuticals, Irvine, CA, USA), now referred to as OnabotulinumtoxinA, and Dysport (Ipsen Biopharm Ltd., Wrexham, UK), referred to as AbobotulinumtoxinA, as recommended by the US Food and Drug Administration. They require different doses to achieve similar results, in a proportion of approximately 1:3 [510, 511]. Other forms of botulinum toxinA do not have enough data in urology to be considered for this report, including Xeomin (IncobotulinumtoxinA) (Merz, Germany), Prosigne (Lanzhou Institute of Biological Products, China) [512], and Neuronox (Medy-tox, South Korea).

AbobotulinumtoxinA for refractory IDO was published in 2007 with similar results to OnabotulinumtoxinA [468]. Recently, a series of 22 patients with IDO underwent injection of 500 U of AbobotulinumtoxinA and were randomized to injections including or excluding the trigone [504]. Similar results were obtained regarding side effects (18% retention and no reflux) with the trigone-included group showing better results. Another large case series of 234 patients either with various types of neurogenic bladder dysfunction (NBD) or IDO underwent respectively 500 U and 250 U of AbobotulinumtoxinA including 57 men with IDO. Success was 91% for NBD and 93% for IDO, with 12% retention only in the male patients [513]. In a study using a type A neurotoxin, produced in a medical school laboratory and purified by a procedure using a lactose gel column, Lee et al. [471] reported improvements in 89% of patients treated for incontinence due to IDO and NDO. Mangera et al. [514] did a systematic review on management of lower urinary tract diseases comparing OnabotulinumtoxinA and AbobotulinumtoxinA. They identified good-quality
studies for OnabotulinumtoxinA in adults and lack of such studies for Abobotulinum- toxinA, although this does not imply that OnabotulinumtoxinA is more effective than AbobotulinumtoxinA.

Many studies with botulinum toxin detrusor injection use different outcome measures for results and are variable in reporting the presence of residual urine and the need for intermittent catheterization, but 6-75% of cases may develop a high post void residual urine [469,471,473,476]. A retrospective study looking at risk factors for adverse events in a series of 217 patients treated with OnabotulinumtoxinA showed an overall 63.3% success, with male gender, baseline PVR ≥100 ml and dosage >100U as predictors of urinary retention or difficulty voiding. Besides being an alternative for treatment of refractory DO, currently available data do not support superiority of any specific treatment plan, and therapy options should be tailored to the specific patient and physician preference [515]. Higher doses such as 200 units in IDO resulted in incomplete emptying, necessitating intermittent catheterization in 6 out of 16 patients (37.5%) in one study [476]. Sahai suggests a careful follow up of the patients after the injections, starting IC in symptomatic patients if post void residual urine is more than 100-150 ml [516].

Many reports do not separate genders and mix neurogenic and idiopathic etiologies. A large number of publications are reviews of the literature [517-535]. There is a randomized double blind OnabotulinumtoxinA placebo controlled trial showing favourable difference against saline injections for frequency and incontinence, but not for urgency [476]. Quality of life analysis showed improvement even with the occurrence of 38% of urinary retention [536]. In a dose-finding randomized double blind placebo controlled study with a total of 313 IDO patients of both sexes, all OnabotulinumtoxinA dosages (50-300U) were better than placebo, but the 100 and 150 U dosages were best in regard to the balance between efficacy and side effects [537,538]. In women, a placebo controlled randomized study with 200U of OnabotulinumtoxinA for IDO showed a 60% clinical response but was terminated early due to 43% of patients having increased PVR [539].

Conclusions

**Efficacy of botulinum toxin A for IDO: level 1 of evidence, Grade of recommendation A** (for OnabotulinumtoxinA). Fewer studies for AbobotulinumtoxinA and the lack of studies for other A toxins do not allow similar recommendation.

**Dosage of botulinum toxin A for IDO:** between 100 and 150 U (for OnabotulinumtoxinA). No studies for other types. **Level 1 of evidence; Grade of recommendation A.**

Location of injection: the majority of studies use 20 or 30 injections, and spare the trigone (Table 13). Alternative sites such as submucosal or including the trigone, have levels 2 and 3 of evidence. **Grade of recommendation C.**

**Predictability of complications:** Risk factors for retention or difficulty voiding are: male gender, baseline PVR≥100ml and a dosage >100U. **Level 3 of evidence; Grade of recommendation C** (for OnabotulinumtoxinA– for other types, no conclusion possible).

The committee cautions that although the efficacy and safety of botulinum toxin A for IDO is being established there are still concerns regarding the data. Its use in men is not as widely reported as its use in woman; the issue of voiding difficulty and the need for intermittent catheterization has not been addressed in men. There are no long-term or cost effectiveness studies compared to alternatives. Furthermore the recommendations cannot be extended to other toxins due to lack of studies.

**Electrical stimulation and neuromodulation**

Electrical stimulation of the genital area was first used to control incontinence due to DO of different etiologies on an empirical basis [540]. Later, it was suggested that sphincteric contraction induced by electrical stimulation can promote an inhibitory effect on detrusor activity, thus suppressing DO [541]. Many studies of external electrical stimulation for bladder inhibition of idiopathic urgency incontinence have been published, mainly in female patients [542-549]. The results vary from 45% to 85% success, with a mean of 38%, and 26% improved. Electrodes implanted in the pelvic floor, have not yielded good results [547].

Sacral neuromodulation has been reported as alternative therapy for urgency incontinence, urinary retention, chronic pelvic pain, and for simultaneous urinary and fecal incontinence [550]. Good results have also been published in treating neurogenic bladder dysfunction [551,552]. The working mechanism of neuromodulation in the treatment of lower tract dysfunction is still unknown [553,554]. A suggested mechanism is somatic afferent inhibition of sensory processing in the spinal cord [555,556], therefore it may be a centrally acting treatment modality that is different from botulinum toxin, which is an end-organ therapy that specifically targets the bladder [557].

Long-term results suggest a sustained effect on restoring voiding in appropriately selected cases, but a revision rate of 42% at 5-year follow up remains a problem [558]. The 14-year revision rate from a single center was 39%, which decreased after the introduction of new materials [559]. On-demand use, as suggested by Oerlemans et al. [560] may improve this revision rate by prolonging battery life. Its use in refractory idiopathic urgency incontinence has been limited to relatively few patients, mostly women. Bosch and Groen [561] presented results of chronic implantation in 15 women and 3 men, with
an average age of 46 years. Significant improvements in voiding frequency, average voided volume, number of incontinence episodes and number of pads used were found, with no deterioration in response to stimulation with time. However, with subsequent experience in 14 men only 2 patients had a partial response and the rest ultimately failed [562]. Shaker and Hassouna [563] implanted 18 patients with refractory urinary incontinence, but only 2 were in men. Groen, Bosch and van Mastrigt reviewed 33 implanted women and found no effect on urethral resistance and bladder contraction strength, thought to be due to the depressant effect of sacral (S3) nerve neuromodulation on detrusor overactivity [564]. Groenendijk et al. in a retrospective study for the Sacral Nerve Stimulation Study Group, reported urodynamic aspects of 111 patients implanted, but only 8 men were included [565]. They found a better result on urgency incontinence in patients without DO. The difference was not significant. This tendency was also found by South et al. in 67 women implanted [566]. Clinical or urodynamic values to predict the outcome of sacral nerve stimulation has been difficult to define. Evaluation of 19 women suggested that urethral overactivity seemed to be a good parameter to predict a favourable outcome [567].

Some studies do not specify the etiology of the DO and neurogenic and non-neurogenic causes are grouped together [563]. Some reports focus on technical or specific aspects of the procedure and the same patients may be included in different publications [565,568-570]. Implantation in children may be feasible in selected cases [571,572] and poorer results are expected in older women [102]. The outcome in older men is unknown since there are no reports.

Table 14 [478,558,573-582] shows recent studies.

Some reports are literature reviews [554,583-585] or detail technical modifications [586,587]. There is one systematic review on efficacy and safety of sacral neuromodulation for urgency incontinence, but 13 of the articles analyzed are abstracts and it is also difficult to ascertain whether the same patients are included in different publications [588].

There are some publications with level 1 [573,574 or 2562,576,577] evidence and with a grade of recommendation of B. However, due to relatively few men in the clinical trials, and poor results in one of the prospective trials, its general applicability to men with urgency incontinence may be limited. The scenario remains unchanged after about 26,000 patients implanted [589]. In a recent review, Apostolidis [590] concluded that further research is needed to improve patient selection, identify prognostic fact-

tors, clarify the mechanism of action, and reduce complications and revision rates.

Level of evidence 3. Grade of recommendation C.

c) Surgical treatment by detrusor myectomy and augmentation

Previously used treatments of surgical bladder denervation, open bladder transection, cystolysis, endoscopic phenol injections, hydrostatic bladder distention did not yield good results.

Bladder autoaugmentation or detrusor myectomy has been reported as an alternative to augmentation in neurogenic and non-neurogenic dysfunction. Table 15 [591-593] shows results of this treatment in patients with non-neurogenic detrusor overactivity. There are few long term results available [593]. The use of silastic intravesical balloon as a scaffold after myectomy seems to improve results in neurogenic patients but was not tested in IDO [594]. Additional and longer-term experience is still required to properly assess this procedure. (Level of evidence 3; grade of recommendation C-D)

Enterocystoplasty results are detailed in table 16 [592,595-601], which includes both male and female patients. Some publications are not clear about the type of surgery specifically done in IDO and about the gender. Good results vary from 58% to 88%, with an average of 77%. Approximately 10 to 75% of patients require intermittent catheterization for bladder emptying. Ileum was the most frequently used bowel segment followed by sigmoid colon, although no scientific reason for the use of any particular segment was given. The surgery, as reported in other sections, has a significant complication rate and should be considered carefully when applying it to these patients. (Level of evidence 3; grade of recommendation C)

2. REDUCED BLADDER CAPACITY

Fibrosis of the wall produces a low-volume low-compliant bladder, leading to diminished functional capacity. Symptoms of frequency and nocturia occur as a result of progressive decrease in bladder volume, but urinary incontinence may also be the consequence of a very small capacity, especially if accompanied by urethral weakness. The diagnosis can be suggested by the micturition chart, and confirmed by urodynamics. The causes can be congenital or acquired. Acquired causes include multiple surgeries, inflammatory processes (chronic cystitis, interstitial cystitis, tuberculosis, schistosomiasis, and chemical cystitis) or following radiation.

Bilharzial contracted bladder is a problem that is primarily limited to endemic areas in Africa and the Middle East. Schistosoma haematobium migrates to the veins of the vesical and pelvic plexuses, where the female begins to lay eggs, promoting a initial inflammatory response. As a result, granulomatous lesions form in the lamina propria. Mucosal reactions vary from hyperplasia to polypoid cystitis. A contracted bladder occurs in 2% of cases [602]. Bladder augmentation seems to offer reasonable results in these cases.

Similarly, small fibrotic bladders due to other etiologies can be treated successfully with enterocystoplasty. The results of this surgery are presented in Table 17 [603-631]. The results are similar in all etiologies except for radiation. The poorer results after radiation may be due to other tissue damage in the surgical area. New conformal techniques for radiotherapy may improve results in the future, so that the need for augmentation cystoplasty decreases.

Almost all of these studies do not distinguish bowel segments or separate males from females in reporting results. Therefore, it is not possible to correlate any particular aspect with the chance of success or failure. However, overall the results seem reasonably good with the exception of patients who have undergone radiation. (Level of evidence 3; Grade of recommendation C)

Urethrocutaneous or rectourethral fistula may have congenital, inflammatory, neoplastic or traumatic origins. It is important to vary the etiologies because each type may require a different surgical strategy. All reports except one are retrospective case series. The report by Shakespeare et al. [632] is from a prospectively collected database of patients treated with radiotherapy for prostate cancer. (Level of evidence 3; Grade of recommendation C)

1. URETHROCUTANEOUS FISTULA (UCF)

a) Acquired UCF

Hidden foreign bodies have been described as a rare cause of both strangulation of the glans penis and urethrocutaneous fistula. Tash and Eid [633] presented the case of a 30-year-old man who developed a urethrocutaneous fistula and penile shaft necrosis after a condom broke during intercourse. Neither the patient nor several physicians could identify the retained ring of condom, which had been buried under newly epithelialized skin. He underwent removal of the foreign body under general anaesthesia, followed 5 months later by a formal urethrocutaneous fistula repair.

Urethroperineal fistula, as a complication of open perineal prostate cryosurgery, occurs as an immediate perioperative complication in 10.7% [634]. Thomas et al. [635] retrospectively evaluated 250 patients after radical perineal prostatectomy and revealed only 1 (0.4%) urethroperineal fistula. Fakhri et al. [636] published an unusual complication of mycetoma. The patient had an infection with Actinomadura madurae that involved abdominal wall, perineum and urethra. This resulted in urinary extravasation with a urethrocutaneous fistula.

b) Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography (Figure 3), urethroscopy, fistulography, urethral ultrasound or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess [637].

Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure [638]. (Level of evidence 3; Grade of recommendation C)

2. RECTOURETHRAL FISTULAS (RUF)

Culp and Calhoon described five basic groups of RUF according to the etiology [639]: congenital, iatrogenic, traumatic, neoplastic, and inflammatory.

a) Congenital RUF

Endo et al. [640] described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from 1976 to 1995 were analysed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be categorized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down’s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights.

The purpose of Rintala’s study was to compare the long-term outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) to that of posterior sagittal anorectoplasty (PSARP). In boys with high anorectal anomalies, PSARP was superior to SP-SAP pullthrough in terms of long-term bowel function and faecal continence [641].

b) Acquired RUF

Acquired RUF may occur after pelvic trauma, surgery of the prostate or rectum, pelvic cancer, radiation (either external beam or brachytherapy),
cryosurgery, prostatic hyperthermia, prostatic high intensity focussed ultrasound (HIFU), inflammatory bowel disease affecting rectum, or rarely prostatic inflammation.

Benchekroun and co-workers [642] report a series of 11 RUF observed over a 25-year period. The etiologies were surgical trauma (5 cases), fracture of the pelvis (2 cases), inflammatory lesions (3 cases), and one fistula was congenital. Colostomy was performed in 2 patients, surgical closure of the fistula was performed in 7 patients: abdominoperineal (3 cases), perineal (2 cases), transperitoneal (1 case) or by transanosphincteric incision (1 case).

In 1972 Smith and Veenema [643] reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only 4 fistulas developed in this group.

Roberts et al. [644] published a series of 11,452 men who underwent open (RRP) or laparoscopic (LRP) radical prostatectomy. Rectal injury occurred in 18 men -12 in the RRP group (0.12%) and 6 in the LRP group (0.47%). When recognized intraoperatively and primarily repaired, rectourethral fistula was prevented in 87.5% of men. Primary repair performed with vascularized tissue interposition prevented rectourethral fistula development. In men with unrecognized rectal injury, the rectourethral fistula tended to persist and eventually required delayed surgical repair. Thomas et al. [645] reported that rectourethral fistulas developed in 13 of 2,447 patients (0.53%) after RP. In 7 of 13 patients (54%) a rectal lesion was primarily closed at radical prostatectomy. With conservative management in 3 patients, all 3 healed spontaneously. None of these patients had fecaluria. Three of the 9 patients 3 (33%) experienced spontaneous fistula closure after temporary colostomy and transurethral catheterization. In this group 6 patients (67%) required additional surgical fistula closure, which was successful in all. Surgical fistula closure (1) without colostomy in presence of fecaluria failed.

The most common single cause of RUF in the series of 23 male patients published by Tiptaft et al. [646] was a fracture of the pelvis and iatrogenic causes (two cases after transurethral prostatic surgery, two cases after open prostatectomy, and three cases after urethral instrumentation. Noldus et al. [647] reported 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino [648] summarized the incidence of rectal injury during RRP in 3834 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4%.

Nyam et al. [649] reviewed records of all patients who were diagnosed with RUF between January 1981 and December 1995 and 16 males were identified. All patients were interviewed by telephone for follow-up. The mean age was 68 years and the mean follow-up was 80 months. Adenocarcinoma of the prostate in 15 patients and recurrent transitional cell carcinoma of the bladder in one patient were the underlying malignant diseases. Nine patients had had a RRP with 2 fistulas after radiation, 2 after brachytherapy, and 3 after a combination of radiation and brachytherapy. One patient formed a fistula after cystectomy and dilation of a stricture. This heterogenous group of patients received multiple therapies including initial colostomy (7 patients), transanal repair (2 patients), transperineal repair (2 patients), colon anastomosis (3 patients), and muscle transposition (3 patients). Four of the patients required a permanent stoma.

Badalament et al. [650] managed one patient (0.4%) with a urethreorectal fistula after cryoablation therapy for prostate cancer. Zippe [651] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter 634 found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al. [652] reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow-up was 33.5 months and RUF occurred in 1%.

Montorsi et al. [653] reported a RUF after transrectal prostatic hyperthermia (43 degree C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month.

Kleinberg et al. [654] summarized results of 31 patients with stage T1 or T2 prostatic carcinoma following CT guided transperineal I125 implants and reported that only one patient developed a prostatorectal fistula that was managed with an ileal conduit.

Fengler and Abcarian [655] published their experience of eight patients with RUF in the course of treatment of prostate cancer (3 fistulas after radiation therapy alone, 3 after prostatectomy and 2 after both surgery and radiation therapy). Larson et al. [656] evaluated 5719 patients after radiation for prostate cancer. Ten had documented RUF. Lane et al. [657] treated 21 men with RUF following primary external beam radiotherapy and one after adjuvant external beam radiation therapy for prostate cancer. Time from the last radiation treatment to fistula presentation was 6 months to 20 years. Four patients underwent proctectomy with permanent fecal and urinary diversion. Successful fistula closure was achieved in the 9 patients who underwent urethral reconstruction. Chrousier et al. [658] identified a total of 51 patients with a history of external beam radiation for prostate cancer that subsequently had
a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

Shakespeare et al. [632] reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1455 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. They concluded that gastrointestinal specialists should not perform biopsy of the anterior rectum in patients who have had BT unless there is a very high clinical suspicion of malignancy. Marguet et al. [659] described 6 cases of RUF in patients treated with brachytherapy plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. They also concluded that biopsy of rectal ulcers in the clinical setting of combined radiotherapy should not be performed.

Chang et al. [660] published a case of prostatic malakoplakia masquerading as a rectal tumor due to formation of a fistulous tract to the rectal muscular layers. Cools et al. [661] reported a very uncommon type of fistula between the large bowel and the prostatic urethra due to Crohn’s disease. Felipetto et al. [662] described a prostatocutaneous fistula as a complication of pseudomonas prostatitis.

Transrectal high-intensity focused ultrasound (HIFU) destroys prostate cells by coagulative necrosis of the tissue. Recent reports of efficacy also include morbidity. Rebillard et al. [372] reported RUF in 0-3% in a review involving 37 articles/abstracts.

Buckley et al. [663] concluded that there has been a major shift in the cause of RUF from primarily surgical to approximately 50% resulting from radiation/ablation therapy. Surgically induced RUFs typically are small, located in bladder neck/trigonal region and can be closed primarily. Radiation/ablation induced fistula are large (>2 cm), involve the prostatic urethra and are fibrotic often requiring a combination of onlay grafting and interposition muscle flap for closure. The anterior, perineal sphincter-sparing approach may be the optimal approach for closure of most RUF (simple or complex). Lacarrière et al. [664] noted that the use of radiotherapy had a major impact on its prognosis. The flap, which seemed to have the best results, was the gracilis muscle flap.

c) Diagnosis of RUF

RUF may be strongly suspected from the patient’s history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Rectal examination, proctoscopy, careful urethroscopy, intraurethral injection of methylene blue dye, radiopaque contrast agent placed into the bladder and then voided usually appears in the rectum on X-ray, are the most important diagnostic steps [637,665] (Figure 4).

d) Therapy of RUF

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others [645]. Gibbons 666 stressed the need for a diverting colostomy for 3-4 months.

Figure 4. Cystogram demonstrates a rectourethral fistula that occurred after a laparoscopic radical prostatectomy
However, as surgeons obtained more experience, bowel preparations became standardized, and effective antibiotics were developed, and the enthusiasm for colostomy diminished. Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

e) Surgical Approaches

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (e.g., omentum [667], gracilis muscle [668], or scrotal flap [669]) has been described. Surgical approaches include transabdominal, transvesical, or direct exposure of the RUF.

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Rivera et al. [670] staged RUF as: stage I, low (less than 4 cm from anal verge and nonirradiated); stage II, high (more than 4 cm from anal verge and nonirradiated); stage III, small (less than 2 cm irradiated fistula); stage IV, large (more than 2 cm irradiated fistula); and stage V, large (ischial decubitus fistula). Diverting colostomy was performed for stages III to V 6 weeks before definitive therapy. Some of the patients in addition to the RUF will also have urethral strictures that have to be managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions. [671]

The surgical approaches including the numbers of reported patients are listed in Table 18 [639, 642, 643, 646, 647, 655, 665, 669, 672 - 688]

1. PERINEAL APPROACH

In 1926, Young [672] dissected the rectum away from sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis, in 1947 [673], described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al. [674] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al. [689] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in Figure 5. Pratap et al. [690] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF.

Figure 5A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder.

Figure 5B. Retrograde urethrogram after transperineal closure of RUF
Table 18. Surgical approaches to rectourethral fistulas

Samplaski et al.\(^{691}\) reported transperineal repair with gracilis muscle interposition in 13 patients with complex RUFs of varying etiologies. One patient developed recurrence. They demonstrated low morbidity, high success rates, and reasonable bowel and bladder function postoperatively.

2. Posterior Sagittal Approach

Kraske in 1885\(^{692}\) described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccygectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumour-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson\(^{677}\) used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

3. Posterior (Parasacrococcygeal) Transssphincteric Approach

In 1969 Kilpatrick and Mason\(^{679}\) updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated trans-
abdominal or transperineal approaches to RUF. It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum [655]. After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization. After closure of the prostatic urethra it is recommended that the full-thickness rectal wall flaps are close in a “vest over pants” technique (Figure 6). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles (Figure 7). Fengler and Abcarian [655] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al. [681] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al. [680] in the management of a case of the urethroprostato-rectal fistula after a gunshot wound.

Stephenson and Middleton [678] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transssphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin [684] reported preliminary experience with the transssphincteric, transanal surgical approach to correct acquired urethral fistula in five men. Mean patient age was 56.6 years (range 37 to 72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1. The time from the diagnosis of urethral fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethral fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al. [693] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn’s disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn’s disease and in another with ulcerative rectocolitis.

Erickson et al. [694] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the ex-

Figure 6. Rectourethral fistula repair. Full thickness rectal wall is mobilized to close in a “vest over pants” technique to close the fistula.

aggerated lithotomy position. In a modified prone position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure.

Lorente et al. [695] reported early successful closure in 10 patients with the posterior transsphincteric York-Mason technique, with good recovery of urinary and fecal continence. Pera et al. [696] reported on 5 patients successfully treated after RP with the York Mason technique. They reported minor morbidity and no impairment of continence.

4. Transanal Approach

Parks and Motson [683] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal (Figures 8 [697] and 9). They modified the transanal technique by denuding the rectal mu-

cusa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers’ fascia proximal to the fistula for four centimeters. Tiptaft et al. [646] also used a special anorectal retractor for this surgery.

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al. [647] reported 23 patients (3.9%) with rectal injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seven fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al. [665] treated 30 men with RUF caused by war wounds. He used the method of posterior transspincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in ‘spontaneous’ RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

5. Anterior Transspincteric, Transanal Surgical Approach (ASTRA)

In 1973 Gecelter [685] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The anal sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al. [698] reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by anterior transspincteric, transanal surgical approach (ASTRA).

6. Endoscopic Approach

Wilbert et al. [687] reported two patients with RUF who were repaired endoscopically transanally. The patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum. The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al. [688] used cyanoacrylic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administered endoscopically through an open-end 6F ureteral catheter. Quinnlan et al. [699] presented the case of an iatrogenic fistula in a 71-year-old man treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al. [700] reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM): the RUF occurred after laparoscopic radical prostatectomy. Pigalarga et al. [701] described a case of successful repair of iatrogenic RUF through a multidisciplinary approach consisting of cystoscopy, urethral stent placement, colonoscopy, and transanal endoscopic microsurgery assisted rectal advancement flap.

7. Other Modifications

Youssef et al. [675] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous dartos flap procedure. The RUF resulted from crush pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphyseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous dartos flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous dartos flap may fulfill the principles for successful repair of RUF. Varma et al. [702] also concluded that dartos muscle interposition is a straightforward technique that can result in successful fistula repair, but should not be used in immune-compromised patients or after radiation therapy.

Felipetto et al. [662] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam [703] prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond. Verriello et al. [704] used fibrin sealant (Quixil) to inject it into the fistula tract and a rectal mucosal flap was used to close the internal opening. The fistula healed in few weeks, and the patient remained symptom free after 1 year of follow-up.

Chirica et al. [705] reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex
rectourinary fistulas after radical prostatectomy or following anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7. Lesser et al. [706] reported a case of radiation and salvage cryoablation induced RUF after treatment of prostate cancer which was successfully repaired with a combined endorectal advancement flap with an AlloDerm graft.

f) Summary

A review of recent literature shows an increasing number of papers describing treatment. All available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a lack of valid epidemiologic data about the incidence of UCF and RUF. The diagnostic algorithm has not changed in many years.

The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and undiversion). An endoscopic approach using biological sealants is promising. Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF, and the management of these difficult conditions should remain in the hands of experts working in tertiary referral centres. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients.

All reports are still only retrospective case series (Level of evidence 3; grade of recommendation C).

X. THE ARTIFICIAL URINARY SPHINCTER (AUS)

Different devices designed to control urinary incontinence in the male began to appear in the middle of the 18th century [707]. The gold standard today is the artificial urinary sphincter (AUS) designed by F.B. Scott, W.E. Bradley, and G.W. Timm in 1973 [708]. The original model underwent a number of modifications, but the basic principle remained the same. It consists of a fluid filled hydraulic system with a cuff around the urethra, a pressure regulating balloon and an activating device, the pump, placed in the scrotum.

1. AVAILABILITY AND COST

The use of the AUS has increased dramatically since its introduction in 1975 when 90 AUS devices were implanted until 2008 when 4818 procedures were done, with 61% implanted for PPI. [709, 710]

In 2005, just over 10% of US urologists perform AUS surgery with the vast majority (92%) performing 5 or fewer surgeries a year and there were only 8 surgeons who implanted 21 or more AUS devices per year. [710]

The results of an e-mail survey among urologists and gynecologists were previously published in the 3rd ICI, whereby members of the International Continence Society were asked if the AUS was available in their country; and if so, what was the price of the device (in US dollars). About 10% of the members responded by email from 31 countries. The high price in some countries at the time (Georgia, Hong-Kong, Romania and Saudi Arabia) precluded its use. Very few gynecologists implant the AUS, probably since the majority of patients receiving the device are male.

2. INDICATIONS

The indication for AUS placement is for the treatment of SUI that is persistently bothersome despite 6-12 months of active conservative management. As the most common cause of SUI in men is iatrogenic injury during prostate cancer surgery, it follows that the most common indication for AUS is post-prostatectomy incontinence (PPI). The use of the AUS for the treatment of PPI varies regionally. For example, within the United States, state-by-state use of the AUS ranges from 1% to 10% of all RRP patients, with an average of 6% of RRP patients ultimately undergoing AUS implantation.[711]

Previous radiotherapy to the pelvis is not a contraindication for AUS placement in males,712 as the ultimate outcome seems to be similar in men whether or not they have received radiation therapy [713], although a higher incidence of urethral atrophy, erosion and infection requiring surgical revision has been reported in irradiated patients compared to those not irradiated (41% vs 11%). Despite this observation, long term continence and patient satisfaction appear not to be adversely affected in the irradiated male patient [713].

The compressive effect of the AUS is temporarily relieved when the patient squeezes the scrotal pump, transferring fluid from the urethral cuff to the pressure-regulating balloon. Subsequently, the bladder can then empty either by bladder contraction and/or by abdominal straining. Accordingly, patients voiding with the Valsalva maneuver because of an underactive or neurologically acontractile bladder, do not seem to be at an increased risk of complications [714]. It should also be noted that patients with previous anti-incontinence procedures show a significantly higher explantation rate [715].

Clinical experience suggests that enterocystoplasty or gastrocystoplasty can be done simultaneously...
with the implantation of the AUS [716,717]. However, AUS placement at the time of cystoplasty is associated with earlier infections, especially during the first 3 years post-operatively [718]. In the long-term (> 3 years) the infection rate is the same whether the AUS is implanted after or at the time of cystoplasty. AUS can also be successfully implanted in patients after bladder substitution [387], and in those with locally recurrent prostate cancer with a relatively good prognosis [719], or those with severe post-radical prostatectomy anastomotic stricture in whom a stent has been placed previously [398].

Finally, advanced age is not a contraindication to AUS placement. A retrospective analysis by O'Connor and colleagues of a cohort of men over age 75, revealed excellent success rates, with 21 of 29 men (72%) achieving successful continence. Revision rate was 14% at an average of 5 years follow-up, with 14% requiring explantation, and 21% requiring device deactivation due to deterioration in overall health precluding proper use of the AUS at an average of 47 months after placement [720].

3. SURGICAL TECHNIQUES

The original technique of implantation is illustrated in Figure 10. The cuff of the sphincter is placed around the bulbar urethra via a midline perineal incision, while the pressure regulating balloon and the scrotal pump are inserted via a separate inguinal incision. The inguinal incision is carried through the fascia, above the level of the ligament and an area in the prevesical space is bluntly cleared. The pressure-regulating balloon is placed there and filled with 23 cc of saline or contrast after which the fascia is closed. A tunnel is made under Scarpas fascia into the scrotum deep to the dartos fascia where a pocket for the pump is developed. The cuff tubing is transferred from the perineum to the inguinal incision after which the excess tubing is cut off and the appropriate connections are made with the quick connect system.

Another surgical approach has been described using a single, upper transverse scrotal incision which allows the placement of all 3 components of the system, the cuff, the pump in a scrotal pouch, and the reservoir behind the fascia transversalis [304]. Alternatively, the pressure-regulating balloon may be placed through a separate inguinal incision, with the cuff and control pump placed via a single trans-scrotal incision, with the connections among scrotal pump, balloon reservoir, and urethral cuff tubing made in the usual inguinal incision. While the trans-scrotal approach potentially minimizes the invasiveness of the AUS surgery, by limiting the surgical approach to a single incision [304], a few reports have revealed that surgical success might be diminished compared with perineal cuff placement and abdominal balloon reservoir placement [721,722]. A multicenter retrospective study by Henry et al of 158 patients operated on at 4 centers noted that in patients treated with a perineal versus trans-scrotal AUS the perineal group had a completely dry rate of 44%, versus 28% in the scrotal group (p<0.03) and had much higher rates of “social continence” as well. Thus the perineal approach for initial artificial urinary sphincter implantation appears to control male stress incontinence better than the trans-scrotal approach.

The trans-scrotal approach appears particularly useful for simultaneous placement of an AUS and inflatable penile prosthesis through a single incision, with Kendirci and colleagues [723] reporting a urethral erosion rate of 9%, an overall revision rate of 14%, and a social continence rate of 100% in 22 patients at 17 months average follow-up. Sellers, et al. [724] recommend the simultaneous surgery for cost-efficacy. They demonstrated a $7,000 cost savings when both devices were implanted simultaneously through a scrotal approach, compared to staged implantation with 2 separate surgeries.

Recent experience with the relatively new 3.5 cm cuff has demonstrated significant efficacy with no increase in complications during 14 months of study at one site [725]. The 3.5 cm cuff has become the predominant size used for primary and revision surgery at that center.

4. COMPLICATIONS

Complications following implantation of the AUS can be divided into the categories of incontinence, erosion and/or infection, and unusual complications. While the number of AUS procedures performed varies geographically throughout the world. Certain “centers of excellence” perform substantially more procedures than do community hospitals [711]. However, the total number of procedures done in a given center does not seem to be a determining risk factor for complications. Comparable erosion/infection rates have been reported from centers with fewer than 50 or more than 100 cases [282]. This suggests that erosion and infection may be more closely related to the physiologic state of the patient rather than the experience of the surgical team, provided standard precautions are strictly applied. Nevertheless, as experience with the AUS has grown the overall revision rate has reportedly decreased [710].

a) Incontinence

Incontinence following implantation of an AUS can result from (1) alteration in bladder function, (2) atrophy of the urethra, or (3) mechanical failure of the device. These causes may co-exist.

1. ALTERATION IN BLADDER FUNCTION

Lai and Boone noted that based on postoperative patient symptoms and the need for anticholinergic medication up to 23% of men undergoing AUS for PPI can develop denovo OAB [268]. UDS were not repeated postoperatively to define the bladder changes associated with this.
A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to expose the bulbar urethra.
B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size.
C. The belt-like cuff is positioned around the urethra.
D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir.

H. Connectors are placed to join the tubes from the cuff and reservoir to the corresponding tubes from the pump in the RLQ incision.

Figure 10. Artificial Sphincter Technique
Alteration in bladder function has been reported principally in patients with neurogenic bladder dysfunction, especially in children [726-731]. These changes include de novo involuntary detrusor contractions, decrease in bladder compliance, and the development of a high-pressure system, causing incontinence, hydronephrosis and ultimately renal failure. Modifications in detrusor behavior (including its consequences on the upper urinary tract) occur in up to 57% of such cases [726-737]. It should be pointed out, however, that there has never been a published report of hydronephrosis following implantation of an AUS for incontinence after prostatectomy [738]. While the ideal candidates for sphincter implantation are those with an incompetent urethral sphincter, and a low pressure, relaxed, and compliant bladder [735], data described earlier demonstrated that even those with “unfavourable” urodynamic factors may have a good outcome after AUS placement [58].

2. **Atrophy of the urethra**

Urethral atrophy may occur at the cuff site secondary to long-term mechanical compression of the periurethral and urethral tissues. However, some authors do not mention it as a possible cause of AUS failure [336,738,739]. About 4 months following implantation, cuff efficiency diminishes, presumably because pressure atrophy occurs in every patient to some extent 740. The incidence of urethral atrophy leading to revision varies from 3% to 9.3% [253,259,262,423,736,741-743]. Atrophy can be lessened with nocturnal deactivation of the cuff [744].

b) **Mechanical failure**

The causes include perforation: of one of the components with loss of fluid from the system, air bubbles or organic debris within the system causing inadequate function of the pump, disconnection of one of the tubes, or kinking of a tube. Introduction of “kink-free” tubing has virtually eliminated this last complication. The incidence of these complications varies widely and ranges from 0% [741] to 52.5% [269] with the longest follow-up. In this latter study, the cuff seemed to be the most vulnerable part of the system (22 cuff failures in 18 patients, most of them occurring during the first 2 to 3 years following implantation), followed by pump failure (6 times in 4 patients). Blockage is an exceptional event, occurring only once in 61 patients followed from 10 to 15 years [269]. In a publication from Baylor [262], chronicling a 13-year experience with the AUS, mechanical failure occurred at an average of 68.1 months postoperatively. An unusual mechanical complication has been reported. The locking tab became displaced distally into the cycling portion of the cuff preventing the fluid from flowing into the cuff surrounding the urethra.[745]

c) **Erosion and/or infection**

Erosion and infection are two major complications that almost invariably necessitate removal of the prosthesis. Their incidence may be reported separately, or more commonly together as a single complication. The incidence of these complications varies from 0% to 24.6% [253,336,423,729,735,736,741-743,746,747]. Most recent large series report an incidence of infection and erosion generally less than 8% [56,261,262,274,738,739,748,749]. As would be expected, the highest incidence has been reported with the longest follow-up (10-15 years) [253]. Lai and colleagues [262] from Baylor reported that erosion occurred at an average of 19.8 months postoperatively rather than in the peri-operative period. Previous surgery [750] at the site of cuff placement increases the risk of erosion. This, however, may be decreased by delayed cuff activation [751]. A recent study by Lai et al. [752] noted that patients undergoing a “secondary” implant (after a prior explant for erosion or infection) had a four-fold higher erosion rate compared to “virgin” cases. Some authors, however, did not find an increased incidence of complications when a new cuff was implanted at the site where several months before, a cuff has been removed for infection or erosion [753]. Other risk factors include urethral catheterization and urethral endoscopic manipulations with an activated sphincter in place [754]. This point is important and it is crucial that patients with an AUS understand that if they are to have a catheter placed they should ask their physician to have a urologist deactivate the AUS first.

A likely etiology of early erosion is intra-operative laceration of the urethra when dissecting it from the corpora cavernosa, where a difficult anatomical plane exists. Intraoperative recognition of urethral injury can be facilitated by retrograde perfusion sphincterometry using a flexible cystoscope35. While recognition of a urethral injury may alert the surgeon to the necessary termination of the procedure, urethral erosion may still occur without a known urethral laceration [755].

As mentioned above, while the majority of authors consider previous radiotherapy a risk factor for increased infection and erosion, it is not a contraindication to implantation of an AUS in the male patient with PPI [252,254,276,332,713,739,756]. Overall patient satisfaction is similar in those who have been irradiated, compared to those who have not been [252,263,713]. Furthermore, the degree of satisfaction does not diminish with an increased number of surgical revisions [267,757].

d) **Rare complications**

Several unusual and rare complications have been reported in the literature, such as the intravesical migration of the reservoir with secondary stone formation in the bladder [758], or a giant urethral diverticulum at the site of a previously removed cuff because of erosion and urinary extravasation [759].

5. **Durability of AUS components**

When defining durability of one of the components or the AUS as a whole, one should distinguish
between explantation of the device due to device malfunction (e.g. leak in one of the components) or complications caused by an otherwise properly functioning sphincter unit (e.g. cuff erosion, infection at the site of implantation, etc.). This distinction is rarely made in the literature. Durability of a device is defined as time elapsed during which no mechanical problem alters the normal function of the device. This should exclude the second group from further analysis.

There are very few references in the literature pertaining to the length of time a device functioned normally before its removal due to mechanical failure. In a multicenter trial, for neurogenic bladders, conducted in France [736], the authors mention that the “mean operational life” of the sphincter was 56 months (range 3-118 months). Haab et al [259] analyzed 68 patients and noted that the mechanical failure rate dropped from 44.4% to 12.4% since modifications were made to the device, mainly the cuff component. Survival time of these components was not provided. Similar conclusions can be drawn from a series from the Mayo Clinic [265] where the modification of the cuff design (narrower back) resulted in a substantial drop of the reoperation rate at 5 years. In the “narrow back” group 17% (31/184) required reoperation. In that cohort, non-mechanical failure decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff [265]. Mean time to reoperation was 26.2 months (mean 2-68 months). Using Kaplan-Meier statistical analysis for this group of patients, the overall 5-year expected product survival was 75%. In Lai’s report regarding Baylor’s 13-year experience with the AUS, only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years [262]. In a review, Venn et al. [336] analysed the outcome of 100 patients in whom an artificial urinary sphincter was implanted for more than 10 years. Thirty-six percent of them still had the original sphincter and were continent at a median follow-up of 11 years. The bulbocavernous, as compared to the bladder neck cuff, provided a slightly better continence rate at 10 years, 92% and 84%, respectively. The lowest erosion rate occurred with the bulbocavernous cuff. Device survival rate at 10 years was 66% in this series.

In a series of 30 boys with spina bifida Spiess et al. [760] found that the mean lifetime of all AUS was 4.7 years, with no statistically significant difference in sphincter survival of those inserted at the bladder neck or the bulbous urethra (4.6 and 4.9 years, respectively). A sharp drop was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point. In a series of 35 adolescents with neurogenic voiding dysfunction implanted with a bulbocavernous cuff over an 11-year period, with an average follow-up of 5.5 years, Lopez Pereira and colleagues [761] reported a 20% mechanical failure rate, with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, who thereby required augmentation cystoplasty. However, continence was achieved in 91.4% of individuals.

In other series, the global long-term (2 to 7.7 years) revision rate, for any of the above mentioned reasons varies between 16% and 50% [261, 262, 266, 267, 424, 757, 761-763]. In Webster’s report [757] of 554 implantations over a 10 year period, (i.e. performed since the 1987 device modification), he noted a mechanical failure rate of only 31/554 (5.5%). Non-mechanical failure was 88/554 (15.9%), with 63/554 (11.3%) due to urethral atrophy and 21/554 (3.8%) due to cuff erosion. Of the total cohort, 21.4% required at least one revision surgery, while 78.6% did not. Of those 119 patients who required reoperation, 76.5% required no further treatment (similar to the non-reoperation rate of the initial cohort), while 23.5% required re-operation for either mechanical or non-mechanical failure. Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence status was comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day urinary control. Patients with neurological deficits seem to have a higher risk of non-mechanical failure and the overall continence rate may be lower compared to non-neurologic patients [32].

6. DIAGNOSTIC PROCEDURES RELATED TO ARTIFICIAL SPHINCTER FAILURE

The diagnostic evaluation of urinary incontinence after the placement of the AUS is critical for the management of these patients and represents a challenging problem for the urologist. Several diagnostic and management algorithms have been proposed, some relatively simple, others more complex [32, 33, 276, 282, 737, 764-766]. Figure 11 shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

Physical examination should exclude infection at the site of the cuff or the scrotal/labial pump. Difficulty compressing the pump suggests tube kinking, fluid loss or an obstructed system. Loss of fluid from the system may be suggested by the inability of the pump to appropriately refill after just one or two pumps.

Plain X-rays of the abdomen or pelvis may show fluid loss, if the system is filled with radio-opaque solution [767, 768] (Figure 1). Alternatively, sonography of the pressure-regulating balloon may show volume loss. One should obtain a baseline plain film after the primary implantation when the reservoir is filled with contrast for subsequent comparison as radio-
Figure 11. Algorithm for managing incontinence after AUS placement.

Figure 12. Endoscopic view of AUS cuff erosion into the bulbar urethra. The patient had undergone radiation after radical prostatectomy.
graphic imaging of the balloon does not detect changes until at least 50% of its volume has been lost [15]. Cystometrogram or complete urodynamic study will demonstrate changes in bladder behavior following insertion of the AUS as described above. Cystourethrography could eventually demonstrate a urethral diverticulum at the site of previous cuff erosion (Figure 2). Endoscopy will disclose any urethral erosion by the cuff (Figure 12).

Retrograde perfusion sphincterometry has been reported to diagnose the loss of compressive pressure in the urethral cuff [32]. It is done by infusing fluid from the meatus in a retrograde fashion. If the AUS cuff is functional and the urethral is intact there should be no flow when the pressure equals the AUS balloon pressure. This technique can also be used intraoperatively to detect urethral perforation or to adjust the pressure in the cuff [35]. This seems to be more useful than urethral pressure profile (UPP) [733].

Intraoperative electrical testing, using an ohmmeter [747,765] has been described to determine the site of fluid leakage from the system. This test can be helpful to avoid the need to change the whole system, and allow replacement of the leaking part only.

7. TREATMENT OF COMPLICATIONS

As outlined above, complications directly related to the presence of an artificial sphincter can be divided into categories: de novo OAB (which is typically treated as OAB), urethral atrophy, and/or mechanical failure, and infection/erosion. The treatment of these complications deserves comment, as no detailed reference can be found in the literature dealing exclusively with the treatment of these complications.

a) Atrophy of the urethra

Several therapeutic options exist to increase cuff pressure around the atrophied urethral wall: changing the balloon reservoir for one generating a higher pressure, downsizing the cuff diameter [15, 254, 769], or increasing the amount of fluid in the system. The most common approach is downsizing of the cuff. Another approach consists of placing the cuff inside the corporal tunica albuginea on the dorsal aspect of the urethra (transcorporal). This allows a safer mobilization of the urethra and adds some supplementary bulk of tissue to the circumference of the urethra, possibly decreasing the risk of erosion [272]. It should be mentioned, however, that there is a risk of reduced erectile function with this technique. The vast majority of such patients, however, already suffer from erectile dysfunction secondary to the prostate cancer surgery.

The implantation of a double-cuff AMS 800 had a recent period of increased popularity, as a primary procedure in the totally or severely incontinent patient [273,770], or as a salvage procedure, by adding a second cuff, following a failed previous single cuff [270,271,770]. Dimarco’s group [271] and others showed excellent results with the addition of a second urethral cuff, placed 1.5–2.0 cm distal to the primary cuff. Alternatively, a circumurethral wrap of an organic bulking agent can be fitted, with subsequent placement of the AUS cuff over the biologic external urethral bulking agent [771]. Early reports of primary double cuff placement did not demonstrate any significant increase in morbidity with the double-cuff as compared with the single cuff system [273], and patient satisfaction also seemed to be higher [274] at an average of 21–41 months follow-up. However, O’Connor et al. [275] recently described their experience with 28 men who underwent double cuff placement and in contrast to an earlier report of theirs found that with longer follow-up there was no difference in continence between those men and 28 who underwent single cuff placement. In addition those who had the double cuff placement had a higher rate of additional surgery due to complications.

b) Mechanical failure

As with any device, mechanical failure can be expected with the AMS 800 AUS. The treatment involves surgical replacement of the failed component and reconnecting the system.

c) Infection

With overt infection the accepted treatment option is removal of the entire device and appropriate antibiotics. A second system can be subsequently implanted with equally good results [751]. It has been demonstrated, however, that immediate reimplantation of a new AUS after the removal of an infected, but not eroded, prosthesis can be a valid option with an overall success rate of 87% [772]. In 2007, AMS introduced the InhibiZone-coated artificial urinary sphincter (rifampin and minocycline hydrochloride coating) [773].

d) Erosion

In cases of urethral cuff erosion, the “offending” cuff must be removed. No clear guidelines exist whether removal of the whole system is superior to removal of the cuff alone but it must be assessed for infection and if present the whole device should be removed. When in doubt remove the entire system. Reservoir erosion into the bladder has been described following the removal of an eroded cuff [758]. Furthermore, it is not known whether it is nec-
necessary to allow the urethra to heal over a catheter versus surgical repair. Most though would leave a catheter to allow for spontaneous healing and wait at least 4-6 months before placing another cuff. When a new cuff is placed it should be positioned away from the erosion site. In case of the erosion of one of the cuffs of a double system removal of the eroded cuff can successfully convert a double-cuff system into a single cuff system [774]. It is logical that intra-operative urethral injury may precipitate cuff erosion if unrecognized.

8. CONSENSUS PROTOCOL FOR FOLLOW-UP OF PATIENTS WITH AUS

As complications continue to be seen for years after implantation [775], it is helpful to have a structured follow-up plan. However, no standardized recommendations are available in the literature.

The consensus upon which the members of this subcommittee agreed and which is based on expert opinion are as follows:

1. Perioperative antibiotics are required. Gram-negative enteric bacteria and Staphylococcus epidermidis are the most frequently encountered microorganisms in infected prostheses [754].

2. Hospital stay should be kept to a minimum.

3. Urethral catheters, if inserted, should be withdrawn within 24-48 hours of surgery and the preoperative continence management continued.

4. The sphincter device should not be activated immediately postoperatively. In the initial period scrotal edema and pain prevent patients from manipulating the pump adequately. When this subsides after 6 to 8 weeks the device can be activated. Earlier activation may also be acceptable. Irradiated patients may benefit from a longer initial period of deactivation, up to 12 weeks [254]. Nocturnal deactivation should be considered in high-risk patients [253].

5. Patients are reviewed at 3 months after activation to ensure the device is working adequately, and to assess the continence status.

6. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time, alteration in bladder function may jeopardize renal function in the neurogenic patients. Periodic ultrasound evaluation of the upper urinary tract and monitoring of renal function is essential. If changes occur, urodynamic studies should be done to rule out detrusor overactivity. In non-neurogenic patients, periodic ultrasound may not be necessary.

7. When changes in the continence status occur diagnostic procedures depicted in Figure 11 should be considered. (Level of evidence 3; Grade of recommendation B-C)

1. EVALUATION OF MALE INCONTINENT PATIENTS

Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (Level of evidence 1-2: grade of recommendation A).

- A voiding diary is helpful to assess functional capacity and total urine output (Level of evidence 1-2: grade of recommendation B).

- Pad tests may be useful in certain circumstances (Level of evidence 1-2: grade of recommendation B).

- Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria or poor urinary concentrating ability (in the absence of diuretics) is documented.

- Additional testing with cystoscopy and appropriate imaging of the urinary tract may be helpful in guiding therapy (Level of evidence 2-3: grade of recommendation B).

- The committee felt that multichannel urodynamics may be useful prior to invasive treatment for incontinence. (Level of evidence 3: grade of recommendation C)

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

After a period of conservative management, which may also be from 6 to 12 months (Level of evidence 3-4; grade of recommendation C):

- The artificial sphincter is the preferred treatment for properly selected men who have stress incontinence after radical prostatectomy with the longest record of safety and efficacy. The AUS has been reported extensively for men with moderate to severe incontinence. (Level of evidence 2-3; grade of recommendation B)

- Male slings are an alternative approach with intermediate data supporting their safety and efficacy in men with more moderate degrees of PPI. Long-term data are beginning to accumulate. However,
the literature contains results on many different kinds of slings. (Level of evidence 3; grade of recommendation C)

- Injectable agents are an inferior option. (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have also been reported. (Level of evidence 3; grade of recommendation D (no recommendation possible))

3. INCONTINENCE FOLLOWING OTHER TREATMENTS FOR PROSTATE CANCER

- The artificial sphincter is most widely used but radiation may be a risk factor for an increase in complications. (Level of evidence 3; grade of recommendation B)
- Slings have variable results after radiation. (Level of evidence 3; grade of recommendation C)
- Injectable agents (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have not been successful in this setting. (Level of evidence 3; grade of recommendation D (not recommended))

4. INCONTINENCE FOLLOWING PELVIC TRAUMA (Level of evidence 3; grade of recommendation C)

- The artificial sphincter is most widely reported.
- Lower urinary tract reconstruction has also been reported on a limited basis.

5. INCONTINENCE IN ADULT EPISPADIUS-EXTROPHY COMPLEX (level of evidence 3; grade of recommendation C)

- Patients should be treated in centres of excellence.
- A patient-directed approach should be taken.
- The choices include further bladder neck reconstructive surgery, bladder neck closure, bladder reconstruction or diversion with bowel.
- The data are insufficient for a specific recommendation.
- Transition is important between the pediatric and adult urologist.
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications

6. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

- Botulinum toxin-A bladder injection is a minimally invasive treatment with efficacy (Level of evidence 1-2; grade of recommendation B).
- Neurourodulation is a treatment option with success reported in a limited number of male patients. (Level of evidence 3; grade of recommendation C)
- Detrusor myectomy has also been reported to be successful in a small number of male patients. (Level of evidence 3; grade of recommendation C)
- Augmentation cystoplasty is potentially successful in controlling symptoms but may be associated with unacceptable side effects. (Level of evidence 3; grade of recommendation C)
- Urinary diversion is a final option. (Level of evidence 3; grade of recommendation C)

7. REDUCED CAPACITY BLADDER

- Augmentation cystoplasty has been successful in most etiologies. (Level of evidence 3; grade of recommendation C)

8. URETHROCUTANEOUS FISTULA AND RECTOURETHRAL FISTULA (Level of evidence 3; grade of recommendation C)

- Etiologic factors causing acquired urethrocaneous fistulae are demonstrated by clinical, endoscopic and imaging studies.
- Similar diagnostic maneuvers are applied to rectourethral fistulae.
- Surgical reconstruction is applied as required.
- In those that do not close with or without temporary urinary and fecal diversion, surgical reconstruction may be carried out.
- Most repairs are now carried out after prior fecal diversion.
- Various techniques are available for closure and can be done in collaboration with colorectal surgeons.

9. MANAGEMENT OF AUS COMPLICATIONS (Level of evidence 3; grade of recommendation C)

- Incontinence may result from alteration in bladder function, urethral atrophy, or mechanical malfunction.
- Infection and/or erosion of components demand surgical removal of all or part of the prosthesis.
- A treatment algorithm is presented to aid in management and in follow-up of patients.
10. NEW TECHNOLOGIES (Level of evidence C; grade of recommendation D)

- Tissue engineering has not been widely reported in males apart from isolated reports of preliminary studies. [776, 777]

- A new one-piece adjustable artificial sphincter has been reported with social continence (0-1 pads/day) in 28/36 men at 6 months after device activation. [778] The removal rate was 11% for erosion/infection.

FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices should continue to be evaluated
- Accuracy in reporting of early research results is mandatory
- Mechanisms of post-prostatectomy incontinence and device effects need further research

CLINICAL TRIAL RECOMMENDATIONS

- Randomized trials (AUS and slings)
- Standardized workup and outcome measures including QoL
- Evaluation of the role of urodynamics in the workup
- Complete reporting of complications and outcomes especially those of slings
- Standardised definitions of cure/improved/unchanged/worse
- Reporting of procedures to salvage failures
- Long-term results (>2 years)
- Standardized reporting of durability

A. Introduction

This chapter is intended to present a further assessment of surgical interventions for urinary incontinence in women. The intent of this chapter is to build upon data that were previously collated for the ICUD Report of 2009. This chapter updates the current status of surgical interventions for stress urinary incontinence and includes additional data that have been forthcoming regarding new interventions (such as transobturator tapes and single incision slings).

The further enhancement on sections related to clinical research and specific outcomes reporting on clinical trial design has been updated with experience from recently reported multi-institutional trials which assess surgical interventions for incontinence.

SEARCH STRATEGY

Material collected for this chapter was based on electronic searches of Medline, EMBASE, Cinhaj, Cochrane Database of Systematic Reviews and the NICE website (www.nice.org.uk). Review papers were separately searched for additional references not identified by initial database search. Individual papers where then selected from April, 2008 to present in European, UK and North American journals of Urology, Gynecology, and Urogynaecology. Additionally, conference preceedings from 2008 were also reviewed inclusive of ICS, IUUG, AUU, AUGS. Hence, some more recent abstracts are included in the following reviews based upon time to press and non-identification of associated publications with those abstracts. Approximately 454 articles were identified for inclusion in addition to the original 762 which were included in the 2009 chapter. Search terms included; Urinary incontinence: stress, mixed, urge. Surgical procedures; minimally invasive, urogyno, vaginal, urologic, urinary tract, urethra, vagina, bladder, ligaments; colposuspension, vesicosuspension, urethrosuspension; vesicourethral or urethrovesical; colpofixation; Burch; Marshalls, Marchetti, Krantz; paravaginal, pubococcygeal, obturator; bladder, neck needle; ligament fixation; colporraphy; anterior or vagina; Surgical mesh; sling, bladder, surgical or synthetic, or biological or autologous; tape; urethra, suburethra, midurethra, transurethra, pubovesical; retropubic, suprapubic; pubovaginal, implant: Bologna, Ingelman, Sundberg; Prostheses: injections; bulking agents, Contigen; collagen; Macroplastique, silicones; microparticulate; hyaluronic acid; carbon particles; polytetrafluoroethylene; biocompatible materials; urinary sphincter, artificial.

Since the last review more high quality evidence is available based upon randomised controlled trials at multi-institutional programs. Level I, Level II and Level III evidence are included in the current publication. Additionally, systematic reviews where appropriate have also been included to update those referenced in the 2009 chapter. Additionally, national and international guidelines such as the National Institute for Health and Clinical Excellence (NICE) in the UK were also included where appropriate for complete summation of current status of interventions for stress urinary incontinence in women. It is to be noted that transobturator tape data are now of sufficient maturity to be included at length in addition to other mid-urethral data, both regarding standard retropubic as well as single incision approaches.

I. SURGERY FOR STRESS INCONTINENCE (INCLUDING COMPLICATIONS)

1. URETHRAL BULKING AGENTS

Since the last International Consultation, bovine collagen (Contigen®) has become obsolete due to manufacturing cessation. Currently available agents include; calcium hydroxyl apatite (Coaptite®, carbon coated Zirconium (Durasphere®, polydimethylsiloxane elastomer (Macroplastique®) and polyacrylamide hydrogel (Bulkmid®). Additionally limited data has been published regarding non-animal stabilized hyaluronic acid/dextranomer NASHA-dx (Zuidex®). Recent experience has also been reported with adult stem cells for the indication of stress urinary incontinence.
Urethral bulking agents may be injected either transurethrally or periurethrally in a retrograde manner, using either ultrasonographic, direct cystoscopic or implacer-guided device implantation. Device implantation optimally occurs in the proximal urethra, either single or multiple injections with strategic planning for reinjection at some point after initial injection. Clinical trials have defined specific injection schedules (usually three injections) as part of trial therapeutic algorithms. Optimal injection technique has yet to be standardized, although it does appear that urethral mucosa visualization at procedure completion is not predictive of final outcome. Prior systematic reviews have formed the basis of NICE guidance [National Collaborative Center for Women’s and Children’s Health, 2006, National institute for Health and Clinical Excellence, 2006b]. Methodologic problems with most non-regulatory trials limit the ability to generalize the results of those trials to clinical experience.

Ghoniem, et al [2009][1] reported a randomized controlled trial of polydimethylsiloxane elastomer versus Contigen in 247 women. Repeat injection was allowed at three months after initial delivery for persistent incontinence. Efficacy was determined at one year post last injection using Stamey Grade scoring, pad weight change and quality of life assessment. 122 patients received polydimethylsiloxane elastomer. Additionally, 125 patients received Contigen. At one year post treatment, 61.5% of patients who received polydimethylsiloxane elastomer had improved by one Stamey Grade as compared to 48% of controls. The cure rate at one year was 36.9% of the Macroplastique group and 24.8% in the Contigen group, which was statistically significant. Pad weight changes (one hour pad weight) were 25.4 mL from baseline in the polydimethylsiloxane elastomer group and 28 mL in the Contigen group. Both groups had improvement in quality of life assessments (28.7% and 26.4% respectively).

Ghoniem, et al recently reviewed clinical outcomes associated with the use of polydimethylsiloxane elastomer as a bulking agent for stress incontinence. They identified a total of 958 patients in 23 cohorts in their review. Overall, short term (defined as less than six months) improvement rates were 75% with 64% improvement rates long-term (greater than 18 months). Cure rates were 43% at less than six months and 36% at greater than 18 months using a variety of definitions including pad weight, number of pads used and subjective reporting. The authors noted that as re-injection rates increased, there was improvement in long-term stress incontinence outcomes. Safety events associated with injection included retention, irritative voiding symptoms, dysuria, and urinary tract infection. [Ghoniem, 2012] [2]

The same study population was assessed at 24 months from last injection in subsequent publication. At that time, 67 patients in the polydimethylsiloxane elastomer arm were available for follow-up of whom 45 or 67% were continent. Of those patients who were dry at 12 months [38], 33 remained cured at 12 months. Additionally, 12 of 29 patients improved at 12 months, progressed to urinary continence at 24 months. Global quality of life scores and subscales all were statistically improved from baseline. Pad weight changes decreased from 24 grams at baseline to 4 grams at 12 and 24 months. There was no long-term complication noted in this population. [Ghoniem, 2010],[3]

Polyacrylamide hydrogel has also been reported as a potential agent for bulking. Lose, et al [2010],[4] reported on the use of polyacrylamide hydrogel in 135 women with urinary incontinence (either stress or mixed) who were followed-up for 12 months after injection. Of that group, 47 (35%) required repeat injection. At one year, overall subjective response rate was 66%. Incontinence episodes per 24 hours decreased from baseline of 3 to 0.7 at one year. Additionally, overall urine leakage by pad gram weight decreased from 29 grams at baseline to 4 grams at end of trial. Overall ICIQ demonstrated improvement in quality of life. The most frequent adverse event in this trial was urinary tract infection (10 patients).

Toozs-Hobson, et al, [2011][5] reported a two year follow-up of polyacrylamide hydrogel in 135 women. At twenty four months, 64% of patients remained responders (as compared to 67% at twelve months). Responder was defined as subjective improvement. Overall decreases in urinary incontinence episodes and volume of urine incontinence (pad weight) were stable as compared to twelve months evaluation, as were other objective outcomes and quality of life data.

Gopinath [2011][6] reported a periurethral abscess associated with the use of this agent which required surgical drainage.

Non-animal stabilized hyaluronic acid/dextranomer has been compared to bovine collagen by Lightner, et al [2009],[7] This trial utilized an implacing device for non-animal stabilized hyaluronic acid/dextranomer injection. Bovine collagen was delivered endoscopically under direct vision. This trial failed to demonstrate equivalence of non-animal stabilized hyaluronic acid/dextranomer to direct vision injected bovine collagen in all primary and secondary outcome variables. 84% of women who were injected with bovine collagen experienced a 50% reduction in urinary incontinence in provocative testing versus 65% in the non-animal stabilized hyaluronic acid/dextranomer group. Of note, non-animal stabilized hyaluronic acid/dextranomer was associated with injection site sterile abscesses in 8.4% of patients, injection site mass in 4.4% of patients and pseudo cyst formation in 2.2% of patients. Irritative voiding
symptoms and injection site pain were more common with non-animal stabilized hyaluronic acid/dex- tranomer than with bovine collagen.

Lightner, et al [2010][8] reported a single institutional review of 56 patients who underwent implantation with non-animal stabilized hyaluronic acid/ dextranomer. This trial included 35 women and 6 men. Of the women, 4 developed pseudo abscess formation requiring multiple operative interventions also associated with a high rate of failure amongst all women with ISD.

Mohr, et al [2012][9] reported a large series of 514 women treated with bulking therapy with either collagen, hyaluronic acid, ethylene vinyl alcohol (no longer marketed,.) or polyacrylamide hydrogel. Outcomes were reported using standardized pad tests, visual analogue score for severity of incontinence and Kings Health Questionnaire. 61 patients in the entire study were lost to follow-up. Overall pad testing was negative in 73.2% of women after bulking therapy with statistical improvement in both pad weight and visual analogue score changes for each of the agents used at one year post implantation. Re-injection was permitted six weeks after initial injection in this study.

The role of bulking agents as salvage therapy for women who undergone prior mid-urethral sling procedures and were not satisfied with postoperative results was assessed by Lee, et al [2009][10] The authors reported 23 women who had undergone mid-urethral slings who then received therapy with polydimethylsiloxane elastomer or carbon coated zirconium beads. They noted a cure rate of 34.8% at a median follow-up of ten months and improvement in secondary outcomes. Overall, 92% of patients reported benefit from therapy and the authors reported no complications.

Recently an update to the Cochrane Analysis of Urethral injection therapy has been published [Kirchin, 2012]. [13] This analysis identified 14 further trials for non-injectable agents. The Cochrane Analysis concluded there was no difference in manner of delivery (peri- versus trans-urethral injection) method, although there was a trend towards higher early complications with peri-urethral injection. Additionally, weak evidence supports mid-urethral injection resulting in improved patient satisfaction compared to bladder neck injection. The Cochrane analysis also concluded that all bulking agents appeared to provide similar overall improvements as compared to bovine collagen. Non-animal stabilized hyaluronic acid/ dextranomer appeared to be associated with higher rates of injection site complications (16% with non-animal stabilized hyaluronic acid/ dextranomer as compared to none with bovine collagen). In the few trials that have compared injection therapy with surgical management, better overall objective cure was obtained in surgical as compared to the injection groups.

The overall conclusion of the Cochrane analysis was that the evidence base remained insufficient to guide practice, specifically regarding optimal choice regarding bulking device, mechanism delivery, or identification of the optimal patient for bulking.

Research in autologous stem cell based urethral bulking continues. To date, no large scale randomized trials have been published, although, abstracts have been presented at various meetings. Durability and length of follow-up will be critical to assess the contribution of this possible bulking option. [Du,2012][14]

Recommendation

Bulking agents provide an option in the management of women with stress incontinence. Optimization of results is dependent upon repeat injections to achieve and sustain efficacy. Additionally, efficacy with at least some bulking agents appears to diminish with time and may be inferior to surgical interventions. Overall complication rates associated with bulking agents appear to be relatively low (Grade B). Continued development of new materials for injection should be under strict regulatory guidance and evaluation using RCT design construct and long-term follow-up (at least 12 months after last injection) (Grade D) (Evidence level II/III).

2. RETROPUBIC MID-URETHRAL SLINGS (MUS)

The tension-free vaginal tape (TVT) procedure for treatment of female stress urinary incontinence was first introduced by Ulmsten et al. in 1996. [15] The development of the TVT operation was an attempt to support the middle portion of the urethra, instead of restoring anatomy and correcting urethral hypermobility at the bladder neck. The idea of supporting the “mid-urethra” has been derived from the results of several research projects conducted during the last thirty years. The work of Zaccharin in 1968 and DeLancey in 1994 had already shown that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was closer to the middle portion of the urethra than the bladder neck. [16, 17] In 1978, Owman et al. found that the most densely innervated portion of the urethra was the middle part and Huisman in 1983 showed in histological studies that the mid-urethra had the most abundant vascularisation. [18] Additionally, Westby et al. in 1982 showed in radiographic studies how the urine stream was interrupted at the mid-urethra
on holding in continent women and Asmussen et al. in 1983 showed that the maximal urethral closure pressure was situated at the midurethra.[19, 20] It quickly became apparent that focusing on the mid-urethra might bring improvement in the performance of incontinence surgery.

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90 % in primary cases of SUI [Ulmsten et al., 1996; Ulmsten et al., 1998; Nilsson, 1998; Ulmsten et al., 1999; Nilsson et al., 2001], [15, 21-24] in recurrent cases [Rezapour and Ulmsten, 2001; Kuva and Nilsson, 2003],[25, 26] in mixed incontinence cases [Rezapour and Ulmsten, 2001], [25] and in an unselected group of women including primary, recurrent and mixed incontinence as well as women with intrinsic sphincter deficiency [Nilsson and Kuva, 2001]. [24] Since those initial reports of success, several groups have reported long-term outcomes exceeding 5 years [Ankar- dal et al., 2006; Doo et al., 2006; Deffieux et al., 2007; Chene et al., 2007; Song et al., 2009] and 10 years after the TVT procedure [Nilsson et al., 2008; Olsson et al., 2010][27] [28] A variety of follow-up regimens and definitions of success reveal that the effects of the TVT on resolution of SUI are durable over the long-term.

Since the last ICI review was conducted, the literature regarding the TVT and other retropubic MUS procedures has expanded at an almost exponential pace. As an example, only 12 RCTs comparing MUS to other procedures were available for review and most of these were small (<50 patients in each arm) and underpowered. The number of RCTs and large cohort studies available today significantly exceeds the previous review, and, unless otherwise mentioned, only fully-published studies have been included herein.

a) Retropubic MUS vs. no treatment (table 1)

A multicentre, prospective RCT performed by Campeau et al. enrolled 69 elderly who initially consented to be randomised to either undergo immediate TVT surgery or to wait for 6 months before submitting to the same surgery (control group). [29] The main outcomes measured at every visit (pre-randomisation, 8-12 weeks and 6 months) consisted of the Incontinence-Quality of Life (I-QOL) Questionnaire, the Patient Satisfaction Questionnaire and the Urinary Problems Self-assessment Questionnaire. The analysis included 31 patients in the immediate surgery group and 27 subjects in the control group. Perioperative complications in the immediate surgery group were bladder perforation (22.6%), urinary retention (12.9%), urinary tract infection (3.2%) and de novo urgency (3.2%). At 6 months, the mean scores on each questionnaire were significantly in favour of the TVT group. [EL=1/2]

b) Retropubic MUS vs. open colposuspension (table 1)

Since the ICI-4 review, only 3 additional studies have published comparing TVT and open colposuspension [McCracken et al., 2007; Tellez Martinez-Fornes et al., 2009; Wu et al., 2010]. [30-32] In a nonrandomised trial with significant failed-to-complete follow-up, McCracken et al. found no difference in subjective success rates via questionnaire between colposuspension and TVT at 5 to 10 years. [30] In an RCT randomising 49 women to TVT or colposuspension, Tellez Martinez-Fornes found no significant difference in subjective success rates (cured/improved) between the 2 procedures at follow-up periods of 6, 12, and 36 months. [31] In a retrospective, nonrandomised trial comparing 105 women who underwent TVT with 81 women who underwent MMK, the authors found that while the short-term success rate of the MMK was 89%, the rate fell to 68.2% at 5 years and 32% at 10 years. [32] In comparison, the short-term success rate of the TVT was statistically similar to the MMK (90%) but decreased only to 84.3% at 5 years. Women who underwent TVT also experienced shorter operative time, less blood loss, and shorter hospital stay. [EL=3/4]

Four of the studies from ICI-4 comparing TVT with open colposuspension used objective outcome measures for defining cure: 1 hour pad test [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Ward et al., 2004; Ward et al., 2008], [33-37]cystometry [Ward et al., 2002], [33] and a cough-stress test [Ward et al., 2002; Ward et al., 2004; Bai et al., 2005],[33, 36, 38] One study only used subjective outcome measures [El-Barky et al., 2005]. [39] None of these studies found any statistical differences in objective cure rates between the two operations. The cure rate ranged between 63 and 87 % in the TVT groups and between 51% and 90 % in the open colposuspension groups. The time period of follow-up was between 3 and 24 months in all five trials except the 5-year extension of the U.K. & Ireland TVT Trial Group [Ward et al., 2008]. [37] These 5-year outcome data are hampered by a significant lost to follow-up rate (58% in the TVT group and 67 % in the colposuspension group). The criteria of subjective cure were for the most part poorly defined and validated QOL questionnaires were only used in the 2002 study;[33] There was no difference in subjective cure between the TVT and the colposuspension groups. [EL=1/2]

As in the study by Tellez Martinez-Fornes, operative time, hospital stay and time for resuming normal activity was significantly shorter in the TVT groups [Ward et al., 2002; Liapis et al., 2002; EI Barky et al., 2005],[33, 34, 39] Ward et al. [2002] found that the percentage of intraoperative bladder perforations was significantly greater in the TVT group (9%) than in the colposuspension group (3%), while EI Barky et al.

*: Included in ICI-4
*: Included in Systematic Review (Novara, 2010)
†: Included in Cochrane Review (Ogah, 2011)

Key: RP MUS = retropubic midurethral sling; F/U = follow-up (months); LE = level of evidence; TVT = tension-free vaginal tape; o = objective; s = subjective; N/A = not available; OC = open colposuspension; LC = laparoscopic colposuspension; ITT = intention to treat
reported no perforations in the colposuspension group and two in the TVT group (p < 0.05). [33, 37] Wound infections were more common in the colposuspension group (p < 0.05). Significantly more patients experienced delayed voiding in the colposuspension group in the Ward et al. [2002] study and in the 2 years follow-up report of the same study there were significantly more patients in the colposuspension group needing intermittent self catheterisation (p < 0.0045) and surgery for pelvic organ prolapse (p < 0.0042). [33, 36] [EL=1/2]

The Cochrane review comparing the outcomes of minimally-invasive suburethral sling operations with open colposuspension included 9 trials, and included 5 of the trials mentioned above [Ward et al., 2002; Liapis et al., 2002; Wang et al., 2003; Bai et al., 2005; El Barky et al., 2005]. [40] The remainder of the studies were either in abstract form or provided a comparison between transobturator MUS and colposuspension. A total of 729 women studied within the first 12 months after surgery showed subjective cure rates of 79% with MUS and 82% after open colposuspension. This difference was not statistically significant (RR 0.96, 95% CI 0.90 to 1.03). In 2 trials [including Ward et al., 2004] follow-up at 2 years also failed to show a statistically significant difference (RR 1.11, 95% CI 0.91 to 1.34). In the 3 trials evaluating objective cure rates [including Liapis et al., 2002, and Wang et al., 2003], there was no significant difference at 12 months (RR 1.04, 95% CI 0.94 to 1.14), after 2 years (RR 1.01, 95% CI 0.92 to 1.11) and after 5 years (RR 0.90, 95% CI 0.77 to 1.04). [EL=1/2]

A limitation to the conclusions that can be drawn from the aforementioned study results is the fact that most of the trials include fewer than 50 patients in each arm and lacked any mention of power calculations. The trials by Ward et al. enrolled a greater number of patients and included power calculations, but did not reach the required number of patients. [33, 36, 37]

c) Retropubic MUS vs. laparoscopic colposuspension (table 1)

Four of the 12 RCTs in ICI-4 comparing retropubic MUS with traditional incontinence procedures compare TVT with laparoscopic colposuspension [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41] [40] [39] [38] [37] [36] [35] [34] [33] [32] [31] [30] [29] [28] [27] [26] [42] [43] Two additional trials have been published since that review [Foote et al., 2006; Tong et al., 2008] as well as an update of the Paraiso et al. study [Jelovsek et al., 2008]. [44-46] The Cochrane review included 5 fully-published manuscripts [Persson et al., 2000; Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004; Foote et al., 2006] along with 2 abstracts. [40]

In the studies comparing TVT or Supra Pubic Arc Sling (SPARC; a monofilament polypropylene MUS placed through a top-down approach) with laparoscopic colposuspension objective cure was assessed by a pad test in 2 of the 6 studies [Persson et al., 2000; Valpas et al., 2004], [43, 47] and by a cough-stress test in 3 of the studies [Ustun et al., 2003; Paraiso et al., 2004; Valpas et al., 2004]. [41, 42, 47] The criteria for cure or improvement were unclear in the study by Foote et al. [44]. The trial by Valpas et al. with the greatest number of patients enrolled showed a significantly higher objective and subjective cure rate in the TVT group than in the laparoscopic colposuspension group (p < 0.0001), [47] while the other studies showed similar cure rates for both procedures ranging between 72.9% and 96.8% in the TVT groups and between 58.8% and 87% in the laparoscopic colposuspension groups. It was thought that the Valpas et al. trial may have shown a significant difference in outcomes in favour of TVT due to a difference in laparoscopic technique (using mesh rather than sutures to perform colposuspension). [40] In their trial, Paraiso et al. performed postoperative multichannel urodynamics in 32 laparoscopic Burch colposuspension and 31 TVT patients showed a higher rate of urodynamic stress incontinence at 1 year in the laparoscopic Burch colposuspension group, 18.8% versus 3.2% (p = 0.056). [41] There was a significant improvement in the number of incontinent episodes per week and in UDI and IIQ scores in both groups at 1 and 2 years after surgery (p < 0.001). However, postoperative subjective symptoms of incontinence (stress, urge, and any urinary incontinence) were reported significantly more often in the laparoscopic Burch colposuspension group than in the TVT group (p < 0.04 for each category). At long-term follow-up of the previous study, Jelovsek et al. confirmed that the TVT has similar efficacy to the laparoscopic Burch for the treatment of SUI. [100] While not always bothersome, the authors cited a substantial number of women in either group who had some degree of incontinence 4 to 8 years after surgery. Although laparoscopically-performed colposuspension is regarded as a less-invasive operation than the open colposuspension the MUS procedures had significantly shorter operating time, hospital stay, and time for resuming normal activity than the laparoscopic colposuspension. [40] [EL=2]

As with the studies comparing open colposuspension with MUS, the conclusions of studies comparing MUS with laparoscopic colposuspension may be limited due to underpowering. Dean et al. performed a systematic review of laparoscopic colposuspension (n = 264) and TVT (n = 290) which included 7 trials. [101] There was no statistically significant difference in the reported subjective cure rate between laparoscopic colposuspension and TVT within 18 months (RR 1.12, 95% CI 0.98 to 1.29). However, within the same time period, the overall objective cure rate was statistically significantly higher for TVT (RR 1.16, 95% CI 1.07 to 1.25). There were no significant differences be-
between the two procedures with regards to perioperative complications, de novo detrusor overactivity, voiding dysfunction, procedural costs and QoL scores. The authors confirmed that the TVT procedure was quicker to perform and was associated with a shorter hospital stay. [EL=1/2]

A systematic review by Novara et al. evaluated open and laparoscopic colposuspensions together with retropubic MUS. [48] Women receiving MUS had significantly higher overall (OR 0.61; 95% CI 0.46 to 0.82, \( p=0.00009 \)) and objective (OR 0.38; 95% CI 0.25 to 0.57, \( p<0.0001 \)) cure rates than those receiving colposuspension. A clinical and economic subanalysis of the Valpas et al. study suggested that over a follow-up period of 1 year the TVT is more cost-effective than laparoscopic mesh colposuspension as a primary treatment for female SUI. [103] [49][EL=1/2]

d) Retropubic MUS vs. traditional sling

This comparison will be addressed in the section on traditional pubovaginal slings.

e) Retropubic MUS vs. retropubic MUS (table1)

The favorable results obtained with the TVT operation have resulted in several modifications of the procedure and the use of different tape materials. These retropubic modifications have been poorly clinically evaluated and only 6 randomised studies comparing these with the TVT have been published. The meta-analysis by Novara et al. did not evaluate the comparison between different types of retropubic MUS procedures. [48] In ICI-4, 3 RCTs compare the TVT with the SPARC [Andonian et al., 2005; Tseng et al., 2005; Lord et al., 2006]. [50-52] The study by Lord et al. included 147 TVT and 154 SPARC cases and showed no statistical difference in estimated blood loss of >100 mL (TVT, 21.8% vs. SPARC, 18.2%), de novo urgency (TVT, 40.5% vs. SPARC, 42.4%), objective cure (TVT, 97.3% vs. SPARC, 97.4%) or vaginal mesh extrusion (TVT, 4.8% vs. SPARC, 10.5%). [51] Acute urinary retention (TVT, 0% vs. SPARC 6.5%; OR = 95% CI 2.2-\( \infty \); \( p=0.002 \)) and subjective cure (TVT 87.1% vs. SPARC 76.5%; OR 2.07, 95% CI 1.13-3.81; \( p=0.03 \)) were statistically significantly different. Tseng et al. reported a 12.9% of bladder perforation in the SPARC group with none in the TVT group. [52] While the difference did not reach statistical significance in this small study (31 patients in each group), the authors felt it to be clinically significant. [EL=1/2]

Four additional non-randomised studies compared TVT with SPARC [Dietz et al., 2004; Gandhi et al., 2006; Kim et al., 2006; Paick et al., 2008].[53-56] In the Dietz et al. study, there were no significant differences for subjective cure/improvement, patient satisfaction, or symptoms of incontinence. [56] The cough-stress test was positive in 8 of 37 women who underwent SPARC compared to 4 of 69 TVT patients (\( p=0.019 \). The TVT had a more negative effect (\( p=0.001 \)) on postoperative voiding. In the Gandhi et al. study, 107 of 122 women returned for objective postoperative evaluation after surgery. [55] The TVT procedure was associated with higher subjective (86% vs. 60%, \( p=0.001 \)) and objective (95% vs. 70%, \( p<0.001 \)) SUI cure rates, while there was no difference between the TVT and SPARC groups in the resolution of subjective and objective UUI. Kim et al. found no difference in objective cure rates at 1 year of follow-up and complication rates were similarly low. [54] Paick et al. found no significant difference in cure of SUI or cure of all incontinence between TVT and SPARC at 6 months. [53] [EL=3/4]

In ICI-4, 3 RCTs compared TVT with the intravaginal slingplasty (IVS) procedure, which utilises a multifilament, miniporous polypropylene tape material [Rechberger et al., 2003; Lim et al., 2005; Meschia et al., 2006]. [57-59] Only the study by Lim et al. was included in the Cochrane analysis. [40] In the study by Meschia et al. that included 95 patients in each group, the objective cure rate was 85% for the TVT and 72% for the IVS and the subjective cure rate was 87% and 78%, respectively, with no difference between groups. [58] There was a 9% vaginal extrusion rate during the 2 years of follow-up in the IVS group, and 0% extrusion in the TVT group. Rechberger et al. found no significant difference in cure rates between the groups at a mean of 13 months of follow-up.[57] Lim et al. compared TVT with both IVS and SPARC, with 65 patients in each group. [58] The subjective cure rates between 6 and 12 weeks of follow-up were 87.9% in the TVT group, 81.5% in the IVS group and 72.4% in the SPARC group, the differences not being significant. Interestingly, the authors found a significantly greater rate of tape extrusion in the SPARC group compared to both TVT and IVS (\( p<0.04 \)). An additional retrospective study found a significant difference in favour of TVT in objective SUI cure rate at 3, 12, and 60 months compared with IVS, while the subjective cure rates did not differ significantly at any of those time intervals (Prien-Larsen & Hemmingsen, 2009). [60] Vaginal extrusions were found in 11.8% of the women in the IVS group compared with 0% in the TVT group. [EL=1/2]

Most concerning is the report by Balakrishnan et al. in which they followed the subgroup of IVS patients of the Lim et al. study for up to 30 months and found that 13% had sling extrusions requiring sling removal. [61] Additionally, of the 29 patients (47%) of the initial IVS group who were seen 12 to 34 months post-operatively, 24% experienced sling erosion with sinus formation requiring sling removal. Further infectious complications, like retropubic abscess and pyogenic granuloma associated with
vaginal extrusion, indicate that the IVS may behave clinically like microporous synthetic materials rather than other polypropylene slings.[62, 63] [EL=3/4]

Two additional studies compared TVT against other retropubic midurethral MUS procedures. Agarwala found no difference in subjective (94% vs. 92%) and objective (96% vs. 94%) cure rates in 96 women consecutively assigned to TVT or to Lynx mid-urethral sling (Boston Scientific; monofilmament polypropylene), respectively. [64] Yoon et al. compared TVT to the IRIS (innovative replacement of incontinence surgery) with a follow-up of 3 years. [65] The instrument of the IRIS system is comprised of a nondisposable metal handle to which two metal needles can be attached. The needles have an outer diameter of 5-6 mm and the non-absorbable polypropylene tape, which is 11 mm wide and 450 mm long with a plastic sheath cover, is fixed to the needles. The tape of the IRIS system is polypropylene monofilmament mesh (Trelex; Meadox Medicals, Oakland, NJ/Boston Scientific, NJ, U.S.A.), and the diameter of the pore size is greater than 75 µm such as the tape of TVT. Success rate encompassing both objective and subjective criteria were not statistically different between the 2 procedures at 12 and 36 months. Likewise, the incidence of perioperative complications and postoperative voiding dysfunction was not statistically different. [EL=3]

The Cochrane review encompassing 4 aforementioned RCTs [Andonian et al., 2005; Lim et al., 2005; Tseng et al., 2005; Lord et al., 2006] and an abstract, found that in 492 women studied within the first 12 months after surgery, women were significantly more often subjectively dry with the TVT than SPARC (85% vs. 77%; RR 1.10, 95% CI 1.01 to 1.20). [40] In a total of 636 participants, women were statistically significantly more likely to be objectively cured with the TVT than SPARC or IVS (92% vs. 87%; RR 1.06, 95% CI 1.01 to 1.11). There were significantly fewer women experiencing bladder punctures during trocar passage after TVT compared with SPARC (4.7% vs. 8.5%; RR 0.55, 95% CI 0.31 to 0.98), as well as fewer vaginal extrusions (RR 0.27, 95% CI 0.08 to 0.95). No statistically significant difference was seen in overall perioperative complications, but the confidence interval was wide (RR 0.98, 95% CI 0.53 to 1.84). There were no statistically significant differences between the 2 groups with respect to postoperative de novo urgency symptoms and UUI, as well as urodynamic detrusor overactivity. Finally, there were no statistically significant differences in QoL indices between the 2 procedure groups. [EL=1/2]

The Cochrane review also evaluated 3 of the aforementioned RCTs [Rechberger et al., 2003; Lim et al., 2005; Meschia et al., 2006] that compared TVT to IVS.[40] At 12 months, the higher subjective cure rates seen with TVT did not reach statistical significance (83% vs. 77%; RR 1.08, 95% CI 0.98 to 1.19). Objective cure for the TVT was significantly higher than for the IVS (83% vs. 72%; RR 1.15, 95% CI 1.02 to 1.30). There were few perioperative complications and the combined results from 2 small trials did not show a statistically significant difference (RR 1.16, 95% CI 0.36 to 3.69). However, the confidence intervals were wide. There were no statistically significant differences in the rates of de novo urgency symptoms and UUI, detrusor overactivity, and postoperative voiding dysfunction. [EL=1/2]

f) Retropubic MUS vs. transobturator mus (table 2)

A unique complication of the retropubic MUS procedures has been inadvertent puncture of retropubic and, on occasion, intra-abdominal viscera or neurovascular structures. The most common organ punctured is the bladder and the rates of puncture have varied between 0.8% and 21% in different reports [Wang et al., 2004; Andonian et al., 2005]. [50, 66] Two systematic registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide and one from Austria including 2795 operations [Kuua and Nilsson, 2002; Tamussino et al., 2001]. [26, 67] The rates of bladder perforation were 3.8% and 2.7%, respectively. In an effort to minimise the incidence and morbidity of bladder injuries, Delorme in 2001 introduced a modified tape procedure in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramina on both sides.[68] De Leval further modified the outside-in transobturator tape procedure (TOT) procedure to be an inside-out procedure, now called the tension-free vaginal tape-obturator (TVT-O). [69]

The comparison between the retropubic and transobturator MUS procedure has become the most-documented topic in sling surgery over the last 5 years. ICI-4 reported on a total of 9 RCTs comparing RP with TO midurethral slings. TVT was compared with the inside-out TVT-O in 6 randomized trials [Liapis et al., 2006; Laurikainen et al., 2007; Meschia et al., 2007; Zullo et al., 2007; Araco et al., 2008; Rinne et al., 2008], [70-75] and with the outside-in TOT in 2 trials [Andonian et al., 2007; Porena et al., Araco et al., 2008]. [76, 77] Wang et al. compared the TOT with SPARC and found no difference in cure rate or rates of complications between the group of 31 TOT patients and 29 SPARC patients.[78]

The studies evaluated in ICI-4 were quite heterogeneous. Five of the studies comparing TVT with TVT-O included power calculations either for detection of differences in cure rates and complication rates [Meschia et al., 2006; Laurikainen et al., 2007; Rinne et al., 2008], [70, 71, 75] or only for detection of differences in complications [73]. The study by Liapis et al. reported no power calculations. [70] No differences in the overall objective or subjective cure rates were seen between the TVT and the TVT-O procedures.

*: Included in ICI-4
^: Included in Systematic Review (Novara, 2010)
†: Included in Cochrane Review (Ogah, 2011)

Key: RP=retropubic; MUS=midurethral sling; F/U=follow-up; LE=level of evidence; TVT=tension-free vaginal tape; TOT=transobturator tape; m=months; s=subjective; o=objective; TVT-O=tension-free vaginal tape obturator; ITT=intention to treat; RCT=randomized controlled trial; SUI=stress urinary incontinence; ISD=intrinsic sphincter deficiency; IVS=intravaginal slingplasty; DO=detrusor overactivity; OR=odds ratio; CI=confidence interval; NS=not significant.
Objective cure was assessed by 17 studies with 2434 participants using a variety of measures such as urodynamic assessment, negative cough-stress test, 1-hour pad test of ≤ 2 g, 1-hour pad test of ≤ 1 g, and 24-hour pad test of ≤ 5 g. [40] The cure rate using the obturator route was significantly lower at 84% versus 88% for the retropubic route (RR 0.96, 95% CI 0.93 to 0.99). However, the confidence interval was narrow and the difference between the groups (4%) may not represent a clinically significant difference in the short term. There was no significant difference in women whose improvement and cure rates were demonstrated objectively (RR 0.96, 95% CI 0.91 to 1.02). [EL=1/2]

In 14 trials, there were no statistically significant differences in the rates of tape erosions (RR 1.58, 95% CI 0.83 to 3.00) or, in 5 trials, the need for repeat incontinence surgery (RR 1.52, 95% CI 0.90 to 2.59). [40] However, once again, the confidence intervals in both cases could include a clinically significant difference favouring the RP approach. There was significantly higher occurrence of groin pain (12%) in women with a TO approach compared with supra-pubic pain in women with a retropubic sling (1.7%, RR 6, 95% CI 3 to 11). There was no statistically significant difference between the groups in terms of detrusor overactivity (RR 1.22, 95% CI 0.56 to 2.63) in 3 trials, or de novo urgency and urgency incontinence (7% with the TO route versus 6% via the RP route (RR 1.08, 95% CI 0.75 to 1.56) in 14 trials, but the confidence intervals were wide because these were relatively rare events and clinically significant differences could not be ruled out. However, postoperative voiding dysfunction occurred significantly less frequently in the TO route group (4% versus 7%, RR 0.63, 95% CI 0.44 to 0.89). [EL=1/2]

The systematic review by Novara et al. included 13 RCTs that compared classic TVT with inside-out TOT: TVT-O in 10 studies [71-75, 84, 89, 90, 92-96] and a less invasive free tape in a single study [Naumann et al., 2006 (abstract only)]. [48] Nine studies compared TVT to outside-in TOT: ObTape in 3 studies, [76, 77, 80] Monarc in 4 studies, [86, 87, 97], Freeman et al., 2008 (abstract only)] Iris-TOT in a single study, [Kim et al., 2004 (abstract only)] and Obtryx in a single study. [98] The implanted devices were not specified in a single study. [99] A single trial compared TVT to both TVT-O and Monarc, [Schein er et al., 2009 (abstract only)] a single trial compared retropubic IVS to outside-in IVS, [142], and 2 trials compared SPARC sling to Monarc.[78, 81]

Overall (OR: 1.02; 95% CI OR: 0.78 to 1.33; p = 0.90), and subjective (OR: 0.97; 95% CI OR: 0.75 to 1.24; p = 0.80) continence rates were overlapping in the two procedures. [48] Among the studies providing subjective outcomes using validated questionnaires, postoperative UDI-6 (WMD: 0.07; 95% CI: -0.39 to 0.53; p = 0.76) and IIQ-7 (WMD: 0.01; 95% CI: -0.22 to 0.24; p = 0.95) scores were
similar. Notably, retropubic MUS were followed by significantly higher objective continence rates (OR: 0.80; 95% CI OR: 0.65 to 0.99; p = 0.04). Moreover, a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI OR: 0.52 to 0.96; p = 0.03), whereas no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI OR: 0.66 to 1.22; p = 0.51). Sensitivity analyses limited to studies of higher methodological quality showed only a nonstatistically significant trend in favour of TVT with regard to objective cure rate (OR: 0.74; 95% CI OR: 0.54 to 1.01; p = 0.05). No differences in subjective and overall continence rates were found in the other sensitivity analyses. [EL=1/2]

With regard to complications, bladder or vaginal perforations (OR: 2.5; 95% CI OR: 1.75 to 3.57; p < 0.0001) were significantly more common following retropubic MUS, without any significant difference between inside-out and outside-in TOT. [48] Again, as expected, the prevalence of postoperative haematoma was significantly more common following placement of retropubic MUS (OR: 2.62; 95% CI OR: 1.35 to 5.08; p = 0.005). In fact, the rates of vaginal extrusion were slightly higher following TOT (OR: 0.64; 95% CI OR: 0.41 to 0.97; p = 0.04), due to the studies using ObTape, a device removed from the market due to a high risk of erosion and extrusion. Finally, the risk of urinary tract infections (OR: 0.95; 95% CI OR: 0.69 to 1.31; p = 0.74), the need for clean intermittent catheterisation or re-catheterization (OR: 1.16; 95% CI OR: 0.84 to 1.59; p = 0.37), and the reoperation rate (OR: 1.1; 95% CI OR: 0.75 to 1.59; p = 0.62) were not significantly different between retropubic and transobturator MUS. Interestingly, the prevalence of storage LUTS was significantly higher in those patients randomised to RT (OR: 1.35; 95% CI OR: 1.05 to 1.72; p = 0.02), without any significant difference between inside-out and outside-in TOT. A nonstatistically significant difference in favour of TOT was found for voiding LUTS (OR: 1.56; 95% CI OR: 0.97 to 2.5; p = 0.07). In sensitivity analyses limited to studies of higher methodological quality, only a nonstatistically significant trend in favour of TOT was found for storage LUTS (OR: 1.44; 95% CI OR: 0.99 to 2.09; p = 0.06) and voiding LUTS (OR: 1.59; 95% CI OR: 0.85 to 2.97; p = 0.15). Similarly, with regard to the risk of all the other complications and reoperation, no differences were identified in the other sensitivity analyses. [EL=1/2]

The largest RCT to date comparing retropubic and transobturator MUS was recently published by Richter et al. [37] This was a multicentre, randomised equivalence trial with the primary outcome being objective (a negative stress test, a negative pad test, and no retreatment) and subjective (self-reported absence of symptoms, no leakage episodes recorded, and no retreatment) success at 12 months. The predetermined equivalence margin was ±12% points. A total of 597 women were randomly assigned to a study group and 565 (94.6%) completed the 12-month assessment. The rates of objectively assessed treatment success were 80.8% in the RP group and 77.7% in the TO group (3.0%-point difference; 95% CI: −3.6 to 9.6). The rates of subjectively assessed success were 62.2% and 55.8%, respectively (6.4%-point difference; 95% CI, −1.6 to 14.3). The rates of voiding dysfunction requiring surgery were 2.7% in the RP group and 0% in the TO group (P = 0.004), and the respective rates of neurological symptoms were 4.0% and 9.4% (P = 0.01). There were no significant differences between groups in postoperative urgency incontinence, satisfaction with the results of the procedure, or quality of life. Thus, the success rates met the predetermined criteria for equivalence of the 2 procedures. [EL=1]

There have been numerous additional, non-randomised trials published in peer-reviewed literature. [100-118] The majority of these concluded that there is no statistically significant difference in subjective or objective outcome measures between retropubic and transobturator MUS procedures. As concluded in the RCTs, postoperative complications are more common in the retropubic MUS group. [EL=3/4]

**g) Other studies**

Two additional topics deserve mention. Pelvic floor muscle training (PFMT) with or without biofeedback is a recognised and effective treatment for various pelvic floor conditions, including SUI, UUI, and pelvic pain. While a trial comparing MUS procedures and PFMT has not been published, there is a design for a prospective RCT in place to address this question [Labrie et al., 2009]. [58] This multi-centre RCT will be include women between 35 - 80 years old with moderate to severe, predominantly SUI, who have not received specialised PFMT or previous anti-incontinence surgery. Women will be assigned to either PFMT for a standard of 9-18 sessions in a 6-month period or TVT-O surgery. The main endpoint of the study is the subjective improvement of urinary incontinence. Objective cure, a secondary outcome, will be assessed from history and clinical parameters. Subjective improvement in QoL will be measured by generic (EQ-5D) and disease-specific (UDI & IIQ) QoL instruments. The economical endpoint is short term (1 year) incremental cost-effectiveness in terms of costs per additional year free of urinary incontinence and costs per Quality Adjusted Life Years gained. Finally, treatment strategy and patient characteristics will be combined in a prediction model, to allow for individual treatment decisions in future patients. Four hundred female patients will be recruited from over 30 hospitals in the Netherlands.

Finally, single-incision mini-slings (SIMS) have emerged as an additional option for the woman
procedures have not yet reached medium-term follow-up, a recent abstract at the 2011 International Continence Society Annual Meeting presented a systematic review and meta-analysis of SIMS and MUS procedures \[Abdel-Fattah et al., 2011\].\[59\] Nine studies were included, comparing TVT-Secur (6 studies; \(n=548\)), Mini-arc (2 studies; \(n=160\)) and Ophira (one study; \(n=50\)) to traditional MUS. A total of 758 women were included and 60 women were lost to follow-up (MUS \(n=23\), vs. SIMS \(n=37\)). The meta-analyses showed a significantly lower patient-reported cure rate with SIMS when compared to MUS, specifically TVT-O (RR 0.84, 95% CI 0.71 to 0.99), however a non-significant difference in favour of TVT was seen (RR 0.79, 95% CI 0.37 to 1.67). These results were supported on sensitivity analysis when studies of unclear quality were excluded. SIMS were associated with significantly lower objective cure rates when compared to MUS, specifically TVT-O (RR 0.88, 95% CI 0.77 to 0.99). In addition there was a significant difference in favour of TVT when compared to SIMS. This was also confirmed on sensitivity analysis when studies of unclear quality were excluded. A shorter operation time was associated with SIMS (WMD -8.67 minutes, 95% CI -17.32 to -0.02), and this was due to the significant difference in operation time in the single TVT comparison. There were significantly lower day-one pain scores in the SIMS group (WMD -1.74, 95% CI -2.58 to -0.09). Repeat continence surgery was significantly higher in the SIMS group (RR 6.72, 95% CI 2.39 to 18.89). Tape erosion and de-novo urgency incontinence were significantly higher in the SIMS group (RR 3.86, 95% CI 1.45 to 10.28 and RR 2.08, 95% CI 1.01 to 4.28, respectively). There were non-significant differences between both groups in respect to post-operative voiding difficulties (RR 1.47, 95% CI 0.78 to 2.74) and other minor (postoperative wound infection, haematoma, UTI, and haematuria) post-operative complications (RR 1.59, 95% CI 0.74 to 3.45). There was no significant difference in the QoL scores between the groups (WMD -33.46, 95% CI -87.55 to 20.62). Statistical heterogeneity was found throughout the analysis and was highest in patient reported cure rate, QoL scores, and operative time. [EL=1/2]

h) CONCLUSIONS / RECOMMENDATIONS

There is evidence that the retropubic TVT is more effective than colposuspension and is equally effective as traditional autologous fascial sling operations. [EL=1/2] Operation time, hospital stay, and time to resume normal daily activity is shorter with the TVT than with colposuspension. Post-operative voiding problems and need for urogenital prolapse surgery are more commonly associated with colposuspension, while bladder perforation is more commonly associated with TVT. [EL=1/2] TVT is more effective than the IVS and the SPARC procedure; however, the studies are heterogeneous. Inadvertent bladder puncture during SPARC (top-down) placement is more common than bladder puncture during TVT (bottom-up). [EL=1/2] Overall, retropubic and transobturator MUS procedures perform equally at a short term follow-up of 6 to 12 months. (Level 1/2) The rate of complications, including bladder puncture, vaginal extrusion, and hematoma formation are higher for the retropubic MUS. [EL=1/2]

Retropubic MUS is recommended as an effective treatment for stress urinary incontinence, which has longevity. [Grade A] Outcomes using subjective and objective criteria indicate that the retropubic MUS is at least equivalent, and usually superior, to other anti-incontinence procedures. [Grade B]

3. TRANSOBTURATOR MID-URETHRAL SLINGS

a) Evolution of the TOT including proposed advantages

The introduction of the tension-free vaginal tape (TVT) in 1995 \[171\] as well as the\[172\] development of other retropubic mid urethral slings, changed the way stress urinary incontinence (SUI) is treated. These procedures, although effective, were not without complications. Beyond voiding phase dysfunction, complications including bladder perforation, bowel perforation and vascular injury were described. \[26, 173, 174\] \[175\]The majority of serious complications reported from these procedures were thought to be related to penetration of the retropubic space. \[176\]

In 2001, Delorme first described placement of a synthetic sling avoiding the retropubic space by placing the sling through the obturator foramina.\[68\] Thus the first alternative to the retropubic tapes, the transobturator tape (TOT) was born. By avoiding the retropubic space, the major complications associated with retropubic passage of trocars were theoretically avoided. Another potential advantage of the transobturator method was the potential elimination of intraoperative cystoscopy. This point is still debated today.\[177\] Delorme’s original description of the TOT required passage of the trocar from “outside-in”. In 2003, de Leval aimed to further reduce the chance of bladder and urethral injury and described placing the trocar of the vaginal tape from “inside-out”.\[69\] These two methods remain the major division of transobturator slings and are both still widely used today.

Further efforts have been recently made to modify the inside-out method. In an attempt to minimise post-surgical leg pain, the length of mesh used has been shortened and surgeons have tried to minimise the number of punctures to the obturator membrane \[172, 178\] Initial results have shown improvement in leg pain in the immediate post-operative
period, without sacrificing efficacy (at 1 year). Further confirmatory studies are needed to strengthen these findings.

b) Initial prospective cohort trials

The original TOT procedure was performed in 40 women, 16 of whom had isolated SUI. The authors reported 15/16 were “totally continent” and the remaining patients improved with short term follow up (3-12 months). [68] There were no intraoperative complications. Post-operatively, the only complication was 1 episode of sepsis. Following this study, Delorme et al. published a series of 32 patients treated with the transobturator tape with at least one year follow-up (UraTape® Mentor-Porge’s, a non-woven, non-knitted thermally-bonded polypropylene) [179, 180] With a mean follow-up of 17 months, and a rigorous definition of cure (defined by patients reporting no protection and no SUI, along with a negative cough test with a full bladder) 22/29 patients (90.6%) were cured and 3/32 (9.4%) were improved. Preoperatively, 43.7% (14 patients) had pure SUI, and 56.3% (18 patients) had mixed incontinence. Of note, 4 patients had prior anti-incontinence procedures (3 TVT, 1 Burch and 1 with multiple procedures) and 5/32 had preoperative urethral closure pressures of <20cm H20. Again, no intraoperative complications were recorded. There was one patient who required self-catheterisation but retention resolved in this patient by 4 weeks. There were 5 patients with voiding disorders suggestive of bladder outflow obstruction. Two patients developed de novo urgency incontinence and one had worsening of her preoperative urgency.

Short term safety and efficacy data are also available from a prospective multicentre cohort study. [176] In this study, 183 women received the UraTape (outside-in TOT) and follow up data were obtained at a mean of 7 months (1-21 months). All women had SUI associated with hypermobility, 26 had mixed incontinence and 26 had concomitant (POP) surgery performed at the time of their TOT. Intraoperatively, there was a complication rate of 2.2% including 1 bladder perforation, 2 urethral perforations and 1 lateral vaginal sulcus perforation. Seventeen patients were not cured of stress incontinence including 5 patients that had the sling removed for vaginal extrusion (3) and urethral erosion (2). 4 patients reported post-operative de novo urgency, 2 of which also complained of urinary leakage. At 6 months 83% (of 130 patients) were cured and 5.4% were improved.

Based on data from the prospective series from Costa et al. and other case reports, extrusions and infections were linked to the silicon part of the UraTape and the tape was modified to the Obtape®. [176, 181, 182] This modification was introduced in 2003. This newer tape was made of monofilament strands of nonwoven polypropylene fibre with interlacing monofilaments forming pores of 50 mcg (smaller than the 75 mcg needed to allow for the migration of macrophages and leukocytes). The materials used for transobturator slings have continued to be modified to decrease risk of erosion, extrusion and infection. Today, all commercially available synthetic transobturator slings (as well as retropubic slings) are made of Amid type I polypropylene mesh and have an extrusion and erosion rate well below 5%. This is much lower when compared to the transobturator Obtape® with vaginal erosion rates as high as 13%.[183] [184]

The first description of the “inside-out” modification by de Leval also included feasibility/safety data from 107 patients.[69] Of these, 74 suffered from isolated SUI, and the remaining 33 women had POP, 15 had associated SUI, and the remaining 18 had prophylactic slings for occult SUI. There were no intraoperative complications or perioperative complications reported. At one month, one patient had a minor vaginal erosion and 2.8% of patients had urinary retention (2 of the 3 had concomitant prolapse surgery). 15.9% of patients complained that they had moderate pain or discomfort in the thigh fold. All pain had resolved by one month.

After the original inside-out cohort was described, patients from the same institution were then offered participation in a prospective observational study (TVT-obturator or TVT-O, Ethicon, Somerville NJ, USA). [185]102 patients out of 253 consecutive patients fulfilled the inclusion criteria and agreed to participate in the trial. 4.9% (5/102) of this group did not complain of SUI but had occult SUI. There were no urethral or bladder perforations and one patient had a vaginal sulcus laceration noted intra-operatively. No patients presented with vaginal or urethral erosion at follow-up. After catheter removal, 2 patients had an “important PVR” of >400ml. This voiding dysfunction resolved (after CIC in one and SPT What’s SPT in the other) by the last reported follow-up. There were 99 women with at least 12 month follow-up (mean follow-up of 14.9 months) and the complete cure rate was 91% while SUI symptoms improved in 5% of patients. Worsening or de novo urgency symptoms or urgency urinary incontinence (UUI) were reported by less than 10% of the patients. Approximately 75% of those with preoperative urgency and/or UUI experienced disappearance or improvement of these symptoms postoperatively. Voiding difficulties developed in 7% of the patients.

This same group of 102 women, who underwent a transobturator inside-out sling, were followed for a minimum of 3 years (median 40 months) and complete data were available for 91 (89.2%). [185] Issues of erosion or persistent pain were not found with this medium term follow-up. Four patients required tape release or tape incision, all within the first year. Disappearance and im-
The clinical significance of this 4% difference in improvement rates was questioned. Cure of SUI was defined as the disappearance of subjective SUI, as assessed by a SUI symptom scale score equal to zero. One patient developed a vesicovaginal fistula 2 years after sling placement. The authors did not believe that this was secondary to the TVT-obturator, but rather was due to a prior history of pelvic radiation. An additional 2 patients developed symptomatic POP between the first and second year and each went on to have an uncomplicated laparoscopic repair.

There are several large, multicentre European studies that examined the safety of the original TVT. [67, 186, 187] Similarly, a study was performed to address the safety of the inside-out transobturator approach. [188] This study compiled a registry of 984 women from 86 centers in France. There was an overall perioperative complication rate of 2.2%, with vaginal wall perforation (1.3%) and hematoma (0.7%) being the most common. The post-operative complication rate was 5.2%, with residual leg pain being the most common complication (2.7%). Reintervention, urinary retention, vaginal erosion, and paravesicle hematoma were all reported with percentages of less than 1 (0.9%, 0.8%, 0.6% and 0.1% respectively). Although the design of this study was aimed at safety, the paper does report efficacy at 4-12 weeks. Surgeons assessed 90% of patients as completely cured and 8.7% as improved, with only 1.2% of patients being similar to their preoperative status. Of those 303 patients with preoperative overactive bladder (OAB), cure was reported in 54.5%, improvement in 40.25%, and 5.3% noting no change. Other large single institution studies have also looked at safety of the inside-out transobturator sling. [189]

c) Transobturator Outside-in versus Inside-out

It was suggested by Delorme et al. that there is a greater risk of nerve injury (dorsal nerve of the clitoris) with the inside-out passage of the trocar. [180] A cadaveric study suggested that the inside-out technique required the trocar to pass closer to the obturator canal and was more likely to injure the obturator nerve (or vessels) that travel in this space. [190]

The association between inside-out obturator slings and an increased risk of complications compared to outside-in obturator slings has not been supported in clinical studies. Latthe et al. used a meta-analysis with direct and indirect comparisons of randomised trials to assess the effectiveness and complications for the inside-out (TVT-O) and outside-in (TOT) transobturator slings. [191] The conclusion was that there was equivalent short-term effectiveness between the two methods. By indirect comparison, fewer bladder injuries and voiding difficulties were seen in the inside-out tapes.

In 2009, a Cochrane Review of minimally invasive synthetic sub-urethral sling operations for SUI contained an analysis of the inside-out outside-in approaches (comparison #5) and concluded that there were no statistically significant differences in any of the outcomes measured. [40] However, the review acknowledged that the four trials randomised trials that this conclusion was based on were all small in size. [192-195]

Houwert et al. presented medium term follow up from their prospective comparative randomised trial.[196] They did not find any statistical significant difference, but it is not clear that the study was powered appropriately to show a difference. Abdel-fattah et al. published a study that was powered to show a 10% difference in success rates between the two methods of obturator sling placements. [197] They enrolled 107 inside-out and 171 outside-in patients. This prospective single blinded study did not show any differences in objective cure rates (87.6% inside-out vs. 83.2% outside-in, \( p = 0.2 \)) or patient reported success rates as reported by Patient Global Impression of Improvement (83% inside-out vs. 77% outside-in, respectively, \( p = 0.138 \)) at 6 months follow-up. [197] There were statistically more vaginal angle perforations with the inside-out approach compared the inside-out method (17 vs. 3, respectively, \( p=0.001 \)). Women in the inside-out group more commonly reported severe post-operative thigh pain, but this was not statistically significant (6.7% vs. 3.5%, \( p=0.19 \)).

d) Comparator Trials: Transobturator versus Retropubic MUS in the Index Patient

Once cohort studies had confirmed the feasibility of transobturator mid-urethral slings, a number of small RCTs and quasi-RCTs were performed comparing transobturator to the then gold standard, retropubic mid-urethral sling. A Cochrane review [40] and two recently updated meta-analyses [48, 191] use the pooled data of these RCTs to compare the outcomes of retropubic and transobturator MUSS.

In a Cochrane Review, Ogah et al. found 24 trials comparing outcomes between retropubic and transobturator MUSS.[40] Subjective cure or improvement rates were reported in 10 of these trials and meta-analysis revealed no statistically significant difference between approaches (83% subjective cure in each group, RR 1.00, 95% CI: 0.96-1.05). Objective cure was measured by urodynamic evaluation, cough-stress test, one hour pad test of \( \leq 2 \) g, one hour pad test of \( \leq 1 \) g, or 24 hour pad test of \( \leq 5 \) g various means in 17 studies. The transobturator route was found to have a significantly lower cure rate than the retropubic route (84% vs. 88%, RR 0.96, 95% CI 0.93-0.99). The clinical significance of this 4% difference in objective cure versus no difference in subjective cure has been questioned.
In a recent systematic review and meta-analysis, Latthe et al. found 12 RCTs that compared TOT with TVT, and 15 that compared TVT-O with TVT.[191] When compared at 1–44 months, the subjective (OR 1.16; 95% CI 0.83–1.6) and objective (OR 0.94; 95% CI 0.66–1.32) cure of TOT was similar to TVT. For TVT-O, the subjective (OR 1.06, 95% CI 0.85–1.33) and objective cure (OR 1.03, 95% 0.77–1.39) was also similar to TVT.

Novara et al examined 11 RCTs comparing TVT with inside-out TOT and 9 RCTs comparing TVT with outside-in TOT.[48] Meta analysis revealed that continence rate according to any definition of cure (OR: 1.02; 95% CI: 0.78–1.33; p = 0.90), and subjective continence rates (OR: 0.97; 95% CI: 0.75–1.24; p = 0.80) were similar between the two procedures. Overall, retropubic tapes had significantly higher objective continence rates when compared to the transobturator tape group (OR: 0.80; 95% CI: 0.65–0.99; p = 0.04). Interesting, a statistically significant difference in favour of TOT was shown when comparing objective continence rates between TVT and inside-out TOT (OR: 0.71; 95% CI: 0.52–0.96; p = 0.03) but no difference was found comparing TVT to outside-in TOT (OR: 0.90; 95% CI: 0.66–1.22; p = 0.51). However, when studies of lower methodological quality were excluded only a non-statistically significant trend in favour of TVT was found. (OR: 0.74; 95% CI: 0.54–1.01; p = 0.05).

The majority of RCTs used in the aforementioned Cochrane review and meta-analyses were small, had short- to medium term follow-up and were designed only to detect superiority. This has precluded robust conclusions regarding long-term success and equivalence efficacy with this data.

Angioli et al. provide long-term data regarding the success rates of TVT and TVT-O in a multicentre RCT. [198] At 5 years follow-up, objective cure, defined as a negative cough stress test, was similar between TVT and TVT-O (71.4% vs. 72.9%; p=1). After 5 years, patients in this trial were asked to describe their overall satisfaction. 60% and 62% of women reported that they were satisfied or very satisfied with the results of their TVT and TVT-O respectively (p=1).

TOMUS (Trial of Mid-Urethral Slings) is a large multicentre, equivalence RCT designed to compare the efficacy and safety of retropubic and transobturator mid-urethral slings. [170] The 12-month outcomes of 565 women were recently reported. The criteria required for objective treatment success were a negative provocative stress test, a negative 24-hour pad test, and no retreatment (behavioural, pharmacological, or surgical) for SUI. The unadjusted rates of objective treatment success met the predefined criteria for equivalence, less than a 12 percentage-point difference. (80.8% in the retropubic sling group and 77.7% in the transobturator sling group; 3.0 percentage-point difference; 95% CI: 3.5 to 9.6). The subjective treatment success criteria were the absence of self-reported SUI symptoms as assessed with the use of the Medical, Epidemiological and Social Aspects of Aging questionnaire, no leakage recorded in a 3-day voiding diary, and no retreatment for SUI. The unadjusted rates of subjective treatment success did not significantly differ between groups but the predetermined criteria for equivalence was not met (62.2% in the retropubic sling group and 55.8% in the transobturator group, 6.4 percentage point difference; 95% CI, -1.6 to 14.3).

e) Comparator Trials: Transobturator versus Retropubic MUS in patients with Intrinsic Sphincter Deficiency (ISD)

The diagnosis of ISD in the literature has traditionally been based on the urodynamic finding of a Valsaile leak-point pressure (VLPP) < 60 cmH20 or a mean urethral closure pressure (MUCP) < 20 cm H2O. A retrospective study of 300 women with SUI and ISD found an overall cure rate for TVT to be significantly higher than TOT (78.3% vs. 52.5%; p<0.0001). [111] Jeon et al. retrospectively compared 253 patients with ISD and found that after 2 years cure rates were 86.94% and 34.89% for TVT and TOT respectively (p<0.0001). [156] Schieltz et al. [87] randomised 184 women with urodynamic evidence of SUI and ISD to receive TVT or TOT. At 6 months, urodynamic SUI was present in 21% in the TVT group compared to 45% in the TOT group. [87] Similarly, in a large RCT, a VLPP < 60 cmH20 was a predictor of poor outcome in the transobturator sling group but not in the retropubic sling group.[88] In these studies ISD was defined by a low VLPP or MUCP, but there is no mention of urethral mobility. Contradictory to these findings, Rapp et al. retrospectively reviewed their results and found no significant differences in continence rates across different preoperative VLPPs.[113] In a large observational study, women with SUI were stratified according to preoperative MUCP and VLPP and followed for 5 years after TOT. The objective overall cure rates were similar across all strata indicating that MUCP and VLPP may not be predictive of outcome in TOT. [199] In the TOMUS trial, there was no material change in the rates of treatment success according to objective or subjective criteria when the analyses were adjusted for VLPP and MUCP. [170]

The data comparing retropubic and transobturator MUS outcomes in patients with ISD appears equivocal. Recent studies suggest that evaluation of urethral mobility in ISD patients can be more informative. A cohort of 107 women with SUI had their urethral mobility measured prior TOT and at 10 months subjective cure was assessed. Women with preoperative urethral mobility < 45 degrees were at least 4 times more likely to report postoperative incontinence compared to women with preoperative urethral mobility > or = 45 degrees (29.4% vs 6.9%, RR 4.29, 95% CI 1.59–11.60, p=0.005). [200] Halilolu et al. divided 65 women with SUI into three groups prior to receiving TOT: i) patients with ISD with a VLPP < or = 60 cm
H2O and a Q-tip test > 30 degrees (ISD and hyper-mobile urethra), II) patients with ISD who have VLPP < or = 60 cm H2O and Q-tip test < or = 30 degrees (ISD without hypermobile urethra), and III) patients without ISD who had VLPP > 60 cm H2O and Q-tip test > 30 degrees (hypermobile urethra without ISD). [201] All cure and improvement rates were statistically lower in group II at 6, 12, and 24 months leading authors to conclude that lack of urethral hypermobility may be an important risk factor for TOT failure in patients with ISD.

f) Complications of Obturator Slings

Complications of MUS are categorised as intraoperative complications (bladder, urethral, visceral and vessel injury), immediate postoperative complications (voiding dysfunction, groin pain, infection) and chronic problems (de novo urgency, sling erosion/extrusion). Placement through the obturator foramen avoids the space of Retzius, decreasing more serious intraoperative trocar complications. In 2008 Novara et al. conducted a systematic review and meta-analysis of complication rates in mid-urethral slings.[202] When comparing retropubic vs. transobturator approach, bladder perforations (OR 2.33; 95% CI: 1.26–4.32; p = 0.007), pelvic hematoma (OR 4.83; 95% CI: 1.22–19.15; p = 0.03) and storage lower urinary tract symptoms (OR 1.81; 95% CI: 1.13–2.91; p = 0.01) were less frequent in women who had undergone a transobturator sling. Rates of vaginal erosions, urinary tract infections and reoperation rates were similar amongst groups. The 2009 Cochrane review by Ogah et al. on mid-urethral slings found that the transobturator approach was associated with a shorter operating time, less blood loss, less postoperative voiding dysfunction, and fewer bladder perforations, but more groin pain (12% vs. 1.7%, RR 6, 95% CI: 3–11) than the retropubic route.[40] In 2010 Latthe et al. updated their systematic review which assessed the effectiveness and complications of transobturator slings.[191] Adverse events such as bladder injuries (TOT, OR 0.11, 95% CI 0.05–0.25; TVTO, OR 0.15, 95% CI 0.06–0.35) and hematomas (OR 0.06, 95% CI 0.01–0.30) were less in the TOT than TVT. Voiding difficulties (TOT, OR 0.61, 95% CI 0.35–1.07); TVTO, OR 0.81, 95% CI 0.48–1.31) were slightly lower in TOT but this was not statistically significant. Groin/thigh pain (TVT-O, OR 8.05, 95% CI 3.78–17.16) and vaginal injuries (TOT, OR 5.82, 95% CI 1.85–18.3; TVTO, OR 1.69, 95% CI 0.73–3.91) were more common in the transobturator tapes. Mesh erosion in TVT-O (OR 0.77, 95% CI 0.22–2.72) and TOT (OR 1.11, 95% CI 0.54–2.28) was similar to TVT.

A recent publication by Brubaker et al. reported on 2 year adverse events in patients enrolled in the TONUS trial who were undergoing retropubic or transobturator midurethral slings. [203] UTIs were the most common adverse events in both groups with a higher incidence in the retropubic group (16.7% vs. 9.1%, p = 0.02). Patients in the retropubic group had higher rates of bladder perforation (5% vs. 0%, p < 0.001), voiding dysfunction requiring surgery or catheter use (3% vs. 0%, p = 0.002) and postoperative bleeding (2% vs. 0%, p = 0.2). Neurological symptoms, defined as new paresthesias or alterations in motor function in the first 6 weeks after surgery, were more frequent in the transobturator group than in the retropubic group (9.7% vs. 5.4%, p = 0.04). Mesh complications were reported in 3-5 % of women and these rates were similar in both groups.

But and Fageneij randomised 120 patients to Monarc (inside-out transobturator sling) or to TVT-O (outside-in). [193] There was a higher incidence of vaginal wall perforations and lacerations in the Monarc (0% vs. 15%), and the TVT-O was more painful than the Monarc (p = 0.0015). Liapis et al. evaluated 114 patients randomised to TVT-O and Monarc, finding no statistically significant differences between the two procedures. [195] In patients that have undergone the Obtape, there have been reports of higher rates of vaginal erosion, ischiorectal abscesses, adductor myositis with symptoms of leg pain, difficulty ambulating and cellulitis. The newer polypropylene slings have been associated with a lower incidence of complications. However, the true incidence of major complications is probably limited by the heterogeneity of the outcome measures and the short-term follow-up of most of the studies. Future studies with validated outcomes and long-term follow-up are needed.

g) Transobturator Slings in Special Populations

1. Mixed Urinary Incontinence

Mixed urinary incontinence (MUI) is defined as the complaint of involuntary leakage from the urethra, associated with urgency, and also with exertion, effort, sneezing or coughing. How mid-urethral slings affect patients with MUI is less apparent. Many studies have demonstrated an improvement or cure in OAB symptoms and UUI in those patients undergoing sling procedures for the stress component of MUI with cure rates ranging from 50-74%. [204] Other studies have reported a decrease in subjective and objective cure rates but still quality of life improvement after treatment in women with MUI [53, 205]. Two studies by Paick et al reported on patients with MUI.[53, 205] The first, which reported on 73/274 with MUI who underwent TVT with more than six months follow-up, showed that the mixed UI group had the same cure rate for stress urinary incontinence (SUI) as the SUI-only group. They also found that 16.4% of the mixed UI group had persistent UUI, so that the overall UI cure rate was lower for the mixed UI than the SUI group, but still quite favourable (78.1% vs. 95.5%). In their second study, they evaluated 144 women with mixed UI who had undergone TVT, Sparc or TOT slings. There were no significant differences in the three groups in terms of the cure rate for SUI (SUI; TVT, 95.8%; SPARC, 90.0%; TOT, 94.0%; p = 0.625) and for total cure (TVT, 81.9%; SPARC, 86.4%; TOT, 82.0%; p = 0.965). There were no risk factors for cure of SUI, except detru-
sor overactivity (DO) on urodynamic studies. There was one difference between groups preoperatively; the TOT patients had less severe UUI than those patients who underwent the SPARC or TVT.

In 2008 Gamble et al. evaluated 305 women with MUI and found 31.5% of women had postoperative resolution of detrusor overactivity (DO). [204] Sling type was strongly related to persistence of DO with a 53% persistence of DO in the transobturator tape group, followed by retropubic (64% after TVT, 66% after SPARC), and 86% after bladder neck slings ($p < .001$). Botros et al. evaluated 276 patients with MUI who underwent retropubic slings (TVT, $N = 99$; SPARC, $N = 52$) or transobturator slings (Monarc, $N = 125$).[206] Patients who underwent transobturator sling placement (8%) had significantly less de novo subjective UUI compared to the patients who had TVT (33%) and SPARC (17%) ($p = 0.04$). In patients with preoperative UUI, 14-16% who underwent TVT or SPARC had worsening of their UUI symptoms while only 6% of the transobturator sling group did ($p = 0.02$). There was no difference in rates of resolution of DO or de novo DO among the three groups. Ballert et al. evaluated 83 women who underwent TVT [203] and TOT-O? TVT-O? [87] using pre- and post-operative AUASI (American Urologic Association Symptom Index) scores to evaluate lower urinary tract symptoms.[207] Patients with UUI had lower postoperative AUASI scores than patients with MUI. There were no differences between patients who underwent TVT or TVT-O in any category. In 2011 Lee et al. performed an observational cohort study evaluating risk factors for persistence of urgency or UUI after midurethral slings. [208] Out of 1112 women who completed the questionnaire, 754 patients had preoperative urgency or urgency urinary incontinence. 955 patients underwent retropubic slings and 270 patients underwent transobturator slings. The overall subjective rate for persistent urgency and UUI was 40.3% and 32.3% respectively. Age (OR 1.03, 95% CI: 1.02-1.04), baseline symptoms severity (OR 1.41, 95% CI: 1.10-1.78) and coexistent DO (OR 2.04, 95% CI: 1.39-3.01), were risk factors for persistent urgency while concomitant prolapse surgery (OR 0.54, 95% CI: 0.38-0.75) and transobturator sling surgery (OR 0.61, 95% CI: 0.39-0.94) decreased the risk. There was no difference in type of sling surgery and persistence of UUI. These studies are consistent with results published by Novara et al. who performed a meta-analysis of randomised controlled trials comparing transobturator vs. retropubic MUSS.[33] Results showed a higher prevalence of storage lower urinary tract symptoms in patients randomized to retropubic slings than in patients randomized to transobturator slings (OR 1.35; 95% CI OR: 1.05-1.72; $p = 0.02$).

In conclusion, women with mixed urinary incontinence benefit from sling surgery. It appears that placement of a transobturator sling provides the greatest improvement in OAB and UUI symptoms and seems to have the lowest rates of de novo urgency and UUI; it also appears to have the greatest resolution of DO. However, women with mixed urinary incontinence should be carefully counseled preoperatively as persistence or worsening of symptoms may have a negative impact on quality of life and may lead to poor overall satisfaction after surgery.

2. Recurrent SUI

There have been multiple studies reporting on outcomes after repeat anti-incontinence surgery, however the appropriate choice of a secondary continence procedure for women with recurrent SUI is poorly studied and the available studies are limited by their small numbers. Two studies of repeated mid-urethral slings report cure rates of 74–76% at 18 months, which is lower than cure rates for primary surgery.[209, 210] Lee et al. performed a retrospective study on repeat midurethral slings.[209] 13 patients underwent retropubic and 16 patients underwent transobturator slings. Overall cure was 75.9% and overall improvement was 6.9%. Cure rates were 92.3% for the retropubic approach and 62.5% for the transobturator approach, however this was not statistically significant ($p = 0.089$). Stav et al. evaluated 1,225 women with SUI, among these 77 patients had repeat mid-urethral slings.[211] The subjective stress incontinence rate was 62% in the repeat group compared to 86% in the primary group ($p < 0.001$). A repeat retropubic approach was significantly more successful than a repeat transobturator approach (71% vs. 48%, $p = 0.04$). These results could be due to a higher incidence of intrinsic sphincter deficiency or lack of urethral mobility in patients undergoing a repeat mid-urethral sling (31% vs. 13%, $p < 0.001$). A recently published study by Abdel-Fattah et al. reported on outcomes on a total of 46 women with recurrent SUI after previous failed continence surgery.[212] 18 patients underwent “outside-in” and 28 underwent “inside-out” procedure. Overall subjective and objective success rates in this group were 70% and 77% but it should be noted that these numbers included 10 women with failed colposuspension. Higher success rates were seen in women who underwent the inside-out TVT-O compared to the ‘outside-in’ TOT but this study was not adequately powered to make this comparison. Biggs et al. evaluated 27 patients who underwent TVT-O after a previous anti-incontinence procedure.[213] There was an 80% success rate assessed by PGI-I (“very much better” or “much better”) at a mean follow-up of 25.7 months.

A repeat synthetic mid-urethral sling procedure has significantly lower cure rates than a primary sling procedure. Although the data are limited, it seems that in patients who failed a primary anti-incontinence surgery, a repeat retropubic approach has a higher success rate than the repeat transobturator approach especially in cases with intrinsic sphincter deficiency.

3. Elderly

Thirty-seven million people are aged > 65 years (12% of the total US population) and 5.3 million of these are aged > 85 years. With the national life span
increasing, it is estimated that by 2030, 1 in 5 people in the United States will be aged > 65 years, and 1 in 4 elderly individuals will be aged > 85 years. Advanced age is related to increased prevalence of urinary incontinence and there is evidence of a higher rate of DO and ISD in the elderly population. Surgical intervention is considered the most efficient and durable approach to treat SUI and mid urethral slings have become the treatment of choice in the majority of patients. The effect of age on outcomes of mid urethral slings is still scarce and the definition of elderly varies across studies. There are some studies that evaluate the efficacy of retropubic slings in the older population but there are limited data assessing safety and efficacy of the transobturator slings in elderly vs. younger patients. Sevestre et al. analysed a series of 76 patients with a mean age of 76 years who underwent TVT.[214] There were no major postoperative complications, however, 13.7% of the patients had postoperative persistent SUI and 18.4% had urgency incontinence. De novo urgency without incontinence was detected in 21% of the patients. In another study, pre- and postoperative quality of life parameters were compared in a small series of 21 elderly and 46 younger stress-incontinent patients that underwent TVTs.[215] At postoperative follow-up of 3-24 months, SUI was improved in 91% of the younger and 80% of the elderly patients and all quality of life parameters were significantly improved in all age groups. Perioperative morbidity and complications are also a consideration in older patients. In the study of Gordon et al. the incidence of early postoperative morbidity was similar in both age groups who underwent TVTs. [216] However, several cases of significant age-related morbidity were noted among elderly patients: two cases of pulmonary embolism, two cases of cardiac arrhythmia, one case of severe pneumonia, and one case of deep vein thrombosis. All major complications occurred in elderly patients who were undergoing concomitant prolapse surgery. The risk of de novo urgency was 18% at one year in older vs. 4% in the younger patients. Barber et al. identified predictors of recurrent urinary incontinence one year after treatment with retropubic and transobturator slings. [85] They found that increasing age was the only identified variable that was independently associated with recurrent SUI (adjusted OR 1.7; 95% CI: 1.1-2.6 per decade). Chen et al. found that surgical failure after inside-out transobturator sling was significantly greater in women aged 60 years old or older, compared with those younger than 60 years (adjusted OR 11.7; 95% CI: 1.8-76) in a small series of 54 women. [217] Groutz et al. evaluated patients aged 70 or older (n=97) and compared them to patients younger than 70 (n=256) who underwent TVT-O.[218] The mean follow up was 30 months ± 17 months. The incidence of persistent, urodynamically confirmed, SUI was similar in both age groups (5%). However, asymptomatic urodynamically SUI was significantly more common among elderly patients (19% vs. 3.7%, p <0.05). The incidence of persistent OAB was similar in elderly and younger patients (68% and 62%, respectively), while de novo OAB was significantly more common in elderly patients (11.9% vs. 4.7%, p <0.05). Postoperative morbidity was similar in both groups except the elderly group had a higher incidence of recurrent UTI’s (13.7% vs. 6.2). Even though there are limited data and further studies are needed, it appears that transobturator slings are both safe and efficient in elderly patients and women should not be excluded from mid-urethral slings based on their age.

4. Concomitant Prolapse Surgery

Approximately 40% of women with pelvic organ prolapse (POP) also report SUI.[219] Asymptomatic women who undergo prolapse surgery have a 11-20% risk of developing de novo stress incontinence. [220] Patients who leak during preoperative testing after reduction of their prolapse have a risk of up to 80% of developing de novo SUI.[221] The role of concomitant slings in patients undergoing POP repair has been debated, with some studies showing differences in cure rates or complications and others finding no differences. In a prospective observational study, Liang et al. evaluated 49 patients with stage 3 or 4 prolapse and occult stress incontinence.[222] In 32 (65.3%) patients a concomitant TVT procedure was performed and the remaining 17 (34.7%) patients had a prolapse repair only. The rate of postoperative SUI was significantly lower in those who had a TVT placed (9% vs. 65%) and the rate of detrusor overactivity was lower in patients who had prolapse repair alone after surgery (6% vs. 16%). Casiano et al. compared outcomes after retropubic mid-urethral slings with and without concomitant prolapse repair. [223] After 2.7 years survival free of “any” incontinence (Incontinence Severity Index score, >0) was similar in both groups (adjusted hazard ratio, 1.07; p=0.77). Women with concomitant repair for advanced prolapse tended to be more bothered by frequent urination (adjusted OR 1.78; p=0.08) and more likely to require urethrolysis (OR 6.11; p=0.04) than those without prolapse repair. There is only one study that reports on transobturator slings and prolapse surgery. Wang et al. evaluated 140 women who underwent TVT (n = 70) and TOT (n = 70) with SUI with or without POP.[224] In the TVT group 30 patients and in the TOT group 22 patients had concomitant prolapse surgery. Surgical results were similar in both groups and concomitant pelvic reconstructive procedures had no effect on surgical results. At 1-year follow-up, the objective cure rates for patients with isolated SUI were 95% in the TVT group and 93.75% in the TOT group. For patients with concomitant POP, the cure rates were 90% in the TVT group and 86.36% in the TOT group. There are no randomised trials in patients undergoing pelvic organ prolapse surgery and obturator slings but with the currently available literature, it would appear that it is beneficial to treat concomitant SUI and prolapse. There are no current studies on the role of transobturator slings in occult SUI.

1329
5. Obesity

Obesity is gradually increasing worldwide and epidemiological studies have found a link between obesity and urinary incontinence with odds ratio for the presence of urinary incontinence as high as 1.6 to 5 with each unit increase in body mass index (BMI). [225, 226] The role of mid-urethral slings in obese women has been debated due to concerns for higher failures and a potential increase in intraoperative and postoperative complications. Numerous studies have been carried out evaluating obesity as an independent predictor in patients that have undergone TVTs. [227, 228] [229] [230] [231-234]

Hellberg et al. reported a decrease in cure of 52.1% in patients with a BMI higher than 35 compared to 81.2% in those with a BMI less than 25. Six other studies have shown overall cure rates that approach 90% with no difference in the obese vs. the non-obese patient.[231] However Greer et al. in their meta-analysis included these seven studies and did find a significant difference in cure rates between the two groups with cure rates being 81% and 85%, respectively (p = 0.001; OR 0.576, 95% CI: 0.426–0.779). [227] There are very limited data evaluating outcomes for transobturator slings in obese women. Liu et al did a retrospective review evaluating the TVT-O procedure in overweight and obese women. [235] They retrospectively evaluated 129 patients who had undergone TVT-O and they were stratified according to their BMI, normal weight (n=29), overweight (n = 58), and obese (n = 32) groups. The median follow up was 24 months and there were no statistically significant differences in between groups comparing objective or subjective surgical outcomes, in the incidence of de novo DO, in quality of life scores or postoperative complications. Another study undertaken by Rechberger et al. found no significant association between BMI and surgical outcome at 18 months of follow-up among normal weight (n = 43), overweight (n = 81), and obese (n = 73) women who underwent transobturator slings. [88] However, they did notice a trend towards worse outcomes in overweight patients. Haverkorn et al. conducted a retrospective study evaluating patients that had undergone a transobturator sling (Monarc) in women with a BMI higher than 30 (n = 117) and BMI less than 30 (n = 161) with a minimum follow up of 12 months. [236] The percentage of women achieving global cure and SUI cure was significantly higher in non-obese women (83.9% and 91.9%) than in obese women (70.9% and 81.2%) (p < 0.001). Obese women achieved improvement in quality of life similar to those of non-obese women. Although the results from these studies are conflicting, it seems that regardless of BMI, transobturator slings may be an acceptable method of treatment for SUI in obese patients. Follow up in these studies is limited and larger studies are needed to confirm these findings and to evaluate the long term effects of the procedure.

h) Conclusion and recommendation

Sufficient Level I II evidence exists which evaluate mid-urethral tapes (retropubic). Current series include retrospective cohort studies and high level RCTs. There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. Quality of evidence is A / B.

4. SINGLE INCISION MINI SLINGS (SIS) (TABLE 3)

The single incision mini slings have been developed in an attempt to further reduce the morbidity associated with continence surgery and to provide an outpatient or office procedure to treat stress urinary incontinence. The blind passage of needles, during TVT and TOT procedures, through the retropubic space or the obturator foramen respectively is associated with a small risk of vascular, nerve or visceral injury [202]. The shorter SIMS will theoretically minimise this risk.

The concept of the single incision sling is not novel. Smith presented a small series of SIMS in 1987[237], however this was a porcine dermis sling which in vivo probably degrades and hence long term cure rates were poor.

The first commercially available mid-urethral single incision sling, TVT-Secur (Gynaecare), was launched in 2006 with no published human trial data. The last 6 years have seen a increase in the number of commercially available single incision slings. There are currently 9 different products available. All are made of type I polypropylene mesh however the length & anchoring mechanisms are variable. (Figure 1)

The method of insertion is either U shaped, inserted in the same manner as the TVT or the H “hammock” insertion of the TOT. There is currently very little good quality RCT data to support the use of these slings.

Ten trials have been published including 1072 women. 6 of the RCTs published compared TVT-Secur to MUS, 2 compared MiniArc to MUS, 1 compared TVT-Secur to MiniArc and to MUS, and one compared Contasure to TVT-O. The numbers in each trial are relatively small (60-194).

Five of the seven trials of TVT-secur found it to be inferior to TVT or TVT-O. Several different outcome measures were report in these 7 trials, making it difficult to compare the trials directly. Two of these trials were stopped prematurely following an interim analysis which demonstrated TVT-secur results to be significantly less effective than the comparator MUS. Hamer et al [245] also reported concerns about the morbidity associated with TVT-secur. They reported three significant complications in 67 cases, one hemorrhage 1000ml, one urethral perforation and one perforation of the bladder.

Three trials compared MiniArc to MUS, two found no significant difference between MiniArc and obturator tapes however the third trial by Basu et al[240] reported a considerably worse outcome for MiniArc compared to TVT, 9 out of the 37 patients who underwent the MiniArc subsequently had a TVT. Table 3 summarises the data currently available.
In 2011 Abdel-Fattah et al. published a meta-analysis of RCT comparing SIMS to standard MUS, the review included both full text publications and conference abstracts. A total of 758 women in nine RCTs with a mean follow-up of 9.5 months were included. SIMS were associated with significantly lower patient-reported and objective cure rates compared with MUS (risk ratio [RR]: 0.83; 95% confidence interval [CI], 0.70–0.99, and RR: 0.85; 95% CI, 0.74–0.97, respectively).

One of the reasons for the development of SIMS is to reduce the morbidity of continence surgery. Hence trial design should include an assessment of morbidity, including perforation, hemorrhage, chronic pain and voiding difficulty. The meta-analysis demonstrated that there was no significant difference in the perforation rate between SIMS and MUS, the confidence intervals (CI) for these parameters were however extremely wide. There was also a trend toward more voiding difficulties following SIS but again the CI were very wide.

Proponents of SIMS have speculated that the initial poor results reflect an incorrect insertion technique used in early trials. SIMS were initially inserted in the tension free manner by which TVT are inserted, however SIMS insertion has evolved and the current insertion technique is in closer proximity to the urethra and with greater tension than TVT.

Jeffery et al. have published the protocol Cochrane review of SIMS which will enable ongoing assessment of data.

Due to the considerable variation in the anchoring mechanism of each type of SIMS, data from one device cannot be extrapolated to another. There is a need for further RCT. Currently the recommendation is that SIMS should only be performed in the context of research.

All reports are Level I - III in terms of evidence and there continues to be a lack of durable outcomes reporting for this technique. Current series suggest that some efficacy may be inherent to these interventions, however, comparable efficacy to either retropubic or mid-urethral tapes has yet to be proven. Grade of recommendation is –B/ C.

5. TRADITIONAL SLING PROCEDURES

As in the previous ICI4 review, the term ‘traditional’ sling procedure is used here, in line with the terminology used in the latest Cochrane review. This is done mainly to distinguish open sling procedures typically placed at the region of the bladder neck from the newer, minimally-invasive mid-urethral tapes (MUS) procedures.

Sling procedures came into prominence in the beginning of the twentieth century. In 1907, Giordano transplanted gracilis muscle and wrapped it around the urethra. [250] Soon thereafter, other autologous tissues were transplanted under the urethra to provide additional support: pyramidalis [251], levator ani [252], rectus fascia [253], gracili [254], and bulbocavernosus muscle and fat [255]. While it was
hypothesised that the transplanted muscle would retain its contractility and act as a neo-sphincter to prevent SUI, these procedures compressed the urethra and created a partial obstruction. Complications such as recurrent cystitis, urethral sloughing, and fistula formation were common.

The modern autologous bladder neck sling exists mainly due to the work of Aldridge in the 1940’s and McGuire and Blaivas in the latter part of the twentieth century. [256-258] The majority of sling procedures have involved a combined abdominovaginal approach, although procedures performed entirely through an abdominal approach have been described. Suspended, or ‘sling on a string,’ methods have been developed in order to reduce the invasiveness of the procedure and to shorten the length of sling material. These shorter slings can also vary in length, from a “mid-length” sling (7-10 cm) to a “patch” sling (2-4 cm). As with needle suspension procedures, bone anchoring has been used as an alternative form of sling suspension, although the benefit of this additional step has not been adequately studied.

Sling materials may vary widely and individual materials may have only a modest effect on initial sling efficacy. However, these materials may considerably affect the long-term outcomes of sling procedures and the associated morbidity. Materials may be synthetic or biological. The latter include autografts (rectus fascia, fascia lata, round ligament, dermis, vaginal skin, and gracilis, levator, and rectus muscles), cadaveric allografts (fascia, dermis, and dura mater) and xenografts (porcine dermis and small intestinal submucosa, bovine dermis and pericardium). Case series of autologous rectus fascial (ARF) sling were reviewed within the systematic review underlying the NICE guidance on urinary incontinence. [259] Ten series including a total of 1280 women were considered. Studies had a mean or median duration of follow-up between 2 and 6 years, while in three studies, maximum follow-up of 15–18 years was reported. Subjective cure rates ranged from 26% to 97% (median 81%); and cure rates that included subjective and objective elements ranged from 73% to 95%. Satisfaction rates of 86% and 92% were reported in two studies.

Synthetic sling materials have included nylon, polyethylene, polytetrafluoroethylene (PTFE), and polypropylene. On occasion, these polymers have been ‘enhanced’ with synthetic or biologic coatings in an attempt to improve their biocompatibility profiles. Many additional variations in the technique have been described, although it is unclear which of these materially influence the outcome. Several case series have published outcomes for polyethylene and PTFE slings with short-term cure rates typically in the 80-90% range, depending on the definition [EL=3]. Vaginal extrusion, erosion, and sinus formation have been common with these materials. Since the last ICI review, there have been no additional studies published and the number of these procedures performed appears to have waned significantly in favour of polypropylene midurethral slings.

Both biological and synthetic sling materials are analysed together in the Cochrane review [Rehman et al., 2011], although these were considered separately in the systematic review underlying the NICE guidance on urinary incontinence. [249, 259] NICE has also published a non-systematic review of biological sling procedures under its Interventional Procedures Programme. [260] The most recent Cochrane review included 26 RCTs (or quasi-randomised trials) describing a total of 2284 women of whom 1287 were treated with suburethral traditional slings. Sample sizes ranged from 20 to 655 participants. Several of these trials are available only in abstract form and remain unpublished as full peer-reviewed papers. Owing to the significant number of recent meeting abstracts about surgical procedures for SUI, only full publications have been included in this section. Additional studies have been included, but the majority of these are case-control studies and have a relatively low level of evidence.

There have been no trials identified that compared traditional suburethral sling operation vs. no treatment, sham operation, conservative management (e.g. pelvic floor muscle training, electrical stimulation, cones, biofeedback), anterior repair, laparoscopic retropubic suspension, or artificial urinary sphincter [Rehman et al., 2011]. [249] One trial studied patients with MUI treated with oxybutynin or surgery [Osman, 2003]. [261] The type of surgery was selected according to Valsalva leak point pressure (VLPP): those women with VLPP ?> 90 cm H2O underwent an ARF sling and those with VLPP ?> 90 cm H2O underwent Burch colposuspension. The results for the total surgically managed group were similar to those for the subgroup having slings. The study suggested that slings are significantly better for treating MUI than oxybutynin. Results were analysed in terms of patient reported incontinence within one year (RR 0.18; 95% CI 0.08 to 0.43). Fewer women had persistent UUI after the sling surgery (RR 0.29; 95% CI 0.09 to 0.94).

a) Traditional sling vs. bulking agent (table 4E)

One RCT compared ARF sling with periurethral silicone cone injection in women with SUI secondary to ISD in whom conservative treatment had failed [Maher et al., 2005]. [165] At 6 months, no significant differences were seen between groups in subjective cure (1-hour pad test) or satisfaction, QOL (UDI-6, IIQ). Significantly more women undergoing sling surgery were objectively cured on the basis of urodynamic assessment (81% vs. 9%; p=0.0001), but duration

Key: RP MUS=retropubic midurethral sling; F/U=follow-up (months); LE=level of evidence; TVT=tension-free vaginal tape; o=objective; s=subjective; N/A=not available; OC=open colposuspension; LC=laparoscopic colposuspension; ITT=intention to treat
of the procedure, catheterisation, inpatient stay, and time to return to normal activities were significantly longer in the sling group. A survey of two-thirds of the women at 5 years found no statistically significant differences between groups in urinary symptoms or in satisfaction with surgery, although fewer women in the silicone bulking group were satisfied (29% vs. 69%) (n=45). [EL=2].

Open continence surgery (a suspension procedure in 46% and ARF sling in 54%) was compared with periurethral collagen in women with SUI or MUI in an additional RCT [Corcos et al., 2005]. [164] As in the previous study, there were no significant differences in patient satisfaction or QOL (SF-36, IIQ) between groups at 1 year. Using ITT analysis, there was no significant difference in continence rates at 1 year (52% collagen, 55% surgery). If only the 89% of women who underwent the randomised intervention were considered, the continence rate with surgery was significantly higher (72% vs. 53%; p=0.01). The incidence of adverse effects was significantly higher in the surgery group: urinary retention 13% vs. 2%, transient voiding difficulty 36% vs. 17%, UTI 6% vs. 0% (n = 133). [EL=2]

b) Traditional sling vs. colposuspension (Table 4A)

Nine randomised or quasi-randomised trials were identified from the literature. Six of the trials compared suburethral slings with open abdominal retropubic suspension [Henriksson & Ulfsten, 1978, Enzelsberger et al., 1996, Sand et al., 2000, Demirci & Yucel, 2001, Bai et al., 2005, Albo et al., 2007] while one trial reported the long-term outcomes [Culligan et al., 2003] and another reported the complications [Chai et al., 2009] of aforementioned trials. [38, 119, 121-126] One additional trial compared suburethral slings with the Stamey transvaginal needle suspension [Hilton, 1989]. [120] The Cochrane review systematically evaluated the six trials comparing suburethral slings with open retropubic suspension and an additional trial that was only published in abstract form [Rehman et al., 2011]. [249]

One RCT compared dura mater sling with open colposuspension in 72 women with recurrent SUI after hysterectomy [Enzelsberger et al., 1996]. [121] At a minimum follow-up of 32 months, the combined objective and subjective cure rates were 92% after dura mater sling compared with 86% after colposuspension. While both were common, significantly more women in the sling group developed postoperative voiding difficulty or urinary retention. More women in the colposuspension group developed a postoperative rectocele. Bladder perforation and de novo urgency were common in both groups. The time to spontaneous voiding was significantly longer in the sling group (n = 72). [EL=1/2].

Three trials compared ARF sling with open colposuspension. In a small trial alternating 17 women each to ARF and colposuspension, ARF was superior to colposuspension at 12 months follow up by objective measures (94% vs. 88%) [Demirci & Yucel, 2001]. [124] In a second trial randomising women to ARF, colposuspension, and TVT, ARF was significantly superior to colposuspension at 12 months (92.8% vs. 87.8%) using a subjective and objective definition of cure [Bai et al., 2005]. [38] The significant difference in the two procedures was not evident at 6 months follow-up (92.8% vs. 90.9%). Finally, a large RCT performed by the Urinary Incontinence Treatment Network revealed that ARF was significantly superior to colposuspension both in its cure of SUI (47% vs. 38%) and overall incontinence cure (66% vs. 49%) at 24 months [Albo et al., 2007]. [125] Fifty percent of the women underwent concomitant surgery for pelvic organ prolapse (POP) and 79% (265:255) were available for the 24-month outcome assessment. Women undergoing ARF sling had a higher percentage of postoperative UTIs within the first six weeks of follow-up, voiding and storage urinary symptoms [Chai et al., 2009]. [126][EL=1]

Two small RCTs evaluated an expanded polytetrafluoroethylene patch sling (PTFE; Gore-Tex®) and open colposuspension, with the second trial providing long-term subjective and objective outcomes [Sand et al., 2000; Culligan et al., 2003]. [122] [123] Although the groups were different at baseline in terms of the proportion with detrusor overactivity (DO) (95% colposuspension vs. 41% sling), cure rates with PTFE were not significantly different from open colposuspension at 3 months (objective 100% vs. 90%) and 2.5 years (objective 100% vs. 85%; subjective 84% vs. 93%) (n = 36). No significant differences were found between groups in hospital stay or time to catheter removal. [EL=2]

In the Cochrane review, trials comparing rectus fascia with other materials heavily weighted the comparison of different types of sling [Rehman et al., 2011]. [249] Furthermore, the results of the most recent, and by far the largest and most rigorous RCT of colposuspension and ARF sling heavily weighted the results of the analysis [Albo et al., 2007]. [125] This trial randomised 655 women of whom 520 were assessed at 24 months, while the next largest trial randomised 72 women [Enzelsberger et al., 1996]. [121] The summary statistic, combining urodynamically and symptom only diagnosis, showed a lower incontinence rate with sling procedures (RR 0.75; 95% CI 0.62 to 0.90). The data from the trials where women all had urodynamic SUI showed no significant difference in urinary incontinence after one year (RR 0.72, 95% CI 0.31 to 1.67). Data beyond five years were provided by only one trial [Sand et al., 2000], and there was no statistically significant difference between the groups, but with very wide confidence intervals (RR 2.31; 95% CI 0.24 to 22.62). [122] Adverse events in general (47% vs.63% (p=0.001)
Only one small trial is available to allow comparison between sling (porcine dermis) and needle suspension (Stamey) in a group of women unsuitable for abdominal colposuspension because of vaginal narrowing secondary to either previous interventions or atrophic change [Hilton, 1989]. [120]. Although there were no differences in objective cure rates at 3 or 24 months, perioperative complications (RR 4.50; 95% CI 1.28 to 15.81) and length of hospital stay (RR 13.00; 95% CI 5.00 to 21.00) favored the needle suspension procedure (n=20). [EL=2]

c) Traditional sling vs. traditional sling (Table 4B)

Our review identified 3 RCTs and 2 quasi-RCT comparing one type of traditional sling with another [Barbalias et al., 1997; Lucas et al., 2000; Viseshsindh et al., 2003; Choe et al., 2000; Kuo, 2001], with an additional RCT providing long-term outcomes of one of the aforementioned studies [Guerrero et al., 2007]. [128, 132-135, 139] The remainder were cohort and case control studies.

ARF and vaginal wall slings were compared in one RCT and two non-randomised retrospective studies [Viseshsindh et al., 2003; Kaplan et al., 1996; Rodrigues et al., 2004]. [127, 139, 141] All of these trials were considered to be of poor quality. The RCT reported high subjective cure, and satisfaction rates (80–100%) for both procedures, with median follow-up of 7 months and maximum follow-up of only 3 months (n = 26) [Viseshsindh et al., 2003] [139][EL=2]. The non-randomised studies reported similar ‘success’ rates with both interventions, ranging from 80% to 97%, with follow-up of 21 months, and 70 months versus 45 months (n = 232, n = 79) [Kaplan et al., 1996; Rodrigues et al., 2004]. [EL=2/3]. Other than the proportions of patients requiring intermittent catheterisation after surgery (2% in the ARF group and 0% in the vaginal wall group), no additional differences were noted in rates of other postoperative complications (e.g. voiding and storage dysfunction, wound infection and seroma formation, and bladder or urethral injury).

One RCT compared two techniques of fascial sling in 168 women with urodynamic SUI 89% of whom had had prior continence surgery [Lucas et al., 2000]. [133] Women underwent a standard fascial sling procedure or a ‘sling on a string’ (a shorter sling mounted on each end with a nylon thread). At 1 year, subjective cure rates were 84% using both techniques. Satisfaction and changes in IQI scores were also similar in both groups, whereas improvements in UDI scores were greater with the standard approach (adjusted for differences in baseline UDI data). A further evaluation of women in this study was reported at 5 to 7 years of follow-up [Guerrero et al., 2007]. [134] There were no significant differences in symptoms of SUI or UIU between groups, with 40%-53% vs. 36%-51% reporting SUI in sensitivity analysis. [EL=1]

Eight non-randomised studies compared the outcomes of autologous and allograft slings in a total of 859 women with SUI [Wright et al., 1998, Brown & Govier, 2000, Soergel et al., 2001, Flynn & Yap, 2002, O’Reilly & Govier, 2002, Almeida et al., 2004, McBride et al., 2005, Onur et al., 2008], while one additional study also compared both interventions with a xenograft material (porcine dermis) [Simsiman et al., 2005]. [129-131, 137, 138, 140, 142, 143, 146] All were retrospective reviews, each with differences in duration of follow-up for the interventions evaluated (between 1 month and 3 years), with dropout rates of 4% to 34%. Additionally, between 16% and 82% in different studies underwent other concomitant surgeries, and all of these studies were considered to be of poor quality. [EL=3]

Four of these studies compared autologous with allograft (cadaveric) fascia lata. Three reported similar results for all outcomes (subjective cure, satisfaction, and UDI-6, IIQ-7 and SEAPI scores) [Wright et al., 1998, Brown & Govier, 2000, McBride et al., 2005], while the fourth study reported significantly higher cure rates in the autologous group [Almeida et al., 2004]. [129, 130, 140, 142] [EL=3] In three studies that compared autologous rectus fascia or fascia lata with allograft fascia lata, two found a significantly higher cure rate in the autologous group [Soergel et al., 2001, Simsiman et al., 2005]; [137, 143] the other found no significant differences in cure rate, although satisfaction rates were higher in the autologous group after 2 years follow-up [Flynn & Yap, 2002]. [36] In the study with a xenograft arm, cure rates were significantly higher with autograft material [Simsiman et al., 2005]. [143] The study comparing ARF to cadaveric dermis found no significant difference in subjective cure rates at a mean follow-up of 18 months and 13 months, respectively [Onur et al., 2008]. [146] [EL=3]

One RCT compared the porcine dermis sling vs. ARF and tension-free vaginal tape (TVT), a retrospective MUS [Guerrero et al., 2010]. [160] It should be noted that the ARF and porcine dermis slings were placed at the midurethra rather than the bladder neck, but suspended above the rectus fascia like traditional slings. The primary outcome was patient-reported improvement rates at 6 months and 1 year. At 6 months, the porcine dermis arm had significantly poorer improvement rates (73%) than TVT (92%) and ARF (95%), and, at 1 year, only 61% of the porcine dermis slings remained as improved, vs. 93% and 90% of the TVT and ARF arms, respectively. At 1 year, women undergoing porcine dermis slings had significantly lower dry rates (22%) as compared to TVT (55%) and ARF...
slings (48%), respectively. Subsequently, the porcine dermis arm was suspended following interim analysis. There was no difference in success rates between the TVT and ARF arms. [EL=1/2].

One non-randomised trial compared porcine dermis sling vs. ARF [Giri et al., 2006], a second compared porcine dermis sling vs. both ARF and TVT [Morgan et al., 2007], and a third trial mentioned earlier compared porcine dermis vs. both ARF and allograft slings [Simsiman et al., 2005]. [143-145]At a follow-up of 36 months, the subjective success rate (cure and improved) after ARF sling was significantly higher than porcine dermis sling (80.4% vs. 54%) [Giri et al., 2006]. [144] Women undergoing porcine dermis slings were found to have significantly higher postoperative symptom severity than women undergoing either ARF sling or TVT [Morgan et al., 2007]. [145]Objective cure rates after ARF were significantly higher (87%) than either porcine dermis sling (54%) or cadaveric fascia lata (64%) [Simsiman et al., 2005]. [143][EL=2/3]

A quasi-RCT compared an ARF sling with a self-fashioned polypropylene mesh sling placed at the bladder neck [Kuo, 2001]. [135, 148] At a median follow-up of approximately 24 months, cure and satisfaction rates were similar but operating time and hospital stay were significantly shorter in the prolene sling group. Delayed voiding occurred in more women in the ARF sling group. No other significant differences were seen between groups in complications (e.g. haematoma, dysuria, de novo urgency or UUI) (n=50). [EL=2] A second, retrospective, non-randomised trial found no significant difference in subjective cure rate (81% vs. 88.9%) in women undergoing ARF and polypropylene mesh (Marlex) slings [Winckler et al., 2010]. [45] It should be noted that both slings in this study were placed at the midurethral but tied without tension above the rectus fascia as in the traditional bladder neck sling. Interestingly, vaginal extrusion rates and rates of surgical intervention for extrusion were not significantly different between ARF and Marlex slings. [EL=3]

One RCT compared ARF and PTFE slings in women with SUI, 92% of whom had had previous continence surgery [Barbalias et al., 1997]. [128] Combined objective and subjective cure rates at 6 months follow-up were 81% and 88%, respectively. No complications were reported in the ARF sling group; however, urethral erosion, recurrent UTI and de novo DO were very common with PTFE (n = 48). [EL = 1] A quasi-randomised comparison of MycroMesh patch sling (PTFE mesh impregnated with silver diacetate and chlorhexidine) with vaginal wall sling gave no statistical analysis, but found combined subjective and objective cure in 95% vs. 75% at mean follow-up of 22 months [Choe et al., 2000]. [132][EL=2] Again, the need for sling removal was common, reported in up to 31% (median 8%) in a review of case series within the systematic review underlying the NICE guidance on UI [National Collaborating Centre for Women’s & Children’s Health, 2006, National Institute for Health & Clinical Excellence]. [259][EL=3].

A retrospective cohort study compared an ARF sling with one reinforced with polyglactin mesh in women with urodynamic SUI, one-third of whom also had UUI (n=51) [Maher et al., 2001]. [136] Follow-up differed between groups and, overall, no clear difference was seen between groups in success rates. As with most studies, results depended on the definition of success used. No significant differences were noted between groups in terms of complications (e.g. wound infection, incisional hernia, voiding dysfunction, and de novo DO). [EL=3]

A small, non-randomised trial compared ARF to bovine dermis sling (n=85) [Wilson et al., 2008]. [147] Patients were allocated to material by institution and all had ISD, advanced age, and/or recurrent SUI after previous anti-incontinence surgery. At 12 months follow-up, the SUI-specific cure rates (consisting of subjective stress SEAPI domain and negative cough stress test) and global cure rates (consisting of SEAPI composite score and visual analog score) were not significantly different between the two slings. QOL indices (UDI-6, IIQ-7) were significantly improved in both groups. There were significant differences in several preoperative demographic variables between the groups.

The Cochrane review included 4 published trials in their statistical comparison [Barbalias et al., 1997; Lucas et al., 2000; Viseshsindh et al., 2003; Guerrero et al., 2008], as well as 2 trials in abstract form [Rehman et al., 2011]. [249] A total of 379 women studied after 12 months showed no statistically significant difference in incontinence rates (RR 0.89; 95% CI 0.72 to 1.10). However, results reported improvement after one year in favour of the traditional ARF sling (RR 0.33; 95% CI 0.17 to 0.64). The incontinence rate after five years was reported in only one trial [Lucas et al., 2000] and showed no statistically significant difference between different lengths of the autologous material used (RR 1.17; 95% CI 0.86 to 1.59). There was significant heterogeneity in the incidence of perioperative complications between groups in two trials, which was attributed more to complications with the use of Gore-Tex in one trial (RR 0.05; 95% CI 0.00 to 0.80, Barbalias et al., 1997). In the other trial, there was no statistically significant difference between two biological slings (RR1.14, 95% CI 0.78 to 1.66, Lucas et al., 2000). No statistically significant difference was found in assessment of the following adverse events, reported in only one trial [Lucas et al., 2000]: bladder perforation (RR 0.69; 95% CI 0.12 to 4.03), UTI (RR 1.73; 95% CI 0.66 to 4.54), de novo DO or urge symptoms (RR 3.11; 95% CI 0.65 to 14.97), and voiding dysfunction (RR 1.16; 95% CI 0.65 to 2.07).
d) Traditional sling vs. midurethral sling (Table 4C and D)

Our review identified 17 trials that addressed the comparison between traditional sling operations and MUS operations. Eight RCTs compared traditional slings placed at the bladder neck with the retropubic MUS [Arunkalaivanan & Barrington, 2003; Lucas et al., 2004; Bai et al., 2005; Wadie et al., 2005; Kondo et al., 2006; Basok et al., 2008; Sharifiaghdas & Mortazavi, 2008; Amaro et al., 2009;] and 3 additional RCTs provided long-term outcomes of aforementioned studies [Abdel-Fattah et al., 2004; Guerrero et al., 2010; Wadie et al., 2010]. [38, 149, 150, 152, 154, 155, 158, 160, 161, 262] One of the trials [Lucas et al., 2004] was only available as an abstract and 3 studies were non-randomised case control or cohort studies (Hung et al., 2004; Morgan et al., 2007; Trabuco et al., 2009). [145, 151, 153]

Two RCTs compared a traditional ARF sling to a transobturator (TO) MUS (Safyre-t) (Silva-Filho et al., 2006; Tcherniakovskiy et al., 2009). [162, 163] Finally, a non-randomised trial compared perobaginal slings (material not stated) with TVT and TOT (Jeon et al., 2008). [156]

Five RCTs compared ARF sling with TVT and reported on a total of 403 patients (Lucas et al., 2004, Bai et al., 2005, Wadie et al., 2005; Sharifiaghdas & Mortazavi, 2008; Amaro et al., 2009). [38, 152, 158, 161, 262] Two of the studies were recently updated at a longer-term follow-up (Guerrero et al., 2010; Wadie et al., 2010). [153, 160] Cure rates at 12-36 months (subjective +/- objective) varied widely depending on definition and were 55%-95% for both ARF and TVT. Although a statistical difference was not observed at 6 months, one trial (Bai et al., 2005) showed a significant difference in subjective + objective cure rate at 12 months favoring TVT (92.8% vs. 87%). [38] This trial also had a colposuspension arm, which had a 12 month cure rate of 88%. Another trial had a porcine dermis sling arm with a cure rate of only 53% (Lucas et al., 2004; Guerrero et al., 2010). [160] The remainder of the RCTs did not reveal a statistical difference in cure rates between ARF and TVT. [EL=1/2]. One RCT found no statistical difference in objective and subjective cure rates at 12 months after cadaveric fascia lata slings and the intravaginal slingplasty (IVS), a multifilament, polypropylene MUS (Basok et al., 2008). [155]

One non-randomized trial that also included a porcine dermis arm found no statistical difference between ARF slings and TVT (Morgan et al., 2007). [145] Symptom severity, as assessed by validated questionnaire, was not significantly different between the ARF sling and TVT groups. As mentioned in the previous section, symptom severity was significantly higher in the porcine dermis group than in the other 2 groups. [EL=2/3] A second retrospective study compared traditional sling (material not stated), TVT, and the transobturator tape (TOT) (Jeon et al., 2008). [156] Overall complication rates were not significantly different between the sling groups. At 2 years postoperatively, the cumulative cure rates of the traditional sling, TVT, and TOT groups were significantly different (87.3% vs. 86.7% vs. 34.9%, respectively; p<0.0001). The risk of treatment failure in women who received TOT was 4.6 times higher than in women who underwent traditional sling. The 7-year cumulative cure rates of traditional sling and TVT groups were 59.1% and 55.1%, respectively. [EL=2/3] One trial each found no statistical difference in outcomes between traditional polypropylene sling and TVT (Hung et al., 2004) and ARF sling and Uretex, a monofilament polypropylene sling (Trabuco et al., 2009). [151, 159] [EL=2/3]

One RCT comparing porcine dermis sling with TVT found no significant differences operating time, hospital stay, complication rates, or subjective cure at 1 year (85% vs. 89%) (Arunkalaivanan & Barrington, 2003), nor in cure (88% vs. 82%) or satisfaction at 3 years, assessed by mailed questionnaire (77% vs. 80%) (Abdel-Fattah et al., 2004). [48, 55] [EL=1]. It is not clear why this study found comparable results between porcine dermis and TVT, whereas the 3-arm trial cited above found such significantly poorer results after porcine dermis to require the premature curtailment of recruitment (Lucas et al., 2004; Guerrero et al., 2010). [160, 161]

Two small RCTs compared ARF sling to Safyre-t transobturator MUS (Silva-Filho et al., 2006; Tcherniakovskiy et al., 2009). [59, 60] At a follow-up of 12 months, subjective + objective cure rates were not statistically different (95% vs. 90.5%) in one trial (Tcherniakovskiy et al., 2009), while higher pad weight at 6 months was observed for the ARF group in another trial (39g vs. 8.4g) (Silva-Filho et al., 2006). [162, 163] [EL=2]

The Cochrane database identified 12 trials that addressed the comparison between traditional sling procedures and minimally invasive, MUS operations. [249] Ten of these studies have been summarised in our assessment and 2 studies were only in abstract form. [38, 149, 152, 154-156, 158, 160, 163, 262] Data on incontinence after the first year were available from four RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Guerrero et al., 2010). [38, 149, 154, 160] Incontinence was reported by 31.6% of those women in the traditional sling and 25.3% of those in the MUS groups. This was not statistically significant (RR 1.23; 95% CI 0.91 to 1.66). This translates to 311 per 1000 women being incontinent after a traditional sling compared with 253 per 1000 after a MUS. Improvement after a year was addressed by two trials (Arunkalaivanan & Barrington, 2003; Guerrero et al., 2010) and there was no statistically significant difference between the two types of sling (RR 1.30; 95% CI 0.57 to 2.94). [149, 160]
Pooled data from 3 trials (Arunkalaivanan & Barrington, 2003; Kondo et al., 2006; Tcherniakovsky et al., 2009) showed a statistically significant higher risk of perioperative complications after traditional sling operations (RR 1.59; 95% CI 1.03 to 2.44). [149, 154, 163] Seven RCTs (Arunkalaivanan & Barrington, 2003; Bai et al., 2005; Kondo et al., 2006; Sharifiaghdas & Mortazavi, 2008; Song et al., 2004 (abstract only); Tcherniakovsky et al., 2009; Wadie et al., 2005) reported bladder perforation. [38, 149, 152, 154, 163, 262] There were more perforations after MUS procedures, but this did not reach statistical significance (RR 0.62; 95% CI 0.34 to 1.11) and the confidence interval was wide. The combined results from 3 trials showed less de novo urgency symptoms after MUS (RR 3.13; 95% CI 0.96 to 10.24) but this did not reach statistical significance and the confidence interval was wide. However, 3 trials showed that development of de novo DO was significantly less after MUS operations (RR 3.21; 95% CI 1.29 to 8.03). This was principally due to the higher weighting given to the largest trial (Basok et al., 2008). [155] The combined results from 5 trials showed that more women had postoperative voiding dysfunction after traditional slings than after MUS (RR 1.60; 95% CI 0.94 to 2.71) but this did not quite reach statistical significance and the confidence interval was wide. More women in the traditional sling group required release of sling (9% versus 2%), reported in two trials (RR 3.67; 95% CI 0.95 to 14.22) but again this was not statistically significant. There was no statistically significant difference in urinary retention up to 6 weeks (RR 5.51; 95% CI 0.68 to 44.63) from one trial and vaginal erosion (RR 0.35; 95% CI 0.02 to 8.10) based on one trial.

e) CONCLUSIONS / RECOMMENDATIONS

The conclusion of the Cochrane review was that data on traditional sling operations remain too few to adequately address the effects of this type of surgical treatment. They highlight the fact that many studies fail to address appropriate outcome measures to address the broader effects of the surgery, such as general health status and health economics. They also emphasise that reliable evidence on which to judge whether or not traditional slings are better or worse than other surgical or conservative management is currently not available.

From the available evidence, ARF sling is the most widely evaluated biological sling and is an effective and durable treatment for SUI. [EL=1] Limited data suggest that pubovaginal sling using porcine dermis is also effective, [EL=1] although data relating to other biological slings are few, and generally of poor quality. The inclusion of the large trial on traditional slings (Albo et al., 2007) strengthened the trend towards a better performance of the traditional slings in terms of patient reported incontinence rates, but higher early post-operative voiding dysfunction rates compared to open colposuspension. [EL=1]

The limited data available suggest that the overall rates of late surgical complications are similar after sling and colposuspension; however, the pattern of complications may vary.

Meta-analysis showed a significantly greater patient-reported improvement of symptoms, using autologous materials, both within and after 1 year. There is no high level evidence of a difference in efficacy between biological and synthetic sling materials, although adverse events may be more common following the use of synthetic materials for ‘traditional’ sling procedures [EL=3]. Some synthetic slings, such as Gore-Tex, may have a higher incidence of erosion, infections and urgency symptoms. There is no high level evidence of a difference in efficacy between different biological sling materials, although those studies that find a difference all favour autologous materials [EL=2] However trials were few in number, with short follow-up and small populations. More evidence is needed to compare slings made of autologous materials with synthetic or exogenous biological materials.

Minimally invasive MUS operations appeared to be as effective as traditional suburethral slings in the short term (RR 0.97; 95% CI 0.78 to 1.20), although the confidence interval was compatible with minimally invasive slings being 20% better or 12% worse. [EL=1] The operating time and length of stay were also significantly shorter with minimally invasive synthetic MUS operations, and women had less perioperative complications and DO. The main perioperative complication of minimally invasive sling procedures is bladder puncture, although this does not appear to have longer term implications.

Autologous fascial sling is recommended as an effective treatment for stress urinary incontinence, which has longevity. [Grade A] Further high quality research is required to clarify the place of ‘traditional’ sling procedures in relation to other procedures, and to establish the optimum sling materials. [Grade D]

6. LAPAROSCOPIC COLPO SUSPENSION (TABLE 5)

a) Laparoscopic versus open colposuspension

The Cochrane review of laparoscopic colposuspension includes details of 22 RCTs that include laparoscopic colposuspension [263], 14 more than their initial review [264]. Of these 22 trials, ten compared laparoscopic colposuspension with open colposuspension [265-274].

Eight of the ten studies comparing laparoscopic colposuspension with open colposuspension were included along with eight retrospective cohort studies in a recently published meta-analysis [275].

We identified two further RCTs on laparoscopic colposuspension [276, 277]; in addition one study
Table 5. Published level 1 & 2 evidence relating to laparoscopic colposuspension for the treatment of stress urinary incontinence

Notes: patient numbers are given as – total no. followed up or analysed / total no. recruited (no. in index group: no. in comparator group)
SS = sample size; ITT = intention to treat
previously only in abstract form has recently been published [267], and two have further publications with longer-term follow-up [278] or cost-effectiveness data [279].

Studies included in the Cochrane review had different lengths of follow-up, although eight studies had follow-up in the region 6 to 18 months. In comparison with open colposuspension they found subjective cure rates to range from 58% to 96% in the open and 62% to 100% in the laparoscopic group within the 18 months follow up, with a non-significant 5% lower relative subjective cure rate for laparoscopic colposuspension (RR 0.95, 95% CI 0.90 to 1.00) [263] [EL=1]. The two studies with follow-up at five years or beyond unfortunately remain unpublished and available in abstract form only. Both these studies were relatively small, and their results are inconsistent, one finding better subjective outcome from the laparoscopic procedure [273], and one favouring the open procedure [272]; the methodology of this latter study in particular has been questioned [EL=2].

Overall, the objective cure rate as judged by cough stress testing or pad test within 18 months was statistically significantly lower following laparoscopic colposuspension (RR 0.91, 95%CI 0.86 to 0.96) [EL=1]. Between 18 months and five years there was no significant difference (RR 1.01, 95% CI 0.88 to 1.16); again however, there was heterogeneity with one small trial greatly favouring open procedure [272] and the other favouring laparoscopic [273] [EL=2]. When objective cure was judged by urodynamic investigations there was a significantly higher success rate following open colposuspension (RR 0.91, 95%CI 0.85 to 0.99).

b) Laparoscopic colposuspension versus other techniques

Eight trials have compared laparoscopic colposuspension with minimally invasive mid-urethral slings [166, 280-284].

In comparison with minimally invasive mid-urethral slings there was no statistically significant difference in subjective cure rates within 18 months (RR 0.91, 95% CI 0.80 to 1.02) [EL=1]. The definition of objective cure varied widely between studies, although overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95% CI 0.85 to 0.99) [EL=1].

Although laparoscopic colposuspension is regarded as a less invasive operation than the open colposuspension the mid-urethra tape procedures had significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01 -0.001) than the laparoscopic colposuspension.

c) Different techniques of laparoscopic colposuspension

Different aspects of the laparoscopic technique (one vs. two sutures [285], sutures vs. Mesh [266, 286, 287] and transperitoneal vs. extraperitoneal approach to laparoscopy [288].

Two sutures either side of the bladder neck resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95% CI 1.14 to 1.77) cure rate than one [285] [EL=2].

When comparing sutures and mesh to secure para-urethral support, sutures resulted in higher subjective (RR 1.28, 95% CI 1.11 to 1.47) and objective (RR 1.20, 95%CI 1.07 to 1.35) cure rate than mesh [266, 276, 286, 287] [EL=1].

The transperitoneal versus extraperitoneal study reported above employed different techniques (sutures vs mesh) and therefore gives little insight into the value of either approach given the superior results obtained with sutures.

The use of glue or fibrin sealants has not been reported outside small case series.

d) Cost effectiveness of laparoscopic colposuspension

Cost effectiveness was assessed in only one trial [270, 289]. This study showed that whilst laparoscopic surgery produced greater quality adjusted life years (QALYs), there was an additional cost when compared to open surgery. The differential mean cost was GB £372 (95% credibility interval [Crl]: 274–471), and at 6 months QALYs were slightly higher in the laparoscopic arm relative to the open arm (0.005; 95% CrI: –0.012 to 0.023). The cost of each additional QALY in the laparoscopic group or incremental cost-effectiveness ratio (ICER) was £74,400 at 6 months, but reduced to £9,300 by 24 months, in view of a further increase in QALYs, but no additional costs (assumed) [289] [EL=1].

Earlier studies have shown TVT™ to be dominant in cost effectiveness terms over both open [290] and laparoscopic colposuspension (albeit using a mesh technique) [279] [EL=1].

e) Complications of laparoscopic colposuspension

Bladder, ureteric and vascular injuries are recognised complications of colposuspension. The Cochrane review reported 21 bladder injuries among 521 laparoscopic procedures (compared with 10 among 507 open procedures) and two studies reported obturator vein lacerations. However, when compared with the traditional open colposuspension, the laparoscopic group was found to have significantly fewer postoperative complications (RR 0.74, 95% CI 0.58–0.96) with lower estimated blood losses and shorter duration of catheterisation.
Longer operating times are a significant disadvantage of the laparoscopic approach; however, women have reported significantly less pain, (Carey et al 2000, Burton 1999)[272, 291] shorter hospital admissions, faster recoveries and quicker return to normal activities. (Cheon et al 2003, Fatthi et al 2001, Kitchener et al 2006 and Su et al 1997)[292-295].

f) **Longevity of laparoscopic colposuspension**

A long-term review of women who had undergone laparoscopic colposuspension more than 10 years previously (Barr et al 2009)[296] compared the results with a group of women who had open colposuspension. Subjective cure rates deteriorated over time from 71% and 67% at 6 months to 52% and 36% at 10 years for the laparoscopic and open procedures, respectively.

The conclusion from the Cochrane review was that the available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension two years postoperatively [263]. The systematic review specific to laparoscopic colposuspension and TVT™ concluded that the evidence so far appears to favour the latter as the minimal-access technique of choice for USI [297]. In both cases however the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long-term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalisable to the urogynecological/urological community at large. The NICE guidance includes amongst its recommendations that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of UI [298, 299]; this same point is emphasised in the meta-analysis from Tan and colleagues [275] [EL=4].

g) **Summary:**

Laparoscopic colposuspension shows comparable subjective and objective outcome to open colposuspension in the short to medium term; longer term outcomes are unknown [EL=2].

Limited evidence suggests that whilst the subjective outcome from laparoscopic colposuspension is similar to the TVT™ the objective outcome is poorer. (EL=2)

Laparoscopic colposuspension may not be good value for money when compared with open colposuspension in the short term (i.e. first 6 months following surgery), but it could be a cost-effective alternative over 24 months [EL=1]; other comparisons however suggest that minimally invasive mid-urethral tape procedures may be dominant in health economic terms.

h) **Recommendations:**

Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise. (Grade D)

Women should be advised about the limited evidence available about the longevity of laparoscopic colposuspension. (Grade D)

Laparoscopic colposuspension might be considered for the treatment of SUI in women who also require concurrent laparoscopic surgery for other reasons. [Grade D]

II. STRESS INCONTINENCE AND PELVIC ORGAN PROLAPSE

Women who present with urinary incontinence as their primary symptom may often have symptomatic or asymptomatic pelvic organ prolapse (POP). In a patient with POP, SUI may be evident and overt or POP may be protective of, or mask, obvious urinary incontinence via urethral kinking. This is termed “occult” SUI and is elicited only during maneuvers to reduce the POP. SUI and POP are intimately related. Coexistent symptoms of SUI may be present in over 60% of women with POP, [38] and occult SUI may occur in up to 80% of clinically continent women with severe POP. [303-306] Postmenopausal women may have up to twice the risk of developing occult SUI. Furthermore, women with both SUI and POP have more lower urinary tract symptoms and more functional impairment than women with POP only. [307]

There is some evidence from Medicare claims data that addressing POP at the time of SUI surgery may avoid an early repeat operation for either POP or SUI; however, the rates of postoperative outlet obstruction are higher. [308] As such, the decision to treat POP surgically at the same operation as the SUI should be determined by the symptoms and bother the POP produces to the patient and the influence that the POP surgery may have on the outcome of the surgery for SUI. In instances where the prolapse is symptomatic, it will be a matter of subjective opinion whether the incontinence or the prolapse is more significant and bothersome (rather than a pathological diagnosis). If the treatment selection is based on subjective assessment, it follows that the outcome from treatment must also be based on subjective rather than objective measures. As with most issues in pelvic floor reconstruction, the decision to perform an anti-incontinence procedure
and the choice of the procedure itself is a source of great debate. The literature evaluating the following clinical scenarios will be evaluated: (a) overt SUI with POP; (b) occult SUI with POP reduction; (c) high grade POP in the absence of occult or overt SUI; and, (d) the status of preoperative urgency urinary incontinence (UUI) and overactive bladder symptoms (OAB) after POP repair.

1. OVERT SUI WITH POP

Women who present with SUI commonly have deficient support of the anterior vaginal wall. Significant POP is generally defined anatomically as the presenting part of the prolapse reaching to within a centimetre of the hymenal remnant. The presence of preoperative POP may have an impact on the efficacy of anti-incontinence surgery, and the outcomes of any surgery to correct SUI should be evaluated along with the incidence of de novo or worsened postoperative obstructive and storage urinary symptoms.

Milani et al noted that the presence of preoperative POP led to a lower cure rate of SUI after either the Burch colposuspension or the MMK procedure, with greater degrees of POP associated with lower SUI cure rates. [309] (Level 3) Additionally, Colombo et al performed a RCT to compare Burch colposuspension with anterior colporrhaphy in women with SUI and Grade 2-3 anterior vaginal wall prolapse. [310] (Level 1/2) The authors found that the Burch colposuspension was better in controlling SUI but that cystocele recurred in 34% of patients. The cure rate for cystocele with anterior colporrhaphy was high (97%) but cure rate of SUI was very low. The authors concluded that neither operation was recommended for combined SUI and advanced cystocele.

In a recent RCT, Costantini et al revealed that Burch colposuspension does not provide a significant cure of SUI in incontinent women undergoing sacrocolpopexy. [10] (Level 1/2 ) Out of 47 women with POP and SUI, 24 underwent sacrocolpopexy and Burch and 23 underwent sacrocolpopexy alone. The primary outcome measures were anatomical outcome and changes in incontinence status as indicated by a bladder diary, daily pad use, and CST, while secondary end points were changes in subjective symptoms and quality of life as measured by the UD I and IIQ. In the Burch group, 13 of 24 patients (54.2%) were still incontinent after surgery compared with 9 of 23 (39.1%) in the non-Burch group. Two women in the Burch group (8.3%) and one in the non-Burch group (4.3%) complained of de novo urinary storage symptoms. There was no significant intergroup difference (p=0.459). No significant intergroup difference emerged in anatomical outcome and UD I and IIQ scores improved in both groups (p = 0.0001) and the intergroup difference was not significant in either questionnaire (p = 0.769 and p = 0.327, respectively).

Moon et al compared the Burch colposuspension (n=49) and TOT (n=60) in consecutive women undergoing sacrocolpopexy for POP ≥ Grade III and SUI. [311] (Level 2) Mean hospital stay was longer in the Burch group (11.3 days vs. 7.8 days, p<0.001), as were the rates of postoperative urinary retention (53.1% vs. 11.7%, p<0.001), de novo urgency (18.4% vs. 3.3%, p=0.01), and recurrent SUI (18.4% vs. 1.7%, p=0.003). The SUI cure rate was significantly higher in the TOT group than in the Burch group (98.3% vs. 69.7%, p <0.001).

Gordon et al prospectively followed 30 patients short-term who underwent TVT at the same time as surgery for severe POP. [312] (Level III) No patients had postoperative symptoms of SUI despite three patients (10%) having positive postoperative stress tests. De novo detrusor overactivity occurred in 13% of subjects. Yip and Pang recruited 302 patients, 250 (82.8%) of when completed 1-year follow-up. [313] (Level II/III) There were 157 (62.8%) patients who had a TVT alone, and 93 (37.2%) had TVT and concomitant POP surgery. All patients had urodynamic studies before and one year following surgery. The objective cure rate for SUI was 87.3% for patients with TVT alone and 80.6% for TVT with concomitant procedures (p>0.05). The subjective SUI cure rates for TVT alone and TVT plus concomitant procedures were 89.2% and 86.0% at 4 months, and 93.0% and 94.6% at 1 year, respectively (p>0.05). The most common complications were postoperative urinary retention (15.2%), de novo detrusor overactivity at one year (10%), and intraoperative bladder puncture (8%). In an additional prospective cohort study and a case series, the TVT combined with vaginal reconstruction resulted in 85% to 95% cure rates for urodynamic SUI. [314, 315] (Level III) The rates of postoperative urinary urgency and voiding dysfunction were 10% and 11%, respectively. Voiding difficulties and post void residuals of > 100 mL were treated with urethral dilatation and the authors did not report any cases of long-term urinary retention.

Transobturator midurethral slings may also be effective in the setting of overt SUI and POP. The addition of TVT-O to anterior colporrhaphy in 50 women with SUI and high grade anterior POP resulted in 1-year objective cure rates for SUI and POP of 92% and 91%, respectively. [316] (Level 3) Overall early postoperative complication rate was 16%, although all were minor. At 12-month follow-up, tape extrusion requiring surgical removal developed in only one patient. The ICIQ-UI SF questionnaire scores were 13.4 +/- 6.8 and 3.5 +/- 3.2 (p <0.01) between preoperative and 12-month follow-up, respectively.

In data from the National Hospital Discharge Survey, the addition of an anti-incontinence procedure did not significantly increase the immediate morbidity in women who underwent POP surgery. [317] Of the 1931 women who underwent POP procedures, concomitant anti-incontinence procedures
were performed in 26.6% and complications were reported in 14.9%. Complications were associated with medical comorbidity (OR 11.2) and concomitant hysterectomy (OR 1.5), while concomitant procedure for SUI was not.

2. OCCULT SUI WITH POP

Overall, the level of evidence supporting a specific anti-incontinence procedure in women with POP and occult SUI is low. Chaikin et al discovered occult SUI after reduction of prolapse with a pessary in 14 of 24 women (58%). [304] (Level III) Ten women with no urodynamic evidence of sphincteric incontinence underwent anterior colporrhaphy and no additional anti-incontinence procedure was performed. Mean follow-up was 44 months (range 12 to 96). None had postoperative SUI but one (10%) had a recurrent grade 2 cystocele. The 14 remaining women with urodynamic stress incontinence after POP reduction underwent anterior colporrhaphy with a bladder neck pubovaginal sling procedure. Mean follow-up in these cases was 47 months (range 12 to 108). In two patients (14%) SUI developed postoperatively and one (7%) had a recurrent grade 3 cystocele. The incidence of UUI did not appear to be significantly influenced by either surgical intervention. Overall 12 patients had preoperative UUI, of whom 9 (75%) had persistent UUI postoperatively. De novo UUI developed in another woman. The authors’ findings suggest that patients without occult SUI may be effectively treated with POP repair alone, while women with occult SUI on urodynamics should be offered anti-incontinence surgery.

Barnes et al reported on 34 women with grade 3-4 POP and occult SUI who underwent a bladder neck pubovaginal sling as the anti-incontinence procedure. [318] (Level III) Sling materials included autologous rectus fascia, cadaveric fascia lata, or a free vaginal wall graft. Mean follow-up was 15 months (range 6 to 39). The mean time required before spontaneous voiding resumed without the need for catheterisation was 11.8 days (range 2 to 46) and no patient developed permanent urinary retention. Two (9.5%) of 21 women without preoperative UUI developed de novo UUI; however, preexisting UUI resolved in 45%. SUI occurred in two women (7%) at four and 19 months postoperatively, while clinically significant uterine prolapse developed in one woman two years after surgery.

Groutz et al reported on 100 women with occult SUI undergoing concomitant transvaginal POP surgery and TVT.[319] (Level 3) The mean follow-up period was 27 months (range: 12-52 months). Two patients had postoperative urinary retention necessitating catheterisation for more than seven days, but neither required any surgical intervention. Vaginal extrusion was diagnosed in three patients, all of whom were successfully treated by partial TVT excision. Two (2%) patients developed urodynamically-confirmed SUI within one year postoperatively; however, postoperative urodynamics revealed asymptomatic urodynamic stress incontinence in 15% of other patients. Thirteen (72%) of 18 patients with preoperative UUI had postoperative persistent UUI, while de novo UUI developed postoperatively in 8 (8%) of patients.

A RCT compared concomitant endopelvic fascia plication at the urethrovesical junction vs. TVT in 50 women with severe POP and occult SUI. [320] (Level 1/2). The addition of a TVT resulted in a higher 2-year objective continence rate than endopelvic fascia plication (92% vs. 56%, respectively; p<0.01). The subjective cure rates were 96% for TVT compared to 64% for plication (p=0.01). Time for resumption of spontaneous voiding, rates of urinary retention, de novo UUI, and perioperative complications did not differ between the groups. Despite negative cystometrograms, de novo UUI symptoms were reported in 12% of the TVT group compared to 4% of the suburethral plication group (p=0.66).

Karateke et al reported on the outcomes of TOT in the treatment of women with occult SUI and POP. [321] (Level 3) Urodynamic evaluation revealed occult SUI in 25 of 79 patients with POP. Post-operative OAB, SUI, and MUI were found in three (12%), two (8%), and one (4%) patients in the occult SUI group, respectively. The corresponding numbers were six (11%), five (9%), and three (6%) in the preoperatively continent group. No significant difference was found between the groups in terms of post-operative OAB symptoms, SUI, and MUI. Groutz et al also reported on the outcomes of TVT-O in the management of occult SUI in women with significant POP. [322] (Level 3) Of the 117 patients, 6 (5.1%) had immediate postoperative voiding difficulties necessitating catheterisation for more than two days. Late postoperative morbidity was assessed in 110 patients with ≥3 months of follow-up (mean 27.2 ± 17.7). Of these 110 patients, 7 (6.4%) had protracted postoperative thigh pain with spontaneous resolution within 1-3 months and 7 (6.4%) had developed recurrent UTIs. There were no cases of vaginal extrusion. The functional outcome analysis was restricted to 92 patients with ≥12 months follow-up. Of these, 13 (14%) were found to have urodynamic stress incontinence; however, only two patients (2.2%) were symptomatic, amounting to a subjective and objective cure rate of 97.8% and 86%, respectively. Of the 34 patients who had had urinary storage symptoms preoperatively, 22 (64.7%) had persistent symptoms postoperatively. An additional four patients (6.9%) had developed de novo urinary storage symptoms, and one patient developed bladder outlet obstruction.

3. NO OVERT OR OCCULT SUI AND POP

There has been a tremendous amount of debate on how to treat women with significant POP who have no complaints of SUI and occult SUI cannot be demonstrated on either cough-stress test or urodynamic evaluation after prolapse reduction. The case for a concomitant anti-incontinence procedure is to
potentially prevent a second surgical intervention in a cohort at high risk for developing SUI. The case against performing anti-incontinence surgery in the same time hinges on the potential for developing de novo or worsened urinary storage and voiding symptoms in a population with minimal to no preoperative symptoms. The literature appears divided on the topic. As mentioned previously, Chaikin et al found that the majority of women with significant POP who do not have overt or occult SUI will not develop overt SUI after transvaginal POP repair alone. [304] (Level III)

The decision to perform a concomitant colposuspension at the time of sacrocolpopexy has been passionately debated. In a well-publicised study by Brubaker et al as part of the Colpopexy and Urinary Reduction Efforts (CARE) trial, stress-continent women undergoing sacrocolpopexy were randomised to receive or not to receive a concomitant Burch colposuspension. [323] (Level I) At two years, 302 of 322 randomised participants were available for analysis. Two years after surgery, 32.0% and 45.2% of women in the Burch and control groups, respectively, met the SUI endpoint (presence of SUI symptoms, positive CST, or interval treatment for SUI, \( p=0.026 \)). The apex was well supported in 95% of women, and this was not affected by concomitant Burch. There was a trend toward fewer urgency symptoms in the Burch group (32.0% vs. 44.5% no Burch, \( p=0.085 \)). In a subanalysis of the CARE trial, Visco et al confirmed that women who demonstrated preoperative occult SUI were more likely to report postoperative SUI, regardless of concomitant Burch colposuspension (controls 58% vs. 38%, \( p=0.04 \); Burch 32% vs. 21%, \( p=0.19 \)). [324] The authors also concluded that occult SUI detection rates varied widely based on the method of prolapse reduction. Interestingly enough, while only 23% of the 1134 members of the American Urogynecological Society (AUGS) responded to a survey about their practice patterns regarding high-grade POP, 57% of the respondents stated that they would not perform a prophylactic Burch colposuspension at the time of sacrocolpopexy in a woman without symptoms of SUI. [325]

Conversely, Costantini et al found that the Burch procedure did not confer a significant benefit in terms of SUI cure to women undergoing surgical prolapse repair.[326] (Level I/II) A total of 66 continent women with POP were randomly assigned to abdominal sacrocolpopexy and concomitant Burch in 34 (group 1) or sacrocolpopexy alone in 32 (group 2). Median follow-up was 97 months (range 72 to 134). Nine of 31 group 1 patients (29%) were incontinent compared with 5 of 31 (16%) in group 2 (\( p=0.553 \)). In group 1, all except one patient were successfully treated for voiding dysfunction. Storage symptoms had disappeared in one patient and de novo storage symptoms had developed in two since the previous follow-up. De novo incontinence developed in two group 2 patients after midterm outcomes were reported. Median UDI-6 and IIQ-7 scores were improved in all groups at last follow-up (\( p<0.0001 \)).

Ballert et al suggested a protocol to determine if MUS should be placed at the time of transvaginal POP repair. [327] (Level 3) A total of 50 women reported clinical (symptomatic) SUI preoperatively, while 55 did not. Regardless of clinical presentation, patients with urodynamically occult SUI underwent simultaneous MUS, while those without urodynamic or occult SUI did not. The risk of intervention due to obstruction after receiving MUS was 8.5%, while the risk of intervention for de novo SUI in patients with no clinical, urodynamic, or occult SUI who did not undergo MUS was 8.3%. The risk of intervention for SUI in patients with clinical SUI but no urodynamic or occult SUI and no MUI was 30%. These data suggest that a prophylactic sling in women without clinical, urodynamic, or occult SUI may be as likely to cause postoperative urinary retention requiring reoperation as it is to prevent postoperative de novo SUI requiring surgery. The evidence also suggests that MUS should be considered for women with clinical SUI (regardless of the presence or absence of urodynamic or occult SUI), as there is a much higher possibility for further intervention for SUI in this population. While this report lacks a control group, the findings of this study underscore the importance of a detailed informed consent discussion between the patient and surgeon.

A study by Liang et al further supported the suggestion that urodynamic evidence be used to guide possible treatment of SUI during POP surgery. [222] (Level III) Among the 79 patients evaluated for severe POP without symptoms of SUI, 32 patients had a positive pessary test and underwent vaginal hysterectomy, anterior and posterior colporrhaphy, and TVT (Group 1). In group 2, 47 patients (17 of whom had positive pessary tests and 30 of whom had negative pessary tests) underwent vaginal hysterectomy and anterior and posterior colporrhaphy alone. Eleven (64.7%) of 17 patients with positive pessary tests who did not undergo TVT had urine leakage after their hysterectomies. Conversely, none of the 30 patients who had negative pessary tests developed symptomatic SUI after vaginal hysterectomy. Among the 32 patients with positive pessary tests who had TVT with their hysterectomies, three developed urine leakage later for a cure rate of 90.6%. Had all patients with high-grade POP undergone TVT, 35% would have undergone an unnecessary anti-incontinence procedure. This study supports the notion that women without symptoms of overt or occult SUI are not likely to leak after undergoing POP surgery alone. Additionally, the Cochrane database recently evaluated the value of anti-incontinence surgery at the time of prolapse repair in continent women and concluded that this practice did not reduce the rate of postoperative SUI (RR 1.39, 95% CI 0.53 to 3.70). [328]
Thus, the value of adding an anti-incontinence procedure to a POP repair in women who are dry before operation remains to be adequately assessed; however, available evidence suggests that the majority of women without occult or overt SUI may remain continent after POP repair alone. While the addition of a Burch colposuspension to a sacrocolpopexy may not add a significant amount of additional morbidity, it may not confer a benefit in terms of preventing the development of overt SUI. Furthermore, the potential benefit of Burch colposuspension cannot necessarily be extrapolated to other prophylactic anti-incontinence procedures. An urodynamic approach to decision making appears to be a prudent one. Adequately powered RCTs are urgently needed to answer these questions and high level evidence may be on the horizon. The details of multicentre, prospective RCTs comparing POP and anti-incontinence surgery in women with overt SUI and those with occult SUI (CUPIDO) have recently been described and recruitment is under way. [329] A second, multicentre RCT is in preparation to determine whether the prevalence of postoperative urinary incontinence differs between stress continent women receiving vaginal prolapse repair with concomitant TVT and those with only sham incisions at 3 months after surgery. [330] A second objective of the OPUS trial is to determine whether it is more cost-effective to place a TVT prophylactically than to treat the SUI symptoms postoperatively as they occur over a 12-month period after the index surgery.

4. UUI AND POP

Symptoms of OAB such as urinary urgency, frequency, and UUI are often seen in women with POP and community-based, hospital-based, and cross-sectional studies have shown that the prevalence of OAB is higher in women with POP vs. those without POP. [331, 332] The prevalence of any OAB symptom approached 50% and increases with advancing age. [332] Symptoms of POP may be an independent risk factor for symptomatic OAB. [332] As such, the impact of POP repair on OAB symptoms and UUI is of great value in preoperative counseling of women with high-grade POP.

The impact of anterior vaginal wall prolapse repair on bladder function has been much debated. Digesu et al reported on a 12-month prospective cohort study of 93 women who had a standard anterior colporrhaphy for cystocele. [333] (Level 3) Post-operatively, urinary frequency resolved in 60%, urgency resolved in 70%, and UUI resolved in 82%, illustrating that anterior repair may lead to resolution of the majority of OAB symptoms. Similar findings were reported in a prospective cohort study of prolapse repair in elderly women by Foster et al. [334] (Level 3) The authors also noted that vaginal reconstructive or obliterator surgery produced a similar improvement in urinary symptoms at 12 months after surgery. Nguyen and Bhatia noted that UUI resolved in 24 of 38 women (63%) and persisted in 14 (37%) after surgical repair of uterine and/or vaginal vault POP. [335] (Level 3) The authors included both transvaginal and transabdominal POP repairs in their analysis. Uninhibited bladder contractions < 25 cm H2O during cystometry (p=0.01) and bladder trabeculation (p=0.03) were each an independent predictor of UUI resolution after POP repair. In a review of MEDLINE and Embase literature, de Boer et al found no evidence for a distinct relationship between the compartment or stage of the POP and the presence of OAB symptoms. [331] The authors also concluded that all treatments for POP, including surgery and pessary management, resulted in an improvement of OAB symptoms. There is no consensus regarding the predictors for OAB symptom resolution and individual OAB symptoms had different predictors. [331] When there is concomitant DO and POP, DO resolves in a proportion of the patients and bladder outlet obstruction appears to be the primary mechanism by which POP induces OAB symptoms and urodynamics DO.

5. CONCLUSIONS

There is Level II/III evidence to support a concomitant anti-incontinence procedure at the same time as repair of POP in a woman with overt SUI. There is Level II/III evidence supporting pubovaginal sling, retropubic MUS, and transobturator MUS as effective anti-incontinence options in a woman with overt SUI and POP. Anterior colporrhaphy alone and pubocervical fascia plication are not effective options for overt SUI in women undergoing POP repair. (Level II/III) Burch colposuspension may not be more effective than no additional surgery in curing overt SUI in women undergoing sacrocolpopexy. (Level II/III) There is Level III evidence that bladder neck pubovaginal sling, retropubic MUS, and transobturator MUS are effective in resolving occult SUI during POP repair. There is controversy whether prophylactic Burch colposuspension is effective in improving the chances of developing overt SUI after sacrocolpopexy. (Level I) There is Level 3 evidence to support not performing a concomitant anti-incontinence procedure in a continent woman at time of POP repair. There is Level III evidence that treatment of prolapse by reconstructive or obliterator surgery improves overactive bladder symptoms.

III. NEUROMODULATION

1. SACRAL NEUROMODULATION

a) Recent Cochrane review

A recent Cochrane review [336] examined, systematically the evidence of the effects of implantable stimulation devices in the treatment of urinary incontinence, urgency or frequency, and urinary retention.

Eight RCTs were considered eligible and were included in the analysis.
At 6 months follow up SNM was found to be superior to no treatment for all indications as there were highly significant changes in all the outcomes measured (leakage episodes, number of voids, rating of urgency, having no leakages, reduction in number of voids, pad usage, volume at first contraction, and bladder capacity). Both the SF-36 mental and physical scales favoured the immediate implant group but the results were not statistically significantly different between the treatment and no treatment groups.

The quality of the studies included was rated poor. There were no studies comparing SNM with other treatment methods.

The review concluded that SNM can be of benefit in selected patients with overactive bladder symptoms, retention without organic obstruction, and in those for whom other methods of treatment have failed.

**b) Long term results**

1. **Refractory UIi**

The long term results of SNM have been addressed by several case studies. There are 4 studies reporting median or mean follow up of >5 years. Two of the studies are presented in the last ICI report and these are the largest ones. Most of the long-term studies do not report the complete continence rates.

2. **Long term results – Efficacy Over Time**

De Groen et al [337] evaluated the long-term results of neuromodulation in 60 patients with refractory idiopathic urgency urinary incontinence. All subjects recruited from a single institution and were assessed prospectively at regular intervals for at least 5 years after implantation. The success rate gradually decreased from 52 patients (87%) at 1 month to 37 (62%) at 5 years. Complete continence persisted in 15% of patients. The analysis was extended to the 41 patients who passed the 10-year follow-up. At least 25 of these women (61%) were still on active SNS. The 10-year success rates did not appear to be different from the 5-year results suggesting that a deterioration of the results is observed during the first 5 years which stabilised thereafter. A total of 57 adverse events occurred in 32 (53%) patients the majority of those being related to hardware failure and pain or discomfort at various sites. Pain was managed conservatively. A total of 23 reoperations, including the 2 explantations, were done in 15 patients (25%). (Level 3 evidence)

3. **Urgency And Frequency**

There are no new studies examining the long term results of SNM in patients with urgency frequency. The largest study so far (van Kerrebroeck) has been presented in the last ICI report. A more recent small case series [338] examined the long term efficacy of sacral neuromodulation in patients with IC/PBS not responding to medical treatment. Overall 22 patients had a permanent generator implantation. Success with the device was defined as greater than 50% improvement in the chief complaint of urinary pain, urgency and frequency or urgency incontinence. For an average follow up of 59.9 months 17 of 22 patients (77%) reported long-term cure or more than 50% improvement in those symptoms. However 50% of patients underwent explantation due to technical reasons, infection, battery depletion, or pain at the implantation site (Level 3 evidence).

Zabihi et al [339] evaluated the efficacy of bilateral caudal epidural sacral neuromodulation for the treatment of refractory chronic pelvic pain (CPP), painful bladder syndrome, and interstitial cystitis (IC). Thirty consecutive patients (21 female, 9 male) with severe refractory symptoms underwent bilateral S2–S4 sacral neuromodulation for CPP/IC. Patients were evaluated with the O’Leary IC symptom and problem index (ICSI, ICPI), the short form of the Urogenital Distress Inventory (UDI-6), and the RAND 36-item health survey (SF-36) preoperatively and 6 months postoperatively. The mean and minimum follow-up were 15 and 6 months, respectively. Of the 30 patients, 23 (77%) had a successful trial stimulation and were permanently implanted. Among these patients, the ICSI and ICPI scores improved by 35 (p = 0.005) and 38% (p = 0.007), respectively. The pain score improved by 40% (p = 0.04) and the UDI-6 score by 26% (p = 0.05). On average, patients reported a 42% improvement in their symptoms. SF-36 scores did not improve significantly. (Level 3 evidence)

4. **Non Obstructive Urinary Retention (Table 6)**

The effectiveness of SNM in women with urinary retention has been confirmed by previous RCT (Jonas 2001) and has been presented in the last ICI report.

The long term efficacy of SNM for women with urinary retention particularly those with urethral hyperactivity (Fowler’s syndrome) has been presented by Datta et al [340]. Thirty (50%) had a one stage and the rest a two stage procedure. Overall, 43 of 60 (72%) women were voiding spontaneously, with a mean postvoid residual volume of 100 mL; 30 (50%) no longer needed to use CISC. The efficacy of the 2 stage compared to the one stage procedure was similar (73% vs 70%). Women with a normal urethral sphincter electromyogram had worse outcomes than women with an abnormal test (43% vs 76%). There were 99 adverse events (AEs) and 63 surgical revisions for the women during a total of 2878
months of SNS experience. In all, 73% of the women had an AE during their treatment with SNS (Level 3 evidence).

A recent retrospective single centre study [341] examined the long-term efficacy and durability of sacral nerve stimulation (SNS) for the treatment of refractory, non-obstructive urinary retention. Forty patients were included (29 with complete retention requiring CISC) and 11 with incomplete retention (high post-micturition residuals). Of the 40 patients 28 (70%) responded successfully to the test stimulation and underwent a placement of an IPG. At a mean follow-up of 40.03 +/- 19.61 months, 24 (85.7%) of 28 patients demonstrated sustained improvement of greater than 50% with significantly reduced number and volumes of catheterisations/day and improvement of post-micturition residuals. The Interstim device was removed in 4 patients (14.3%) and required revision in further 6 (21.4%) (Level 3 evidence).

5. Effect of SNM on Sexual Function

The effect of SNM on the female sexual function was investigated by a small pilot prospective single centre study [342]. Overall 36 women with severe frequency, urgency, retention, and chronic pelvic pain refractory to medical and other treatments were enrolled and were assessed by the Female Sexual Function Index (FSFI) questionnaire preoperatively and 6 months postoperatively. Twenty-one patients had some form of pelvic pain component to their symptoms, and 15 had voiding dysfunction without pain. The overall score on the FSFI improved by 52% (p = 0.05). Results were better in patients who underwent the treatment for voiding dysfunction (n = 15) compared to those who had pain as their primary complaint. In this group, the overall score improved by 157% (p = 0.004). Those who underwent the procedure for the indication of IC/CPP (n = 21) did not show a statistically significant change in their scores.

Another small study [342] showed that in sexually active women who had a permanent sacral neuromodulator implanted there was no difference in the sexual function before and 6 months after implantation as assessed by the FSFI.

6. Patient Satisfaction

Long-term clinical efficacy of SNM has been assessed and confirmed by many studies. However it is quite unclear how this can be translated to patient satisfaction and improvement of quality of life bearing in mind that there are technical problems and adverse effects needing constant medical attention in a significant proportion of these patients.

The long term QOL data were assessed in 2 previous reports. [343] [344]

Leong et al [345] examined the long-term satisfaction of patients with an implanted SNM for various medical indications such as overactive bladder syndrome, non-obstructive urinary retention, combined overactive bladder and retention, and pelvic pain. Overall 275 patients received a postal questionnaire regarding satisfaction and experiences with the system, such as side effects, complications, burden, impact on sexuality and defecation changes. The response rate was 75% (207 patients) with a median post-implantation period 77 months (range 12 to 214). The patient satisfaction rate was high at 90% and significantly related to the perceived clinical effect and 85% if all explanted cases (13 patients) were considered as failures. Satisfaction had no direct relationship with patient age, gender, duration of therapy or type of complaint for which SNM was offered, but was significantly lower in patients with more than 1 pelvic floor comorbidity. The patient’s attitude towards

Table 6: Summarises the follow-up data for patients with non obstructive urinary retention who were treated with SNM (from 1. Bosch JL. An update on sacral neuromodulation: Where do we stand with this in the management of lower urinary tract dysfunction in 2010? BJU Int 2010, Nov;106(10):1432-42.)

yearly follow-up and the ability to use the patients programmer was positively related to the degree of satisfaction. Overall 40% reported having some limitations or concerns with SNM such as exclusion from MRI and passing through metal detectors after an INS was implanted, possible changes in future reimbursement. Most patients perceived regular pain (56%) and discomfort (40%) at the INS site. (Level 3 evidence)

7. Neurogenic Lower Urinary Tract Dysfunction (LUTD)

The efficacy and safety of the use of SNM for the treatment of neurogenic lower urinary tract dysfunction was examined in a recent meta-analysis [346]. This included overall 357 patients from 26 independent studies (prospective and retrospective cohort studies and case reports) with level of evidence ranging from 2b to 4. There was no RCT available for analysis. The pooled success rate was 68% and 92% for the testing and the permanent phase of SNM respectively for a mean follow up of 26 months. With regards to adverse events the pooled rate was 0% during the first stage to 24% for the chronic phase of the treatment. The most frequent adverse events were lead migration and pain at the site of permanent neuromodulator further surgery was performed in 45 of 224 patients. The available evidence from this meta-analysis suggest that SNM may be effective and safe for the treatment of patients with neurogenic LUTD (level of evidence 2) but further well designed adequately powered studies are needed before SNM is routinely recommended for the treatment of neurogenic LUTD.

The use of SNM in patients with neurogenic LUTD is limited by the fact that quite often they need to be investigated by magnetic resonance imaging studies.

The progressive nature of the neurologic disease in some patients could be a limiting factor in the effectiveness of the SNM.

8. Selection Of Patients

• Testing procedure

The application of the two-stage procedure using the permanent tined lead appears to be superior to the percutaneous PNE technique

A study by Bannowsky et al.[347], in a retrospective case control study examined urodynamic and clinical outcomes of the two different testing techniques and found that permanent quadripolar electrodes led to significant differences in the overall response rate (81.8% versus 47.6%) and urodynamic parameters (max detrusor pressure, bladder capacity) compared to the PNE.

This has to be balanced against the cost implications: the permanent electrodes are several times the cost of the cheaper PNE wires.

In a recent study [348] 41 of 76 (54%) who failed to respond to PNE were subsequently tested with tined lead procedure permanent stimulators. Of those 18(44%) were implanted with a neurostimulator after a successful response suggesting that the tined lead procedure is more sensitive screening tool. At 53-month follow-up 12 of these patients (67%) had a successful outcome, which was not statistically different from the success rate in patients with a positive response to an initial PNE or TLP test.

The response rate to PNE as compared to the 1st stage tined-lead placement test (FSTLP) were directly compared in a prospective single centre study[349].

One hundred patients with refractory idiopathic overactive bladder syndrome (OAB) or non-obstructive urinary retention, screened with both PNE and FSTLP. The positive response rate on PNE was 47%. FSTLP showed a 69% positive response rate, which was negatively related to age. The 22% gain in positive response was statistically significant (p < 0.001) and positively associated with female gender and younger age. This study also suggests that the FSTLP may be a more sensitive screening method than PNE. (Level of evidence 2)

• Unilateral versus Bilateral lead placement at screening phase

A retrospective study by Pham et al. [350] compared the success of the bilateral to unilateral neuromodulator lead placement in 124 patients undergoing screening for permanent placement of sacral neuromodulation. Fifty-five (44%) patients underwent unilateral stage I lead placement and 69 (56%) received bilateral S3 leads. Successful stage I trials were reported in 32/55 (58%) and 53/69 (76%) of unilateral and bilateral cohorts, respectively (P = 0.03). There was no difference in wound infection or other complications. (Level of evidence 3)

• Pre-treatment psychological problems

Psychiatric comorbidity has previously been proposed as a negative predictor by some authors.

In a recent single centre prospective study the relationship between psychiatric history and the outcome of chronic SNM treatment was assessed. Fifty four patients with symptoms of OAB or chronic non-obstructive problems completed the Amsterdam Biographic Questionnaire (ABQ), which measures the personality traits of the patient, and the Symptom Check-List-90-Revised (SCL-90-R), which is a screening instrument for
neuroticism, and for current level of complaints. Of those 15(28%) reported a history of psychiatric disorder in their medical history. The authors found that a history of psychiatric disease was not related to the outcome of test stimulation, but was shown to be a positive predictor for the occurrence of AEs with permanent SNM treatment. *(Level of evidence 4)*

- **Urodynamics**

A recent study [351] examined urodynamic diagnosis as a predictor of outcome. 111 patients undergoing permanent SNM after a successful PNE test were divided into those with DO (67) on urodynamics and those without DO (44). Both groups showed a statistically significant improvement in bladder volumes at first sensation of filling (FSF) and at maximum fill volume (MFV) before voiding for both UI subgroups, compared with baseline. Resolution of DO post treatment occurred in 51% of patients, however the success in those patients was not significantly different from those with persistent DO. Interestingly patients with UI and no DO had a higher rate of clinical success (73%) than those with UI and DO (61%) although this did not reach to statistical significance. *(Level of evidence 3)*

- **Comparison to the botulinum toxin-A (BTX-A)**

The efficacy rates reported for both SNM and BTX-A in patients with refractory OAB appear to be similar.

The use of BTX-A has recently been approved by the FDA for use in patients with OAB due to neurological conditions such as spinal cord injury and multiple sclerosis. SNM is more invasive but offers long term efficacy whereas treatment with BTX-A injections is less invasive but needs to be repeated on a less-than a year basis in order to provide sustained efficacy. In addition it has been reported that 20% of patients treated with BTX-A injections need to enhance treatment efficacy with anticholinergics and a small proportion report reversible voiding difficulties and need to self catheterisation.

At present there is no RCT published to compare the efficacy and safety of the two methods.

However there are published studies examining the cost-effectiveness of these 2 methods.

Siddiqui et al [352] suggested that BTX-A would be a cost-effective therapeutic option for refractory urgency incontinence in the first 2 years of therapy. Costs were analysed from the societal perspective and in relation to effectiveness. All direct costs related to the treatment modalities as well as the costs of incontinence were calculated but not the indirect costs (lost productivity second-

ary to incontinence) due to the limited data available. Two years is a short duration for a chronic condition. The prolonged effect of SNS and the cost and time needed for repeat BTX-A injections might change significantly the comparison of cost effectiveness for a longer duration of treatment.

In another study Leong et al [353] by comparing the costs and effects value of the two methods in patients with refractory OAB concluded that starting with SNM, treatment is cost-effective after 5 years compared to BTX. However, when different scenarios were examined, such as the use of local anaesthesia for BTX treatment and SNM peripheral nerve evaluation or bilateral test, SNM was not cost-effective.

It is also acknowledged that the costs for surgery and for the devices may vary significantly between countries and even between hospitals within one country.

**c) Conclusion and Recommendations**

Sufficient **Level II /III** evidence exists evaluating implantable neuromodulation. Current series include retrospective cohort studies and no high level RCTs. There is a need for further prospective randomised assessment of this intervention – especially from the durability standpoint. **Grade of recommendation is A / B**

### 2. PERCUTANEOUS TIBIAL NERVE STIMULATION (PTNS)

**a) Efficacy**

Several case series have shown a reduction of frequency, urgency, urgency urinary incontinence in 60-80% of patients with no serious adverse events. Recent research provides level I evidence that PTNS is efficacious in the treatment of refractory OAB.

**b) PTNS vs Placebo (sham device)**

A multicentre, double-blind, RCT (SUmiT) [354] compared the efficacy of PTNS to sham through 12 weeks of therapy. A total of 220 adults with overactive bladder symptoms were randomised 1:1 to 12 weeks of treatment with weekly percutaneous tibial nerve stimulation or sham therapy. In the sham group a Streitberger placebo needle was used to simulate the location and sensation of PTNS needle electrode insertion without actually puncturing the skin. In addition two active TENS surface electrodes were placed, one under the little toe and one on the top of the foot. Sham stimulation parameters were determined based on subject first sensory level of localised stimulation through a TENS unit.

Patients were evaluated by overactive bladder and quality of life questionnaires as well as 3-day voiding diaries before treatment and at week 13.
At 13 weeks follow-up there was moderate or marked improvement in overall bladder symptoms in 54.5% (60/110) and 20.9% (23/110) of subjects respectively ($p<0.001$). All individual symptoms such as frequency, nighttime voids, voids with moderate to severe urgency and urgency urinary incontinence episodes demonstrated statistically significant improvement from baseline to 13 weeks for the PTNS group compared to the sham group (Table 7). This was also confirmed on voiding diaries.

There were no serious adverse effects with 4% (5/110) reporting bleeding and discomfort at the needle site and one case of ankle bruising and a further one with leg tingling.

In a further RCT[355], 35 patients not responding to anticholinergics were randomised to PTNS or control group. The control group (17 patients) received an original placebo treatment using a 34 gauge needle placed in the medial part of the gastrocnemius muscle. Patients were considered to be responders if they had a reduction in urgency incontinence episodes greater than 50%. After 12 weeks of weekly treatments 71% (12/17) in the PTNS group and 0% (0/12) in the placebo group were considered responders ($p < 0.001$). (Level of evidence I - II)

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of response to this intervention

c) PTNS vs tolterodine ER

Another multicentre RCT showed comparable efficacy of PTNS to medical treatment (OrBIT trial)[356].

A total of 100 adults with urinary frequency (> 8 times/day) were randomised 1:1 to 12 weeks of treatment with weekly PTNS or to 4 mg daily extended-release tolterodine. Voiding diaries and an overactive bladder questionnaire were completed at baseline and at the end of therapy. Global response assessments were completed by subjects and investigators after 12 weeks of therapy. The two groups were comparable for baseline characteristics and OAB symptoms.

At 12 weeks 79.5% (35/44) of the PTNS and 54.8% (23/42) of the tolterodine patients considered themselves to be cured or improved ($p = 0.01$).

Urinary frequency, urgency urinary incontinence episodes, urgency severity and nighttime voids, voided volume and QoL improved significantly in both groups but there was no difference between the PTNS and the tolterodine patients. (Level of evidence I)

d) Long term data

A long-term follow-up of the OrBIT Trial evaluated the durability of PTNS benefits[357].

Patients who were randomised to weekly PTNS in the OrBIT trial were offered an additional 9 months of treatment with assessments at 6 and 12 months from baseline. Outcome measures included voiding diary data, overactive bladder questionnaires, global response assessments and safety assessments. A total of 33 percutaneous tibial nerve stimulation responders continued therapy with 32 and 25 subjects completing 6 and 12 months of therapy, respectively. Subjects received a mean of 12.1 treatments at various intervals during an average of 263 days, with a mean of 21 days (median 17) between treatments.

Sustained improvement was shown with 94% (30/32) of patients continuing periodic treatment considering themselves to be cured or improved at 6 months and 96% (24/25) at 12 months follow-up. Overactive bladder questionnaire symptom severity was significantly improved from 12 weeks to 12 months ($p <0.01$) as well as from 6 to 12 months ($p <0.01$). No serious adverse events were reported.

| Overall bladder symptoms (intent to treat) | 60/110 (54.5) | 23/110 (20.9) | $<0.001$ |
| Overall bladder symptoms | 60/103 (58.3) | 23/105 (21.9) | $<0.001$ |
| Urinary urgency | 44/103 (42.7) | 24/105 (22.9) | 0.003 |
| Urinary frequency | 49/103 (47.6) | 23/105 (21.9) | $<0.001$ |
| Urinary urge incontinence | 39/103 (37.9) | 23/104 (22.1) | 0.02 |

Table 7: PTNS: Improvement of global response assessment at 13 weeks compared to baseline (Level of evidence I)
e) Mode of action

The exact mechanism of PTNS on bladder function is unclear but it is thought that this is mediated through the retrograde stimulation of the sacral nerve plexus. The posterior tibial nerve is a peripheral nerve with mixed sensory and motor fibres. It originates from spinal roots L4 through S3, which also contribute directly to sensory and motor control of the urinary bladder and pelvic floor. A recent study suggests that a plastic reorganisation of cortical network triggered by peripheral neuremodulation could be a mechanism of action of PTNS[358].

f) Neurogenic DO

The efficacy and safety of PTNS was evaluated by a prospective multicentre study in 16 women with MS and LUTS unresponsive to anticholinergics.[359] Patients were offered 12 sessions of PTNS. Assessment of LUTS was by validated, self-administered chart and questionnaires, testing the subjective and objective relevance of LUTS for patients and their impact on QoL before and after treatment. There was a significant reduction in daytime frequency, nocturia and the mean post-micturition residual and there was an increase of the mean voided volume. Eighty-nine percent of patients reported treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King’s Health Questionnaire. No adverse events were reported. (Level of evidence III)

Kabay et al.[360] suggested that PTNS can be acutely effective to suppress detrusor overactivity in patients with neurogenic detrusor overactivity due to Multiple Sclerosis. The researchers performed urodynamics before and during PTNS treatment and found that there was a significant improvement of mean volume of first involuntary detrusor contraction from 145.2 ml, to 244.7 ml and of the maximum cystometric capacity from 204.8 ml, to 301.2 ml during the stimulation period. The results have been criticised as the PTNS was applied after a 2nd filling of the bladder and this repeat cystometry during the stimulation could have affected the urodynamic parameters. (Level of evidence III)

In a further study[361] the same group of researcher found similar results of an acute effect of PTNS on detrusor contraction in patients with neurogenic DO due to Parkinson’s Disease. (Level of evidence III)

IV. ENTEROCYSTOPLASTY

Vesical enlargement, or augmentation cystoplasty (AC), has been used for many years with varying degrees of success for refractory detrusor overactivity (DO) and related incontinence. Other than idiopathic detrusor overactivity (IDO), indications for enterocystoplasty include small capacity bladders due to fibrosis, tuberculosis, radiation, or chronic infection, neurogenic detrusor overactivity (NDO), poor bladder compliance, as well as others [362-365] AC typically involves a segment of the bowel that is removed from continuity with the fecal stream, detubularised, and patched into the bisected bladder. This method increases bladder capacity and decreases bladder pressure caused by uninhibited detrusor contractions. Additionally, incorporation of bowel into the bladder results in decreased bladder contractility and an increased interval in the volume to first involuntary bladder contraction during cystometric evaluation.

Virtually any portion of the GI tract can be utilised for enterocystoplasty, and each segment has its own unique favourable properties as well as inherent complications [365, 366] There is no ideal segment for all cases. Technically, the surgeon must be aware that the selected bowel segment should contain a suitable length of mesentery to reach into the deep pelvis for a tension free anastomosis between bowel and bladder. There has been no general agreement on whether it is more favourable to bivale the bladder sagittally or transversely during enterocystoplasty; however, it is considered ideal to create the broadest possible opening in the bladder and thereby create the widest possible anastomosis between bladder and bowel resulting in the most spherical configuration possible. The bowel is divided and detubularised on its antimesenteric side prior to anastomosis to maximally reduce peristaltic contractions. Again, the goal of enterocystoplasty is to create a high capacity, low-pressure reservoir during the filling/storage phase of the micturition cycle. When successful, and properly combined with other concomitant reconstructive procedures (i.e. ureteroneocystostomy, slings, artificial urinary sphincters, continent catheterisable channels, etc.), enterocystoplasty can protect the upper urinary tract from pressure-related injury, infection, and vesicoureteric reflux while ideally providing complete urinary continence.

Apart from the inherent risks of open abdominal surgery associated with bowel and bladder anastomoses, AC carries several distinct long-term risks. The risks of this surgery include kidney or bladder infections, new-onset recurrent UTIs, metabolic derangements, mucus production, and,
in rare cases, bladder tumours. As a segment of bowel is used for AC, the available absorptive surface area of the bowel is reduced, and the incorporation of bowel segments into the urinary tract may have metabolic consequences [367]. Hyperchloraemic metabolic acidosis can occur if ileal and/or colon segments are used, as well as malabsorption of vitamin B12 and bile acid after the use of ileal segments. Blackburn et al demonstrated a reduction in serum B12 level with time following ileocystoplasty in 44% of their patients at 7-year follow-up and recommended that these patients should have their B12 levels measured in the long term [368].

There has been concern about the incidence of secondary malignancies that may develop as a long-term consequence of bladder augmentation. Using colonic segments, tumours are most likely to occur at the ureteral implantation site. To prevent metabolic complications, careful patient selection and meticulous lifelong follow-up, as well as prophylactic treatment, are mandatory. Endoscopy for early detection has been recommended, starting 10 years postoperatively for patients who underwent surgery for a benign condition. Of interest, Higuchi et al retrospectively review their registry of 153 patients with an ileal/colonic AC and a matched control population and found that AC does not appear to increase the risk of bladder malignancy over the inherent cancer risk associated with the patient's underlying congenital abnormality [369]. Immunosuppression irrespective of bladder treatment was an independent risk factor for malignancy in their patient population.

Conclusion and Recommendations

Level I Evidence:

There have been no randomised controlled trials, double blind or sham-controlled trials or cohort studies which have examined the effects of enterocystoplasty for the treatment of NDO or directly compared it to another therapy for the same indication, (Recommendation grade C). Also the role of enterocystoplasty is not defined in subjects with idiopathic detrusor overactivity. (Recommendation grade D)

Other Evidence:

The conclusions of several recent reviews on the role of AC indicate that the overwhelming predominance of literature is dedicated to AC in patients with a neurogenic bladder [370, 371]. By some estimates, approximately 10% of reports in the literature have examined the results of AC in adults with IDO. These include only case series (LOE=4). Since the publication of the 4th International Consultation on Incontinence, there have been few additions to the AC literature for IDO (See Table). The studies differ in several ways. Most include both males and females, and some include a varying number of patients with NDO. Additionally, length of follow-up differs widely and the criteria for success may be considerably different and inconsistently reported [372]. Outcome measures have included mostly non-validated questionnaires and subjective patient assessments. Furthermore, continence rates must also be considered with caution, as many AC procedures are combined with bladder outlet procedures [364]. Overall, there does not appear to be a consensus whether patients with IDO or NDO achieve better outcomes [364, 373, 374] The reasons for the inconsistencies in patient satisfaction in neuropathic patients and non-neuropathic patients remain unclear.

Several variations on the standard AC have been recently described. Novel bowel options include urothelium lined seromuscular colocystoplasty and an appendicular-based caecal flap [375-377]. The recent incorporation of robotic-assisted laparoscopic surgery (RALS) and laparoendoscopic single site (LESS) procedures has further added to the surgical options for AC [34-40]. While the initial results are encouraging, long-term outcomes are uniformly absent. Overall, due to its invasive nature and potential for long-term adverse effects, AC is considered to be one of the last choices of treatment in refractory IDO cases [378].

V. AUTO AUGMENTATION

Initially described by Cartwright and Snow, auto augmentation of the bladder was described as an alternative option to AC, especially in children with neuropathic bladder [379, 380]. Auto augmentation may be performed by incision (detrusor myotomy) or excision (detrusor myectomy) of a portion of the detrusor muscle. Either technique aims to create an iatrogenic bladder mucosal “bulge” or pseudodiverticulum and an increase in the storage capacity of the bladder with a concomitant decrease in storage pressures. The reported advantages of detrusor auto augmentation over enterocystoplasty is the avoidance of complications related to the use of bowel in the urinary tract including malignancy, mucous formation, stones, surgical morbidity related to opening and reanastomosis of the GI tract, and metabolic acidosis [364, 381, 382].

Level I Evidence:

There have been no randomised controlled trials, double blind trials or cohort studies which have examined the effects of auto-augmentation as a treatment for non-neurogenic detrusor overactivity incontinence. (Recommendation grade D)

Other evidence:

There are few studies on auto-augmentation in the adult non-neurogenic population and there
have been no additions to the literature since the publication of the 4th International Consultation on Incontinence (See Table 8). One small study of 5 patients with urgency incontinence showed promising results in all patients at the initial postoperative visit, but clinical deterioration and failure occurred in 4 of the 5 patients at three months follow-up [383]. (LOE=4) Mean bladder capacity increased but mean volume to first involuntary bladder contraction decreased. Four of the 5 patients continued to have involuntary bladder contractions on cystometry. One additional retrospective study including 61 patients with NDO and IDO compared detrusor myectomy to AC [384]. Comparable clinical success was reported for the two procedures; however, there was a 22% incidence of serious complications in the 27 patients undergoing AC, compared to only 3% of the 33 patients undergoing detrusor myectomy.

Long term follow-up of auto augmentation in children with neurogenic bladder have for the most part demonstrated disappointing results, which have been attributed to eventual fibrosis of the pseudodiverticulum [382, 385, 386]. Recently, Chrzan et al reported promising results on 49 detrusorotomies performed for neuropathic bladder at a mean follow-up approaching 10 years [387]. Bladder behaviour was assessed as good, fair or poor depending on the volume and intravesical pressure. In 24 patients, good bladder compliance and capacity were seen before detrusorectomy. Good and fair outcomes were observed in 35 (71%) patients at 1 year and in 39 (79%) patients 6 years after detrusorectomy. In 30 (60%) patients, there was hardly any difference between the first and second follow-up. In 9 (18%) patients, formal AC was necessary. Seven patients improved during follow-up, 5 of them after resuming oxybutynin. In 11 patients, oxybutynin could be stopped, and in 2 the dosage could be reduced to once daily.

In an attempt to improve long-term outcomes with this procedure and create a biological “backing” and blood supply for the pseudodiverticulum, a number of variations of this procedure have been described. These variations have included the use of demucosised bowel segments, stomach, peritoneum and rectus abdominis muscle [382, 388-392]. Additionally, the use of an inflatable balloon placed in the bladder for 2 weeks after auto-augmentation improved long-term capacity and compliance [393]. Long-term follow-up demonstrating favourable clinical results with these variations is lacking. This technique is no longer considered as an option for surgical management of detrusor overactivity. (Recommendation grade F).

VI. URETHRAL DIVERTICULUM

1. PREOPERATIVE STAGING

Since the last consultation, relatively insignificant data have emerged on the treatment and surgical management urethral diverticula. No new data have been published regarding classification systems and many are now characterised on the basis of MRI, presentation and size. A variety of imaging techniques need to be investigated for urethral diverticula. The MRI is widely used for evaluation. Dwarkasing, et al., in 2011 [408] reported a study of 60 women undergoing evaluation of urethral diverticula. They emphasized the importance of T2-weighted sequences and the use of endoluminal coil placement in the vagina to produce best overall results. Using a combination of techniques, they had 100% sensitivity and specificity for diagnostic tests. Some groups, however, have found MRI to be nonconsistent with findings at surgery. Chung, et al., [409] [2010] assessed a case series of 76 women who underwent diverticulectomy (41 actually ? had pre-operative MRI scanning. In ten of those patients the discrepancy between MRI imaging and surgical findings was noted. MRI mis-diagnosed one diverticulum as a Bartholin’s cyst. In another case a sterile abscess was diagnosed as urethral diverticulum. In two cases MRI was not sensitive enough to determine a malignancy within the diverticulum. Porten et al., [2011] [410] assessed MRI evaluation and other imaging modalities including VCUG and CT scan. MRI was felt by these authors to be a useful adjunct for determining the extent of surgical dissection and any other complicating factors related to the diverticulum size or presentation. Han, et al., [411] [2007] analysed 30 women undergoing diverticulectomy with pre-operative MRI. They found the MRI useful for surgical planning especially in cases of large, complicated or circumferential diverticula.

Foster et al., [412] [2007]) also identified the utility of MRI imaging in diagnosis and surgical planning in women. In a study of 27 women, 15% of the patients had altered surgical management based upon pre-operative staging with MRI scanning.

Additional staging studies continue to be utilised including VCUG. Double blind retrograde urethrography is not considered of historic interest only. Recent data regarding transvaginal ultrasonographic evaluation also demonstrated the utility of this technique Wu et al., [413] (2009) reported the utility of transvaginal ultrasound for determination of size, content and location of the diverticulum and had good correlation with operative findings.

2. TREATMENT

Since the last report, various management options have been reported. Ljungqvist, et al., [414]

Key: Dx: diagnosis; N: neurogenic; I: idiopathic; O: other; C+I: cured and improved.
(2007) reported a long follow-up series of 68 women who underwent standard urethral diverticulectomy. They noticed over a 26 year follow-up, that 11 of the 68 women experienced diverticula recurrence and urinary incontinence of varying degrees. Dyspareunia was also noted in these patients with recurrence. Despite this, 92% of the patients would recommend surgery, in their study. One small fistula was also identified over long-term follow-up in their patients. Recent analysis of surgical procedures performed in the United States of America over a twenty year period, (Burrows, et al, 2005) [415] assessed frequency of interventions for diverticulectomy in the United States at 6.7 per 1 million women per year. Rates of intervention were three-fold higher for African American as opposed to Caucasian women. Overall frequency of surgical intervention for diverticula has decreased over time.

Several authors have described standard resection techniques and these appear to be the most commonly and now currently reported (open diverticulectomy, transvaginal resection with periurethral dissection and layered closure being the most common technique). This technique now is the most commonly performed, (Rovner, et al, 2007) [416]. Lee et al (2009) [417] reported the use of SIS graft and noted good response in a single patient where this was utilized. Additionally, bovine pericardium has also been used for this purpose (Tolosa Eizaguirre, et al, 2012) [418]. Native tissue appears to be best for this purpose. Additionally, pericardium has recently been described as another type of interpositional graft with good results in a single case study (Gunasekaran et al, 2011) [419] Recent urologic guidelines, Dmochowski et al., [420] stressed the importance of not placing synthetic materials over a fresh urethrotomy at the time of diverticular repair due to concerns regarding erosion.

Recently, increased reports of diverticula formation related to midurethral tape formation have been identified. The first report in the English literature occurred in 2007 (Hammad) [421], since then Mahdy, et al, 2008, [422] and Athanasopoulos, 2008 [423] have both described diverticula occurring after implantation of transvaginal tape presumably due to excess tension placed on the midurethral tape.

The importance of differential diagnosis continues to be critical as women with chronic pelvic pain are sometimes found to have a urethral diverticulum (Fletcher, et al 2009) [424]. Foley et al,2011,[425] identified the importance of critical evaluation in differential diagnosis and accurate assessment of these individuals. Another important aspect in consideration of surgical management of urethral diverticula is potential risk of malignant chane within these. Thomas et al. 2008 [426], Ninety women going through diverticulectomy at a single institution. Neoplastic changes were identified in five patients of whom all were glandular carcinomas. The potential for metaplasia occurring in these lesions is needs to be stressed. Reoperation for diverticulum has recently been assessed. (Ockrim, et al 2009)[427] evaluated a group of women who had undergone previous intervention for diverticulum requiring repeat resection. The resection was secondary either to incomplete resection and/or recurrence of the diverticulum. The authors found that a standard approach utilising a sling or Martius fat pad labial graft interposition provided the best results in their complicated series.

3. RECOMMENDATIONS

All reports are Level III in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature there is a need for prospective randomised assessment of management of these patients. Functional assessment across all domains of pelvic floor activity (pain, continence, urinary storage, and sexual function) are critical to the complete assessment of urethral diverticulae.

(Grade of recommendation B/C)

VII. ARTIFICIAL URINARY SPHINCTER IN WOMEN

The artificial urinary sphincter continues to be used as a surgical option for sphincter dysfunction in women solely a salvage procedure (after multiple failed previous procedures or special circumstances). There is limited but now some long term experience with the sphincter as a primary intervention.

Since the last publication, there have been several longer term follow-up studies which will be referenced below. The device may be placed either transvaginally, trans-abdominally or recently described as being placed laparoscopically. Success (cure or improvement of stress incontinence) rates overall range between 76 and 89 per cent.

More recent results have been reported in small groups (Hoda,et al) [428] reported experience with two women who underwent open implantation of a sphincter(endooscopic extraperitoneal approach, laparoscopic) . The overall operating time for these cases was 120 minutes. Both women were reported as being continent after the device implantation A slightly larger experience with laparoscopic insertion of artificial urinary sphincter reported has been reported by Roupret et al [429] . Twelve women underwent laparoscopic insertion of a sphincter over a two year period, eleven of whom had undergone previous procedures. After a variable period of activation ranging from four to fourteen weeks, with a mean follow-up of 12.1 month (range 5.2 to 27) incontinence was cured in 88% of the women. Com-
plications included the need for open conversion in two patients, two bladder injuries, two vaginal injuries with an overall complication rate of 25%.

Mandron, et al, [430] contemporaneously reported their experience with 25 patients undergoing laparoscopic AUS implantation over a four year timeframe. No cases required open conversion and the authors reported only an intraoperative complication, Of vaginal perforation. Five of the patients developed urinary retention which required re-catheterisation for a short period (no longer than four weeks). At a mean follow-up of 26.1 months, two patients failed due to vaginal erosion and required removal of the AUS, however, 23 patients reported continence, either total [19] or social (minimal pad use) [4].

Longer term follow-up has been reported by several groups recently. Chung et al [431] reported twenty-five year a single institution experience with sphincter implantation in 47 consecutive women, of whom 35 had failed previous anti-incontinence surgery. Two wound infections were identified after insertion. Of the 47 patients 83% still retained a functional sphincter at follow-up. Eight (17%) required removal due to erosion or infection. Additionally 20 revisions were required; the majority due to mechanical complications. Kaplan–Meier analysis revealed slightly over 80% of devices still working after 100 months. Continence rate (no pad use) at the time of follow-up was 59%.

Vayleux, et al., [432] reported an analysis of 215 women undergoing sphincter implantation over a 22 year period. 88% of women had undergone previous treatment for incontinence, 73.5% of the patients were considered continent (0 to 1 pad use) at follow-up. 170 (or 79%) were satisfied. The revision rate in this group was 15.3% after a mean interval of 8.47 years. 15 explantations (7% of total) were performed. The major risk factor for intraoperative complications was a history of smoking (10.7%). Multivariate analysis revealed age to be the major risk factor for failure (odds ratio 2.46), which occurred in 23.7% of the subjects. In addition, pelvic radiotherapy was also associated with failure (4.37 odds ratio). The largest long term analysis was recently published by Costa, et al., [433] . Over a 20 year period, 376 devices were implanted in 344 women. At mean follow-up of 9.6 years, 85.6% of patients were fully continent (no incontinence), 8.8 were socially incontinent (occasional incontinence episode) and 5.6% were incontinent (defined as one pad or more incontinence). Three, five and ten year device survival rates by Kaplan-Meier analysis were 92%, 88.6% and 69.2%. Mean mechanical survival time was 176 months (14.7 years). The authors identified three factors for AUS survival including number of previous incontinent procedures, presence of associated neurogenic disease, and simultaneous augmentation procedure. Recent Cochrane Database Review (Lipp, et al), [434] failed to identify any subsequent new data regarding the experience of artificial urinary sphincters.

Two trials have also assessed role of the sphincter in women as a salvage procedure. Chung et al., [435] reviewed 29 patients in whom AUS was implanted after failed anti-incontinence procedures. 5 (17%) of those patients required explantation of the device either due to erosion or infection. In addition, 13 revisions were performed with device malfunction accounting for 95% of those cases. Overall survival analysis revealed 90% malfunction of the device at less than 100 months from the time of implant. There was a significant decrease in pad use noted in the trials and overall continence rates (no pad use) were 70% in this study.

Other additional device modifications have included the use of a larger implanted cuff (greater than 8cm). Revaux, et al., [436] reported 50 women who underwent implantation with a large cuff device over a 23 year period, of whom 86% had undergone previous incontinence procedures.

At a mean follow-up of eight years, 34 women had complete resolution of their incontinence (68%). Factors that were associated with device survivability included less than two pregnancies, urethral closure pressure higher than 19cm of H2O and a cuff size equivalent to 8 cm.

Several consensus statements regarding use of the artificial urinary sphincter have recently been published. Chartier-Kastler, et al., [437] noted a higher risk of erosion and revision rates in women after multiple previous procedures. The authors concluded that the theAUS should be implanted at high volume specialist centres with appropriate knowledge and experience in the management of complex cases of incontinence.

Richard, et al., [438] reported the recommendations of the committee in Women’s Urology and pelviperineology of the French Association of Urology. This guideline recommended avoidance of patients who had not had multiple prior procedures and where a well standardised technique performed by surgeons with regular experience and sufficiently long deactivation after implantation, long term monitoring as key aspects for device success.

Lovatis et al., [439] summarised the guidelines for the evaluation of treatment of urinary incontinence for the Society of Obstetricians and Gynaecologists of Canada. The authors concluded that the AUS was an option in patients with significantly decreased dexterity and mobility (recommendation of III-C).

Modifications of the sphincter have been reported and evolution of the device types continues.
Garcia-Montes, et al., [440] reported a new type of sphincter known as the FlowSecure device. Feasibility of implantation was assessed and noted to be reasonable. The authors concluded that further research and development of the device should continue.

**Conclusion and Recommendations**

All reports are **Level III/IV** in terms of evidence and there continues to be a lack of comparative reports assessing different techniques. All current series are retrospective in nature and there is a need for prospective randomised assessment of management of these patients. **(Evidence Level III/IV)**. Evidence is available to support the use of the artificial sphincter for the indications of recurrent and primary incontinence **(Grade of recommendation is B/C)**.

**VIII. CONFOUNDING VARIABLES**

**1. INTRODUCTION**

Surgery remains the mainstay in the management of women with stress urinary incontinence and there are many different operations and procedures reported. Success rates are often found to vary significantly; this may be due to many confounding factors some of which may be modifiable and some which are not.

The purpose of this review is to update the previous report on confounding variables published in the 4th consensus with the more recently reported evidence. A Medline search was performed from 2008 onwards and, for convenience; the confounding variables are subdivided as in the previous report. For the purposes of this update only new studies will be included.

**2. AGE**

There have been several recent papers investigating the effect of age on continence surgery since the last report and a large Australian epidemiological study has demonstrated that the number of procedures, particularly in the elderly is increasing. [441] Data from Medicare Australia from 1994 -2009 were analysed and showed that there was almost a doubling of procedures for stress urinary incontinence over a three year period following the introduction of mid-urethral tapes. Over the 15 year period there was an 87% increase in women over 55 years old as compared to a 1% increase in younger women. Mid urethral slings were the most commonly performed procedure and accounted for 85.5% of all operations for stress urinary incontinence performed in 2009 (14 mid urethral slings for every one colposuspension).

Although now less commonly performed both colposuspension and pubovaginal sling remain efficacious procedures for stress urinary incontinence. The Stress Incontinence Surgical Treatment Ef-
sling which found a significant detrimental effect of age and menopausal status. [445]

Patient reported outcomes have become increasingly important in the evaluation of women following surgery and a small retrospective cohort study has been reported in 122 younger women (<65 years) and 70 older women (≥ 65 years) who had combined surgery for SUI and urogenital prolapse. [446] At mean follow up of 10 ± 1.2 months both groups reported significant subjective improvement in symptoms and QoL although the older group had an increased risk of SUI treatment failure (OR 1.10; 95% CI: 1.05-2.5) but not prolapse treatment failure (OR 0.90; 95%CI: 0.29-2.8). A further study investigated preoperative and postoperative factors which correlated with surgical satisfaction in 371 women following fascial or mid urethral sling surgery. [447] Overall increasing age (OR 0.8; p=0.002), body mass index (BMI) (OR 0.8; p=0.003) and autologous fascial sling (OR 0.5; p=0.003) were associated with decreased odds of satisfaction.

3. RACE

There have been four papers evaluating the effect of race on the outcome of continence surgery since the last report. A large epidemiological study examining 129 778 women who underwent continence surgery in the United States in 2003 found the overall rate of 12 surgical procedures per 10 000 women. This figure was 10 per 10 000 (95% CI: 7-12) in white women and dropped to 3 per 10 000 (95% CI: 0-9) and 6 per 10 000 (95% CI: 0-13) in women of other ethnicity. [448] This is further supported by Medicare data from the United States which showed higher operation rates for SUI in white and Hispanic women when compared to black or Asian women (p<0.01). [449]

A further analysis of the Stress Incontinence Surgical Treatment Efficacy Trial examined the effect of racial group in 654 women (11% Hispanic, 73% non-Hispanic white, 6.7% non-Hispanic black and 8.9% were of other ethnicity) following colposuspension or pubovaginal sling. Overall there were no differences seen between groups in any of the urinary incontinence measures investigated. [450]

The function of the continence mechanism has also been compared in a cross sectional population based study of 335 black and white women aged 35-64 years classified as continent (n=137), stress incontinent (n=102) and urge incontinent (n=96). [451] When comparing black women to white women the maximum urethral closure pressure (MUCP) was 22% higher (68.0 vs 55.8 cmH20; p<0.0001). In addition white and black women complaining of stress incontinence were found to have an MUCP 19% and 23% respectively lower than controls. The MUCP in white women with urgency incontinence was as low as those white women with stress incontinence although black women with urgency incontinence had normal urethral function.

4. OBESITY

Whilst there are now considerable data linking severity of incontinence with obesity the evidence regarding the effect on continence surgery is less robust. Evidence from a large series of mid urethral tape procedures has shown no effect of BMI in terms of outcome. [445] This is supported by a further study of 195 women who were followed up for one year following TVT which showed no difference in outcome in different BMI cohorts. [452] The risk of perioperative morbidity however is higher in those patients with lower BMI (14.0% vs 4.3%; p=0.04). After controlling for confounding factors BMI < 30 kg/m2 remained a risk factor for bladder injury (OR 4.63; 95% CI: 1.20 -17.86) as did previous continence surgery (OR 3.55; 95% CI: 1.01-12.50). [454]

5. PSYCHIATRIC ILLNESS

There have been no new relevant publications since the last report.

6. ACTIVITY

There have been no new relevant publications since the last report.

7. PREVIOUS CONTINENCE SURGERY

Surgical success rates often tend to be lower in those women having redo continence surgery and there have been several studies examining this since the last consensus statement. The efficacy of redo colposuspension has been reported in a case series of 52 women from one centre with an objective cure rate of 78% and a subjective cure rate of 80%. [455] The role of redo laparoscopic colposuspension following a failed mid urethral tape has also been assessed in a smaller retrospective case series of 16 women. At a median follow up of 24.5 months objective and subjective cure rates were 54.5% and 92.9% respectively. [456]

There is now also a considerable amount of data examining the efficacy of mid-urethral tape procedures following failed previous surgery. The efficacy of TVT following failed previous continence surgery has been reported in a prospective follow up study of 130 women in Finland. Of these 60 women had recurrent and 70 primary incontinence. Overall there were no differences between the groups in terms of transient voiding difficulties and complications. At three year follow up satisfaction rates were 86% and 91% in the recurrent and primary groups respectively and the subjective cure rate was 93%.
in both. At follow up 20% of those having recurrent surgery complained of de novo urge symptoms as compared to 5.7% in the primary group. [457] A small series of 24 women with recurrent urinary incontinence and intrinsic sphincter deficiency following Burch colposuspension has also reported an objective success rate of 70.8% following TVT. [458]

In addition to studies investigating the use of the retropubic approach there are also several studies investigating the efficacy of the transobturator approach in recurrent stress incontinence. A secondary analysis in a large Scottish study comparing inside-out TOT with outside-in TOT in 341 women assessed outcome in a subgroup of 46 women with recurrent incontinence at one year. [212] Overall the subjective and objective success rates were 69.9% and 76.5% respectively and there were no differences between the two routes. Once again in this study a low MUCP (<30 cmH2O) was the only independent risk factor for failure (OR: 4.52; 95%CI: 1.51-56.1; p=0.016). A smaller series of 29 women with recurrent stress incontinence following a previous colposuspension has also been reported in 29 women who had a TVT or TOT with cure rates of 62.1% after one previous procedure and 57.1% after two. [459]

There is now also increasing evidence to support the use of a redo mid-urethral sling in those women who have previously had a failed mid-urethral sling. In a large series of 1,225 women reported from Australia 1112 were a primary procedure and 77 were secondary procedures. [460] All redo slings were placed without removal of the first. Those women having a redo procedure were more likely to have intrinsic sphincter deficiency (31% vs 13%; p<0.001) and cure rates were 86% and 62% in the primary and secondary procedures respectively. A repeat retropubic approach was significantly more successful that a repeat transobturator approach (71% vs 48%; p=0.04). Whilst complications were similar in both groups de novo urgency (30% vs 14%; p<0.001) and urgency incontinence (22% vs 5%; p<0.001) were more common with redo surgery. A further study has reported on 31 patients who had a TVT after a failed mid urethral tape with an 18 month follow up. Overall objective cure assessed using a pad test was 74% with a 6% improvement rate and 19.5% failure rate whilst objective cure assessed with urodynamics was 77.4%. The subjective cure rate was 71%. [210] (also, see section on mid-urethral slings).

8. CONCOMITANT HYSTERECTOMY

There have been no new relevant publications since the last report.

9. SEVERITY AND DURATION OF SYMPTOMS

There have been no new relevant publications since the last report.

10. DETRUSOR OVERACTIVITY AND STRESS INCONTINENCE

There have been four papers assessing the effect of detrusor overactivity as a confounding variable in stress incontinence surgery since the last report.

A large Australian cohort study has reported on 754 consecutive women with stress urinary incontinence and urgency (SUI) and 514 women with stress urinary incontinence and urgency urinary incontinence (UUI) who had a mid urethral sling and were followed up for a mean of 50 months. [208] Overall persistent urgency was commonly reported in both groups (SUI 40% and UUI 32%). In the SUI group coexistent detrusor overactivity (OR 2.04; 95%CI: 1.39-3.01), baseline symptom severity (OR 1.41; 95% CI: 1.10-1.78) and age (OR 1.03; 95% CI: 1.02-1.04) increased the risk of persistent urgency. Conversely transobturator sling (OR 0.61; 95% CI: 0.39-0.94) and concomitant prolapse surgery (OR 0.54; 95% CI: 0.38-0.75) decreased the risk. In the UUI group coexistent detrusor overactivity (OR 1.86; 95% CI: 1.18-2.93) baseline symptom severity (OR 1.88; 95% CI: 1.38-2.56), previous continence surgery (OR 2.18; 95% CI: 1.28-3.70) increased the risk of persistent urgency whilst apical prolapse surgery (OR 0.33; 95% CI: 0.15-0.70) decreased the risk.

A further study of 121 women has investigated the risk factors affecting outcome after TVT and TOT. Multivariate analysis revealed that preoperative detrusor overactivity was an independent risk factor affecting cure after TVT (OR 113.1; 95%CI: 1.84-6592.77; p=0.02) or TOT (OR 23.7; 95%CI: 1.63-344.53; p=0.02) and MUCP <40 cmH2O (OR 3.01), baseline symptom severity (OR 1.41; 95% CI: 1.10-1.78) and age (OR 1.03; 95% CI: 1.02-1.04) increased the risk of persistent urgency whilst apical prolapse surgery (OR 0.33; 95% CI: 0.15-0.70) decreased the risk.

A case control study in 34 women with mixed incontinence matched for age and type of procedure has shown a significantly higher rate of failure in the TOT group (29.4%) compared to the TVT group (0%). In addition women were significantly more likely to require repeat surgery following TOT (OR 10.1; 95% CI: 2.6-38.2). [116]

11. URETHRAL OCCLUSIVE FORCES

Since the last report there have been several papers investigating the role of the urethra on outcome following continence surgery.

The role of urethral mobility and intrinsic deficiency on outcome following mid urethral tape has been assessed in two studies. The first of these investigated 134 women following transobturator tape insertion. Overall 86% reported subjective cure and 14% complained of persistent symptoms. Median preoperative urethral mobility was significantly lower amongst treatment failures compared to those women who were cured (40 (10-60) degrees vs 50 (10-90) degrees; p=0.0049). In addition women with
preoperative mobility <45 degrees were at least four
time more likely to report incontinence when com-
pared to those with ≥45 degrees mobility (29.4% vs
6.9%; RR 4.29; 95% CI: 1.59-11.60; p=0.005). [200]

A prospective 2 year study of 65 women has also
found that intrinsic sphincter deficiency with a fixed
urethra is associated with a poorer objective out-
come at 24 months following TOT when compared
to intrinsic sphincter deficiency and urethral hyper-
mobility and hypermobility alone (66.7% vs 87.5%
and 96.6% respectively). [201]

Two studies have also examined the role of ure-
thral retro-pressure resistance (URP) and surgical
outcome. The first of these reported on 100 women
and found no relationship between URP and sever-
ity of incontinence assessed by a 24 hour pad test.
In addition there was no correlation between URP
and incontinence severity. Following mid urethral
tape insertion the objective cure rate was 84.9%
although there were no significant differences in
pre and post operative URP values (62.7±19.4 cm
H2O vs 61.2 ± 20.4 cm H2O; p=0.57). [461] A fur-
ther study of 69 women has shown that URP is not
predictive of outcome following TVT. [462]

12. SURGEON’S EXPERIENCE

All surgical procedures and surgeons are subjected
to the effect of a ‘learning curve’ and this has re-
cently been assessed in two studies evaluating the
outcome of mid urethral tapes. The learning curves
of TVT and TOT have been compared in a study of
83 women and overall found TVT procedures were
longer (p=0.025) although the duration was reduced
after the surgeon had performed 15 procedures.
[463] The effect on outcome was not assessed.

The impact of surgical experience and the effect
of the learning curve has also been investigated in
the use of Single Incision Mini Slings (SIMS) in
a prospective study of 131 patients who had TVT
Secur. Overall the study clearly demonstrated im-
poved surgical outcome in those patients who had
their procedures performed by more experienced
surgeons. In addition whilst surgical time and intra-
operative complications were not associated with
surgical experience, the length of postoperative
catheter use and hospital stay decreased with in-
creasing experience. [464]

13. ADJUVANT OESTROGEN THERAPY

The role of oestrogens and lower urinary tract dys-
function remains controversial although there is
evidence to suggest that vaginal oestrogen therapy
may be useful in women with symptoms suggestive
of OAB Since the last report two studies have in-
vestigated the role of adjuvant oestrogen therapy in
women having continence surgery.

The role of adjuvant vaginal oestrogen therapy
has been assessed in a prospective study of 59
post-menopausal women having a TVT procedure.
[465] Patients were randomised to surgery with and
without vaginal oestrogen therapy and followed up
over 6 months. Overall the incidence of OAB symp-
toms at baseline was 7% and this rose to 32% at 6
months. Urinary urgency was significantly higher in
those women not receiving vaginal oestrogen ther-
apy (28% vs 4%; p=0.01) although decreases in fre-
quency and nocturia were not significantly different.

More recently the role of adjuvant vaginal oestradiol
(Vagifem, Novo Nordisk) 25mcg has been assessed
in a prospective randomised study of 190 post-
menopausal women who had a TVTO procedure
with 6 month follow-up. Overall there was no statis-
tically significant difference between those women
who received oestradiol and those who did not in
terms of peri operative complications and hospital
stay. However in the post-operative period those
women treated with vaginal oestradiol showed a
statistically significant decrease in the symptoms of
urgency and frequency although not nocturia and
urgency incontinence. Equally there were no differ-
ence in efficacy rates between the two groups. [466]

IX. CLINICAL TRIAL OUTCOMES
USED IN STRESS URINARY
INCONTINENCE RESEARCH

The last decade has seen a massive expansion in the
field of stress urinary incontinence (SUI) research.
While initially criticised for poor quality research, sig-
nificant advances have been made especially in the
area of clinical trials. Indeed, in the United States,
the National Institute of Health has helped foster
this improvement with development of clinical trials
networks such as the UITN and the PFDN. In addi-
tion, we have seen a maturation in the field of SUI
research including improvements in the quality of
trials and the instruments utilised. Use of validated
outcome measures and properly conducted prospec-
tive trials are now the standard with emphasis being
placed on comparative efficacy trials.

The increase and improvements seen in SUI re-
search has also brought to light the problems that
investigators typically encounter when assessing
SUI outcomes. Strohbehn reported “there are as
many shades of dry as there are shades of gray”
in his editorial response to the UITN’s SISTER trial
which reported a wide range between different SUI
outcome measures [467]. In this prospective ran-
domised clinical trial comparing the Fascial Sling
and Burch procedures, success for overall incon-
venience was 47% vs 38%, respectively compared
to SUI specific success which was 66% vs 49%
respectively. [125] Indeed, it is difficult to think one
can clearly report SUI surgery outcomes when in-
vestigators have trouble defining the population
before treatment is initiated. Brubaker reported
variations in the categorisation of a cohort of wom-
en enrolled in a clinical trial who were planning to undergo SUI surgery. While all women were report-
ed to have pure or predominant SUI for study inclu-
sion, the range of women with mixed incontinence 
was 8.3% to 93.3% depending on what definition 
was used. If such variations exist in the defining of 
subjects enrolled in SUI trials from the onset, it is 
natural to expect wide variations in how outcomes 
are reported post operatively. [468] Rapp reported 
such wide variations when looking at different defi-
nitions of success after SUI surgery. In the same 
cohort of women, successful outcomes ranged 
from 33% to 87% depending on the definition used 
for success. [469]

Outcome assessments can be broken down into 
objective and subjective measures. [470] Objective 
parameters typically include: physical exam, pad 
tests, voiding diaries, urodynamic studies. 
Subjective assessments typically include patient 
reported measures such as validated instruments 
that measure symptoms , patient bother, satisfac-
tion and HRQOL. However, these outcome tools 
are usually limited to a specific area and improve-
ment in one area may not mean improvement in 
other areas or could even be at the detriment of 
another area. In addition, the degree of improve-
ment experienced by one patient might be con-
sidered a “success” in that patient however the 
same improvement may be perceived differently 
by another patient. Furthermore, outcome mea-
sures limited to specific domains may not take 
other symptomology into account. For example, 
resolution of SUI might be considered a success 
by itself however if it were to occur in conjunction 
with urinary retention or worsening irritative void-
ing symptoms and urgency incontinence, the pa-
tient might not agree. Indeed, the majority of SUI 
outcome assessments rarely take complications 
into account. It is clear that focusing on a single 
measure is often inadequate and necessitates the 
need for measuring multiple outcomes which im-
poses greater burden on patients. [471] (SUNG). 
Lastly, no single instrument is universally accept-
ed by all investigators although significant head-
way has been seen in the adoption of instruments 
advocated by professional organisations such as 
the International Continence Society and the In-
ternational Consultation on Incontinence.

In response to the shortcomings seen with tradi-
tional SUI research outcomes, investigators have 
increasingly relied on greater use of composite 
outcomes as well as patient reported outcomes 
that especially assess global response. The use 
of composite outcomes have increased especially 
with the advent of clinical trial networks. While 
providing more comprehensive assessments, 
composite outcome often create a stricter defini-
tion of success especially if all of the components 
of the composite must be satisfied. Many of the 
large scale trials often include multiple outcomes 
measures as primary or secondary outcomes 
which allows them to be more comprehensive. 
However, a vast number of outcome measures 
have been utilised in the field of SUI research. 
While more comprehensive listings of SUI clinical 
trials can be found in the respective sections of 
this chapter, examples of trials utilising different 
outcome parameters that have been published 
since the last ICI report are listed in the following 
tables. Table 9 provides a sampling of composite 
outcomes used in SUI trials. Table 10 provides a 
sampling of patient reported outcomes measures 
used in SUI trials.

While many of the self-reported measures can be considered “patient reported”, the concept of true Patient Reported Outcomes (PRO) is one that is more complex and encompasses a more global assessment. The use of PRO’s has gained acceptance as noted by the fact that most research funding sponsors, industry and regulatory agencies now require inclusion of outcome measures that include the patient’s perspective. The NIH recently established the Patient Reported Outcomes Measurement Information System (PROMIS) for women with urinary incontinence [471] (Sung). True PRO’s measure patient impressions in a more global context by encompassing 4 domains: 1) Symptoms, 2) Functioning, 3) General Health Perception and 4) HRQOL. The International Consultation on Incontinence has adopted the use of PRO’s and established the ICI Modular Questionnaire (ICIQ) Project that includes the assessment of a wide spectrum of urinary, bowel and vaginal symptoms along with their impact on HRQOL (Coyne) [477].

Another outcome measure that has recently gained popularity is the patient global impression of severity (PGIS) and the patient global impression of improvement (PGII). Initially validated by Yalcin, use of such global assessment instruments provides a single response which is easier for the patient and clinician to understand [478] (Yalcin). Furthermore, the measurement is all encompassing since the subject takes success and complications into account when responding. Indeed, the UITN recently adopted the use of the PGIS and PGII for use as a major eligibility criterion and as the primary outcome in the VALUE trial which will look at the impact of urodynamic studies on SUI Surgery outcomes. [479]

I. INTRODUCTION

Pelvic organ prolapse (POP) is a common problem affecting up to 50% of parous women and 6.3% of women will have undergone a surgical correction for pelvic organ prolapse by the age of 80. Prolapse surgery is an increasingly important aspect of gynaecological practice due to our ageing population, the decreasing rate of hysterectomy due to alternative treatments of menorrhagia and finally decreasing rates of cervical interventions for cervical dysplasia following introduction of vaccinations for Human Papilloma Virus. Already prolapse surgery is performed at least as frequently as continence surgery and, the operating and admission times are at least three times greater than for continence surgery. Given the increasing time and resources that will be required for POP surgery in the future it is paramount that we perform effective, durable, cost effective interventions with minimal morbidity. This chapter serves to outline and summarise the information relating to POP surgery reported in the English-language scientific literature after searching PubMed, Medline, Cochrane library and Cochrane database of systematic reviews, published up to January 2012, with Level 1 evidence. Level 2 or 3 evidence have been included if Level 1 data were lacking.

II. PREVALENCE AND INCIDENCE OF POP

There is a lack of epidemiological studies of the natural history, incidence and prevalence of POP.

It is widely accepted that 50 percent of women will develop prolapse but only 10 to 20 percent of those seek evaluation for their condition [Phillips 2006]. In the current literature, the overall prevalence of POP varies significantly depending upon the definition utilised, ranging from 3-50 percent (Table 1). Where POP is defined and graded on symptoms the prevalence is 3-6 percent as compared to 41-50 percent when based on examination, because mild prolapse on examination is common and frequently asymptomatic (Phillips 2006, Samuellson 1999, Nygaard 2004, Swift 2003). On examination anterior compartment prolapse is the most frequently reported site of prolapse and is detected twice as often as posterior compartment defects and three times more commonly than apical prolapse [Hendrix 2002, Handa 2004]. Following hysterectomy 6 to 12 percent of women will develop vaginal vault prolapse [Marchionni 1999, Aigmueller 2009] and in two-thirds of these cases multi-compartment prolapse is present [Morley 1988].

There is little knowledge about the natural history of POP. The reported incidence for cystocele is around 9 per 100 women-years, 6 per 100 women-years for rectocele and 1.5 per 100 women-years for uterine prolapse [Handa 2004]. Some data show that there is a 1-year incidence of POP of 26 percent and a 3-years incidence of 40 percent with regression rates of 21 percent and 19 percent, respectively. In general, older parous women are more likely to develop new or progressive POP than to show regression. Over a three year period 11 per cent of the women aged over 65 had prolapse progression of more than 2 cm whilst only 2.7 percent had a regression by the same amount [Bradley 2007].

Luber has shown in a large demographic study that the peak incidence of symptoms attributed to prolapse is between ages of 70 to79 whilst POP symptoms are still relatively common in women of younger age (Figure 1) [Luber 2001].

Demographic changes including an ageing population have significant implications for the future planning of women’s health services. Wu et al [Wu 2009] have predicted that by 2050 the number of women suffering from symptomatic POP in the United States will increase at minimum by 46 percent (from 3.3 up to 4.9 million women and in a “worst-case scenario” up to 200 percent or 9.2 million women with POP. These figures were based upon population growth statistics in the United States however models that evaluate the impact of decreasing parity and increasing elective caesarean section rates are required to more accurately predict future rates of POP.
Figure 1. Shows the distribution of POP among women seeking care, US 2000 (Modified Luber 2001)

Incidence and Prevalence of Prolapse Surgery

Both incidence and prevalence for prolapse surgery increase with age. Women older than 80 years are currently the fastest growing segment of the population. The estimated lifetime risk of an American woman undergoing at least one surgical intervention by the age of 80 is 6.3 percent with 30% requiring subsequent surgery [Ol-sen 1997]. However, a more recent, prospective study showed a significantly lower reoperation rate of only 13 percent which may be explained by improved surgical procedures [Clark 2003]. The longevity and durability of POP surgery are important variables for planning and require ongoing evaluation.

The annual incidence for POP surgery is stated to be between 1.5 [Boyles 2003] and 1.8 [Shah 2007] cases per 1000 women-years with the incidence peaking in women between 60-69 years. Shah et al also demonstrated a peak incidence in 70 year old women however surprisingly high numbers of younger women were also undergoing surgical treatments reflecting a similarity in the prolapse symptoms reported in younger women by Luber 2001 ([Shah 2007]). In a more recent study Smith et al [Smith et al 2010] reported a lifetime risk of undergoing prolapse surgery as high as 19% in Western Australia. This figure is three times higher than the 6.3% lifetime risk for POP surgery reported by Olsen and requires further evaluation of local factors and definitions that may have contributed.

In the US, POP is thought to be the leading cause for more than 300,000 surgical procedures per year [22.7 per 10,000 women] with 25% undergoing reoperations at a total annual cost of more than 1 billion dollars [Brown 2002, Boyles 2003, Silva 2006, Shah 2007]. Also of note during a nine year period [1996 – 2005] the ambulatory costs related to pelvic floor disorder increased by 40% and if these figures are extrapolated to POP surgery the total annual cost would be over 1.4 billion dollars.

The incidence of prolapse which required surgical correction following a hysterectomy is 3.6 per 1000 women-years according to Mant et al from his large cohort study in the UK. The cumulative risk rises to 5 percent 15 years after hysterectomy [Mant 1997].

Further more detailed modelling of factors that will impact on future rates of POP in the community are required so that services can be provided to match the future demands of POP surgical interventions.

III. OUTCOME ASSESSMENT

Pelvic organ prolapse, like all pelvic floor disorders, is a multidimensional phenomenon and “success” of treatment is often difficult to define. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life [Barber 2009], yet until recently these areas have largely been ignored. Fortunately, over the last 15 years, measures to evaluate POP have
improved; there is now an internationally-accepted and reliable assessment of the anatomic support of the uterus and vagina [POPQ] and a number of valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments.[Bump 1996; Barber 2001; Barber 2005; Digeu 2005; Price 2006; Baessler 2010]. A recent joint report from the International Continence Society [ICS] and International Urogynecological Association [IUGA] recommended that the following outcomes be reported in studies of POP surgery: Objective (e.g. POPQ), Patient reported outcomes (particularly the presence or absence of vaginal bulge symptoms), Satisfaction, Quality of Life, and Perioperative data (e.g. operative time, hospital stay, etc) (Toozs-Hobson, 2012). A careful report of short- and long-term complications are also essential to properly weigh the risk-benefit ratio of each procedure.

1. OUTCOME ASSESSMENT: ANATOMY

The Pelvic Organ Prolapse Quantification system (POPQ), introduced in 1996, is the international standard for describing female pelvic organ support. [Bump 1996] The POPQ allows a reproducible and reliable description of the support of the anterior, posterior and apical vaginal segments using precise measurements to a fixed reference point, the hymen and established criteria for “staging” the various levels of pelvic organ support from good support [POPQ stage 0 or I] to almost complete lack of support [POPQ stage IV].[Bump, 1996] The POPQ system has proved a valuable measurement tool that over the last 15 years has improved our understanding of POP and allowed a reliable assessment of the anatomical success of POP surgeries. However, there remain several critical challenges in the anatomical assessment of POP surgery.

First, it is difficult to establish dichotomous anatomical outcome criteria for success and failure, especially in the absence of symptoms. Traditionally, researchers have defined surgical success using the NIH satisfactory anatomic outcome [POPQ stage 0 -1] and defined surgical failure as POPQ stage 2 or greater. More recently it is suggested that these anatomic definitions are too strict as over 75% of women presenting for annual gynecological examinations without symptoms of pelvic organ prolapse would not meet the definition of “optimal anatomic outcome” and almost 40% would not meet the definition of “satisfactory anatomic outcome.”[Samuelsson 1999; Swift 2005] Thus, a substantial number of women considered “surgical failures” by these definitions would be within the normal distribution of vaginal support for parous women. The hymen maybe a more clinically relevant anatomic threshold for surgical success and some researchers have begun defining anatomic failure after surgery as POP that extends beyond the hymen.[Culligan 2005; Barber 2009; Zyczynski 2010; Chmielewski 2011; Sayer 2011].

Second, the five-level staging system of the current POP-Q (Stages 0-IV) may be insufficient to discriminate among clinically important groups of women with POP, placing virtually all such women into Stage II or III. While the staging may facilitate comparisons, it may not describe sufficient detail as the individual POP-Q measurements provide. A third area of uncertainty is whether or not apical prolapse should be considered by the same anatomic standards as prolapse of the anterior or posterior vaginal wall.

Controversy also surrounds the impact that the observer recording the anatomical outcomes has upon reported success rates. Traditionally in the retrospective assessment of anterior compartment trials the reported success rates ranged from 80-100%[Macer 1978; Stanton 1982; Walter 1982; Porges RF 1994]. However, prospective assessment of similar surgical interventions utilising similar definitions of success under the auspices of randomised controlled trials report significantly lower success rate ranging from 37-64%[Sand 2001; Weber 2001]. Further variation is also reported in prospective evaluations of prolapse staging depending upon whether the assessor is blinded to the surgical intervention. Antosh et al[Antosh 2011] demonstrated that the recurrence rate in a RCT comparing native tissue and transvaginal mesh repairs was significantly higher when performed by a blinded versus unblinded assessor at the 3 months (68 versus 53%) and at 1 year (57 versus 43%). Finally, there is an increasingly common trend for authors with financial conflict of interest related to the commercial products being evaluated reporting the outcomes of surgical interventions, which further increases the risk of reporting bias.

2. OUTCOME ASSESSMENT: SYMPTOMS

Women seeking care for POP often have concurrent pelvic symptoms. Elkerkern et al found that in 237 women evaluated for POP 73% reported urinary incontinence, 86% reported urinary urgency and/or frequency, 34-62% reported voiding dysfunction and 31% complained of faecal incontinence.[Elkerkern 2001] The evaluation of a patient with vaginal prolapse requires a comprehensive review of the full spectrum of pelvic floor symptoms and an assessment of how these symptoms affect their quality of life. The most valid way of measuring the presence, severity, and impact of pelvic floor symptoms on a patient’s activities and well-being is through the use of psychometrically robust self-administered questionnaires [Bump 1996; Barber 2001; Barber 2005; Digeu 2005; Price 2006; Baessler 2010].

We have gained an improved understanding of the relationship between pelvic organ support and the development of symptoms. Most symptoms often attributed to POP have at best weak to moderate correlations with worsening pelvic organ support, however, the one symptom that is almost consis-
ently acknowledged by patients with advanced POP is the presence of a vaginal bulge that can be seen or felt.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Tan 2005] The absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient’s assessment of overall improvement and improvement in quality of life after surgery, while anatomic success alone does not.[Barber 2009] The hymen seems to be an important “cut off point” for symptom development. Women with prolapse beyond the hymen have more pelvic floor symptoms and are more likely to report a vaginal bulge than women with prolapse at or above the hymen.[Ellerkmann 2001; Swift 2003; Barber 2005; Bradley 2005; Swift 2005; Tan 2005]

3. OUTCOME EVALUATION: QUALITY OF LIFE
Health-related quality of life [HRQOL] refers to a person’s total sense of well-being and considers multiple dimensions including (but not limited to) their social, physical, and emotional health. Measures of HRQOL can be classified into two types: generic and condition-specific. Generic HQOL instruments are used to assess quality of life in a broad range of illness or populations while condition-specific measures are designed to measure the impact of a specific disease on HRQOL. Women with advanced POP (stage 3-4) have decreased generic and condition-specific HRQOL compared to women with normal vaginal support.[Jelovsek 2006] It is recommended that investigators describe the impact of POP surgical treatment on HRQOL. Most studies that have assessed condition-specific HRQOL after POP surgery have demonstrated a significant improvement postoperatively. Improvements in generic HRQOL after POP surgery have been seen in some studies but not others. Maher et al reported significant improvements in condition-specific and generic QOL after SSLF, similar to that after abdominal sacrocolpopexy.[Maher 2004] The CARE trial reported significant improvements in condition-specific quality of life following sacrocolpopexy at three months and two years.[Brubaker 2006; Brubaker 2008] Barber et al demonstrated significant improvements in generic and condition-specific HRQOL in a prospective cohort of elderly women receiving vaginal surgery for POP and demonstrated similar improvements in women undergoing reconstructive surgery and those receiving colposclerosis.[Barber 2007] While some of these condition specific HRQOL incorporate assessment of sexual function [Baessler 2010] specific validated questionnaires on sexual function are available and provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire [PISQ][Rogers 2001] and the Female Sexual Function Index[FSFI][Rosen 2000] are two questionnaires frequently used. The joint ICS/IUGA paper on reporting outcomes after prolapse surgery has also recommended authors report the sexual function status of all individual participants pre and post intervention as seen in Figure 3 (Toozs-Hobson, 2012).

4. OUTCOME ASSESSMENT: REOPERATION
Reoperation after POP surgery for recurrence is an important measure of procedure efficacy. It is important to realise that reoperation rates are likely to represent the “tip of the iceberg” in terms of unsuccessful surgical outcomes as many women with recurrence of symptomatic prolapse may not elect another operation, nonetheless the repeat surgery for recurrent POP is an undesirable outcome that should, in most cases, be considered a surgical failure. The rates of reoperation after POP surgery vary widely in the literature, in large part because of varying definitions and timeframes. Olsen et al using administrative data from a large U.S. healthcare system reported a lifetime reoperation rate of 29.2%.[Olsen 1997] Importantly, this study included both POP and stress incontinence surgery and did not distinguish between reoperation for incontinence or POP in their report. Moreover, the authors did not distinguish between reoperation for POP in the same compartments originally operated versus the development of new POP in a new segment of the vagina [“de novo POP”]. More recently several investigators have looked specifically at the issue of site-specific recurrence with re-operation rates ranging from 3.4%-9.7%.[Miedel 2008; Kapoor 2010] In a meta-analysis of 258 studies evaluating reoperation rates after apical prolapse repairs, Diwadkar et al, reported a reoperation rate of 3.9% [95%CI 3.5-4.4%] for traditional vaginal vault suspensions (sacrospinous ligament suspension and uterosacral vault suspensions) after a mean of 32 months, 2.3% (95% CI 1.9-2.7%) for sacrocolpopexy with a mean follow-up of 26 months and 1.3% (95% CI 1.0-1.7%) after transvaginal mesh procedures at a mean follow-up of 17 months.[Diwadkar 2009] Notably, the total reoperation rate if one includes reoperations for recurrent POP and for complications was highest in the transvaginal mesh group (8.5%).[Diwadkar 2009]

In order to provide some clarity for future studies reporting reoperation rates after POP surgery, the joint ICS/IUGA report on reporting outcomes after prolapse surgery has proposed the following standardised terminology for POP surgery studies[Toozs-Hobson 2012]:

 Primary surgery for POP is the first procedure required for the treatment of POP in any compartment

Further surgery This gives a global figure for the number of subsequent procedures the patient undergoes directly or indirectly relating to the primary surgery. This is subdivided into:

a. Primary prolapse surgery/different site. A prolapse procedure in a new site/compartment following previous surgery in a different compartment (e.g. anterior repair following previous posterior repair).
b. Repeat surgery: is a repeat operation for prolapse arising from the same site. Where combinations of procedures arise, e.g. new anterior repair plus further posterior repair these should be reported separately i.e. repeat posterior repair and primary anterior repair.

c. Surgery for Complications: e.g. mesh exposure or extrusion or pain or patient compromise e.g. haemorrhage (see complications section)

d. Surgery for non-prolapse related conditions: e.g. subsequent surgery for stress urinary incontinence or fecal incontinence.

5. DEFINING TREATMENT SUCCESS

The definition of success substantially affects treatment success rates following POP surgery.[Barber 2009] Since the publication of the NIH Workshop recommendations, considerable variability in defining treatment success still persists in studies evaluating surgery for prolapse. A number of trials define success as POPQ stage 0 or 1 consistent with the Workshop’s “satisfactory anatomic outcome” definition with one reporting success rates as low as 30% using standard surgical techniques.[Weber 2001; Brubaker 2005] Some have used the Baden-Walker prolapse grading system rather than the POPQ system.[Maher 2004] Other studies have used a combination of anatomic criteria and the presence or absence of symptoms to define treatment success. [Paraiso 1996; Barber 2000; Brubaker 2005] Such variability makes it difficult to compare study results. Moreover, there are many unknowns, including clinical relevance of these definitions or how different outcome definitions might affect the comparison between treatment arms within a study.

A recent secondary analysis of the CARE trial described POP surgical success rates after sacrocolpopexy using 18 different definitions of treatment success with differing requirements for anatomic, symptomatic and/or retreatment outcomes.[Barber 2009] Treatment success varied widely depending upon definition used (19.2% to 97.2%). 71.4% considered their surgery “very successful” and 85.2% considered themselves “much better” than before surgery. Definitions of success requiring all anatomic support to be proximal to the hymen had the lowest treatment success (19.2% to 57.6%). 94.3% achieved surgical success when it was defined as the absence of prolapse beyond the hymen. Subjective cure (absence of bulge symptoms) occurred in 92.1% while absence of retreatment occurred in 97.2% of subjects. Subjective cure was associated with significant improvements in the patient’s assessment of both treatment success and overall improvement, more than any other definition considered [p = .0002 and <.0001 respectively]. Similarly, the greatest difference in symptom burden and HRQOL between treatment successes and failures was noted when success was defined as subjective cure (absence of vaginal bulge symptoms; p<.0001). These authors concluded that the absence of vaginal bulge symptoms postoperatively has a significant relationship with a patient’s assessment of overall improvement, while anatomic success alone does not. Based on this analysis along with the currently available literature on the distribution of pelvic support loss in the general population and on data on the relationship between pelvic organ support loss and symptom development, authors from the NIH Pelvic Floor Disorders Network have recommended that: 1) any definition of success after POP surgery should include the absence of bulge symptoms in addition to anatomic criteria and the absence of re-treatment and 2) using the hymen as a threshold for anatomic success seems a reasonable and defensible approach.[Barber 2009].
The committee concludes that authors when reporting outcomes on the surgical management of prolapse should include a variety of standardised anatomical and functional outcomes. It is expected such measures will improve the reporting of surgical outcomes and aid in meaningful meta-analysis of pelvic organ prolapse outcome data in the future.

- Anatomical outcomes reported should include all POP-Q points and staging utilising traditional definition of success and also with the hymen as the threshold for success. Assessment should be prospective and assessors blinded as to the surgical intervention performed if possible and without any conflict of interest related to the assessment undertaken. (Grade C)

- Subjective success postoperatively should be defined as absence of vaginal bulge (Grade C).

- Functional outcomes are best reported using valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments (Grade C).

- Sexual function is best reported utilising validated condition specific HRQOL that assess sexual function or validated sexual function questionnaires such as the Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ) or the Female Sexual Function Index (FSFI). The sexual activity status of all study participants should be reported pre and post-operatively under the following categories: sexually active without pain, sexually active with pain or not sexually active (Grade C).

- Prolapse surgery should be defined as primary surgery, and repeat surgery subclassified as primary surgery different site, repeat surgery, complications related to surgery and surgery for non-prolapse related conditions (Grade C).

### IV. ANTERIOR COMPARTMENT SURGERY

Ahlfelt stated in 1909 that the only remaining problem in plastic gynaecology was the permanent cure of cystocele and now more than a century later this problem persists [White GR 1909]. Following high reported objective failure rates and reoperation rates after native tissue repairs and the success of mesh tapes in continence surgery and mesh utilised abdominally at sacral colpopexy the last decade has seen an unprecedented introduction of biological and permanent meshes in the management of anterior compartment prolapse.

1. NATIVE TISSUE REPAIRS

Historically anterior colporrhaphy was the standard procedure in the management of anterior compartment prolapse with objective success rates ranging from 80-100% in retrospective series [White 1978; Stanton 1982; Walter 1982; Porges RF 1994]. White [White GR 1912] as early as 1912 demonstrated the importance of paravaginal defects in anterior compartment prolapse. Richardson [Richardson AC 1976] in 1976 described a series of defects in the pubocervical fascia explaining why no single repair should be applied indiscriminately to all with anterior compartment defects. He also advocated the abdominal paravaginal repair which has a 75-97% success rate for cystoceles reported in case series (Table 2) [Richardson AC 1976; Richardson 1981; Shull 1989; Scotti 1998; Bruce 1999]. The surgical technique of the laparoscopic paravaginal repair is well described however little information is available on the efficacy of this approach. Shull [Shull 1994] also reported on the safety and efficacy of the vaginal paravaginal repair in 1994. Although the success rates of the vaginal paravaginal repair for cystoceles in case series vary from 67-100% [White GR 1912; Shull 1994; Grody M; 1995; Elkins T 2000; Mallipeddi 2001; Young 2001] significant complications have been reported recently. Mallipeddi [Mallipeddi 2001] reported on complications in a series of 45 including: 1 bilateral ureteric obstruction, 1 retro-pubic hematoma requiring surgery, 2 vaginal abscesses; 2 transfusions. In a series of 100 women Young [Young 2001] reported a 21 major complications and a 16% transfusion rate.

No randomised control studies have evaluated the abdominal or vaginal paravaginal repair in isolation. Benson et al [Benson 1996] and Maher et al [Maher 2004] have reported RCT's on upper vaginal prolapse comparing abdominal sacral colpopexy and vaginal sacrospinous colpopexy. Abdominal paravaginal repair was performed in the abdominal group if required and an anterior colporrhaphy without or without vaginal paravaginal laterally. Both authors reported the abdominal group to have a statistically lower rate of postoperative anterior vaginal prolapse than the vaginal group.

Raz et al [Raz 1989] popularised the needle suspension type procedure for cystoceles and reported success rates in case series may vary from 90-98% [Gardy 1991; Raz 1991; Benizri 1996]. The addition of polyglactin mesh to the repair appears to have little impact on the success [Safir M 1999] [160]. Dmochowski et al [Dmochowski 1997] reported a lower success rate using a stricter outcome definition of success.

Goldberg et al [Goldberg 2001] reported results from a case control study of women with cystocele and stress urinary incontinence. He suggested that the addition of the pubovaginal sling to the anterior colporrhaphy significantly reduced the recurrence rate of cystocele from 42% in the control group to 19% in the anterior colporrhaphy and sling group [P<0.05].
In line with our surgical colleagues there has been a move towards the use of prosthesis to augment native tissue repair in reconstructive Gynecology. This movement took much of its impetus from two early papers. Firstly, Olsen et al [Olsen 1997] reported a reoperation of 29% following prolapse and or continence surgery and Weber [Weber 2001] reported a 70% failure rate of native tissue anterior compartment repair. Recent re-evaluation of the Olsen’s same demographic 10 years later revealed a significantly lower re-operation rate of 17% [Denman M 2008] and the reader should be cautious in making conclusions even from this data as the surgical interventions performed in 1995 are not representative of interventions performed today. More importantly, Weber et al [Weber 2001] and Sand et al [Sand 2001] in randomised control trials reported the anterior colporrhaphy

</table>
porrhaphy to be successful in the management of cystocele in only 30% and 57% respectively. Recent re-analysis of data from Weber’s paper using the hymen as the threshold for objective success reported considerably better outcomes with only 10% of subjects developing anatomic recurrence beyond the hymen, 5% of subjects developing symptomatic recurrence and re-operations less than 1% at 23 months follow-up [Chmielewski 2011].

During the decade between these initial and subsequent publications surgeons have introduced a plethora of biological and mesh grafts to improve the outcomes of anterior compartment prolapse surgery.

2. SYNTHETIC GRAFTS IN ANTERIOR COMPARTMENT SURGERY

As seen in Table 3 as early as 1996 Julian et al [Julian 1996] demonstrated in a prospective case control study that in women who had undergone at least 2 previous vaginal repairs, the overlaying of a Marlex (Bard) mesh to the anterior colporrhaphy reduced the recurrence rate of cystocele from 33% to 0%. The Marlex mesh was associated with a mesh erosion rate of 25%. Flood et al [Flood 1998] in a retrospective review of 142 women with Marlex mesh augmentation of anterior colporrhaphy demonstrated a 100% success rate for cystoceles at 3.2 years and a mesh erosion rate of only 2%.

Absorbable meshes are an attractive option as an augmenting material as they offered the increased strength during the early healing phase without the augmenting material as they offered the increased strength during the early healing phase without the augmenting material as they offered the increased strength during the early healing phase without the augmenting material as they offered the increased strength during the early healing phase without the augmenting material as they offered the increased strength during the early healing phase without the augmenting material as they offered the increased

overlay in the anterior compartment has been reported. Cervigni reported on 218 women and found a 76% objective success rate at three years. Mesh erosions were identified in 12.3% and vaginal stenosis in 7.7% [Cervigni 2007]. De Tayrac reported on 55 women at 3-year review with a 89% success rate, 9.1% mesh erosions, 5.5% mesh shrinkage and 16.7% dyspareunia [de Tayrac 2006]. He concluded that lower weight and coated meshes were required to limit the rate of complications and duly reported on 132 women, 12 months following low weight coated polypropylene mesh with a 92% success rate [de Tayrac 2007]. Unfortunately local problems remained with mesh erosions in 6.3% and de novo dyspareunia in 12.8%. Rane et al provided a 5 year review of 376 consecutive women with grade 3 anterior compartment prolapse after Perigee (AMS) and reported a 94% success rate, 11.1% mesh extrusion rate and deteriorating sexual function in 4% [Rane 2011].

Carey et al [Carey 2009] performed an RCT comparing anterior and posterior fascial plication and repair with self styled anterior and posterior polypropylene Gynemesh (Ethicon) overlay and reported no significant advantage to adding a mesh overlay at one year. The morbidity in the mesh group was lower than that reported above with a mesh erosion rate of 6.5% and no difference in dyspareunia and denovo dyspareunia rates between the groups.

Five randomised control trials have been published comparing armed or trans-obturator polypropylene mesh and traditional anterior colporrhaphy (Table 3). Nieminen et al [Nieminen 2010] compared 104 women undergoing anterior compartment prolapse repair with self-styled 6x11cm low weight monofilament 4 armed polypropylene mesh (Parietene light, Sofradim Co, Trevoux, France) with 97 undergoing traditional anterior colporrhaphy. Concomitant hysterectomy and posterior compartment prolapse surgery was allowed. At 3 years the objective success (stage 0 or 1 Aa and Ba) rate was 87% in the mesh group and 59% in no mesh group [P<.001]. Awareness of bulge was seen in 18% in the repair group as compared to 10% [p=0.07] in the mesh group. The mesh exposure rate was 19% with 66% requiring surgical correction. The reoperation rate for prolapse was 10% in the native tissue group with all but one of the recurrences in anterior compartment. In the mesh group the prolapse reoperation was 6% with all six recurrences occurring in the posterior or apical compartments.

Sivaslioglu et al reported on 43 undergoing low weight self styled polypropylene mesh as compared to 42 undergoing site-specific vicryl repair and at 12 months found the objective success rate was significantly higher at 91% in the mesh group as compared to 72% in the non-mesh group[Sivaslioglu 2007]. The mesh erosion rate was 6.9% and de novo dyspareunia was reported in 4.6% in the mesh group. Quality of life assessment demonstrated no difference in outcomes between the groups and no patient in either group underwent further surgery for anterior compartment prolapse.

Nguyen compared anterior polypropylene [Perigee, AMS] mesh [n=37] with anterior colporrhaphy [38]. At 1 year the objective success rate was higher in the mesh group (89% vs. 55%). Functional outcomes including quality of life, sexual activity and dyspareunia were similar in both groups with a 5% mesh erosion and 2% unilateral leg pain that settled at 8 weeks following the mesh surgery.Nguyen 2008.

Altman and colleagues reported on behalf of the Nordic transvaginal mesh group a multicentre study (funded by Karalinska Institute and Ethicon unrestricted grants) comparing anterior colporrhaphy [n=182] to anterior transvaginal trocar mesh kit

</table>
(Prolift) [n=186] in women with symptomatic stage II or greater cystocele [Altman 2011]. Although the need for concomitant prolapse and continence surgery were exclusions an undetermined number of women with posterior and apical compartment prolapse well beyond the introitus were included. Reviewers were unblinded, surgeons were reviewers and conflict of interest statements are not available for authors or members of Nordic transvaginal mesh group. At one year, the success rate [composite Point Ba <-1 and absence of vaginal bulging] was significantly greater after the mesh repair 61% as compared to colporrhaphy group 35%. The subjective success rate was also significantly greater after the mesh repair (75% versus 62% p=0.008) as compared to the native tissue repair while no difference was detected on validated pelvic floor questionnaires (Urinary Distress Inventory) between the groups. The Prolift mesh procedure was associated with greater morbidity with a longer operating time, greater blood loss, higher rate of intra-operative cystotomy (3.5 versus 0.5%), post-operative denovo stress urinary incontinence [12.3 versus 6.0%], and combined reoperation rate for USI, prolapse and mesh exposure (6% versus 0.5%). Denovo dyspareunia was seen in 7.3% after the mesh surgery as compared to 2% after anterior colporrhaphy [p=0.07] however no difference was detected between the groups utilising the Pelvic organ Prolapse Urinary Incontinence questionnaire [PISQ-12]. The mesh exposure rate was 11.5% [21/183].

Lastly, Vollebregt and colleagues reported a multicentre randomised control trial from the Netherlands with blinded reviewers comparing anterior colporrhaphy [n=58] with polypropylene trans-obturator mesh kit Avaulta [n=56] [Bard] for stage 2 primary anterior compartment prolapse [Vollebregt 2011]. Concomitant hysterectomy and posterior compartment surgery was allowed with hysterectomies being excluded. At one year the objective success rate was significantly greater in the mesh group as compared to anterior colporrhaphy group (91% versus 41%). Reoperation for anterior compartment prolapse was performed in 5% after the native tissue repair and in no patients in the mesh group [p>0.05]. No difference in awareness of prolapse or outcomes using validated questionnaires (Urogenital Distress Inventory and Incontinence Impact Questionnaire) were identified between the groups. The authors attributed the low mesh exposure rate of 4% to not performing hysterectomy and/or collagen coating on the polypropylene mesh. Resolution of preoperative dyspareunia occurred in 80% in the repair group as compared to 20% in the mesh group. Denovo dyspareunia was reported in 15% following mesh and 9% after native tissue repair and denovo rectocele in 23% versus 10% respectively. The authors concluded that despite the significantly improved anatomical outcome in the mesh arm when using a functional outcome as a definition of success that there was not enough evidence to support the trans-obturator mesh in primary anterior compartment prolapse surgery.

The 2012 Cochrane meta-analysis of these RCT found that transobturator meshes had a lower rate of recurrence on examination [59/424, 14%] as compared to anterior colporrhaphy alone [200/410, 49%] RR 3.50, 95% CI 2.71 to 4.52. This finding was consistent for both the self styled [Nieminen 2010; Sivaslioglu 2008] [RR 3.41, 95% CI 2.04 to 5.67] and commercial transobturator polypropylene mesh kits [Altman 2011; Nguyen 2008; Vollebregt 2011] [RR 3.53, 95% CI 2.62 to 4.74]. Three trials demonstrated that anterior colporrhaphy [94/333, 28%] also had a higher subjective failure rate than the anterior transvaginal mesh repair [60/344, 17%] [RR1.62, 95% CI 1.22, 2.14] [Altman 2011; Nieminen, Vollebregt 2008]. Further prolapse surgery was not significantly more common after anterior colporrhaphy 14/459 (3%) as compared to 6/470 (1.3%) after trans-obturator polypropylene mesh [RR 2.18 95% CI 0.93 to 5.10]. No difference was detected in individual studies in validated prolapse specific questions and meta-analysis was not possible due to variations in questionnaires utilised. The operating time and blood loss were significantly greater in the mesh group and there was a tendency towards lower cystotomy rate [0.4% versus 2.7%, RR 0.19 95%CI 0.03,1.07] Altman 2011;Nieminen 2010], denovo dyspareunia [4% versus 8%, RR 0.51 95% CI 0.21 to 1.23] and denovo stress urinary incontinence [7.3% versus 11.4% RR, 0.65 95% CI 0.4 to 1.07,] [Altman 2011, Sivaslioglu 2008; Nieminen 2010] after anterior colporrhaphy. Further continence surgery was performed in 15/368 women following anterior colporrhaphy and 12/380 after polypropylene mesh procedure [RR 1.29, 95% CI 1.22, 2.14] [Altman 2011; Nieminen 2010; Sivaslioglu 2008] [RR 3.41, 95% CI 2.04 to 5.67] and commercial transobturator polypropylene mesh and surgical intervention to correct mesh erosion occurred in 6.3% [34/540].

Withagen in an observational study of 150 women undergoing Polypropylene mesh kit (Prolift) found that after an isolated anterior polypropylene repair there was a 46% incidence of stage 2 prolapse in the untreated compartment [Withagen 2010]. Altman et al, performed no concomitant surgery in the study and no difference in posterior compartment prolapse was identified between the groups or post-operative within the mesh group when evaluating median Point Bp. However, meta-analysis of those studies [Nieminen 2010; Vollebregt 2011] that reported denovo prolapse in the apical or posterior compartment following anterior compartment mesh repair found at a lower rate after the anterior colporrhaphy [14/147, 9.5%] as compared to trans-obturator mesh [26/148 17.7%] [RR 0.49 95% CI 0.24 to 0.97] Both study protocols allowed concomitant posterior compartment
prolapse surgery. Although the reoperation rates for prolapse was similar in Nieminen et al between the 2 groups all the reoperations in AC group were an-
prolapse was similar in Nieminen et al between the posteriors or apical compartment [Nieminen 2010]. This outcome is not surpris-
ing as we have seen previously when the vaginal axis is significantly altered compensatory prolapse can develop in other compartments. Compensatory prolapse is described in the posterior compartment after colposuspension [Ward 2008] or in the anterior compartment after sacrospinous colpopexy [Paraiso 1996; Maher 2001].

In the 8 trials that evaluated 553 patients that under-
went some form of transvaginal mesh in the manage-
ment of anterior compartment prolapse no patient underwent surgical intervention for vaginal pain or dyspareunia. This is in contrast to the Food and Drug Administration (FDA) transvaginal mesh alert were vaginal pain and dyspareunia accounted for 39% of adverse events and was marginally more frequent than mesh erosions at 38% of adverse events reports. While mesh exposures and their management remain well described vaginal pain and dyspareunia associated with anterior transobtu-
rator polypropylene mesh remain poorly character-
ised and will be fully evaluated in the complications and sexual function section of this chapter.

Given the relatively robust anatomic outcomes as-
associated with transobturator mesh many clinicians were surprised that many mesh kit manufactures recently elected to introduce trocarless mesh kits and the majority have little or no data supporting their claims of superiority. Most recently, Moore et al [Moore 2012] described single incision anterior elevate [American Medical Systems, Minnetonka, MN, USA] using a lightweight polypropylene graft (24g/m2) and reported 92% objective success rate at 13 months in 60 patients with anterior and or apical prolapse. No mesh exposures were reported and the authors who reviewed the patients reported a financial relationship with the company manufac-
turing the product being evaluated.

Another new system involves polypropylene mesh [Prosima, Ethicon] overlay with arms extending but not secured to deeper structures. Patients use a Vaginal Support Device that is removed in the outpatient setting 3-4 weeks postoperatively, to splint the mesh while it is being incorporated into the paravaginal tissues. On prospective evaluation performed by surgeons all of whom have declared financial agreements with the manufacturing company, they reported a 77% objective success rate [ <stage 2 POP-Q] at 1 year [Zyczynski 2010] and 69% at 2 years [Sayer 2011] with a mesh exposure rate of 9% in women with Stage 2 anterior and/ or posterior compartment prolapse. Significant fur-
ther prospective comparative trials with blinded in-
dependent reviewers are required for all mesh kits.

3. BIOLOGIC GRAFTS ANTERIOR COMPART-
MENT SURGERY

Alternatively to synthetic prosthetic grafts autolo-
gous material may have a lower risk of host rejec-
tion or infection. Cosson [Cosson 2001] described an autologous 6-8cm long and 4 cm wide vaginal patch suspended from the tendinous arches of the pelvic fascia and tucked under the anterior repair. The success rate [<grade 1 POP] was 93% at a mean follow-up of 16 months.

Allografts from post-mortem tissue banks have been used for many years in orthopaedic surgery and de-
crease the risk associated with harvesting autolo-
gous rectus sheath or fascia lata. Cadaveric fascia lata with or without pubovaginal sling has been utilised to correct anterior compartment prolapse with a success rate varying from 81-100% with ac-
ceptable complication rates[Groutz 2001; Kobashi 2002; Powell 2004; Frederick 2005]. Gandhi et al have reported preliminary results of a randomised control trial comparing anterior colporrhaphy alone and augmented with fascia lata graft for cysto-
celes [Gandhi 2005]. At 1 year they were not able to demonstrate that the addition of the fascial lata graft improved outcomes with the success rate af-
after anterior colporrhaphy alone being 71% as com-
pared to 82% in those augmented with the fascia lata graft [P=0.07]. No complications were reported. Cadaveric dermis has been employed as a graft material in the anterior compartment with success rates varying from 42-84% at 2 years [Chung 2002; Clemons 2003; Behnia-Willison 2007; Ward 2007]. Concerns regarding prion transmission causing infec-
tious diseases [Simonds RJ 1992] or residual antigenicity [Hathaway 2002] that may cause host graft reactions have encouraged the use of porcine or bovine xenografts as detailed in Table 4.

Leboeuf et al retrospectively reviewed 24 women with native tissue four corner defect repair (FDR) and 19 FDR with porcine dermis [Leboeuf L 2004]. At 15 months the success rate was 100% in the FDR group and reduced to 84% if porcine der-
mis overlay was utilised. Wheeler et al reported on 36 women who all underwent high uterosacral vault suspension with anterior repair augmented with porcine dermis and at 17 months found a 50% recurrence rate [Wheeler 2006]. The authors highlighted that despite the high objective failure rate greater that 90% of the women were satis-
fied or somewhat satisfied with the repair and 83% would undergo the surgery again. Handel et al retrospectively compared anterior colporrho-
phy [n=18], porcine dermis [n=56] and polyprop-
elene graft [n=24] in those with cystocele [Handel 2007]. The success rate at 13 months was 94%, 64% and 96% respectively with a 21% rate of vaginal extrusion of the porcine dermis graft. Alternatively to these relatively disappointing
results, a number of groups have reported satisfactory objective results utilising porcine dermis. [Gomelsky 2004] [Simsiman 2006].

Meschia et al in a multicentre randomised clinical trial compared the anterior colporrhaphy [n=103] and anterior colporrhaphy-augmented with 4x7cm piece of porcine dermis [Meschia 2007]. The success rate at 1 year was 93% in the anterior colporrhaphy with porcine graft overlay group as compared to 81% in anterior colporrhaphy alone group [P<0.001] with a 1% rate of graft erosion.

Hviid et al reported a smaller randomised controlled trial comparing polyglactin plication anterior colporrhaphy and porcine dermis graft at one year [Hviid 2010]. The objective failure rate [defined as point Ba ≥-1] was 2/28 in the porcine dermis group as compared to 4/26 in the anterior colporrhaphy and was not significant. Guerette et al compared the anterior colporrhaphy group [n=17]and anterior colporrhaphy with bovine pericardium collagen [n=27] matrix graft reinforcement and reported no difference on objective examination with success rate of 63% after the AC and 77% in the bovine pericardium collagen repair at 2 years(Guerette 2009]. The reoperation rate for prolapse was 37% in AC group and 23% in the bovine pericardium group. Denovo dyspareunia occurred in 5% follow-

Variable definitions of success used.
Feldner et al compared anterior colporrhaphy with 7x10cm small intestine submucosa (SIS) graft in a randomised control trial and demonstrated reduced operating time in AC group (30 min versus 46) as compared to SIS [p=0.02][Feldner 2010]. The objective failure rate of 33% [9/27] was significantly higher after the AC versus 14% [4/29] in the SIS group. The dyspareunia rate was similar in both groups [AC 4/27 versus 5/20 SIS] and no reoperations were reported. Prolapse quality of life assessment [P-QOL] improved postoperatively in both groups with no significant difference between the groups. In another RCT, Natale et al compared polypropylene mesh (Gynemesh) with porcine dermis (Pelvicol). At two years, significantly fewer women had anterior vaginal wall recurrence in the mesh group 28% [27/96] versus to 44% [41/94] of the porcine graft group [RR 0.64, 95% CI 0.43 to 0.96]. Mesh erosion was seen in 6.3% following mesh surgery. Although similar numbers of women reported dyspareunia [10 versus 12], the authors reported superior sexuality outcomes in the porcine graft group as compared to polypropylene mesh [p = 0.03][Natale 2009].

Finally, Menefee et al in a randomised control trial compared three operations, anterior colporrhaphy, vaginal paravaginal repair using porcine dermis graft and vaginal paravaginal with self-styled polypropylene mesh and also reported a higher objective success rate after the polypropylene mesh 86% [25/29] as compared to 52% [12/23] in the porcine dermis arm [Menefee 2011] and 53% [10/19] in the AC arm. The subjective failure rate was not significantly different and was 3.4%,12% and 13% respectively. The graft erosion rate was 1/23 [4.3%] in the porcine dermis group and 4/29 [13.8%] in the mesh group.

The 2012 Cochrane meta-analysis concluded that when anterior colporrhaphy was compared to any biological graft the objective failure rate in anterior compartment was significantly higher in the anterior colporrhaphy group 56/222 [25%] as compared to the biological graft group 31/218 [14%]. Results from 3 trials [Gandhi 2005; Meschia 2007,Guerette 2009] demonstrated no difference in prolapse symptoms when native tissue repair was compared to biological graft repair [RR 1.03 0.61 to 1.75]. Differences in the methodology and the nature of the different biological grafts utilised in five trials [Feldner 2010, Gandhi 2005, Guerette 2009, Hvid 2010, Meschia 2007, Menefee 2011] were considered to be too dissimilar to combine with any other results in a meta-analysis except to highlight that 2 RCT’s [Feldner 2010, Menefee 2011] demonstrated superior objective outcomes following polypropylene mesh as compared to Porcine graft overlay.

While many clinicians believe the primary role of polypropylene mesh may be in complex or high risk prolapse such as recurrent prolapse there is little evidence to support these proposals. Fayyad et al prospectively evaluated 36 women with recurrent anterior compartment prolapse and reported an objective success rate (less than stage 2 anterior compartment prolapse ) of 47% with a mesh exposure rate of 19%[Fayyad 2011].

In a prospective multicentre Dutch RCT trial women who had undergone prior prolapse surgery were randomised between native tissue repairs and tension free Vaginal polypropylene mesh [Withagen 2011]. Allocation concealment was not confirmed and neither patient, surgeon or assessor were blinded. Surgeons performed the reviews and all authors declared a financial relationship with the company manufacturing the commercial mesh product. Unfortunately preoperatively the two groups were significantly different pointing to a systematic failure in the randomization process which discredits the remaining findings of the manuscript.

The reported failure rate in the native tissue group using an unorthodox outcome definition (no prolapse in the treated compartment or reoperation) was 45% AC versus 9% mesh group at 1 year. Utilising the definition any grade 2 prolapse or subsequent prolapse surgery the failure rate was 66% in the conventional surgery group as compared to 49% [p=0.03] in the mesh group. The mesh exposure rate was 16.7% with 6% undergoing surgical intervention. Utilising Patients global impression of Improvement [PGII] and Urogenital Distress Inventory both groups had similar outcomes.

**Conclusion for anterior vaginal compartment repairs:**

The following conclusion can be made regarding surgical interventions for anterior vaginal compartment repairs:

- absorbable mesh augmentation of native tissue repair improves the anatomical outcome as compared to native tissue repair alone with no increased complication rate in meta-analysis of 2 RCTS (Grade B)
- Biological grafts in meta-analysis have improved anatomical outcomes with no change in subjective outcomes as compared to native tissue repairs (Grade B). Conflicting level one evidence supports porcine dermis graft (Meschia, Hvid, Menefee) and single RCT supports small intestine submucosa as graft agent in anterior compartment prolapse surgery (Feldner) (Grade B).
- Consistent level one data supports a superior anatomical outcome for Polypropylene mesh as compared to biological graft (Pelvicol) in the anterior compartment (Feldner, Menefee). Mesh exposure rate was significantly higher in the polypropylene mesh group. (Grade A)
Consistent level 1 evidence demonstrates improved anatomical and subjective outcomes for polypropylene mesh as compared to anterior colporrhaphy (Grade A). These outcomes did not translate into improved functional outcomes using validated questionnaires or a lower reoperation rate for prolapse. The mesh group was also associated with longer operating time, greater blood loss and a non significant tendency towards higher cystotomy, denovo dyspareunia and denovo stress urinary incontinence rate as compared to AC. Apical or posterior compartment prolapse was significantly more common following polypropylene mesh and mesh extrusion rate was 10.4% with 6.3% undergoing surgical correction. (Grade B)

• single Level 3 evidence does not support use of polypropylene mesh for recurrent anterior vaginal wall prolapse (Grade C)

V. UTERINE PRESERVATION DURING POP SURGERY

Traditionally, surgical correction of uterovaginal prolapse includes a hysterectomy despite the fact that the uterus is believed to be a passive structure in the disease process. More recently, women have opted for uterine preservation for a variety of reasons including: desire to maintain future fertility, belief that the uterus affects sexual function or sense of identity, and concern about risks of hysterectomy. While the overall number of hysteropexy studies have increased, most are retrospective or lack a control group. Comparisons between the different hysteropexy procedures are challenging due to the limited numbers of prospective controlled trials measuring a variety of outcomes.

1. PATIENT SELECTION

Careful patient selection is critical prior to considering uterine preserving prolapse surgery. Table 5 list contraindications to uterine preservation. Most studies exclude subjects with menstrual disorders and abnormal uterine or cervical pathology such as large fibroids, endometrial hyperplasia, and cervical dysplasia. A recent study by Frick illustrates the need for hysterectomy in woman with postmenopausal bleeding even with a negative workup because of the high risk [13%] of unanticipated endometrial cancer or hyperplasia [Frick 2010]. Postmenopausal women without bleeding and premenopausal women with regular menses without abnormal uterine bleeding and a negative workup are at low risk for unanticipated pathology.

2. VAGINAL HYSTEROPEXY

The vaginal route can be divided into repairs with and without mesh. The non-mesh repairs include Manchester repair and sacrospinous hysteropexy.

a) The Manchester procedure

The Manchester procedure is one of the oldest prolapse repairs that involves amputation of the cervix and reattachment to the cardinal ligaments. Modified Manchester procedures include plication of the uterosacral ligaments posteriorly and cardinal ligaments anteriorly for improved apical support. Nevertheless, this is primarily a procedure for cervical elongation in premenopausal women that wish to maintain fertility or older women with medical comorbidity. There are high rates of cervical stenosis and menstrual disorders [7-35%] associated with cervical amputation and the use of Sturmdorf sutures [Williams 1966; Tipton 1970; Thomas 1995; Ayhan 2006]. All studies using this technique are retrospective and show relatively good anatomic and symptomatic improvement. One retrospective cohort comparing modified Manchester to total vaginal hysterectomy and uterosacral ligament suspension showed 100% cure of the apical compartment but a 40% success rate based on overall stage in the Manchester group. [DeBoer 2009] Three other retrospective cohorts comparing Manchester to vaginal hysterectomy showed no difference in anatomic or symptomatic outcomes with decreased operating time and blood loss in the Manchester group [Thys ; Thomas 1995; Kalogirou 1996]. Despite good success rates, Kalogirou concluded, “that the Manchester procedure has a limited place in modern gynecology…” Better surgical options exist for pre-menopausal women that wish to preserve fertility including sacrospinous hysteropexy, laparoscopic uterosacral hysteropexy or laparoscopic sacral hysteropexy. For post-menopausal women with medical comorbidity that require a minimally invasive approach, sacrospinous hysteropexy or LeFort colpocleisis would be preferable depending on their desire to preserve vaginal function.

**b) Sacrospinous Hysteropexy**

At sacrospinous hysteropexy the cervix or uterosacral ligaments are transfixed to the sacrospinous ligament using permanent or delayed absorbable suture. In a recent RCT comparing sacrospinous hysteropexy \[n=37\] to vaginal hysterectomy with uterosacral ligament suspension \[n=34\], Dietz et al reported a higher rate of apical recurrences in the hysteropexy group 21% versus 3% hysterectomy group \(p=0.03\).\[Dietz 2010\] Three women had stage 4 uterine prolapse preoperatively that underwent hysteropexy and all developed recurrent uterine prolapse within one year. Subjective outcomes improved for both groups. Hysteropexy was associated with shorter hospitalisation, quicker recovery with more rapid return to work and the total vaginal length was longer 8.8cm versus 7.3cm in hysterectomy group \(p<0.01\). Both groups had high rates of postoperative anterior vaginal wall prolapse \[51% vs. 64%\]. Another RCT unfortunately failed to report objective or subjective outcomes and revealed no difference in sexual function between sacrospinous hysteropexy and vaginal hysterectomy \[Jeng 2005\].

Sexual function domains of the Female Sexual Function Index-7 remained relatively unchanged in the majority of subjects with low rates of dyspareunia \[5%\]. Transient buttock pain occurred in 15% of subjects, similar to sacrospinous ligament fixation. Among the other studies in our review, buttock pain was present in up to 18% of patients and was usually self-limited \[Hefni 2003; Jeng 2005; Hefni 2006; Dietz 2007; Dietz 2008\].

Three cohort studies comparing sacrospinous hysteropexy to vaginal hysterectomy with or without sacrospinous fixation showed no difference in anatomical or symptomatic improvement with the exception of a three-fold increase in overactive bladder and urge incontinence symptoms in the vaginal hysterectomy group \[Maher 2001; Hefni 2003; van Brummen 2003\]. The sacrospinous hysteropexy group had shorter operating time, less blood loss, faster recovery, and fewer complications with similar recurrence and reoperation rates.

Lin and colleagues performed an interesting and unique prospective two-part study \[Lin 2005\]. The first phase identified cervical elongation [relative risk 10.9] and severe prolapse as risk factors for recurrent prolapse after sacrospinous hysteropexy. Among the first 33 patients, cure of uterine prolapse was 93% for those without risk factors compared to 71% for those with at least one risk factor. Next, they excluded patients with severe prolapse and performed a partial trachelectomy for those with cervical elongation resulting in a 96-100% cure rate with no recurrences in the 7 women undergoing partial trachelectomy.

The majority of studies have revealed relatively high success rates for the apical compartment with low complication rates for sacrospinous hysteropexy. Evaluation of available data from Table 6 reveals that:

veals no difference in the mean objective success rate of 87% [373/428] sacrospinous hysteropexy versus 93% [244/262] in the hysterectomy group. While the data on efficacy of sacrospinous hysteropexy are conflicting sacrospinous hysteropexy remains an alternative to vaginal hysterectomy in women who desire future fertility or uterine conservation. However, women with severe advanced prolapse desiring uterine conservation are at high risk of recurrence and should consider alternative approaches for hysteropexy [Lin 2005; Dietz 2010]. Those with cervical elongation should consider partial trachelectomy, which may affect future pregnancy outcomes.

c) Vaginal Mesh Hysteropexy

Several sacrospinous hysteropexy studies show high rates [11-51%] of recurrent anterior vaginal wall prolapse despite performance of a concomitant cystocele repair [Paraiso 1996; Maher 2001; Hefni 2003; Dietz 2007; Dietz 2008; Dietz 2010] and probably secondary to the posterior deflection of the vaginal axis with sacrospinous fixation. Level 1 evidence demonstrates improved anterior vaginal wall anatomical support with the addition of vaginally placed mesh. [Maher 2010] Intuitively, hysteropexy with anterior mesh placement seems ideal to improve anterior vaginal wall support and decrease recurrences in women desiring uterine conservation. Studies involving vaginal mesh repair with uterine conservation frequently include post-hysterectomy subjects and those undergoing concomitant hysterectomy making it difficult to identify outcomes specific to hysteropexy [Feiner 2010]. For the purposes of this section, we excluded anterior vaginal mesh repairs for uterovaginal prolapse that did not require an apical support procedure that would qualify as a hysteropexy.

Collinet et al reported 5-fold increased odds of mesh exposure with concomitant hysterectomy and 6-fold increased odds with an inverted T colpotomy incision [Collinet 2006]. Uterine preservation and minimising the size of the colpotomy were protective. These data support the role of hysteropexy for women with uterovaginal prolapse planning a vaginal mesh repair. However, there are no RCTs or prospective cohort studies comparing vaginal mesh hysteropexy to hysterectomy with prolapse repair. There are 3 retrospective cohort studies confirming the efficacy of vaginal mesh hysteropexy. McDermott et al reported similar high anatomic success, symptomatic improvement and perioperative outcomes with total Prolift hysteropexy and total Prolift colpopexy [McDermott 2011]. The mesh erosion rate was 13% in the hysteropexy group. Chu et al discovered excellent support and high satisfaction when hysteropexy and vaginal hysterectomy were performed in conjunction with Perigee and Apogee, apical arms placed through the sacrospinous ligaments (Chu). The hysteropexy group had shorter operating time, less blood loss, and lower rates of mesh erosions [4% vs. 13%, NS]. Neuman et al reported similar high success and satisfaction for posterior intravaginal slingplasty with hysteropexy and hysterectomy [Neuman 2007]. There was only 1 case of recurrent uterine prolapse despite the fact that cervical amputation was performed in 17% of hysteropexy subjects. Tape erosion rates were similar [11% vs. 14%, NS] and hospitalisation was shorter [1.5 vs. 4.2 days] in the hysteropexy group.

A prospective series of 100 anterior Prolift, sacrospinous hysteropexy and posterior colporrhaphy procedures revealed 75% objective success, 12% uterine recurrences and 11% mesh erosions [Feiner 2010]. Satisfaction was high [94%] because 84% had no prolapse symptoms and all recurrent uterine prolapse were mild, stage 2. Other retrospective and prospective hysteropexy series demonstrate higher cure rates with similar or lower mesh risk [Huang; Nicita 2005; Inoue 2009]. Fatton et al demonstrated a high number of mesh related complications in a multicentre retrospective series of 110 Prolift procedures [Fatton 2007]. There was 1 bladder injury, 5 mesh exposures, 3 granulomas without mesh exposure, 18 cases of mesh shrinkage, and 1 vaginal synchiae. Meta-analysis of the limited available data in Table 7 demonstrates no difference in anatomic success rate of 86% [273/316] in the mesh hysteropexy versus 98% [81/83] in the mesh hysterectomy group [p=0.21]. Nor was there a significant reduction in the mesh exposure rate when mesh repairs were performed with hysteropexy 8.8% versus 13% with hysterectomy [p=0.22]. Newer trocarless kits using lower volume light weight mesh are being promoted for uterine conservation surgery without any supporting data in the peer reviewed literature to date.

3. ABDOMINAL HYSSTEROPEXY

Abdominal hysteropexy has been performed for over a century. Early procedures transected the uterus to the anterior abdominal wall [Swain 1897; Giles 1930]. Other small series have successfully utilised ventral fixation to the pectineal ligaments with or without a graft [Nesbitt 1989; Joshi 1993]. However, abdominal sacral hysteropexy is generally the procedure of choice when performed through an open abdominal incision. Similar procedures can be performed laparoscopically or robotically including sacral hysteropexy and uterosacral ligament suspension. Other laparoscopic options have been described including round ligament suspension [O’Brien 1994] and anterior abdominal wall fixation [Chen 2010]. We present the data for the most common abdominal and laparoscopic techniques.
a) Abdominal Sacral Hysteropexy

Early studies performed in the 1950's either directly sutured the uterus to the anterior longitudinal ligament or used a thin strip of external abdominal oblique fascia tunneled retroperitoneally from the sacral promontory to the posterior cervix for support [Stoesser 1955; Arthure 1957]. More recently, a variety of grafts and techniques have been described. Frequently polypropylene mesh is secured posteriorly to the cervix/vagina or a second graft is passed through windows made in the broad ligament and secured to the anterior cervix/vagina. Addison and Van Lindert published a series of abdominal sacral colpopexy in 1993 containing subsets of women [11 total] undergoing successful abdominal sacral hysteropexy with synthetic mesh [Addison 1993; van Lindert 1993]. Over the past 15 years, there have been multiple small studies evaluating abdominal sacral hysteropexy [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Roovers 2002; Barranger 2003; Roovers 2004; Bai 2005; Costantini 2005; Demirci 2006; Jeon 2008] as listed in Table 8.

Roovers and colleagues performed the only RCT comparing abdominal sacral hysteropexy [n=41] and Burch to vaginal hysterectomy, uterosacral ligament suspension, anterior and posterior colporrhaphy, and needle suspension [n=41] [Roovers 2004]. Anatomic outcomes were similar with high success rates for the apical [95%] and posterior [85-95%] compartments. Anterior recurrences occurred in 61 and 64% of women. Urogenital distress inventory scores improved for all domains with the greatest improvement [92-100%] [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Barranger 2003; Demirci 2006]. In 2 studies, cervical amputation was performed without subsequent problems for 7 women with cervical elongation.

Table 7. Compares vaginal mesh hysteropexy and vaginal mesh hysterectomy outcomes.

There are 2 retrospective cohort studies that each included 3 arms. Jeon et al compared abdominal sacral hysteropexy to abdominal hysterectomy with sacral colpopexy or uterosacral suspension [Jeon 2008]. There were no recurrences in the hysteropexy group. Recurrences were 6.2 times more likely to occur in the uterosacral suspension group compared to the sacral colpopexy group when hysterectomy was performed. Bai et al compared smaller numbers of abdominal sacral hysteropexy to sacral colpopexy with or without hysterectomy [Bai 2005; Jeon 2008]. Success rates were high for all groups [95-100%]. There were 3[16%] mesh erosions in the hysterectomy group that did not require reoperation and no erosions in the other groups. Hysteropexy had shorter operating time and length of hospitalisation. All of the prospective observational trials and retrospective series revealed satisfactory anatomic success [87-100%] and symptomatic improvement [92-100%] [Costantini ; Banu 1997; Costantini 1998; Leron 2001; Barranger 2003; Demirci 2006].

b) Laparoscopic sacral hysteropexy

Laparoscopic sacral hysteropexy techniques are similar to those described with the abdominal sacral hysteropexy with an anatomic success rate

Table 8. Compares vaginal mesh hysteropexy and vaginal mesh hysterectomy outcomes.

Constantini et al reported results of a prospective cohort study comparing abdominal sacral hysteropexy to total abdominal hysterectomy and sacral colpopexy [Costantini 2005]. There were no differences in anatomic success [91% vs. 92%], symptomatic improvement or satisfaction. Three women required vaginal revision due to mesh erosions [8%] in the hysterectomy group. Hysteropexy was associated with shorter operating time, less blood loss, and shorter hospitalisation.

Table 7. Compares vaginal mesh hysteropexy and vaginal mesh hysterectomy outcomes.
of 88-100% with equally high symptomatic improvement and satisfaction. Several of the studies include different combinations of patients including post hysterectomy prolapse undergoing laparoscopic sacral colpopexy, uterine prolapse undergoing both abdominal and vaginal hysterectomy or laparoscopic sacral hysteropexy making it difficult to determine specific results associated with laparoscopic sacral hysteropexy. Table 8 describes the anatomic outcomes of sacral hysteropexy performed laparoscopically or open compared to hysterectomy and sacral colpopexy and demonstrates similar success rates in the two groups 91% [310/339] and 92% [84/91] respectively [p=.17]. The sacral hysteropexy was quicker to perform and also had a lower mesh exposure rate of 1.5% [5/339] versus 8.5% [11/129] versus sacral colpopexy with hysterectomy [p<0.05%].

c) Laparoscopic Uterosacral Hysteropexy

At surgery the plicated uterosacral ligaments are secured to the distal cervix or by plicating the ligaments in the midline with a McCall’s technique. Some add a Moschcowitz culdoplasty at the time of uterosacral suspension. Rosen et al compared laparoscopic uterosacral hysteropexy to total laparoscopic hysterectomy with uterosacral suspension, both groups did reasonably well without noticeable differences in outcomes [Rosen 2008]. When laparoscopic uterosacral hysteropexy was compared to vaginal hysterectomy and colpopexy in 25 age matched pairs, anatomic and symptomatic improvement was slightly better for the laparoscopic group with less blood loss and shorter length of hospitalisation [Diwan 2006]. Other series show similar anatomic and symptomatic success [80-100%] with few complications in women undergoing laparoscopic uterosacral or McCall’s hysteropexy. [Maher 2001; Krause 2006; Medina 2006]. Evaluation of available trials in Table 9 demonstrates a mean objective success rate of 83% [148/176] after laparoscopic uterosacral hysteropexy as compared to 78% [21/27] after laparoscopic hysterectomy and 88% [22/25] after vaginal hysterectomy and uterosacral ligament suspension.

Laparoscopic round ligament suspension was not as successful with all women having a rapid re-

1397
currence of prolapse [O’Brien 1994]. Laparoscopic attachment to the anterior wall with mesh was highly successful in a group of 28 women [Chen 2010]. This technique could potentially increase the risk of posterior compartment recurrences due to vaginal axis deflection anteriorly, similar to a retropubic urehthropexy.

d) Hysterectomy at time of sacral colpopexy

The evidence supporting sacral colpopexy is largely based on post-hysterectomy vault prolapse and it is not clear from the literature whether the excellent outcomes reported in the post- hysterectomy group will be reproduced in the uterine prolapse group. When considering sacral colpopexy for women with uterovaginal prolapse, the literature is relatively sparse. The choice of hysterectomy includes supracervical, abdominal, laparoscopic assisted vaginal and vaginal. Additionally, the mesh can be attached vaginally or laparoscopically following a vaginal hysterectomy. Placement of synthetic mesh over a healing sutured incision plus exposure to vaginal microbes theoretically increases the risk of graft erosion when hysterectomy is performed at the time of sacral colpopexy. While the evidence in the literature is conflicting meta-analysis of all available comparative studies in Table 10 demonstrate that the risk of mesh erosion is approximately 4 times greater if a hysterectomy is performed at the time of sacral colpopexy 8.6% [51/592] as compared to 2.2% [25/1125] without a hysterectomy and 1.7% [1/58] if subtotal hysterectomy is performed. Introducing synthetic mesh transvaginally or laparoscopically after vaginal hysterectomy or through a posterior vaginal excision appears to significantly increase the risk of mesh erosion after sacrocolpopexy[Visco 2001; Tan-Kim 2011].

Therefore, based on the current literature, hysterectomy at time of sacral colpopexy should be selected with caution and patients should be counseled regarding increased risk of mesh exposure. For this reason supracervical hysterectomy and sacral hysteropexy seem to be gaining in popularity however, there is a very significant paucity of data supporting this approach. Clinicians and the patients planning sacral hysteropexy and supracervical hysterectomy should also consider the significant surgical challenge of removing a retained cervix or uterus that is encompassed in mesh.

4. PREGNANCY AND HYSTEROPEXY

For women with uterovaginal prolapse who have not completed their family, conservative management with a pessary should be offered as a first line treatment before surgical hysteropexy. Most believe that definitive surgical management should be deferred until childbearing is completed due to the potential impact of future pregnancy and delivery on pelvic support and surgical repair. In situations where a pessary cannot be fitted properly or for younger patients that refuse conservative therapy for a prolonged period of time, hysteropexy is a reasonable option. There are no documented pregnancies after laparoscopic sacral hysteropexy or vaginal mesh hysteropexy. There were 12 pregnancies after a Manchester procedure with mostly full term vaginal deliveries and only 1 documented recurrence of prolapse. There were 17 pregnan-

LSHP = laparoscopic sacral hysteropexy; LUSLHP = laparoscopic uterosacral ligament hysteropexy; TLH = total laparoscopic hysterectomy; * significant variation in definition success and surgical technique
cies after sacrospinous hysteropexy with half vaginal and half cesarean deliveries at term followed by 2 recurrences. There were a few pregnancies after laparoscopic uterosacral hysteropexy that had mixed routes of delivery at term with 1 recurrence. Giles reported the majority of documented pregnancies that occurred after abdominal wall suture hysteropexy [Giles 1930]. There were 139 pregnancies and 110 full term deliveries that were mostly vaginal [75%] with only 1 recurrence. Ot, other abdominal hysteropexy studies revealed 9 pregnancies with mostly vaginal deliveries and no recurrences.[Stoesser 1955; Joshi 1993; Banu 1997; Barranger 2003]

Despite relatively good outcomes, limited information exists to aid in counseling patients that desire hysteropexy and plan to become pregnant in the future. Unfortunately, we do not know which type of hysteropexy is better for women that desire future pregnancy with respect to fertility, pregnancy and delivery, and postpartum support and durability? We also do not know the true impact of a future pregnancy on long-term success rates and whether a cesarean delivery prevents recurrent prolapse compared to vaginal delivery. Since relatively few women undergo hysteropexy and subsequent pregnancy, it would be difficult to design a feasible study to answer these questions.

**Summary**

In summary a wide variety of surgical options remain for women presenting with uterine prolapse.

- Uterine preservation is a suitable option in women with uterine prolapse without contraindications to uterine preservation. However longterm data is limited and the need for subsequent hysterectomy unknown (Grade C).

- Sacrospinous hysteropexy is as effective as vaginal hysterectomy and repair in retrospective comparative studies and in a meta-analysis with reduced operating time, blood loss and recovery time. However in a single RCT there was a higher recurrence rate associated with sacrospinous hysteropexy as compared to vaginal hysterectomy (Grade D). Severe prolapse increases the risk of recurrent prolapse after sacrospinous hysteropexy.

- In consistent level 2 evidence sacrospinous hysteropexy with mesh augmentation of the anterior compartment was as effective as hysterectomy and mesh augmentation with no significant difference in the rate of mesh exposure between the groups. (Grade B)

- Level one evidence from a single RCT suggests vaginal hysterectomy and uterosacral suspension was superior to sacral hysteropexy based on reoperation rates despite similar anatomic and symptomatic improvement. (Grade C).

Table 10. Describes rate of mesh exposures at sacral colpopexy with and without hysterectomy and with subtotal hysterectomy.
VI. APICAL SUPPORT PROCEDURES

While anterior vaginal prolapse is most common, loss of apical support is usually present in women with prolapse that extends beyond the hymen [Swift 2000; Delancey 2002]. There is growing recognition that adequate support for the vaginal apex is an essential component of a durable surgical repair for women with advanced prolapse [Toozs-Hobson 1998; Shull 1999]. Because of the significant contribution of the apex to anterior vaginal support, the best surgical correction of the anterior and posterior walls may fail unless the apex is adequately supported [Rooney 2006; Hsu 2008]. While recognition of apical defects is one of the biggest challenges in the preoperative evaluation of pelvic support defects, surgical correction of the apex has several good options with relatively high success rates. Apical suspension procedures can broadly be separated into those performed transvaginally and those performed abdominally. Abdominal procedures can be performed via laparotomy or using conventional laparoscopic or robotically assisted-laparoscopic techniques. Although precise estimates are not available, most studies suggest that the abdominal approach is most common with 80-90% of procedures being performed through this route [Olsen 1997; Brown 2002; Boyles 2003; Brubaker 2005]. The individual woman’s surgical history and goals, as well as her individual risks for surgical complications, prolapse recurrence and de novo symptoms affect surgical planning and choice of procedure for apical POP.

1. SACROSPINOUS LIGAMENT SUSPENSION (SSLS)

One of the most popular and widely reported transvaginal procedures for correcting apical prolapse is the SSLS. First described in 1958 [Sederl 1958], this procedure suspends the vaginal apex to the sacrospinous ligament either unilaterally or bilaterally, typically using an extraperitoneal approach. Observational series and clinical trials suggest that while apical recurrence after SSLS is uncommon [2.4% to 19%], recurrence of anterior vaginal prolapse is more problematic [6% to 28.5%] (Table 11). A meta-analysis by Morgan et al found an overall failure rate at any site of 28.8% [95% CI 18.4%-36.3%] with failure of the anterior segment seen in 21.3% [17-3-25.3%], apical segment of 7.2% [95% CI 4.0 – 10.4%] and posterior segment of 6.3% [95% CI 4.2-8.4%]. Whether the relatively high rate of anterior vaginal prolapse recurrence seen with SSLS is due to the posterior deflection of the vaginal axis, as many authors suggest,[Shull 1992; Benson 1996; Paraiso 1996; Colombo 1998] or simply represents a general predilection of anterior support to fail after pelvic reconstructive surgery remains unknown [Weber 2005]. Reoperation rates after SSLS range from 1.3% to 37%, with all but two series reporting rates less than 9% (Table 11).

Information on the functional or QOL outcomes of SSLS is limited. Maher et al demonstrated significant improvements in condition-specific and generic QOL after SSLS, similar to that after abdominal sacrol colpopexy [Maher 2004]. A meta-analysis of randomised and observational studies found a pooled average for failure to provide relief of prolapse symptoms after SSLS of 10.3% [95% CI 4.4-16.2%] [Morgan 2007]. The pooled average for failure to provide patient satisfaction after SSLS in this analysis was 13% [95% CI 7.4%-18.6%] [Morgan 2007]. Although infrequent, serious complications associated with SSLS include buttock pain and sacral/pudendal neurovascular injury. In a review of 22 studies that included 1229 SSLS procedures, 3 patients [0.2%] had life-threatening hemorrhage from sacral or pudendal vascular injury and the overall transfusion rate was 2% [Sze 1997]. Buttock pain occurred in 3% of subjects, the vast majority of which resolved by 6 weeks postoperatively [Sze 1997].

2. UTEROSACRAL LIGAMENT SUSPENSION (USLS)

The USLS was first described by Miller [Miller 1927] in 1927 and later popularised by Shull in the late 1990s. The USLS suspends the vaginal apex to the proximal remnants of the uterosacral ligaments using an intraperitoneal surgical approach. This procedure restores the vagina to its normal axis, avoiding the retroflexion associated with SSLS. The current evidence supporting the use of USLS is limited primarily to uncontrolled retrospective case-series and evaluation of these data confirm a mean objective success rate of 85% [range 48-96%] and mean reoperation rate for prolapse of 5.8% [range 0-12%] (Table 12). A meta-analysis performed by Margulies et al found

* Prospective and Retrospective cohorts with n >50 published since 1985 and SSLS arms of 3 RCTs comparing SSLS to Abdominal sacrocolpopexy (ASC); **POP staging systems, if used, are indicated as ‘grade’ for Baden-walker (Baden 1972) or ‘stage’ for POPQ (Bump 1996); # optimal and satisfactory outcomes combined
pooled rates of anatomic success [POPQ Stage 0-1] of 81.2% [95%CI 67.5-94.5%] for the anterior segment, 98.3% [95% CI 95.7 - 100%] for the apical segment and 87.4% (95% CI, 67.5%-94.5%) for the posterior segment [Margulies 2010]. Postoperative prolapse symptoms were reported in 5 of 11 studies in this review and were relieved in 82-100% of patients. These promising results are balanced by ureteral kinking/injury rate of 1%-11% with this procedure [Margulies 2010]. A review of 700 consecutive vaginal prolapse surgeries found intraoperative ureteral kinking/injury of 5.9% directly attributable to USLS. However, 87% were identified at cystoscopy before the completion of the index surgery and relieved by removing suspension sutures intraoperatively with no long-term consequence to the patient [Gustilo-Ashby 2006]. Only 3 of 355 ULS [0.9%] performed in this series required additional procedures to relieve or correct ureteral obstruction or injury. Margulies et al identified 10 studies including a total of 820 women that reported on perioperative complications of ULS [Margulies 2010]. The ureteral reimplantation rate in this series was only 0.6%. Blood transfusions were reported in 1.3%, cystotomy in 0.1%, and bowel injury in 0.2%. To date, no clinical trials comparing the ULS to sacrocolpopyexy or to SSLS have been published. The Pelvic Floor Disorders Network has an ongoing RCT comparing USLS to SSLS that includes 440 subjects who will be followed for 2 years; results from this trial are expected in 2013. [Barber 2009]

While the USLS is traditionally performed using a intraperitoneal approach, Dwyer and Fatton have described an extraperitoneal variant of the USLS. [Dwyer 2008; Fatton 2009] In their series of 123 consecutive women undergoing an extraperitoneal ULS,

Includes retrospective and prospective cohorts of intraperitoneal transvaginal ULS. *POP staging systems, if used, are indicated as ‘grade’ for Baden-walker(Baden 1972) or ‘stage’ for POPQ. #Includes only subjects who underwent ULS;
93 also received anterior and/or posterior synthetic mesh. The overall anatomic success (POPQ stage 0 – 1) at a mean follow-up of 2 years [range 6 mo – 5 years] was 85.5% with apical success of 95.4%. [Fatton 2009] The reoperation rate for recurrent prolapse was 7%. Ureteral injury occurred in only 1.7%, however the blood transfusion rate was 4.9% and the rate of mesh exposure was 19.3%.

Abdominal and laparoscopic USLS techniques have also been described. Lowenstein et al reported a retrospective review of 107 women who underwent prolapse surgery that included an abdominal USLS [Lowenstein 2009]. In the 75 patients who completed 1 year follow-up, 12% reported recurrent or persistent prolapse symptoms and 7% had an anatomic failure [POPQ Stage 2 or greater]. Complications were relatively few however erosion of the apical sutures [expanded PTFT, Gore-Tex] occurred in 9% at an average time of 56 months [range 3-75 mo] [Lowenstein 2009]. Rardin et al reported a retrospective comparison of 96 patients undergoing vaginal USLS to 22 undergoing a laparoscopic ULS procedure and found no significant differences perioperative morbidity or anatomic or subjective outcomes [Rardin 2009].

3. MAYO/MCCALL’S CULDOPLASTY

Like the USLS, the Mayo/McCall’s culdoplasty uses the proximal uterosacral ligaments to suspend the vaginal apex. The major difference is that with the Mayo/McCall procedure the uterosacral ligaments are plicated in the mid-line to obliterate the posterior cul-de-sac. While commonly performed, data describing the outcomes for this procedure are limited. (Table 13) Colombo and Milani retrospectively compared the outcomes of a modified-McCall’s culdoplasty to the SSLS [n = 62 in each group] [Colombo 1998]. Recurrence after the McCall’s culdoplasty (Baden-Walker Grade >2) was 15% 4 to 9 years after surgery and not significantly different from the SSLS group. Recurrent anterior vaginal prolapse occurred less frequently in the McCall’s group than the SSLS group (6% vs. 21%, p = .04; OR 4.1 [95% CI 1.3 to 14.2] [Colombo 1998]. A large retrospective series of 693 women from the Mayo clinic described an 82% satisfaction rate on subjective follow-up with few complications [Webb 1998]. The rate of subsequent prolapse repair in this population was 5.2%. A retrospective case series of 411 women undergoing Mayo culdoplasty found that a more dorsal “deep” placement of sutures through the uterosacral ligaments reduced the incidence of ureteral obstruction compared to other published series [Aronson 2005].

4. LEVATOR MYORRHAPHY

Francis and Jeffcoate described their retrospective series using levator myorrhaphy in which a wide midline plication of the levator ani muscles is performed to which the vaginal cuff is fixed in 1961.[Frances 1961] A large sponge pack in the rectum is used to avoid overplication and bowel dysfunction. Five of 35 women responding to the questionnaire had transient ureteral complications, one requiring re-operation. Seventeen women were quite satisfied, while six were dissatisfied. Natale et al compared the high levator myorrhaphy to the USLS in a randomised clinical trial of 229 women with Stage 2-4 prolapse. [Natale 2010] All women underwent a hysterectomy and all received placement of polypropylene mesh in the anterior vaginal segment. Anatomic success was not significantly different between groups. The mean total vaginal length was significantly shorter after levator myorrhaphy [7.9 cm vs. 8.9 cm, p = .04]. Urinary, bowel and sexual function did not differ between groups postoperatively. Intraoperative ureteral obstruction was less common in the levator myorrhaphy group [0% vs. 7.9%]; however all cases of ureteral obstruction in the USLS group were corrected intraoperatively with suture removal/replacement with no additional interventions required. [Natale 2010] Other complications including mesh erosion were similar between groups.

5. ILIOCOCCYGEUS FASCIA FIXATION

There are no randomised trials that support the use of this procedure. Several case series have provided

* excludes SSLS group; ** excludes Inmon group
some information. Shull reported that apical support was optimal in 39/42 [83%] of patients, but eight others had apical or other defects. [Shull 1993] Meeks and colleagues reported a 96% objective cure in 110 women followed up to 13 years. [Meeks 1994] In a retrospective case-control study, Maher and colleagues reported similar subjective [91% v 94%] and objective [53% vs. 67%] cure rates with iliooccygeal fixation [n=50] compared to sacrospinous fixation [n=78]. [Maher 2001].

6. TRANSVAGINAL MESH APICAL PROLAPSE

Two randomised control trials are available that evaluated transvaginal polypropylene meshes in apical prolapse. Sokol et al reported a multicentre double blinded RCT comparing uterosacral colpopexy and native tissue repair [n=33] and monofilament polypropylene mesh kit [Prolift n=32] for stage 2 or greater uterovaginal prolapse or vaginal prolapse [Sokol 2011].

At one year the conventional surgery group had no subsequent surgical interventions as compared to 15.6% in the mesh group [p=0.017] including 3 for prolapse surgery (2x sacral colpopexy and 1 iliooccygeal fixation) and 2 interventions for mesh exposure. The objective failure rate (any stage 2 or greater prolapse) was 70% in the conventional surgery group versus 63% in the mesh group [P>0.05]. The subjective failure rate was also similar in both groups, 9.1% in native tissue repairs versus 3.8% in the mesh group. One patient was transfused and 2 inadvertent cystotomies occurred in the mesh group with no perioperative complications reported in the native tissue group. No differences were seen between the groups utilising a wide variety of validated outcome tools. Unfortunately, due to reaching an ethics committee imposed stopping criterion of 15.6% mesh exposure rate the study did not recruit the appropriate sample size and is underpowered to detect a significant difference between the groups if they exist.

Maher et al recently reported results from a randomised trial comparing LSC [n=53] to a total vaginal mesh kit [TVM] [Prolift, Ethicon Women's Health and Urology] [n=55] [Maher 2011]. LSC was associated with longer operating time (mean difference +52 min [95% CI 41.5-62.6], decreased hospital stay [mean difference -0.5 days [95% CI -.93 to -.10] and quicker return to normal activities (mean difference -5.3 days [95% CI -8.4 to -2.3]. Two years after surgery, objective success [Overall POPQ Stage 0 or 1] was seen in 77% of the LSC group compared with only 43% of the TVM group, p <.001 [Maher 2011]. Also, reoperations were significantly higher in the TVM group [22%] than in the group that received LSC [5%, p = .006].

As seen in Table 14 the success rate of transvaginal meshes for apical prolapse in level 3 evidence

is significantly higher and ranges from 87-100% for monofilament polypropylene meshes with mesh erosion rates varying from 0-15%.

7. SACRAL COLPOPEXY

Since its introduction by Lane in 1962 [Lane 1962], sacrocolpopexy has proven to be an effective and durable technique for correcting apical prolapse. In 2010, approximately 34,000 sacrocolpopexies were performed in the U.S. representing 11% of all prolapse surgeries performed during that time period. Traditionally, sacrocolpopexy has been performed via a laparotomy (i.e. abdominal sacral colpopexy) but the use of laparoscopic and robotic approaches is increasing.

a) Abdominal Sacral Colpopexy (ASC)

Observational studies and clinical trials suggest that ASC is a highly effective procedure for apical prolapse. The success rate of ASC, when defined as lack of apical prolapse, ranges from 78-100% (Table 15). When success is defined as no recurrent prolapse in any segment the published success rates are 56% - 100%. A systematic review of ASC performed by Nygaard et al reported a median reoperation rate for recurrent prolapse of 4.4% [range 0-18.2%] and for postoperative stress incontinence of 4.9% [range 1.2% to 30.9%] [Nygaard 2004]. Clinical trials demonstrate significant improvements in prolapse symptoms, urinary function and quality of life after ASC [Maher 2004; Maher 2004; Brubaker 2008]. There is level 1 evidence that ASC has superior anatomic outcomes when compared to SSLS but this is balanced by longer operating time, longer recovery and higher cost [Maher 2010]. There are no randomised trials comparing ASC to ULS or to transvaginal mesh procedures. Given the prolonged recovery and unique complications associated with laparotomy, many surgeons reserve sacrocolpopexy for patients with apical prolapse thought to be of high risk of failure from a vaginal approach, often considering such factors as age, comorbidities, history of previous prolapse surgery, and vaginal length. [Toozs-Hobson 1998; Shull 1999; Maher 2004; Brubaker 2005; Weber 2005] Unfortunately, there is little published data to allow an evidence-based decision about which patient with POP will be best served by an ASC relative to other techniques.

Some surgeons have attempted to decrease mesh complications of ASC by using biological materials instead of synthetic mesh. However, the current evidence suggests that biologic materials such as porcine dermis and small intestinal submucosa also have inferior anatomic success rates compared with polypropylene mesh with similar rates of graft-related complications [Quiroz 2008; Deprest 2009; Claerhout 2010].

Beyond mesh erosion, reported complications of ASC are generally consistent with other major open pelvic surgeries. The systematic review by Nygaard et al reported that wound complications occurred in 4.6% [range 0.4% to 19.8%], hemorrhage or transfusion in 4.4% [2.2% to 16.9%), cystotomy in 3.1% [0.4% to 15.8%], ureteral injury in 1.0% [0.8% to 1.9%] and bowel injury in 1.6% [0.4% to 2.5%] [Nygaard 2004]. One in 20 women in the CARE trial experienced significant gastrointestinal morbidity after sacrocolpopexy. Of 322 women in the study, 19 had symptoms of possible ileus or small bowel obstruction; of these, 4 had reoperation for small bowel obstruction, 11 were readmitted for medical management, and 4 had a prolonged initial hospitalisation for gastrointestinal symptoms [Whitehead 2007].

b) Abdominal sacral colpopexy (ASC) versus sacrospinous ligament suspension (SSLS)

To date, there are three RCTs that directly compare ASC to SSLS.[Benson 1996; Lo 1998; Maher 2004] The Cochrane review on the surgical management of POP by Maher et al summarises these studies and concludes that these trials provide level 1 evidence that there were no statistically significant differences in objective failure at any site [any pelvic organ prolapse RR 0.77, 95% CI 0.39 to 1.53], subjective failure [RR 0.53, 95% CI 0.25 to 1.09], reoperation for POP [RR 1.46, 95% CI 0.19 to 1.11] or patient satisfaction [RR 0.82, 95% CI 0.32 to 2.06] [Maher 2010]. However, ASC was superior to SSLS for the following outcomes: Prolapse < Stage 2 [RR 0.29, 95% CI 0.09 to 0.97], recurrent vault prolapse [RR 0.23, 95% CI 0.07 to 0.77] post-operative stress urinary incontinence [RR 0.55, 95% CI 0.32 to 0.95] and less post-operative dyspareunia RR 0.39, 95% CI 0.18 to 0.86]. In contrast, ASC was associated with a longer operating time (Weighted Mean Difference [WMD] 21 minutes, 95% CI 12 to 30), longer time to recover [WMD 8.3 days, 95% CI 3.9 to 12.7] and was more expensive [WMD US $1334, 95% CI 1027 to 1641] than SSLS [Maher 2010].

c) Laparoscopic Sacral Colpopexy (LSC)

The laparoscopic approach of sacral colpopexy has been adopted by many surgeons over the last decade as an alternative to ASC with the hopes of

*Prospective and Retrospective cohorts with n > 50 published since 1985, ASC arms of 3 RCTs comparing ASC to sacrosacral ligament suspension. #POP staging systems, if used, are indicated as ‘grade’ for Baden-walker or ‘stage’ for POPQ

**NS = not stated; SUI = stress urinary incontinence; RPU = retropubic urethropexy; RCT = randomised clinical trial

***Only abstract reviewed (paper not in English)

****Question 5 on the Pelvic Floor Distress Inventory – “Do you usually have a bulge or something falling out that you can see or feel in the vaginal area?”
reproducing the high success rate of the ASC while decreasing the morbidity and delayed recovery associated with laparotomy. Multiple prospective and retrospective case series demonstrate good short to mid-term success rates with mean objective success rate of 90.5% [range 60 -100%, subjective success rates of 79-98%[Higgs 2005; Rivoire 2007; Sarlos 2008] and mean reoperation rate of 5.9% (Table 16). Recently, several prospective studies have been published that demonstrate significant improvements in pelvic symptoms and quality of life after LSC [Sergent; Maher 2011; Paraiso 2011]. To date, no randomised trials have compared LSC to ASC, however three retrospective comparisons have been published [Paraiso 2005; Hsiao 2007; Klauschie 2009]. While results vary somewhat between studies, in general, LSC is associated with shorter hospital stay, less blood loss with conflicting data on operating time. Objective outcomes appear to be similar between the groups. Well designed high quality clinical trials are necessary to establish independently the effectiveness and safety of the LSC relative to ASC.

There is Level 1 evidence that LSC provides superior outcomes to total vaginal mesh procedure for women with symptomatic Stage 2-4 vaginal vault prolapse as described above. There are currently no comparative studies, randomised or not, evaluating the relative safety and efficacy of LSC and native tissue [non-mesh] vaginal POP repair.

A recent retrospective study assessed the complications rates in 402 LSC cases.[Stepanian 2008] This study compared patients who received concurrent laparoscopically-assisted vaginal hysterectomy with those that had previous hysterectomy. They showed no differences in intra- or perioperative complications and similar rates of mesh erosion between the two groups.[Stepanian 2008] Overall the complication rates for this cohort were 0.75% for hematoma, 2.2% for ileus or small bowel obstruction, 1.5% for bladder injury, 0.75% for bowel injury and 0.25% ureteric injury. At 1 year, the overall mesh erosion rate was 1.2%. In contrast, Tan-Kim et al reported on a retrospective series of 188 minimally invasive sacrocolpopexy and found a significantly higher mesh exposure rate in those who received concurrent total vaginal hysterectomy [TVH] [23%] compared with those who were post-hysterectomy (5%) or received a supracervical hysterectomy [5%].[Tan-Kim 2011] TVH was found to be an independent risk factor for mesh erosion on multivariable regression analysis in this study [OR 5.67; 95% CI 2.88-17.10].

Despite the clinical advantages of a laparoscopic approach, adoption of LSC has been relatively limited probably because of the steep learning curve associated with attaining laparoscopic suturing and knot tying skills that are required to attach the mesh to the vagina and sacrum. Claerhout et al evaluated their learning curve in the first 206 cases performed by a single surgeon.[Claerhout 2009] Operating times declined rapidly during the first 30 procedures in this series and reached steady state (175 minutes) after 90 cases. Using a cumulative sum [CUSUM] approach to evaluate operative time and failures (laparotomy, complication or anatomic failures) they found that adequate learning occurred after 60 cases.[Claerhout 2009] Complication rates remained unchanged throughout this series. Aklandios et al found that there was a steady decrease in LSC operative time in a series of the first 48 cases performed but that a turning point was observed after 18-24 cases.[Akladios 2010] Complication rates were also low throughout this series.

**d) Robotic Sacral Colpopexy (RSC)**

Because of the relatively long learning curve required for LSC, many surgeons have turned to robotic-assisted surgery in order to offer patients a minimally invasive approach to sacrocolpopexy. Robotic surgical systems have been developed with the goal of facilitating technically difficult procedures by improving the surgeon’s vision, dexterity and ergonomics. No data has been published on the learning curve for RSC however expert opinion suggests that the learning curve is shorter for RSC compared to the laparoscopic approach.

The currently available data for RSC are relatively limited and consist primarily of uncontrolled cases series, but meta-analysis suggests anatomic outcomes similar to that of ASC and LSC with objective success rates reported at 60-100% [mean 93%], subjective success of 91-94% and mean mesh erosion rate 5%.[Table 17] To date, there are only two

published studies that provide comparative data for the RSC. Geller et al retrospectively compared 73 patients who received RSC to 105 who received ASC [Geller 2008]. RSC was associated with less blood loss, longer operative time, shorter length of stay and a higher incidence of fever [4.1% vs. 0%] Anatomic outcomes 6 weeks after surgery were similar between groups [Geller 2008].

In the only randomised comparison of RSC to date, Paraiso et al recently published a clinical trial that provides level 1 evidence that RSC results in longer operating time and increased pain and cost compared with LSC.[Paraiso 2011] This single-centre, blinded randomised trial compared RSC [n = 40] to LSC [n=38] in women with stage 2-4 post-hysterectomy vaginal prolapse. Total operative time was chosen as the primary outcome for this study serving as a proxy measure for surgical efficiency. Total operative time was significantly longer in the robotic group compared with the laparoscopic group (+67-minute difference; 95% confidence interval [CI] 43-69; P=.001).[Paraiso 2011] Anesthesia time, total time in the operating room, total sacral colpopexy time, and total suturing time were all significantly longer in the robotic group. Participants in the robotic group also had significantly higher pain at rest and with activity during weeks 3 through 5 after surgery and required longer use of nonsteroidal anti-inflammatory drugs (median, 20 compared with 11 days, P<.005). The robotic group incurred greater cost than the laparoscopic group (mean difference +$1,936; 95% CI $417-$3,454; P=.008).[Paraiso 2011] Both groups demonstrated significant improvement in vaginal support and functional outcomes 1 year after surgery with no differences between groups. It is worth noting that the surgeons in this study had considerable experience with LSC.

A meta-analysis of observational studies on robotic gynaecological surgery, found that the currently available evidence shows that for most gynaecological procedures studied robotic surgery achieved a shorter hospital stay and less blood loss than open surgery.[Reza 2010] However, no clinically significant improvements were noted when robotic surgery is compared with conventional laparoscopic surgery in benign gynaecological procedures.[Reza 2010] The current evidence, while limited, suggests that these conclusions are also applicable for RSC (Table 18). RSC probably has a shorter learning curve than LSC and thus may be more generalisable however published evidence for this is currently lacking. In surgeons with advanced laparoscopic skills, RSC offers no clinical benefit when compared to LSC and results in longer operating times, greater cost and greater postoperative pain.

8. OBLITERATIVE PROCEDURES: LEFORT COLPOCLEISIS, TOTAL COLPOCLEISIS

Obliterative surgery, such as total colpocleisis (also called colpectomy/colpocleisis) or the LeFort partial colpocleisis, corrects POP by closing off the vaginal canal either in part or whole.[FitzGerald 2006] Obliterative procedures are less commonly performed in the Europe, Asia, and Australia compared to the United States, and are usually reserved for women who are elderly, medically compromised, and no longer sexually active.[Jelovsek 2007] The purported advantages of oblitterative surgery in this population are decreased operative time, decreased perioperative morbidity, and an extremely low prolapse recurrence risk. The obvious disadvantage is the elimination of the potential for vaginal intercourse. Preoperative counseling is essential when choos-

MD, missing data #Randomised trial, all other studies are retrospective comparisons; *indicates statistically significant result that is superior to the comparator
ing between the oblitative and reconstructive options. A systematic review of colpocleisis published in 2006 noted colpocleisis appears to be nearly 100% effective for correcting pelvic organ prolapse, however until recently little was known about postoperative functional or quality of life outcomes.[FitzGerald 2006] In the last few years a number of reports evaluating symptom improvement and changes in quality of life after colpocleisis have been reported.[Barber 2007; Hullfish 2007; Fitzgerald 2008; Gutman 2009] Overall, these series have found high rates of patient satisfaction and significant functional improvement with low rates of regret for loss of sexual function. [Barber 2007; Hullfish 2007; Fitzgerald 2008] Barber et al reported results from a multicentre study of oblitative surgery using a prospective cohort design with a concurrent control group of age-matched women undergoing vaginal reconstructive surgery.[Barber 2007] Despite permanent alterations in sexual function, significant improvements in bladder, bowel and prolapse symptoms as well as body image were noted after surgery with no differences between those who received colpocleisis and those who underwent reconstructive surgery. Additionally, significant and clinically important improvements were noted in bodily pain, vitality, social functioning, role-emotional, and mental health summary scales of the SF-36.[Barber 2007] Similarly, a retrospective cohort of women over age 65 by Murphy et al comparing women who underwent colpocleisis [n=45] and similar group women who underwent reconstructive surgery with transvaginal mesh (Prolift, Ethicon Women’s Health and Urology) found that improvements in condition-specific quality of life and postoperative patient satisfaction were comparable between the two treatment groups.[Murphy 2008].

The Pelvic Floor Disorders Network has reported on a large series of women undergoing colpocleisis [n=153] with one year follow-up.[Fitzgerald 2008] All pelvic symptom scores and related bother significantly improved at 3 and 12 months, and 125 [95%] patients said they were either ‘very satisfied’ or ‘satisfied’ with the outcome of their surgery.[Fitzgerald 2008] Bother some stress and urge incontinence were present before surgery in 54% and 41% of subjects respectively. Forty percent of subjects received a concurrent midurethral sling at the time of their colpocleisis and the rates of bothersome stress and urge incontinence one year after surgery was 14% and 15% respectively. Similarly, bothersome bowel symptoms were present in 77% of subjects at baseline. One year after surgery, the majority of bothersome bowel symptoms resolved, particularly obstructive and incontinence symptoms, and development of new bowel symptoms was uncommon [0-14%].[Gutman 2009].

While oblitative procedures are predominantly performed in elderly, frail women who often have multiple co-morbidities, the rate of serious adverse events after this procedure appears to be low. In general, major complications due to performance of surgery on the elderly (e.g. cardiac, pulmonary and cerebrovascular complications) occur at a rate of approximately 2%. [FitzGerald 2006] Major complications due to the surgery itself (e.g. pyelonephritis, blood transfusion) occur at a rate of approximately 4%. [FitzGerald 2006] A systematic review of published series of colpocleisis from 1966 to 2004 reported a surgical mortality rate of approximately 1 in 400 cases.[FitzGerald 2006] One complication that appears to be uniquely associated with oblitative surgery is development de novo rectal prolapse after surgery.[von Pechnmann 2003; Collins 2007] Collins et al in a retrospective cohort of 916 women undergoing vaginal POP surgery at one institution and found that the incidence of postoperative full-thickness rectal prolapse in women who were > or = 65 years old who underwent oblitative surgery was 3 of 74 [4.1%; 95% CI, 1.4-11], with an estimated odds ratio of 22 [95% CI, 2.3-196; P < .002] compared with women who were > or = 65 years old who underwent reconstructive surgery.[Collins 2007].

Conclusions Apical prolapse

- Level 1 evidence suggest ASC has a higher success rate as compared to sacrospinous colpopexy with less SUI and post-operative dyspareunia. ASC had greater morbidity including operating time, inpatient stay, slower return to activities of daily living and higher cost. (Grade A)
- ASC has the lowest inpatient cost as compared to LSC and RSC. LSC has lower inpatient cost than RSC (Grade B)
- In single RCT’s the RSC had longer operating time than both ASC and LSC (Grade B). In small trials objective outcomes appear similar although post-operative pain was greater in RSC.
- LSC as effective as ASC with reduced blood loss and admission time. (Grade C). The data relating to operating time are conflicting
- ASC performed with polypropylene mesh has superior outcomes to fascia lata (Level I) and porcine dermis and small intestine submucosa (Level 3) (Grade B)
- In a single RCT, LSC had a superior objective and subjective success rate and lower reoperation rate compared to polypropylene transvaginal mesh for vault prolapse (Grade B).
- Level three evidence suggest vaginal uterosacral ligament suspension, McCall culdoplasty, iliococcygeus fixation and colpocleisis are relatively safe and effective interventions (Grade C)
VII. SURGERY FOR POSTERIOR VAGINAL WALL PROLAPSE

The prevalence of rectocele in women ranges from 12.9-18.6% and the average annual incidence is estimated to be 5.7 cases per 100 women years [Hendrix 2002; Handa 2004]. Approximately 225,000 operations are performed every year in the United States for pelvic organ prolapse and repair of posterior vaginal wall is performed in between 40-85% [Olsen 1997; Boyles 2003; Whiteside 2004].

Terms used to describe the supportive tissue utilised for posterior wall prolapse repair date back to a publication by Jeffcote in 1961 [Francis WJA 1961]. The concept of site-specific repair stems from observations by Richardson who felt that discrete defects in what he termed rectovaginal fascia should be addressed by a directed repair of the defect thus producing a more anatomical repair in his opinion [Richardson 1993]. In recent years there has been a clearer understanding of the anatomy of the posterior vaginal wall and its support however surgical studies in this area continue to utilise terms that are not anatomically based. The goal of this review will be to provide a brief overview regarding current understanding of the anatomy of the support of the posterior vaginal wall, discuss various anatomic defects that can clearly contribute to posterior vaginal wall prolapse, and finally update the previous ICI report by citing the various studies that have reported outcomes for the surgical correction of posterior vaginal wall prolapse.

1. ANATOMY OF THE POSTERIOR VAGINAL WALL

Historically pelvic organ support as it relates to the anterior and posterior vaginal wall compartments has been described in relation to supportive tissues termed endopelvic fascia. In the anterior segment this has been called pubocervicovesical fascia and in the posterior segment this has been called rectovaginal fascia. Histological studies have noted that what has previously been termed fascia is actually vaginal muscularis in both the anterior and posterior segments,[Farrell 2001] With respect to the rectovaginal fascia it is now well appreciated that there is no such layer between the posterior vaginal wall and the anterior wall of the rectum. At the level of the mid vagina histological assessment of the posterior vaginal wall from the lumen of the vagina to the lumen of the rectum notes the following layers; vaginal epithelium, the lamina propria of the vagina, fibro muscular wall of the vagina (smooth muscle cells, elastin, and type II collagen) adventitia, outer muscular wall of the rectum, inner muscular wall of the rectum, lamina propria of the rectum, and rectal mucosa.

Delancey et al performed cross-sections on nulliparous and multiparous cadavers and noted that the support of the posterior compartment was maintained by a complex interaction of connective tissue and levator ani muscle [DeLancey 1999]. He went on to note that the support of the posterior vaginal wall was best divided into 3 separate and distinct levels of support. Level III support being the most distal portion of the vagina is provided by the perineal membrane and the rectovaginal septum. This level of support has strong attachments to the levator ani complex and is thus less susceptible to pelvic pressure transmission that may cause prolapse. Level II or the mid vagina is supported by its attachments of the vaginal muscularis laterally to the fascia of the levator ani muscles. Level I support or the upper vagina is supported by the cardinal-uterosacral ligament complex.

This same group of investigator’s recently discussed posterior vaginal wall anatomy in a review article and likened it to an open container. The front wall of the container would be formed by the posterior vaginal wall while the bottom of the container is made up of the perineal body and anal sphincters. The levator ani muscles form the lateral sides of the container and the levator plate where the muscles decussate behind the rectum to create the iliococcygeal raphe form the back wall of the container. The uppermost portion of the container would be that created by the attachment of the posterior vaginal wall to the uterosacral ligament which extend below the peritoneum All of these boundaries are subject to defects that can give rise to different structural failures.[Lewicky-Gaupp 2009]

2. ANATOMIC DEFECTS THAT MAY CONTRIBUTE TO PROLAPSE OF THE POSTERIOR VAGINAL WALL

The patient who presents with prolapse of the posterior vaginal wall either in isolation or in conjunction with prolapse of other segments of the pelvic floor could potentially have a posterior enterocele, a rectocele, or a sigmoidocele.[Fenner 1996] These 3 conditions can occur in isolation or in conjunction with each other and will commonly be accompanied by a perineal defect and or a widened genital hiatus.

While it is beyond the scope of this article to discuss clinical and radiographic mechanisms that can be used to differentiate these various defects suffice it to say that they can all result in descent of the posterior vaginal wall in various degrees.

The published literature continues to classify posterior vaginal repairs into what has been termed a “traditional technique” which implies that the repair has been supplemented with a levator ani muscle plication in the midline or a “site specific technique” which implies that discreet defects in the rectovaginal fascia are identified and repaired and no levator plication is performed. To date we are unaware of any studies that have addressed how often a posterior enterocele and or sigmoidocele coexist with a rectocele and how the presence of these defects impacts on ultimate surgical out-
comes. Based on our current understanding of the anatomy of the posterior vaginal wall and perineum it is clear that the defect specific repairs involve plication of the fibromuscular layer of the posterior vaginal wall and based on the initial level of dissection this tissue may be found on the anterior wall of the rectum or may have to be mobilised off the vaginal epithelium to allow an appropriate tension free plication. In patients with advanced prolapse and a widened genital hiatus the only way to address the gaping vagina is to routinely perform a distal levatorplasty. In the authors opinion future surgical studies assessing outcomes of prolapse repair involving the posterior vaginal wall should take into consideration these points, and realise that these procedures are not mutually exclusive and a combination of the techniques, especially in cases of advanced prolapse is commonly required. Other type of repairs that have been reported include transanal repairs, transperineal mesh (biologic or synthetic) augmented repairs, and abdominal sacral colpopexy in which the mesh attachment is extended down to the distal portion of the posterior vaginal wall and or perineum. The authors have also observed that aggressive reattachment of the uppermost portion of the full thickness of the posterior vaginal wall (level III support) to the uterosacral ligament provides significant support to the posterior vaginal wall in patients with high rectoceles or rectoceles in conjunction with a posterior enterocele.

### 3. MIDLINE PLICATION OR TRADITIONAL POSTERIOR COLPORRAPHY

The mean reported anatomic success rates with this type of repair is 83% (range 76-96%) with mean post-operative dyspareunia rate of 18% (range 5-45%) and 26% using vaginal digitation to defecate. (Table 19)

### 4. SITE SPECIFIC DEFECT REPAIR

This technique is similar to traditional post repair in terms of dissection. The aim of the repair is for the surgeon to indentify and individually correct breaks in the rectovaginal septum. Tradition levatorplasty is avoided. The mean anatomic success rate is 83% (range 56-100%) with 18% postoperatively needing vaginal digitation to defecate and 18% experiencing post-operative dyspareunia (Table 20).

Abramov et al retrospectively compared the midline fascial plication and discrete site specific repair for rectoceles [Abramov 2005]. They noted a significantly higher recurrence rate of rectoceles following the discrete site-specific repair (32%) as compared to 13% following the midline fascial plication [P=0.015]. The correction of the rectovaginal fascia defect that allows entrapment of feces on straining in significant rectoceles maybe to large to be repaired with the discrete approach [Kenton 1999] and appears to be corrected by the more robust midline fascial plication.

</table>
In a randomised control trial Paraiso et al. compared three techniques for rectocele repair in a prospective randomized trial [Paraiso 2006]. Patients were randomized to receive either a traditional repair [N=37], a site specific repair [N=37] or a site-specific repair augmented with porcine small intestine mucosa [N=32]. All patients preoperatively had Stage II or greater posterior vaginal wall prolapse. The objective anatomic failure rate was highest in the graft augmented group [12 to 26] at 1 year which was statistically significantly worse then results in the site specific group [6 of 27] and traditional repair [4 of 28]. There was no significant difference in subjective symptoms (worsening prolapse or colorectal symptoms) or dyspareunia between the three groups.

Recently Sung et al reported on a double blind multicentre randomised control trial comparing native tissue repair [70] or native tissue porcine submucosal (SIS) graft [67] for symptomatic grade 2 rectocele [Sung 2012]. The native tissue repair involved either a midline plication or site specific repair with majority undergoing site-specific repair. In the graft group this repair was augmented with porcine SIS overlay. At one year there was no difference between the groups in objective and subjective success rates or in resolution of defecatory symptoms. Post operative dyspareunia rates were not significantly different at 7% in the native tissue group and 12.5% graft group.

In a single trial Vijaya (Abstract #52, ISC 2011 Glasgow) reported at 6 months follow up superior support of the posterior vaginal wall was attained after the fascial plication as compared to levator ani repair. Block randomisation was performed with 26 women randomised to each operation. Allocation concealment, power analysis, and status of reviewers was not reported. Anatomic outcomes were reported via POP-Q point AP and a variety of quality of life assessments were performed without reporting the data.

### 5. TRANSANAL REPAIR OF RECTOCELE

Three trials have evaluated transanal vs transvaginal repairs of rectoceles [Kahn MA 1999; Nieminen 2004; Farid 2010]. Each trial had slightly different inclusion criteria. Kahn included women who had symptoms of prolapse or impaired rectal evacuation with incomplete emptying on isotope defaecography and normal compliance on anorectal manometry [Kahn MA 1999]. Nieminen’s included women with symptomatic rectoceles not responding to conservative therapy. Important women with compromised anal sphincter function and other symptomatic genital prolapse were excluded. In both trials the vaginal repair was performed by gynaecologists and the transanal repair by colorectal surgeons. In Kahn’s trial the posterior vaginal wall repair was performed using levator plication and in Nieminen’s trial the rectovaginal fascia was plicated. Farid’s inclusion criteria required women to have a rectocele

larger than 2 cm on defaecography with symptoms including digitation, incomplete evacuation, excessive straining and dyspareunia. Women with a compromised anal sphincter complex or recurrent prolapse, rectal prolapse, intussusception, or anismus were excluded. The surgery was performed within the surgery department and blinded examiners utilised defecography, anal manometry, and a modified obstructed defecation syndrome patient questionnaire to report outcomes.

Based on these three trials we can conclude that the results for transvaginal repair of rectocele are superior to transanal repair of rectocele, in terms of subjective and objective outcomes. In women with rectocele alone recurrent rectocele occurred in 2 out of 39 women in the vaginal group and 7 out of 48 following the transanal repair, a difference that did not reach statistical significance. Post-operative enterocoele was however significantly less common following vaginal surgery as compared to the transanal group.

Farid [Farid 2010] reported on outcomes of three types of rectocele repair comparing transperineal repair to levatorplasty to transanal repair and noted conclusions similar to the two previously discussed trials. The size of the rectocele on defecography was significantly smaller in the transperineal group (with or without levatorplasty) as compared to the transanal repair. Also functional outcome based on a modified obstruction defecation syndrome patient questionnaire was better after transperineal repair compared to transanal repair.

Puigdollers et al reported results from a prospective cohort of women with rectocele and constipation who underwent surgery via either endorectal or a transperineal approach based on surgeon preference[Puigdollers 2007]. At the end of one year the overall subjective improvement in constipation was reported in 43% [p<0.001] and the need to splint decreased in 52% [p=0.001].

Thornton et al [Thornton 2005] reported in a single non-randomised study outcomes for a cohort of women with symptomatic rectocele who were treated laparoscopically [N=40] vs transanally [N=40]. Level 2B evidence from this study supports the superiority of the transanal approach for symptom relief (55% vs 28%, p<0.02) but lower post-operative dyspareunia rates (22% vs 36%) with the laparoscopic approach.

van Dam et al [van Dam 2000] performed a combined transvaginal and transanal repair in 89 women who were evaluated at a follow up of 52 months. The anatomic success rate was 71% (defined as no persistent or recurrent rectocele on defaecography at 6 months). However de novo dyspareunia was reported in 41% of women and there was a deterioration of fecal maintenance in 7 patients.

6. GRAFT AUGMENTED RECTOCELE
Sand et al [Sand 2001] compared posterior repair with and without mesh and noted rectocele recurrence appeared equal with and without polyglactin (vicryl) mesh augmentation [7 out of 67 vs 6 out of 65]. Neither Paraiso et al or Sung et al noted any benefit to augmenting a native tissue repair with a porcine subintestine submucosal graft overlay [Paraiso 2006; Sung 2012]. Mesh exposure was not reported in these trials. Altman et al reported on a prospective evaluation of insertion of a 7x4cm porcine dermis graft at three years and found a 40% recurrence rate on examination and while there was a significant decrease in rectal emptying difficulties as compared to preoperatively less than 50% reported cure of rectal emptying issues [Altman 2006]. There was no change in the rate of anal incontinence or dyspareunia post-intervention.

7. MODIFIED SACROCOLPOPEXY
The abdominal route has been employed in the correction of posterior vaginal wall prolapse when a co-existing apical defect requires surgery. The technique is a modification of sacrocolpopexy with extension of the posterior mesh down to the distal posterior vaginal wall and or the perineal body. The procedure has been reported completely abdominally or as a combined abdominal and vaginal approach. Table 21 summarises a series of studies that have reported on extended posterior fixation of sacrocolpopexy mesh.

Summary

- Transvaginal Repair of Posterior Vaginal Wall prolapse continues to be reported as either a traditional repair with levatorplasty, midline fascial plication without levatorplasty or site-specific repair. Level one and two evidence suggest midline plication posterior repair without levatorplasty has superior objective outcomes as compared to site-specific posterior repair. (Grade B)

- Higher dyspareunia rate reported when levatorplasty is employed. (Grade C)

- Transvaginal approach is superior to the transanal approach for repair of posterior wall prolapse (Level 1 Grade A)

- To date no study has shown any benefit to mesh overlay or augmentation of a suture repair for posterior vaginal wall prolapse. (Grade B)

- While modified abdominal sacrocolpopexy results have been reported, data on how these results would compare to traditional transvaginal repair of posterior vaginal wall prolapse is lacking.
In women with stage II POP about 55% have concurrent stress urinary incontinence (SUI). This prevalence decreases with increasing POP stages to 33% in women with stage IV POP [Sleker-ten Hove 2009]. However, if the prolapse is reduced digitally or with the help of a pessary, sponge holder or speculum, SUI might be demonstrated in a further 10% to 80%. [Haessler 2005; Reena 2007; Sinha 2007; Ellstrom Engh 2010] This type of SUI is termed occult, masked or latent SUI and is present when stress urinary incontinence is only demonstrable with the prolapse reduced in otherwise continent women. The importance of this finding remains ambiguous [Visco 2008]: the test itself is not optimal [Visco 2008] as it does not necessarily mimic prolapse surgery and may obstruct or put undue tension on the urethra. Although different techniques to reduce the prolapse have been described, a gold-standard has not been established. [Visco 2008; Ellstrom Engh 2010] Neither the speculum nor the pessary test to reduce the prolapse had acceptable positive predictive values to identify women in need of a concomitant continence procedure. The negative predictive values however were 92.5% [95%CI 90.3–1.00] and 91.1% [95%CI 88.5–99.7], respectively. Therefore, women with negative tests for occult SUI preoperatively are at low risk of developing SUI postoperatively. [Ellstrom Engh 2010; Chughtai 2011] Women with occult SUI are at risk of developing SUI after POP repair. Reducing the prolapse may also restore normal voiding function during urodynamics. [Romanzi 1999] These findings demonstrates the importance of testing bladder function in continent women with and without the prolapse reduced.

The Cochrane review on surgical management of POP found that new or denovo SUI symptoms were reported by 187 of 1280 women (15%) after prolapse surgery. [Maher 2010] The term de novo stress urinary incontinence is used to describe stress incontinence that develops following surgical correction of the prolapse, amongst women who were continent prior to surgery. De novo SUI might develop because POP surgery has unkinked the previously obstructed urethra. [Kenton 2005; Mueller 2007] De novo stress urinary incontinence is clearly disappointing to women and this outcome measure is considered in this review.

A third of women with stage II or more POP experience difficulties emptying the bladder. [Sleker-ten Hove 2009] Voiding difficulties might disappear postoperatively because the obstruction caused by the prolapse has been corrected. [Romanzi 1999] In contrast, they might develop because of kinking of the urethra due the surgical technique.

This section of the chapter assesses the effect of POP surgery on bladder function including stress urinary incontinence, overactive bladder and voiding dysfunction. In order to optimally evaluate pre and postoperative bladder symptoms, only studies with standardised or validated pre and postoperative outcome measures, more than 20 operated women and a follow up time of at least 12 months are included and summarised in Table 22. The follow up time of 12 months does not apply to studies assessing voiding dysfunction. We will evaluate the evidence surrounding common clinical scenarios.

### 1. CONTINENT WOMEN UNDERGOING POP SURGERY. WHAT IS THE RISK OF DE NOVO SUI AND IS CONTINENCE SURGERY REQUIRED?

For symptomatically and clinically dry women an anterior native tissue repair yields lower rates of de novo SUI than transobturator anterior mesh procedures. The overall cumulative de novo SUI rate after anterior repairs is 9% [44/481]. In five RCT’s [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011] de novo SUI was found in 31/377 (8%) women and in 13/104 (12%) women in two prospective studies [Hung 2004; Ellstrom Engh 2010]. After armed-mesh repairs the overall cumulative rate is significantly higher at 14% [134/951; p=0.017; chi-square] with a rate of 17% [101/584] in six RCT’s [Hiltunen 2007; Sivaslioglu 2008; Halaska 2010; Altman 2011; Sokol 2011; Withagen 2011] and 9% [33/367] in eight prospective trials [Sentilhes 2007; Ek 2010; Fayyad 2010; Feiner 2010; Sergent 2010; Takahashi 2010; Kuribayashi 2011; Liang 2011].

Five RCT’s directly compared anterior colporrhaphy and transobturator mesh procedures [mesh kits or self-fashioned] and reported 12-months results [Hiltunen 2007; Sivaslioglu 2008; Altman 2011; Sokol 2011; Withagen 2011]. Anterior native tissue repair significantly reduced the risk of de novo SUI (RR...
Although all these trials employed quality of life and symptom questionnaires, different instruments were used and meta-analysis was not able to be performed.

In a longer term follow up of Hiltunen’s trial [Hiltunen 2007], subsequently more women developed new SUI after anterior repair resulting in similar SUI rates after three years of 17% after both anterior repair [15/86] and transobturator mesh procedure [15/84]. [Nieminen 2010].

Similar rates of de novo SUI occurred if the anterior compartment prolapse was repaired using a polypropylene transobturator mesh 2% [2/96] or a porcine dermis graft 1% [1/94]. [Natale 2009]. In a single RCT de novo SUI was significantly more common after sacrospinous fixation and vaginal repairs compared with abdominal sacrolcopexy [8/24, 33% versus 2/22, 9% in a single RCT] [Maher 2004], however, these data need to be reviewed cautiously as in the sacrocolpopexy group continent women pre-operatively received paravaginal repairs which may be effective in limiting de novo SUI postoperatively.

In the large multicentre randomised controlled CARE trial (Colpopexy and urinary reduction efforts), preoperatively continent women were randomly allocated to undergo sacral colpopexy with [n=157] or without colposuspension [n=165]. Brubaker et al. demonstrated at 2 years that Burch colposuspension, performed concomitantly with an abdominal sacrocolpopexy significantly reduced the risk of de novo SUI. Subjective SUI was reported by 38/147 (26%) after additional Burch colposuspension and by 63/155 women (41%) after sacrocolpopexy alone. However, objective testing yielded similar findings in the two groups: 11/116 (9%) and 9/134 women (7%), respectively, demonstrated SUI. The study was terminated prematurely because of the high postoperative SUI rate in women who did not receive concomitant Burch colposuspension and as a result of early termination was underpowered. Unfortunately, irregularities in study design create uncertainty for the reader regarding the study findings. Firstly, different and complicated definitions were used to categorise stress continent prior to and after the interventions that made it more difficult to be classified as stress continent post intervention than prior to the intervention. Thirty-nine percent of women classified as stress continent prior to surgery would have been classified as stress incontinent using the post-intervention definition! Secondly, while surgery was standardised for colposuspension neither the paravaginal repair nor sacral colpopexy was standardised with significant variations in use of suture type and graft materials: in 17% biological grafts, in 43% Mersilene, in 39% polypropylene and in 6% Gore-tex was utilised. [Brubaker 2006; Brubaker 2008] which may have impacted on the continent results. After a follow up of 8 years, Costantini et al. in another smaller RCT reported contrary results with 9/31 women (29%) developing SUI after additional Burch colposuspension compared to 5/31 (16%) after sacrocolpopexy alone. [Costantini 2007; Costantini 2010].

Figure 5 summarises these two RCT’s in a meta-analysis. [Brubaker 2008; Costantini 2010] Because of contrary outcomes resulting in significant heterogeneity, a random-effects model was used. According to this model, women do not benefit from Burch colposuspension in addition to abdominal sacral colpopexy. This is true for subjective de novo SUI [RR 0.96 95%CI 0.35, 2.62] and objective rates of de novo SUI [RR 1.56 95%CI 0.82, 2.95].

2. POP SURGERY AND STRESS URINARY INCONTINENT WOMEN

In women with SUI undergoing prolapse surgery, what kind of prolapse procedure and which continence surgery is required concomitantly in order to reduce postoperative SUI rates? The cumulative success rate for SUI after anterior colporrhaphy in two randomised trial arms was 48% [19/40] [Colombo 2000; Hvid 2010]. Colombo et al. [Colombo 2000] compared to Burch colposuspension and anterior repair for the treatment of women with anterior vaginal wall prolapse and SUI. While women benefited more from Burch colposuspension with regards to SUI [cure of SUI 30/35, 86% versus 17/33, 52%], anterior repair better corrected the anterior prolapse [cure of cystocele 23/35 versus 32/33]. [Colombo 2000].

Prospective POP surgery studies employing transobturator mesh without additional continence surgery show a cumulative SUI success rate of 61% [81/132]
[Sentilhes 2007; Sergent 2009; Sergent 2010]. Success rates improve considerably if a suburethral tape is performed concomitantly [cumulative rate 235/237, 99%]. [Hung 2004; Fayyad 2010; Feiner 2010; Takahashi 2010]Persisting or worsening SUI was described in 9/15 (60%) by Fayyad et al.[Fayyad 2010] who prospectively evaluated the role of transobturator polypropylene mesh without any concomitant surgery in the management of recurrent prolapse.

Whether a suburethral tape (TVT) is inserted concomitantly or after three months did not result in significantly different success rates based on an “on-treatment” analysis of Borstad et al. [83/87, 95% versus 47/53, 89% three months later].[Borstad 2010] Twenty-seven/94 (29%) women were cured of SUI after prolapse surgery alone and did not receive a TVT three months later.[Borstad 2010].

Costantini et al. 2008 compared abdominal sacrocolpopexy or sacrohysteropexy with and without concomitant Burch colposuspension in women with POP and SUI.[Costantini 2008] Similarly to their randomised trial in continent women, Burch colposuspension increased the postoperative SUI rate: 13/24 (54%) versus 9/23 (39%) were incontinent.[Costantini 2008].

3. SHOULD WOMEN UNDERGOING POP SURGERY WITH OCCULT SUI IDENTIFIED PREOPERATIVELY UNDERGO CONTINENCE SURGERY AT TIME OF POP SURGERY?

Three randomised trials addressed this issue [Meschia 2004; Schierlitz 2007; Wei 2011] and found that after the addition of TVT to vaginal prolapse repairs (mainly anterior and posterior colporrhaphy) significantly fewer women complained of SUI [21/116, 18% versus 64/125, 51%]. The meta-analysis of these three trials calculated that a concomitant TVT reduced the risk of postoperative SUI significantly [RR 0.54, 95%CI 0.41, 0.72; Figure 6]. In two trials, including women who tested positive for SUI after the POP was reduced (occult SUI) [Meschia 2004; Schierlitz 2007], whereas in Wei et al. study (OPUS trial) only 34% demonstrated occult incontinence. [Wei 2011] However, they reported data separately for women with a positive stress test after reduction of the prolapse: 41/57 women without and 16/54 with an additional TVT were stress incontinent at three months follow up (Figure 6).

In a retrospective trial of 60 women who tested negative for occult SUI on preoperative urodynamic studies, 15 (25%) developed SUI after vaginal mesh surgery.[Kasturi 2011] However, 12% [7/60] had preoperative symptomatic SUI.

4. OVERACTIVE BLADDER (OAB) SYMPTOMS

OAB symptoms may be associated with POP.[Sleikert-ten Hove 2009] Therefore, prolapse surgery may cure or improve OAB but it may also result in new OAB symptoms. The current Cochrane review on the surgical management of POP [Maher 2010; Maher 2011] calculated that new overactive bladder symptoms developed in 103/854 [12%] women in nine trials with various prolapse surgery.[Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Meschia 2004; Brubaker 2006; de Tayrac 2008; Natale 2008; Natale 2009] Whether women have been treated with anticholinergics e.g. postoperatively is not at all clear and numbers might in fact be higher. The cumulative rate of de novo OAB in women who underwent transobturator anterior mesh procedure

![Figure 5. Meta-analysis of two RCT’s looking at the effect of Burch colposuspension in addition to sacrocolpopexy. Presented are subjective rates of de novo SUI](image)

![Figure 6. The addition of a suburethral sling to vaginal prolapse repairs in women without symptomatic SUI](image)
is 7% [39/557], [Sentilhes 2007; Moore 2009; Faye-ad 2010; Feiner 2010; Halaska 2010; Liang 2011] whereas it is 10% [7/71] in the few studies reporting data after anterior repair with or without suburethral tape.[Meschia 2004; Foster 2007] This difference is not statistically significant [p=0.4].

In a new RCT, Halaska et al. reported de novo overactive bladder in 7/97 (7%) after anterior Prolift, in 7/34 (21%) after anterior Prolift and sacrospinous fixation, in 8/84 (9%) after total Polypropylene mesh repair and in 1/98 (1%) after posterior Prolift only. [Halaska 2010] In another RCT, after vaginal sacrospinous fixation 6/29 women complained of OAB whereas after sacrocolpopexy 11/33 developed symptoms. [Maher 2004] Sacrocolpopexy with or without Burch colposuspension resulted in similar rates of de novo OAB [3/34 versus 2/32] [Costantini 2007]. Similarly, after vaginal POP surgery with or without TVT OAB rates were not different [3/25 versus 1/25]. [Meschia 2004].

In 22/48 (46%) of women with several different prolapse operations urgency incontinence resolved, whereas it persisted in 26/48 (54%) and developed de novo in 3 (12%). [Foster 2007].

5. VOIDING PROBLEMS

The Cochrane review noted new voiding dysfunction in 56/476 (12%) women in six randomised trials with various prolapse surgeries with or without continence procedures [Bump 1996; Colombo 1996; Colombo 1997; Maher 2004; Natale 2007; de Tayrac 2008]. However, variation in defining and reporting voiding problems makes meta-analysis is unfeasible.

After anterior repair, voiding dysfunction ranges from 0% to 37%. [Colombo 2000; Meschia 2004; Gandhi 2005; Meschia 2007; Stekkinger 2011; Withagen 2011]

In their RCT Withagen et al. described significantly different temporary urinary retention rates in 5/97 (5%) compared with 15/93 (16%) after transobturator mesh repair [p=0.008]. Normal micturition was restored in all women within 14 days. [Withagen 2011] Anterior repair with or without concomitant vaginal POP surgery resulted in postvoid residuals exceeding 150 ml in 27/126 (21%) in an RCT comparing transurethral and suprapubic catheterisation. [Stekkinger 2011]

After anterior mesh repair, voiding difficulties occur between 5% and 42%. [Maher 2004; Feiner 2010; Steinberg 2010; Withagen 2010; Feiner 2011; Maher 2011; Withagen 2011] One study looked at postoperative urinary retention defined as the need to discharge the patient with an indwelling catheter because of a failed trial of void. [Steinberg 2010] Voiding dysfunction ranged from 34% [10/29] after isolated anterior mesh repair to 42% [30/71] cases after combined anterior and posterior repairs. After isolated posterior repair 8/4(19%) developed urinary retention. At the 3-months follow up, there were no more voiding complaints. [Steinberg 2010]

If there are postoperative voiding problems with residuals exceeding 150 ml, clean intermittent catheterisation is superior to an indwelling catheter for three days with regards to bacteriuria, urinary tract infection and length of required catheterisation according to one RCT [Hakvoort 2011] and intermittent transurethral catheterisation is equivalent to a suprapubic catheter regimen. [Stekkinger 2011] Insertion of a suprapubic catheter however resulted in more related complications including dislodgment or blockage of the catheter and haematuria. [Stekkinger 2011].

Another RCT [Huang 2010] reported on the duration of postoperative urethral catheterisation between two and four days after anterior repair and found no differences in voiding dysfunction. This was confirmed by an RCT comparing two and five days of routine postoperative indwelling catheter placement. Longer hospital stay and more urinary tract infections were associated with the five days protocol. [Weemhoff 2011] Patients do not seem to benefit from postoperative urethral catheterisation beyond two days. [Huang 2010; Weemhoff 2011].

Summary

Assessed trials were considerably heterogeneous regarding inclusion and exclusion criteria, clinical testing for stress urinary incontinence and operations performed. Also, the lack of separate reports of bladder symptoms account for a difficult interpretation of outcomes.

Continent women undergoing anterior compartment POP surgery have a lower rate of de novo SUI after anterior repair than armed mesh procedures. (Grade A)

Data are conflicting on whether colposuspension should be performed prophylactically in continent women undergoing sacral colpopexy. (Grade C)

In continent women undergoing POP surgery with occult SUI the addition of continence surgery reduces the rate of postoperative SUI (Grade A).

In women with POP and SUI prolapse procedures alone (transobturator mesh and anterior repair) are associated with low success rates for SUI. Concomitant continence procedures reduce the risk of postoperative SUI.

No clear conclusion can be made regarding the management of continent women undergoing POP surgery without occult SUI.

Preoperative bladder overactivity may resolve in 40% undergoing POP surgery and de novo bladder overactivity occurs 12%.

No valid conclusions regarding voiding dysfunction following POP surgery can be drawn from the available data.

Level 1 evidence demonstrates there is no need to leave an indwelling catheter beyond two days and a suprapubic catheter yields similar outcomes to clean intermittent self catheterisation however is associated with more complications.

IX. COMPLICATIONS AND METHODS OF PREVENTION

Pelvic reconstructive surgery for genital prolapse, with or without mesh, results in improved prolapse-related symptoms and quality of life improvement in most of the cases [Jia 2008; Iglesia 2010; Maher 2010] (Level 1). While the use of non-absorbable synthetic mesh in the anterior compartment subjectively and objectively decreases the rate of anterior vaginal wall prolapse recurrence in comparison to native tissue repair Cochrane 2012 (Level 1) however, short term improvement of quality of life or reduced reoperation rates have yet to be demonstrated [Jia 2008; Iglesia 2010; Maher 2010; Altman 2011]. Furthermore, the use of non-absorbable synthetic mesh exposes patient to moderate to severe specific complications.

The first objective of this section is to report non-specific and specific complications related to pelvic reconstructive surgery for genital prolapse with mesh, in comparison to surgery with no mesh. The second objective is to describe the recognised methods of prevention of these complications.

1. CLASSIFICATION OF COMPLICATIONS

Recently, the IUGA (International Urogynaecological Association) and the ICS (International Continence Society) have published a specific classification of complications related to pelvic reconstructive surgery [Haylen 2011]. That classification has been developed to be sensitive to all possible physical complications involving the use of a prosthesis or graft in a female pelvic floor surgical procedure. Both insertion complications (e.g. trocar related) and healing abnormalities are covered. Whilst this creates a large number of possible complication scenarios, appropriate organisation has still been possible by category (C), time (T) and site (S). A key advantage of a standardised classification is that all parties involved in female pelvic floor surgery will be referring to the same clinical issue. It is anticipated that in time this classification will significantly add to clarity in reporting mesh related complications.

2. REOPERATION AFTER VAGINAL MESH SURGERY

Table 23 shows the reoperation rates after vaginal mesh surgery for both non-specific (linked to surgical dissection) and specific (linked to the mesh) complications. Only randomised trials have been used for analysis. Although meta-analysis shows a decreased rate of anatomical recurrences after mesh surgery, the total reoperation rate is increased after transvaginal mesh surgery (8.5%) as compared to surgical procedures using native

tissues (3.2%) (Level 1). The rate of reoperation for prolapse is similar in both the transvaginal mesh group and native tissue repair. Altman, 2011 #137) [Maher 2004; Meschia 2007; Nguyen 2008; Sivaslioglu 2008; Natale 2009; Hvidi 2010; Nieminen 2010; Withagen 2011] (Level 1). Denovo apical or posterior compartment prolapse surgery is significantly more frequent after anterior compartment polypropylene mesh (17.7%) as compared to native tissue repair (9.5%) [Nieminen 2010; Vollebregt 2011].

Similarly, a meta-analysis from Diwadkar et al, including prospective or retrospective observational studies with at least 50 patients and a minimum follow-up of 3-months, has shown an increased rate of reoperation after vaginal mesh surgery in comparison to native tissue repair. (8.5% versus 5.7%) [Diwadkar 2009].

In the only randomised trial that has compared vaginal mesh surgery to laparoscopic sacrocolpopexy with a mean follow-up of 2-year Maher et al has also shown a increased rate of reoperation after vaginal mesh surgery (22% versus 5%, p=0.006) [Maher 2004] (Level 2). Nieminen et al demonstrated a 24% [25/104] rate or reoperation after self styled polypropylene anterior compartment mesh at 3 years [Nieminen 2010].

A recent retrospective study on 524 patients who received a Prolift mesh with a median follow-up of 38 months [range, 15-63], has reported a global reoperation rate of 11.6% including postoperative urinary incontinence (6.9%), mesh-related complications (3.6%), and prolapse recurrence (3%) [de Landsheere 2011].

3. REOPERATION AFTER ABDOMINAL SURGERY

Mean rates of reoperation for prolapse recurrence and for de novo stress urinary incontinence after open abdominal sacral colpopexy are 4% and 5%, respectively [Nygaard 2004; Culligan 2005; Elneil 2005; Handa 2007; Meschia 2007; Jeon 2009].

Table 16 demonstrates the total reoperation rate for laparoscopic sacrocolpopexy is 5.9%, with 2.9% representing complications and 1.7% representing reoperations for prolapse. [Agarwala 2007; Maher 2007; Sarlos 2008; Stepanian 2008; Deprest 2009; Granese 2009; Sabbagh 2010; Price 2011; Sergent 2011].

The rate of reoperation for recurrences after laparoscopic sacrocolpopexy is significantly higher with the use of porcine dermis grafts in comparison to polypropylene mesh [Deprest 2009] (Level 3). Tijdink et al [Tijdink 2011] reported on the surgical management of 60 mesh complications following mesh prolapse surgery. Twelve followed sacral colpopexy and 48 vaginal mesh surgeries. Most women reported more than one complication however the principle presentation requiring surgical intervention was pain in 77% (vaginal pain, dyspareunia or other chronic pain buttock, abdomen or thighs). They detected a distinct difference in symptoms related to mesh complications following transvaginal mesh and ASC. Vaginal pain and dyspareunia were the most commonly reported symptoms necessitating surgical intervention following transvaginal mesh and vaginal discharge and bleeding following ASC. Previous mesh excision procedures had been performed in 29% and complete mesh excision was required in 37% of cases. Peri-operative complications occurred more frequently in those requiring complete excision of mesh. Furthermore perioperative complications were more common in those who had undergone ASC as compared to vaginal mesh surgery (23% versus 1% p=0.001). Finally, recurrence of prolapse was significantly more likely if complete excision of the mesh was required and occurred in 29% as compared to 5% after partial excision of mesh. Resolution of preoperative symptoms was reported in 92% who underwent surgical management of mesh complications.

4. VAGINAL MESH EXPOSURE

It is difficult to know the exact rate of vaginal mesh exposure, as the definition of exposure is variable between studies and meshes used are different. Table 24 shows the rate of exposures after vaginal mesh surgeries in the current available randomised controlled trials. In these trials, the mean rate of exposure was 13.1% [Meschia 2007; Nguyen 2008; Sivaslioglu 2008; Natale 2009; Hvidi 2010; Iglesia 2010; Lopes 2010; Nieminen 2010; Altman 2011; Maher 2011; Vollebregt 2011; Withagen 2011] (Level 1).

Abreviations : RCT, randomised controlled trial; L, Level; SBM, sub bladder mesh; PD, porcine dermis ; CF, cadaver fascia ; MD, missing data ; GT, goretex ; PE, polyester ; PP, monofilament polypropylene ; PPM, polypropylene multifilament ; PPPE, polypropylene + polyester ; PPS, monofilament polypropylene-dimethyl siloxane (silicone) ; PTFE, polytetrafluoroethylene.

95% CI for 13.1% [10.4-15.8] for PP and 0.9% [0-2.1] for PD

The mean rate of vaginal mesh exposure after open sacrocolpopexy was 3% [Nygaard 2004; Culligan 2005; Elneil 2005; Wu 2006; Handa 2007; Jeon 2009]. Table 16 shows the rate of exposures after laparoscopic sacrocolpopexy is 2.5% [Cosson 2002; Antiphon 2004; Gadonneix 2004; Maher 2004; Paraiso 2005; Ross 2005; Rozet 2005; Agarwala 2007; Rivoire 2007; Sarlos 2008; Stepanian 2008; Claerhout 2009; Deprest 2009; Granese 2009; Sabbagh 2010; Price 2011; Sergent 2011] [Paraiso](Level 2).
There is no clear definition of bacterial colonisation around a mesh or mesh infection. Consequently, the rate of infection is currently unknown [Jia 2010]. Some studies have reported up to 80% bacterial mesh colonisation [Boulanger 2008; Vollebregt 2009]. However, the rate of relevant clinical infection (abscess, cellulitis, spondylodiscitis) does not seem to be more than 1%, after both sacrocolpopexy (Level 4) [Akl 2009; Donnez 2009; Walid 2009; de Tayrac 2011], or vaginal mesh surgery (Level 4) [Chen 2009; Lewicky-Gaupp 2009].

In a cohort of 684 polypropylene mesh implanted vaginally (TVM procedure), the rates of pelvic abscess and cellulitis have been reported to occur in only 0.29% and 0.15%, respectively [Caquant 2008] (Level 4).

7. PAINFUL MESH CONTRACTION

Feiner et al defined mesh contraction as an adverse outcome following armed polypropylene mesh repair in which patients experience vaginal pain with movement and dyspareunia and on examination have localised areas of prominent, tense and tender mesh under the vaginal epithelium [Feiner 2010]. They reported a case series of 17 painful meshes and in that series, 90% of the patients have been improved by a reoperation for partial mesh removal, however in three patients a second reoperation with wider excision of the mesh was required. The rate of polypropylene mesh-related pain reported ranged between 4 and 11% according to the definition used (Level 3) [Caquant 2008; Nguyen 2008; Sivaslioglu 2008; Lunardelli 2009; Feiner 2010; Iglesia 2010; Lopes 2010; Moore 2010; Nieminen 2010; Vollebregt 2009].

Maher et al have reported a rate of reoperation for mesh contraction significantly greater after vaginal mesh surgery than after laparoscopic sacrocolpopexy (7% vs 0%, p=0.05) [Maher 2004] (Level 2). Ridgeway et al [Ridgeway 2008] reported a cases series of 19 polypropylene mesh complications that underwent a variety of vaginal and abdominal procedures to partially remove mesh. Six underwent excision for severe pain and one had residual pain following partial excision.

In the 2011 American FDA report regarding trans-vaginal mesh, vaginal pain and dyspareunia

95% CI for 13.1% (10.4 - 15.8) for PP and 0.9% (0-2.1) for PD
were the most common adverse event reported and vaginal pain and dyspareunia were also the most common indications for reoperation following transvaginal mesh in the report by Tijdink et al.[Tijdink 2011] These reports contrast with the common perception in the literature that mesh exposure is the commonest complication associated with transvaginal meshes and requires ongoing evaluation.

8. OTHER COMPLICATIONS

Other rare but severe complications have been described after mesh surgery, such as massive haemorrhage after a trans-obturator mesh procedure, major vessel injury during sacrocolpopexy, trocar hernia, bowel obstruction, ureteric complications, thrombo-embolism.

9. METHODS OF PREVENTION

a) Influence of non specific factors on mesh-related complications (obesity, smoking, age, sexual activity)

Concerning vaginal mesh surgery, obesity (BMI>30 kg/m², OR=10.1) and smoking [OR=3.7] are independent risk factors for mesh exposure [Araco 2009] (Level 3). With regard to sacrocolpopexy, smoking [OR=5.2 ; IC95% 1.7-16] is also an independent risk factor for vaginal mesh exposure [Cundiff 2008] (Level 3). Although there is no specific study in prolapse surgery, to demonstrate the cessation of smoking prior to surgery will decrease the post-operative complication rate (healing problems) in many other surgical specialties these data exist (Level 2).

Current data on the impact of aging on mesh complications are conflicting and no conclusion can be drawn. [de Tayrac 2006; Cundiff 2008; Araco 2009; Ganj 2009; Nosti 2009; Kaufman 2011].

Sexual activity has been reported to be a risk factor for vaginal mesh exposure after vaginal mesh surgery [Letouzey 2010 ; Kaufman 2011] (Level 3) however this could simply reflect that those who are sexually active are more likely to identify a mesh exposure than those who are not.

No study has shown that the following are significantly associated with mesh exposure : diabetes mellitus, corticosteroid use, immunosuppressive therapy, previous pelvic irradiation, history of previous mesh exposure, vaginal atrophy. However, many studies have shown in other surgical specialties that poorly controlled diabetes mellitus is a risk factor for post-operative infection.

b) Oestrogen therapy

Although some authors report routine use of local oestrogen therapy for the pre and post-operative course of prolapse surgery in post-menopausal women [Altman 2011], others did not give any details on such prescription, and there is no comparative study. In multivariate analysis, local oestrogen therapy has no protective effect of vaginal erosion, after vaginal mesh surgery [Guillibert 2009] (Level 3), or after sacrocolpopexy [Kohli 1998] (Level 4).

c) Antibiotic prophylaxis

There is not specific study on the use of antibiotic prophylaxis at the time of mesh reconstructive surgery for prolapse. However, most of studies report their use during surgery [Withagen 2011] [Hiltunen 2007; Carey 2009].

There are no data on the need to identify a urinary tract infection in the preoperative course, nor to perform a vaginal bacteriological test or to use antisepsic or antibiotic meshes.

Prolonged post-operative bladder catheterisation increases the risk of lower urinary tract infection. [Liang 2009].

d) Mesh implantation and visceral injury

Although there is no comparative study, most of authors would consider the use of mesh after a rectal injury during dissection as a contraindication to mesh insertion, due to a perceived higher risk of mesh infection and subsequent recto-vaginal fistula [Jacquetin 2010] (Level 4).

In the anterior compartment, a small series of five cases of recognised intra-operative bladder injury (out of 704 Trans-Vaginal Mesh procedures) has shown that mesh surgery was feasible without subsequent complications after appropriate bladder repair [Popovic 2007] (Level 4). These data are limited and further evaluation is required.

e) Surgeon training

Regarding sacral colpopexy, a learning curve has been shown, with a reduction of operative time and laparoconversion over the first 80 procedures [Claerhout 2009] (Level 3). However, the incidence of severe complications does not seem to be related to the learning curve [Claerhout 2009] [Akladios 2010].

The data regarding the impact of the learning curve for transvaginal meshes on the incidence of post-operative complications is conflicting. Some authors have reported that learning has a significant effect on the complication rate [Dwyer 2004] while others did not [Fatton 2007] [Sentilhes 2007] (Level 3).

10. VAGINAL MESH SURGERY

a) Choose the right mesh for vaginal surgery

For vaginal mesh surgery, the use of non-absorbable synthetic meshes was associated with a reduced rate of short-term recurrences in comparison to the use of absorbable biological or synthetic meshes, for both primary and recurrent cases [Jia 2008] [Iglesia 2010] [Mahe 2010] [Altman 2011] [Withagen 2011] [Nieminnen 2010] [Natale 2009] (Level 1). Contrarily, the use of
absorbable biological or synthetic meshes is associated with a lower risk of vaginal mesh exposure and re-operation in comparison to non-absorbable synthetic meshes [Jia 2008] [Natale 2009] (Level 1).

Concerning the type of non-absorbable synthetic mesh, the use of polyester is associated with an increased risk of vaginal exposure in comparison to polypropylene [33.3% vs 8.8%, \( p < 0.03 \)] [Sentilhes 2008] (Level 4). Furthermore, the use of multifilament polypropylene is associated with an increased risk of vaginal exposure than monofilament polypropylene [Sentilhes 2008] [Deffieux 2009] (Level 4), and the use of microporous monofilament polypropylene is associated with an increased risk of vaginal exposure than macroporous monofilament polypropylene [Baessler 2005] [Guillibert 2009] (Level 4). Composite polypropylene/ polyglactin meshes do not seem to reduce the vaginal exposure rate [7.2% vs 6.9%, \( p = 0.4 \)] [Achtari 2005] (Level 4). Finally, lower-weight meshes, titanium or collagen-coated meshed have currently shown a significant reduction rate of vaginal mesh exposure rates [de Tayrac 2007; Deffieux 2007; Milani 2008; Cervigni 2011] [Sergent 2011] (Level 4). However, comparative studies would be necessary to compared new ultra-light-weight or composite to existing meshes.

b) Interest in mesh kits

The rate of intra-operative complications does not seem to be reduced by the use of a mesh kit rather than a self-prepared mesh [Caquant 2008] (Level 4). However, the rate of vaginal mesh exposure was shown to be reduced by the use of the same mesh in a kit format (4.5% versus 11%, \( p = 0.048 \)), in a retrospective study where the same surgeons had the experience of the technique with the self-prepared mesh before to use the kit [Caquant 2008] (Level 4).

Only one small randomised controlled trial has compared commercial transvaginal mesh kits to self styled mesh, however the techniques used where different (the kit only was trans-obturator) [Finamore 2010] (Level 2).

c) Concomitant hysterectomy

Several studies have shown an increased rate or vaginal mesh exposure with concomitant vaginal hysterectomy [Ganj 2009] [Guillibert 2009] [de Tayrac 2007] [Cervigni 2011] [Collinet 2006] [Lowman 2008], while others did not find any differences [Deffieux 2007] [Sentilhes 2008] [Achtari 2005] Table 25. Meta-analysis demonstrates demonstrates that the addition of hysterectomy to a transvaginal mesh surgery significantly (\( p < 0.001 \)) increases the risk of mesh exposure from 7.3% (98% CI 4.1 to 9.6) without hysterectomy as compared to 19.2% [98% CI 15.8 to 22.7] with hysterectomy.

d) Surgical incision

Although some authors recommend avoiding sagittal or inverted T colpotomy and trimming of excessive vaginal epithelium in order to reduce the rate of vaginal mesh exposure [Fatton 2007], this has not been evaluated by other authors.

11. ABDOMINAL SACROCOLPOPEXY

a) Choice of surgical route for sacrocolpopexy

Laparoscopic sacrocolpopexy is as efficient as open abdominal sacrocolpopexy, with a reduced rate of intra-operative bleeding, hospitalisation and wound complications [Paraiso 2005] [Klauschie 2009] [Hsiao 2007] (Level 3).

The risk of vaginal mesh exposure is higher if the mesh is sutured vaginally during sacrocolpopexy [Higgs 2005] [Visco 2001; Tan-Kim 2011] (Level 4).

Although the feasibility of robotic-assisted and single-port sacrocolpopexy have been demonstrated there is currently not enough evidence to determine if these interventions will have an impact on complication rates.[Xylinas 2010; Paraiso 2011].

b) Choose the right mesh for abdominal surgery

In a retrospective comparative study of open abdominal sacrocolpopexy, Quiroz et al have shown that the short-term mesh-related complication rate was significantly higher with polypropylene than with porcine dermis [24/102 vs 12/134, \( p = 0.003 \)] [Quiroz 2008] (Level 3), however the prolapse recurrence rate using porcine dermis was higher [7/93 vs 0/105, \( p = 0.004 \)]. Another study comparing fascia lata and polypropylene meshes with 5-year review, has shown a long-term increased recurrence rate, but

</table>
with no differences in the rate of complication (Tate) (Level 2). Concerning laparoscopic sacrocolpexy, in a prospective comparative non randomised study, Deprest et al have shown that recurrences at the level of anterior and apical compartment occur significantly more often when using a biograft, in comparison to polypropylene [21% vs 3%, p<0.01 and 36% vs 19%, p <0.05, respectively] [Deprest 2009] [Level 3]. Partially absorbable composite meshes (polyglactin + polypropylene) also seems to increase the risk of short-term recurrences [Granese 2009] (Level 4).

The risk of vaginal mesh exposure seems to be higher with the use of polytetrafluoroethylene than with polypropylene meshes at ASC If you are going to abbreviate you must do it throughout or not at all [15% vs 0%, p=0.03] [Jeon 2009] (Level 4) and 19% vs 5% [Cundiff 2008] (Level 2). Similar results were observed with the use of silicon-coated polyester (19% vs 0%, p<0.05) [Govier 2005] (Level 4).

c) Choose the right fixation to the promontory, vaginal wall and levator ani

Most of authors perform a direct fixation to the vaginal wall using absorbable or non-absorbable sutures, and to the promontory using non-absorbable sutures [Agarwala 2007] [Rozet 2005] [Ross 2005] [Gadonneix 2004] [Antiphon 2004]. Fewer authors use staples for the mesh fixation, both to the vaginal wall and to the levator ani muscle [Cheret 2001] [Claerhout 2009], or tackers to the promontory [Maher 2004], with no specific reported complications. Several cases of spondylodiscitis were reported after the use of tackers to the promontory [Cosson 2001] however this complication also occurs if sutures are utilised. [Sergent 2011] [Rivoire 2007] [Ross 2005] [Antiphon 2004]. Whatever the fixation material use for the vaginal wall, the main method to prevent the occurrence of vaginal mesh exposure seems to avoid breaching the vaginal epithelium. [Paraiso 2005] [Cheret 2001] (Level 4).

d) Concomitant hysterectomy

The risk of vaginal mesh exposure is significantly increased in cases of sacrocolpexy associated with concomitant total hysterectomy (8.6%), in comparison to 2.2% in those with previous hysterectomy [Wu 2006] [Stepanian 2008] [Cundiff 2008] [Nosti 2009] [Quiroz 2008] (Level 4), 1.5% at sacral hysterectomy and 1.7% subtotal hysterectomy [Jeon 2009] [Costantini 2005] [Bensinger 2005] (Level 4) (Table 8 and10).

12. PERITONEAL CLOSURE

Most of authors close the peritoneum after a sacrocolpexy, both after open [Culligan 2005] [Wu 2006] [Stepanian 2008] [Maher 2004; Brubaker 2006] or laparoscopic approach [Maher 2011] [Rivoire 2007] [Rozet 2005] [Antiphon 2004].

13. TREATMENT OF VAGINAL MESH EXPOSURE

Vaginal mesh exposure, both after vaginal mesh surgery or sacrocolpexy is usually associated with vaginal discharge, and sometimes pain, dyspareunia, vaginal infection, and rarely abscess or cellulitis [Deffieux 2007] [Costantini 2011] (Level 3). The choice of treatment has to take into account the type of mesh implanted (need to obtain previous surgical records), clinical symptoms, location and size of exposure.

All cases with abscess or cellulitis need a immediate reoperation to withdraw the maximum (if possible) of the foreign material.

In cases of mesh exposure after vaginal mesh surgery, if there is no abscess or cellulitis, medical treatment is usually undertaken using local oestrogens and/or local antiseptic. However, medical treatment efficacy is low at 23.5% as seen Table 26. [Withagen 2011] [Feiner 2010] [Moore 2010] [Achtari 2005] [Cervigni 2011] [Collinet 2006] After failure of medical treatment, a reoperation under local or general anesthesia is generally performed, in order to remove the exposed portion of the mesh and to close the vaginal epithelium.

In cases of mesh exposure after sacrocolpexy, most of authors report a reoperation by the vaginal approach as first line [Wu 2006] [Stepanian 2008] [Claerhout 2009] [Kohli 1998] [Bensinger 2005] [Begley 2005], because of the risk of spondylodiscitis and of the very low success rate of medical treatment (<15%) [Price 2011] [Stepanian 2008] [Cundiff

Abbreviation: PP, polypropylene
When recurrence occurs after vaginal mesh excision, or in case of associated pelvic infection, total mesh removal by laparoscopy or laparotomy has been described [Quiroz 2008] (Level 4).

**Conclusion**

The use of mesh for pelvic reconstructive surgery is associated with a risk of specific complications, whatever the surgical approach and whatever type of mesh (Level 1).

Preoperatively, patients must be informed of these risks and give their consent for the use of a mesh. Patients must also be informed of conservative and alternative surgical techniques.

**PROPOSED RECOMMENDATIONS TO REDUCE THE RATE OF COMPLICATIONS**

**Grade A**

Transvaginal mesh have a higher re-operation rate than native tissue vaginal repairs.(grade A)

**Grade B**

**Concerning Vaginal Surgery:**

- If a synthetic mesh is placed by the vaginal route, it is recommended that a macroporous polypropylene monofilament mesh should be used.
- Polyester mesh is not recommended.

**Concerning Sacral Colpopexy:**

- It is recommended that the mesh should not be introduced or sutured by vaginal route when a sacral colpopexy is performed.
- The use of silicone-coated polyester, porcine dermis, fascia lata, and polytetrafluoroethylene meshes is not recommended.
- It is recommended to avoid total hysterectomy

**Grade C**

**Whatever the Surgical Route:**

- There is no evidence to recommend routine local or systemic oestrogen therapy before or after prolapse surgery using mesh.
- The first cases should be undertaken with the guidance of an experienced surgeon in the relevant technique.

**Concerning Sacrocolpopexy:**

- Laparoscopic approach is recommended for sacral colpopexy
- The use of polyester (without silicone coating) or polypropylene meshes is recommended.

Suture of the meshes to the promontory can be performed using thread/needle or tacker.

Reperitonealisation is recommended to cover the meshes.

**Expert opinion**

**Whatever the Surgical Route:**

- As with any surgery, cessation of smoking preoperatively is recommended.
- It is recommended to comply with the prevention of nosocomial infections.
- Antibiotic prophylaxis is recommended, regardless of the approach.
- It is recommended that pre-operative urinary tract infections are identified and treated.
- It is recommended that the type and commercial name of mesh used in the operative report.

**Concerning Vaginal Surgery:**

- It is recommended that a non-absorbable synthetic mesh should not be inserted into the rectovaginal septum when a rectal injury occurs.
- The placement of a non-absorbable synthetic mesh into the vesicovaginal septum may be considered after a bladder injury has been repaired if the repair is considered to be satisfactory.
- It is possible to perform a hysterectomy in association with the introduction of a non-absorbable synthetic mesh inserted vaginally but this is not recommended routinely.
- It is recommended to minimise the excision of vaginal tissue.
- Currently, there are not sufficient data to recommend the use of a mesh kit rather a self-prepared mesh.

**X. PELVIC ORGAN PROLAPSE AND SEXUAL FUNCTION**

Sexual health is an essential component of a woman’s well-being. Female sexual dysfunction is defined as a sexual desire, sexual arousal, orgasm and/or sexual pain disorder which causes personal distress [Basson 2000]. Up to 64% of sexually active women attending a Urogynecology clinic suffer from female sexual dysfunction [Pauls 2006]. The data on sexual function after prolapse surgery are conflicting although in most cases sexual function will improve or remain the same.

Apart from anatomical outcome, clinicians increasingly understand the importance of functional data after POP surgery. To measure sexual function, validated questionnaires on sexual function...
are necessary. Some validated quality of life and symptom questionnaires are inclusive of sexual function [Baessler 2010] or there are dedicated questionnaires specific to sexual function that provide a discreet and reproducible method for evaluating sexual health. The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire (PISQ) [Rogers 2001] and the Female Sexual Function Index (FSFI) [Rosen 2000] are two questionnaires frequently used.

1. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITHOUT MESH

Overall, sexual function improves after prolapse surgery without mesh [Ghielmetti 2006; Rogers 2006; Komesu 2007]. In two randomized controlled trials, sexual function was measured after sacrospinous hysteropexy and vaginal hysterectomy. No differences were found between the two groups [Jeng 2005; Dietz 2010]. No validated questionnaires were used.

2. SEXUAL FUNCTION AFTER PROLAPSE SURGERY WITH MESH

Increasing data on sexual function after mesh repair are becoming available. Excellent randomised controlled trials on efficacy of mesh prolapse surgery have been published and while most have not utilised validated questionnaires regarding sexual function most do include data on dyspareunia. Data from level 1 studies comparing transvaginal mesh and native tissue repairs are summarised in Table 27. When comparing sexual function in the anterior compartment with or without mesh, no differences in de novo dyspareunia, post-operative dyspareunia or PISQ scores were found [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Nieminen 2010; Altman 2011; Milani 2011; Vollebregt 2011]. Most women improved or remained the same. In one study by Vollebregt [Vollebregt 2011], baseline dyspareunia disappeared more often after anterior colporrhaphy than after mesh implant [80% vs 20%, p=0.018]. Natale et al showed that the use of Porcine dermis graft (Pelvicol), compared to polypropylene mesh (Gynemesh) in the anterior compartment, was associated with an improvement in the PISQ scores [Natale 2009]. Possibly, porcine dermis allows more flexibility to the anterior wall resulting is less pain, however this requires further evaluation.

In the posterior compartment, fewer RCT’s have been performed comparing native tissue repairs to mesh repairs. Paraiso et al compared three techniques (posterior colporrhaphy, site- specific repair and use of porcine small intestine sub mucosa) [Paraiso 2006]. No differences in sexual outcome were found between the groups and PISQ scores improved after surgery in all three groups. Trials which analysed anterior and posterior mesh together also reported no differences in sexual outcome between native tissue and mesh repairs [Iglesia 2010; Milani 2011; Withagen 2011]. Overall, after mesh surgery in the anterior and/or posterior compartment, de novo dyspareunia ranged from 5-28% of women [Nguyen 2008; Sivaslioglu 2008; Carey 2009; Vollebregt 2011; Withagen 2011]. Data on the apical compartment using mesh showed less dyspareunia after abdominal sacral colpopexy as compared to vaginal sacrospinous colpopexy [Benson 1996; Maher 2004; Maher 2010].

Meta-analyses from all RCT comparing transvaginal mesh and native tissue repairs shown in Table 25 demonstrated no difference in the rate of denovo dyspareunia (mesh 10.6% versus 11.8% native tissue),

</tbody>
</table>
post-operative dyspareunia (14.4% versus 12.5%), and PISQ scores (WMD 0.09 95% CI -0.17 to 0.36).

Although data from RCT's is valuable, sexual function was a secondary outcome measurement and most studies are underpowered to detect differences in sexual function. Therefore, reports from Level 3 cohort studies on the use of mesh were evaluated. The rate of de novo dyspareunia after anterior and/or posterior mesh in these cohort studies was comparable to the RCT's mentioned before and varied between 21-43% (Table 28) [Fayyad 2011; Milani 2011]. Milani et al stated that mesh should be abandoned because of high scores on dyspareunia (20% more dyspareunia after anterior mesh and 63% more dyspareunia after posterior Mesh)(Milani 2005).

However, when measuring sexual function with questionnaires, the impact of transvaginal meshes was variable with some demonstrating poorer sexual outcomes [Altman 2009; Su 2009; Wetta 2009][lower PISQ scores] and some improved outcomes or no change following surgery. [Moore ; Sentilhes ; Milani 2011; Sayer 2011]. Altman et all showed lower scores on sexual function one year after mesh surgery (anterior repair and posterior repair), however this was related to behavioral-emotional function and partner related items, not to physical function [Altman 2009]. Pain and dyspareunia before surgery with mesh was a risk factor for pain and dyspareunia after mesh surgery [Withagen 2011]. There is some evidence that light meshes, partly absorbable meshed or non anchored meshes have less negative side effects on sexual function, however comparative studies or RCT's on this subject have not been performed [de Tayrac 2007; Zyczynski 2010; Milani 2011].

Recommendations

**Grade B**

With regard to the anterior compartment, the use of mesh is neither associated with a worsening in sexual function nor with an increase of de novo dyspareunia compared to traditional anterior colporrhaphy.

**Grade D**

There is insufficient information to provide evidence based recommendation on sexual function after vaginal mesh in the posterior compartment.

There is insufficient information to provide evidence based recommendation on sexual function after new light of partially absorbable vaginal meshes.

It is essential to use validated questionnaires measuring sexual function in women before and after prolapse surgery. We also recommend reporting sexual activity and dyspareunia rates pre and post intervention in all patients.

</tbody>
</table>
Vaginal prolapse is an increasingly common problem affecting approximately 3-6% [Bradley 2008; Lawrence 2008] of community dwelling American women and the lifetime risk of surgery for pelvic organ prolapse varies between 6-19%. [Olsen 1997; Smith 2010] The need for pelvic organ prolapse surgery increases with age and it has been conservatively estimated that the surgical workload related to pelvic organ prolapse will increase by 46% over the next 4 decades as our population ages [Wu 2009]. Despite the high prevalence and frequency of surgery for POP, there is a little information on costs of medical care for this condition. A study in the United States (US) estimated that the direct costs of POP surgery were substantial accounting for $1012 million (95% confidence interval $775, 1251 million) for a total of 226,000 in patient surgical procedures during 1997[Subak 2001].

A European study showed that the number (rate) of admissions for POP surgery was 36,854/1000 women in Germany, 36,679/1000 women in France, and 28,959/1000 women in England during the year 2005[Subramanian 2009]. The total costs were €144,236,557, €83,067,825, and €81,030,907 in Germany, France and England respectively which are also considered to be substantial and required more attention in order to decrease the burden on the countries studied.

Traditionally a Gynaecologists have based their decisions on surgical interventions upon the success rate, patient satisfaction, peri-operative morbidity and complications. With rising health care cost and in a setting of finite resources it is now imperative that clinicians include the financial costs of surgical interventions as a vital part of our decision making process. Despite considerable consumable costs there is a scarcity of cost effectiveness data on pelvic organ prolapse surgery.

Hullfish designed a study to compare the relative cost effectiveness of treatment decision alternatives for post-hysterectomy POP[Hullfish 2011]. The authors used a Markov decision analysis model to assess and compare the relative cost effectiveness of expectant management, use of a ring pessary, and Vaginal Reconstructive Surgery (VRS) and open or robotic sacral colpexy for obtaining months of quality adjusted life over 1 year. Laparoscopy for prolapse and vaginal mesh kits were excluded as the authors do not utilise those two procedures at their institution and colpocleisis was excluded as the baseline case desired preservation of coital function. Only two decision alternatives were found to be cost-effective: pessary use and VRS. Pessary use achieved 10.4 quality-adjusted months at a cost of $10,000 per patient. This cost includes all events for patients initially assigned to pessary use including costs for those patients who eventually underwent to surgery within the 12-month time frame. The VRS alternative obtained 11.4 quality-adjusted months, at $15,000 per patient. Each of the other alternatives achieved fewer quality-adjusted months at greater cost.

Abdominal sacral colpexy (ASC), in rudimentary analysis of inpatient cost has been shown to be more expensive than vaginal sacrospinous colpexy for vault prolapse mainly reflecting the longer operating time and inpatient stay for the ASC. Two cost-minimisation studies have evaluated the relative inpatient cost of robotic sacral colpexy (RSC), laparoscopic sacral colpexy (LSC) and ASC [Patel 2009; Judd 2010] with both finding the ASC was the least costly inpatient option. Patel reviewed 15 cases, 5 each of ASC, LSC and RSC performed in Connecticut USA in 2008 [Patel 2009]. Results showed that ASC was the least expensive at $13,149, LSC $19,308 and RSC most expensive at $24,161. Importantly in this model there were no differences in length of stay and all procedures had long operating time with the robotic procedure being over 2 hours quicker than the laparoscopic procedures which does not reflect common practice in the literature.

Judd et al, using a decision model, estimated the hospital cost of ASC at $5792, LSC at $7353 and RSC at $8508 (excluding the cost of the robotic system) [Judd 2010]. In this model, RSC and LSC became cost equivalent only when robotic operating times was reduced to 149 minutes, robotic disposables were reduced to $2132 or laparoscopic disposables were increased to $3413. Both models of analysis only included inpatient care and may not reflect other benefits of minimally invasive approach such as quicker recovery and possibly faster return to work.

As already reported in the apical prolapse section of this document Parasio et al [Paraiso 2011] performed a RCT comparing RSC [38] and LSC [40] for vault prolapse and reported cost analysis alongside the clinical outcomes which the authors of this document would prefer to see as the standard reporting requirements. The robotic group incurred significantly greater cost than the laparoscopic group [mean difference +$1,936; 95% CI $417-$3,454; P=.008]. Importantly in this study the authors were experienced laparoscopic surgeons who had also completed the learning phase of the RSC.

Over the last decade both clinical efficacy and cost efficiency of the suburethral tapes in continence surgery has been demonstrated. Transvaginal mesh kits have been introduced to prolapse surgery in an attempt to replicate this benefit for the community. Unfortunately a paucity of cost analysis data is available for review. A study on the analysis of the cost-effectiveness of tradition-
al anterior colporrhaphy (AC), non kit mesh and commercial mesh kit for anterior vaginal prolapse repair showed that commercial mesh kits are not cost effective [Murray 2011]. The authors included estimated cost of managing recurrent prolapse and extrusions in the analytic model after performing a meta-analysis of 18 papers relating to anterior compartment repair to determine operating and admission time, recurrence rate and mesh extrusion rate for the three groups. The cost of non kit mesh was $3,380, AC was $3,461 and mesh kit $4,678. Non kit mesh repair is cost-effective, compared with AC, if extrusion rates remain below 25%. One way cost sensitivity analysis demonstrates that when the reoperation rate for AC reached 28% the commercial mesh kits became cost effective. The balance of cost of AC and non-mesh kits depends significantly on recurrence and extrusion rates. Two-way cost sensitivity analysis demonstrated that if re-operation rate of AC is below 20%, AC is more cost effective even if extrusion rate is 0%. When reoperation rate of AC is 30% the non-mesh kit repair is the most effective option if the extrusion rate is less than 25%.

Recently, Maher et al reported a cost minimisation analysis of a RCT comparing total vaginal mesh [TVM n=55] and LSC [n=53] in the management of vault prolapse at 2 years[Maher 2011]. The clinical outcomes have been reported in this document previously. Similarly to Hullfish’s model above the authors captured inpatient, consumable and direct reoperation cost within the two year period. Opportunity cost defined as economic cost to the women associated with recovery time were added to above cost to define total economic cost. Mean total economic costs were significantly lower in the LSC group as compared to the TVM ($4,013.07 95% CI 3107.77, 4918.37). Labour costs were significantly greater for the LSC reflecting that the operating time was twice as long as compared to the TVM procedure. These higher labour costs were offset by lower consumable, inpatient, opportunity? and reoperation costs for the LSC as compared to the TVM.

One way cost analysis for the LSC and TVM demonstrates that cost equivalence would be achieved once the consumable cost reduced to zero, or the reoperation rate was zero in the TVM group or the operating time in the LSC was 130 minutes longer than the TVM. The cost model reported by Maher et al would provide an excellent model that all clinicians could utilise in audit and authors when reporting prolapse outcomes, by simply substituting their own institutions and community cost. The reporting of such cost analysis data is urgently required so that we can deliver efficient and cost effective pelvic organ prolapse procedures that our community requires.

Conclusion

In conclusion, despite the high prevalence and frequency of surgery for POP, there is little information relating to cost. Our findings can be summarised as:

- Economic cost of POP surgeries annually is significant in United States and Europe and over the next decades will grow at twice the rate of population growth due to our aging population
- Programs aimed at reducing the burden of this disease are urgently needed.
- In a single institution study vaginal reconstructive surgery and pessary use were more cost-effective than expectant management, traditional abdominal sacral colpopexy (ASC) or robot-assisted sacral colpopexy (RSC) (Grade C).
- Two studies have demonstrated that ASC has lower inpatient cost than LSC or RSC (Grade C)
- Data from a single RCT demonstrated the LSC to have lower inpatient cost than RSC specifically relating to lower operating time in the LSC group (Grade B)
- Data from a single RCT demonstrated LSC to be a more effective cost minimising surgery than total vaginal mesh for vaginal vault prolapse.(Grade B)
- Data from a meta-analysis of anterior vaginal compartment prolapse operations demonstrated that commercial mesh kits for anterior repair are less cost-effective than non kit mesh and anterior colporrhaphy. (Grade B)

Assessment and Conservative Management of Faecal Incontinence and Quality of Life in Adults

BLISS DZ

I. INTRODUCTION

The definitions of anal incontinence and faecal incontinence, adopted at the previous consultations, [1] are maintained:

"Anal incontinence is the involuntary loss of flatus, liquid or solid stool that is a social or hygienic problem."

"Faecal incontinence is the involuntary loss of liquid or solid stool that is a social or hygienic problem."

There is no consensus on the best definition, anal incontinence or faecal incontinence, to use for an outcome in treatment trials or evidence to guide when one may be more appropriate; this impacts comparison and evaluation of study findings because different criteria for successful outcomes have been employed. The committee recommends that whichever outcome is used in studies and publications, the conceptual and operational definition be made explicit and used in a consistent manner. The terms anal incontinence and faecal incontinence are not synonymous. As the majority of intervention studies have focused on faecal incontinence rather than anal incontinence as an outcome measure, faecal incontinence is covered in this chapter, except where anal incontinence is specified.

This chapter addresses assessment and diagnosis, and conservative management, including medications, of faecal incontinence in adults and the impact of faecal incontinence on quality of life as assessed by qualitative methods. New to this chapter are the topics of faecal incontinence assessment and quality of life. The following related topics, some of which may have appeared in this chapter previously, are reviewed by other committees, often together with their urinary incontinence counterpart: epidemiology of faecal incontinence (Committee 1), faecal incontinence in frail or institutionalized older adults (Committee 11), faecal incontinence in persons with neurological disease or injury (Committee 10), faecal incontinence in children (Committee 9), surgical management of faecal incontinence (Committee 17), faecal incontinence management using technologies (e.g., products and devices) (Committee 20), and quality of life and faecal incontinence severity as measured by quantitative instruments of patient reported outcomes (Committee 5B), primary prevention of faecal incontinence (Committee 21). The one study of primary prevention of faecal incontinence (avoiding or delaying the initial occurrence) using conservative therapies [2] is included in this chapter.

As some knowledge gained in these specific groups may have applications to an adult population, the interested reader is encouraged to review the work of those committees. There is at present a relatively limited evidence base from high quality experimental trials of faecal incontinence, and it remains challenging to provide strong evidence for most interventions. However, expert consensus in this committee and the world literature is unanimous in recommending conservative interventions, singly or in combination, for the majority of patients with faecal incontinence as first-line management.

Conservative management is defined as a non-operative intervention designed to improve faecal incontinence or prevent deterioration. It includes pharmacological treatments. Reducing the severity and related complications of faecal incontinence are included from the view of conservative management outcomes rather than secondary and tertiary prevention. Patient selection for operative versus conservative management remains largely empirical. The committee recommends a trial of conservative management, in the vast majority of patients, before considering surgical options, because these conservative options are comparatively inexpensive and involve no significant morbidity (see algorithm). Exceptions would be patients with acute traumatic anal sphincter rupture or an endosonographically confirmed major defect in the external anal sphincter in the presence of gross faecal incontinence: these patients would be referred for surgical evaluation as first-line treatment.

II. CLINICAL ASSESSMENT

Normal anorectal physiologic function is complex and relies on a several different factors, including
anatomic and neurology factors. Consequently, anorectal dysfunction may affect all ages [1] and symptoms necessitate careful clinical assessment and sometimes specialised tests to assess the background to patients’ symptoms. Several different questionnaires and tests are used and they are frequently used in conjunction with each other, but the clinical utility is sometimes limited.[2, 3]

1. SEARCH STRATEGY

The following search terms were used for PubMed, Web of Science and Cochrane reviews: faecal incontinence, anal incontinence, symptoms, signs, clinical assessment, history, examination, digital examination, clinical features.

2. HISTORY

History gathering requires sensitivity in dealing with this taboo symptom, but also a willingness to ask direct questions about the complaint. Although there are questionnaires about the severity of faecal incontinence or anal incontinence and their impact on quality of life (See Chapter 5B), they are most often used in research and sometimes in clinical practice. Currently there are no uniform set of questions to elucidate the comprehensive set of factors involved in faecal incontinence, and recommended approaches of experts [3] and clinical experience continue to guide practice. In taking a history, the necessary first step is to determine the nature of the incontinence being experienced by the patient. The aim of a history and examination is to identify conditions that are amenable to management and to characterise symptoms so they might be reduced.

a) Type of incontinence

Additional characteristics of faecal incontinence or types of incontinence other than faecal and anal may be identified during assessment. Passive faecal incontinence is the involuntary soiling or leakage of faeces without forewarning of the patient. Flatus incontinence is the inability to control flatus. Passive and flatus incontinence are frequently related to internal anal sphincter dysfunction.[4] Urge incontinence is an inability to defer defecation once the urge is perceived, for long enough to find a toilet. Soiling after defecation can also occur, and is typically related to either a defect in the internal sphincter or poor “snapping shut” of the external sphincter after voiding.[5] It is also important to determine if the incontinence is for liquid stool only, and, if so, then the possibility of a colonic cause of diarrhoea needs to be considered.[6]

b) Etiology

The history of faecal incontinence should include questioning about its potential etiology:

- Dietary history - including intake of caffeine and sorbitol as they may stimulate GI transit or diarrhoea.[7] (Recommendation Grade C)
- Medical history – particularly anti-anginal and antihypertensive medications which may reduce sphincter tone and ferrous sulphate or antacids which may provoke diarrhoea.[8] (Recommendation Grade C)
- Presence of benign anal disease – haemorrhoids, fistula, anal warts.[9] (Recommendation Grade B)
- History of chronic straining or constipation.[10] (Recommendation Grade B)
- Obstetric history[11] (Recommendation Grade B) particularly:
  - Anal fissure surgery (sphincterotomy or anal stretch), fistula surgery, rectal resection surgery
  - History of pelvic radiation – due to risk of radiation proctitis (that can cause decreased rectal compliance) and internal anal sphincter radiation damage.[14] (Recommendation Grade B)
- Symptoms of other pelvic floor problems (urinary incontinence and pelvic organ prolapse), which have similar risk factors[15] (Recommendation Grade C)
- Cognitive assessment in appropriate patients[16] (Recommendation Grade C)

3. PHYSICAL EXAMINATION

a) General, perianal, and digital rectal exam

Examination is focused towards the detection of evidence of incontinence and identifying the cause of incontinence, if possible. Physical examination should include inspection of underclothing for soiling and staining by stool, pus, or mucus. Perianal skin should be examined for signs of irritation such as erythema, rash, and excoriation[17] (Recommendation Grade C). Perianal inspection should also include attempts to identify a patulous anus or one which gapes on gentle traction of the anal verge and/or a “keyhole” deformity of the anal canal which suggests a persisting sphincter defect[18-20] (Recommendation Grade B). Inspection may reveal scars from previous episiotomies or obstetric tears. Abnormalities at the anal verge from previous surgery or a gaping anus suggestive of marked loss of function may be present. Perianal inspection or digital rectal examination should identify the following[14,18,20] (all recommendations Grade C):

- Scars from previous surgery
- Perianal disease – prolapsing haemorrhoids, fistula, anal warts
• External prolapse at rest
• Absence of perineal body – suggestive of obstetric trauma; at its worst this may manifest as a cloacal deformity
• Inspection for sphincter asymmetry whilst patient contracts sphincter – suggestive of regional sphincter defect
• Function of the puborectalis muscle (palpable at the anorectal junction) – assessed by asking the patient to squeeze the sphincter at which time the puborectalis should push the examiner’s finger anteriorly.

Digital examination should also assess for [18-20] (all recommendations Grade C):
• Rectal contents – if faecal impaction is present this could explain incontinence
• Resting tone – indicative of internal anal sphincter function
• Voluntary and reflex squeeze pressure – indicative of external anal sphincter function and potential function, respectively. The latter is elicited most commonly by asking the patient to cough while assessing sphincter tone – a cough causes a reflex near-maximal external sphincter contraction (analogous to the guarding reflex in the bladder)
• Regional sphincter defects – detected as asymmetry
• A thickened sphincter – suggestive of chronic straining and occult rectal mucosal prolapse
• Paradoxical puborectalis contraction – this may be valuable in assessing constipated patients to identify paradoxical contraction as a cause of retained stool, and hence overflow incontinence

True faecal incontinence must be differentiated from conditions that cause seepage such as prolapsing external haemorrhoids, fistulas, low rectal or anal tumors, and poor perineal hygiene. Diagnostic administration of an enema may be useful in this respect; retention of the enema suggests that the patient does not have clinically significant faecal incontinence. This serves to both clarify the patient’s history, but also begins to suggest the anatomical deficit causing the incontinence.

If suggested by earlier findings (history of straining, thickened sphincter), the patient should be asked to sit on a commode and attempt voiding – the perineum should then be inspected for evidence of a rectal mucosal or full thickness prolapsed on straining10 (Recommendation Grade C).

b) Proctoscopy
Proctoscopy with a rigid instrument, or flexible sigmoidoscopy, is a bedside test of value in excluding potentially treatable causes of faecal incontinence: anal tumors or polyps, rectal cancers or adenoma [21] (Recommendation Grade B), solitary rectal ulcer syndrome – a functional disorder of evacuation, in which repeated straining at stool and or rectal self-digitalization may result in an ulcerated area of the anterior rectal wall [22] (Recommendation Grade B).

c) Vaginal examination
Vaginal examination using a Simms speculum may show a rectocele, cystocele and/or uterine prolapse, all of which may contribute to developing faecal incontinence [23] (Recommendation Grade C). Physiological and complimentary radiological tests are used to confirm clinical suspicions and provide objective data on the function of the anorectum. Pelvic floor dysfunction is a complex problem and multiple tests may be needed based on the initial findings and complexity of the planned intervention.

d) Recommendations for practice

- Perform a baseline assessment including a focused medical history, a general physical examination, and an anorectal examination with inspection of perinanal skin. (Recommendation Grade B-C)
- Several conditions should be specifically assessed for in the history and physical examination, as they may be amenable to definitive treatment, including rectal prolapse, haemorrhoids, faecal loading, potentially treatable causes of diarrhoea (e.g., Inflammatory bowel disease and irritable bowel syndrome, infection, adenomas), acute anal sphincter injury, and acute disc prolapse/cauda equina syndrome. (Recommendation Grade B)
- Conduct a digital exam (Recommendation Grade C)
- Perform a proctoscopy (Recommendation Grade B)

e) Recommendations for research

- Assess inter-rater variability of digital rectal examination
- Assess positive and negative predictive value of digital rectal examination to diagnose pelvic floor diseases associated with faecal incontinence

III. SPECIALIZED TESTING

1. ANORECTAL MANOMETRY

a) Indications
Anorectal manometry measures the pressures in the anal canal and the distal rectum. This test
serves as one of the most accepted and used investigations to measure the function of the internal anal sphincter and the external anal sphincter. Evaluation of the sphincter function in patients with faecal incontinence is the primary indication for manometry [24-26] (Evidence Level 2). However, preliminary evidence suggests that rectal sensation should be treated as well.[27]

b) Equipment and testing

Anorectal manometry can be performed with different types of catheters, including solid state, water perfused, air charged, or microballoon catheters. [28] The diameter of the probe should not exceed 5-6 mm and the probe usually includes sensors radially distributed to measure several pressures at each level. Any manipulation of the rectum, such as digital rectal examination or administration of enema prior to a test should be followed by a minimum of 5 minutes of rest to allow sphincter activity to return to baseline.

The stationary pull-through technique is today commonly used, since this technique avoids the reflex sphincter contraction caused by some dynamic techniques. The stationary pull-through measures the resting pressure and the squeeze increase at 6, 5, 4, 3, 2, and 1 cm from the anal verge by extracting the probe in increments of 1 cm from the rectum to the anal verge. Allowing a waiting period between each measurement minimizes artifacts.

c) Anal resting pressure

The anal resting tone is a composite pressure generated by the internal anal sphincter (55%), external anal sphincter (30%) and the anal cushions (15%). [29] There is some radial asymmetry in pressures in the different parts of the anal canal [30] and therefore the pressures in the four quadrants is usually averaged to account for this asymmetry.[25] New equipment provides a more precise measurement of radial asymmetry, but more complete evaluation of this high resolution technique is still lacking. The length of the functional anal canal or high pressure zone is defined as the length of the anal canal with resting pressures exceeding 30% of the rectal pressure.[31]

Patients with faecal incontinence usually have a lower anal resting tone than continent patients or normal controls (Evidence Level 2). [24,32] The degree of faecal incontinence will however not only depend on the anal sphincter tone, since there are many other factors (i.e. stool consistency, rectal compliance, etc.) that play an important role. There is also a lack of defined values of what is the normal range for the anal resting tone.

d) Squeeze increase

The squeeze increase of the anal canal pressure is generated by contraction of the external anal sphincter and can be calculated as the increase in pressure from the anal canal resting tone during maximal anal squeeze. The squeeze increase is also usually measured at 6, 5, 4, 3, 2, and 1 cm from the anal verge with the stationary pull through technique. Decreased squeeze pressures are frequently correlated to injuries in the external anal sphincter, neurologic damage or just poor patient compliance/voluntary control.

The fatigability of the external anal sphincter can be estimated by measuring the patients’ ability to sustain the squeeze effort over time. The squeeze duration is often reduced in patients with incontinence. The squeeze durability may be measured as a fatigue index.[33]

e) Recto-anal inhibitory reflex

Rectal distension or attempted defecation results in an inhibition the tonic activity of the internal anal sphincter and relaxation of this muscle. Presence of an intact internal anal sphincter is dependent on an intact myenteric plexus and it is usually impaired in patients with severe constipation due to Hirschsprung’s disease. The value of react-anal inhibitory reflex testing in patients with faecal incontinence is limited.

f) Rectal sensation and compliance

Rectal sensation (and rectal compliance) can be measured by intermittent balloon distension in the distal rectum and simultaneously monitoring the patient’s response. The first sensation, the first urge and the maximal tolerable volume are usually recorded. Rectal compliance can also be assessed by measuring the pressure and volume relationship when a balloon is inflated in the rectum.

Reduced sensory threshold levels of the rectum (rectal hypersensitivity) in patients with faecal incontinence could indicate a presence of urge faecal incontinence and increased frequency of defecation [34,35] (Evidence Level 3), whereas incontinent patients with increased sensory threshold levels (rectal hyposensitivity) may suffer from passive (overflow) incontinence [36] (Evidence Level 3).

g) Recommendations for practice

- Anorectal manometry can objectively assess anal sphincter function in patients with faecal incontinence. (Recommendation Grade C)
- Focused expertise to perform manometry is required; each center/laboratory should establish its own control values for anorectal manometry and check for reproducibility of the test. (Recommendation Grade B)

h) Recommendations for research

- Assess normal values for rectal manometry in large healthy control samples spanning all ages to serve as comparisons for abnormalities in faecal incontinence
c) Endoanal ultrasonography in faecal incontinence

EAUS has become the gold standard for the morphological assessment of the anal canal. It can differentiate between incontinent patients with intact anal sphincters and those with sphincter lesions (defects, scarring, thinning, thickening, and atrophy) due to vaginal delivery or anal surgery (i.e., hemorrhoidectomy, sphincterotomy, fistula surgery).[40]

Tears are defined by an interruption of the circumferential fibrillar echo texture. Scarring is characterized by loss of normal architecture, with an area of amorphous texture that usually has low reflectivity. The operator should identify if there is a combined lesion of the internal anal sphincter and external anal sphincter or if the lesion involves just one muscle. The majority of lesions of the internal anal sphincter are easily recognized given the prominent appearance of the internal anal sphincter in the mid anal canal, and they appear as hyperechoic breaks in the normally hypoechoic ring. The appearance of an external anal sphincter defect is a break in the circumferential integrity of the mixed hyperechoic band. A defect can have either a hypoechoic or a hyperechoic density pattern. This corresponds to replacement of the normal striated muscle with granulation tissue and fibrosis. A limitation of EAUS remains the identification of external anal sphincter atrophy in patients with idiopathic faecal incontinence because of the vague contours of the muscle ring.

The number, circumferential (radial angle in degrees or in hours of the clock site) and longitudinal (proximal, distal or full length) extension of the defect should be reported. In addition, 3D EAUS allows to measure length, thickness, area of sphincter defect in the sagittal and coronal planes and volume of sphincter damage.[40,41] Two scoring systems have been proposed to define the severity of the sphincter damage.[42,43] Both systems have demonstrated a good intraobserver and interobserver agreement in classifying anal sphincter defects. [41,44]

EAUS has an important role in detecting clinically occult anal sphincter injuries after vaginal delivery. [45,46] In another study, Oberwalder et al.[47] reported that faecal incontinence related to sphincter lesions is likely to occur even in an elderly population of women who experienced vaginal deliveries earlier in life. They found that 71% of women with late-onset faecal incontinence (median age 61.5 years) had occult sphincter defects on EAUS.

Ultrasonographic imaging is useful to evaluate the result of treatments. Dobben et al.[48] reported that patients with a persistent ultrasonographic external anal sphincter defects after sphincteroplasty had a worse clinical outcome than those without an external anal sphincter defect. Using 3D-EAUS, de la Portilla et al. [49] demonstrated that all the implants of silicone to treat faecal incontinence were properly located in the intersphincteric space three months after injection.

2. ENDOANAL ULTRASOUND IMAGING

a) Introduction

Endoanal ultrasound (EAUS) is established as an important part of a colorectal diagnostic work-up [37] and has been recommended as the gold standard investigation to identify anal sphincter injury by the International Continence Society joint report.[38]

b) Endoanal ultrasonography technique

EAUS is usually performed with high multi-frequency (9-16 MHz), 360° rotational mechanical probe or radial electronic probe (frequency: 5-10 MHz). During examination, the patient may be placed in the dorsal lithotomy, in the left lateral or in the prone position. However, irrespective of the position, the transducer should be rotated so that the anterior aspect of the anal canal is superior (12 o’clock) on the screen, right lateral is left (9 o’clock), left lateral is right (3 o’clock), and posterior is inferior (6 o’clock).

The length of recorded data should extend from the upper aspect of the PR to the anal verge.

Three-dimensional (3D) EAUS offers a synthesis of a high number of parallel transaxial 2D images and it is possible to analyze coronal, anterior-posterior, or posterior-anterior as well as sagittal right–left views, together with any oblique image plane. The 3D image can be rotated, tilted, and sliced to allow the operator to infinitely vary the different section parameters. Volume Render Mode (VRM) is a special feature that can be applied to high-resolution 3D data volume so information inside the cube is reconstructed to some extent. The volume-rendered image provides better visualization performance when there are not large differences in the signal levels of pathologic structures compared with surrounding tissues.[39]

With EAUS, the anal canal is divided into three levels of assessment. The upper level corresponds to the hyperechoic sling of the puborectalis muscle and the concentric hypoechoic ring of the internal anal sphincter. In males, the deep part of the external anal sphincter is also identified at this level. The middle level corresponds to the complete ring of the superficial external anal sphincter (concentric band of mixed echogenicity), the conjoined longitudinal layer, the complete ring of internal anal sphincter, and the transverse perinei muscles are visualized. The lower level corresponds to the subcutaneous part of the external anal sphincter.

• Assess capability of an-rectal physiology testing results (anal pressure-rectal sensation-compliance) on predicting outcomes of medical and/or surgical treatments for faecal incontinence
• Assess rectal manometry reproducibility in large control and patients samples
• Evaluate the utility of high definition and high resolution manometry in the assessment of patients with faecal incontinence

EAUS has an important role in detecting clinically occult anal sphincter injuries after vaginal delivery. [45,46] In another study, Oberwalder et al.[47] reported that faecal incontinence related to sphincter lesions is likely to occur even in an elderly population of women who experienced vaginal deliveries earlier in life. They found that 71% of women with late-onset faecal incontinence (median age 61.5 years) had occult sphincter defects on EAUS.
**d) Alternative Ultrasound Modalities in Faecal Incontinence**

1. **TRANSPERINEAL ULTRASONOGRAPHY**

Perineal ultrasound is performed with the patient placed in the dorsal lithotomy position. Conventional convex transducers (main frequency between 3 and 6 MHz, field of view at least 70°) are applied in the perineum between the mons pubis and the anal margin.[40,41] Perineal ultrasound provides sagittal, coronal and oblique sectional imaging, with the mid-sagittal plane the most commonly used as this gives an overall assessment of all anatomical structures (bladder, urethra, vaginal walls, anal canal and rectum) between the posterior surface of the symphysis pubis (SP) and the posterior part of the levator avulsion (LA). The imaging is usually performed at rest, on maximal Valsalva maneuver and on pelvic floor muscle contraction. The access to the mid-sagittal plane allows the following evaluation of the integrity of the perineal body, measurement of ARA, and dynamic assessment of the posterior compartment.

3D perineal ultrasound imaging may be performed with volumetric probes developed for obstetric imaging. The most important clinical application is the assessment of LA injuries. At these injuries, the muscle disconnects from its insertion on the inferior pubic ramus and the pelvic sidewall and is a common consequence of overstretching during the second stage of labor.[50,51]

2. **ENDOVAGINAL ULTRASONOGRAPHY**

Endovaginal ultrasound is performed with the patient placed in the dorsal lithotomy position. The most frequently used transducer for pelvic floor 3D transvaginal ultrasound is a high multi-frequency (9-16 MHz), 360° rotational mechanical probe. The pelvic floor is divided into four levels of assessment.[52] At level I, the bladder base is visualized on the screen in the 12 o’clock position and the inferior third of the rectum. Level II corresponds to the bladder neck, the intramural region of the urethra and to the anorectal junction. Level III: corresponds to the midurethra and to the upper third of the anal canal. Level IV corresponds to the perineal muscles, the perineal body, the distal urethra and the middle and distal third of the anal canal.

**e) Summary of Evidence**

- EAUS is considered as an integral part in the investigation of faecal incontinence. (Evidence Level 2).

**f) Recommendations for practice**

- EAUS is an important part in the assessment of patients with faecal incontinence, since the examination will define the possible presence of anal sphincter injuries. (Recommendation Grade A)

**g) Recommendations for research**

- Evaluate the role of levator ani damage, visualized with pelvic floor ultrasound, on faecal incontinence symptoms and therapy results
- Further characterize and standardize the utility of pelvic floor ultrasound in patients with faecal incontinence.

3. **MAGNETIC RESONANCE IMAGING**

a) **Introduction**

Recently, there has been evidence to show that magnetic resonance imaging (MRI) is accurate in detecting external anal sphincter defects potentially suitable for repair in patients presenting with faecal incontinence [53-66] (Evidence Level 2). MRI can be performed with endoluminal MRI technology or surface phased-array antennas. MRI is an alternative, with relative accuracy in the detection of external anal sphincter defects, although there is reduced local spatial resolution using this technology and less experience in the specific assessment of external anal sphincter defects.[67-71] Recently, there has been evidence to show that the longer-term functional outcome following sphincteroplasty for obstetric-related external anal sphincter defects (the principal cause of clinical faecal incontinence in this population) is somewhat dependent upon the presence of attendant pudendal neuropathy [72-74] and that worse outcome is correlated with neuropathy-associated external anal sphincter atrophy. [75-77] This technique has also been shown to accurately identify external anal sphincter atrophy in comparison with endoanal ultrasound.[78,79]

b) **Normal anal sphincter anatomy at MRI**

The bulk of useful images are obtained with T2-weighting where contrast is described in relation to the surrounding structures, as there are no absolute values for tissue contrast (as there are, for example in computed tomography). In a series of 100 normal volunteers, age- and gender-related differences are demonstrable on endoanal MRI,[80] as women have a significantly shorter external anal sphincter than men.

c) **Anal sphincter defects on MRI**

External anal sphincter lesions are detected as alterations in the normal external anal sphincter anatomical integrity or as scarring, local atrophy, or a definitive defect. The full extent damage is best appreciated in a combined evaluation of the axial and longitudinal plane sequences. Secondary changes to the architecture of adjacent structures (longitudinal muscle, perianal fat) provide...
supportive evidence of a sphincter tear. Variations in normal anatomy of the anal sphincter may be misdiagnosed as sphincter defects, with constitutive differences in the external anal sphincter being observed.

Internal anal sphincter defects are identified as either internal anal sphincter discontinuity or as replacement of the normal smooth muscle by fibrous tissue with concomitant muscle thinning. Internal anal sphincter defects are often found in combination with external anal sphincter defects, especially in women presenting with incontinence. Solitary internal anal sphincter defects are more common in iatrogenic cases of incontinence.

Several studies have evaluated the accuracy of endoanal MRI in detecting anal sphincter defects. Tears of both the internal anal sphincter and external anal sphincter are readily visualized, with an accuracy of 95% for external anal sphincter lesions. [54,56,58,63]

d) Anal sphincter atrophy at MRI

Recent publications on endoanal MRI imaging reemphasize the importance of external anal sphincter atrophy with its potential predictive clinical implications on sphincteroplasty outcome. [54,56,58,81]

e) Role of MRI in the assessment of faecal incontinence

EAUS can be used as a primary imaging technique, given the similar results when compared with endoanal MRI in detecting sphincter defects, the widespread availability of endoanal ultrasound, and the lower costs. There is no doubt, however, that endoanal MRI technology is accurate. Its role in defining and diagnosing external anal sphincter atrophy can both direct sphincter repair and provide some prognostic information.

f) Recommendations for practice

- The place for MRI assessment of anal sphincters is limited. (Recommendation Grade D).
- Patients with faecal incontinence after repeated anorectal surgeries may benefit from assessment with MRI. (Recommendation Grade C)
- Patients with possible, but not proven, external sphincter defect on ultrasound may benefit from further assessment with MRI. (Recommendation Grade C)

g) Recommendations for research

- MRI can define atrophy of the anal sphincter muscles. Study to assess the degree of atrophy influences the outcomes after treatment with surgical sphincter repair and sacral nerve stimulation.

4. DEFECOGRAPHY

a) Introduction

Defecography, also termed as evacuation proctography, is the radiological assessment of the voluntary rectal evacuation of semisolid contrast material, and provides information on anorectal structure and function. It is useful and widely used in the diagnosis and management of obstructed defecation, but the technique is less often utilized in the assessment of faecal incontinence. [82-84] Rao [85] did not include defecography in commonly performed diagnostic tests for faecal incontinence in an evidenced-based summary and American Gastroenterological Association medical position statement [86] concluded that defecography is not of established value in patients with faecal incontinence. Whitehead et al. [87] concluded that defecography is useful in the assessment of perineal descent, pelvic organ prolapse, rectocele, defecation and puborectalis contraction, but they did not include it in the algorithm for the diagnosis and management of faecal incontinence.

On the other hand, defecography was used by 56% of physicians in the routine diagnostic work-up of patients with faecal incontinence in a recent Dutch study. [88]

There are several studies reporting that surgical correction of rectal intussusceptions [89-92] or rectoceles [93,94] result in improved faecal incontinence. [93,94]

There is a suboptimal correlation between symptoms and defecographic findings. Abnormal findings of defecography can be seen in many normal subjects without any anorectal symptoms. [86,95-98] Another problem in performing defecography in patients with faecal incontinence is that those with weak anal sphincters have problems retaining the semisolid contrast material in the rectum when seated on a commode.

b) Examination technique

There are no universally consented standard methods of defecography. Usually, a viscous barium contrast material is injected into the rectum of the patient in the left decubitus position. The semi-solid contrast material can be made by mixing barium with flour, oatmeal or mashed potato. The volume of the injected material is either fixed at around 150ml or up to the volume at which the patient feels the urge to defecate. A radiopaque marker can be placed close to the anus to facilitate interpretation. Barium contrast in the vagina facilitates interpretation of enterocele and prolapse in the anterior and middle compartments.

The patient sits on a commode attached to the footboard of the fluoroscopy table and lateral views of the film are taken at rest and maximum squeeze before rapid film sequences are taken at one frame per second during evacuation, followed by a film taken after the completion of the evacuation at maximum straining. The sequential films is usually by a video recording; cinedefecography.
c) Parameters studied at defecography

The anorectal junction is the distally tapered point of the rectal contrast column caused by posterior impression of the puborectal muscle. The anorectal angle (ARA) is measured by the angle between the line along the anal canal and the axis of the rectum. Normal subjects should be able to evacuate more than two thirds of rectal contrast material within 30 seconds. In addition to assessing rectal evacuation, defecography can reveal rectal intussusception, rectocele, sigmoidocele and enterocele. Rectal intussusception is defined as the invagination of the rectal wall into itself and the degree of rectal intussusception can be classified by Oxford. Rectocele is defined as the outpouching of the anterior rectal wall beyond the normally expected anterior rectal wall at straining. Sigmoidocele and enterocele are defined as the herniation of the lining of the peritoneum by the sigmoid colon or the small bowel, respectively, into the rectovaginal septum and may push on the anterior rectal wall.

Perineal descent may be a sign of the weak pelvic floor muscles and possible pudendal neuropathy. An obtuse ARA implies weakening of the puborectal muscle and possibly the entire pelvic floor muscles. In a study by Piloni et al.[99] the mean ARA at rest differed significantly between patients with faecal incontinence and those without. The normal range of ARA, however, is wide and some patients with normal ARA are continent to stool, whilst some with abnormally obtuse ARA are continent.

Karasick[100] stated that the major indication for performing defecography in patients with faecal incontinence is to diagnose rectal intussusception (Evidence Level 3). Collinson et al.[89] performed defecography in 40 patients whose faecal incontinence could not be explained by anorectal physiology and endoanal ultrasound, recto-anal intussusception was observed in 63% of the patients. Surgical correction of rectal intussusception has been shown to improve faecal incontinence, indicating a possibility that rectal intussusception can be a cause of faecal incontinence (Evidence Level 3). Lazorthes et al.[90] performed defecography in 51 patients with faecal incontinence. Fourteen patients had a recto-anal intussusception and were operated with transabdominal rectopexy. Faecal incontinence improved in all 14 patients and completely resolved in 6 patients. When Collinson et al.[89] performed laparoscopic ventral rectopexy in 24 patients with rectal intussusception and a combination of obstructed defecation and faecal incontinence, incontinence symptoms significantly improved in 92% of the patients.

It is more controversial whether a rectocele can cause faecal incontinence (Recommendation Grade C). Collinson et al.[89] claimed that one of its mechanisms is faecal trapping in the rectum that allows post-defaecatory leakage to occur.

d) Recommendations for practice

- Defecography is of limited value and not always utilized in the diagnosis and management of faecal incontinence. (Recommendation Grade B)

- Defecography can be useful in the diagnosis and management of faecal incontinence by measuring perineal descent and ARA, evaluating involuntary leakage of the contrast material as well as diagnosing rectal intussusception and rectocele. (Recommendation Grade B)

- Defecography might be useful in diagnosing the existence and extent of rectal intussusception and rectocele as a cause of faecal incontinence. (Recommendation Grade B)

e) Recommendations for research

- Identify and characterize the degree of rectal intussusception and prolapse at defecography and correlate this to treatment outcomes after ventral rectopexy.

- Defecography may be supersedes by magnetic resonance imaging (MRI) defecography, which can visualize the pelvic floor and organs as well as avoids radiation exposure.[101-103] The latter technique is, however, not widely available at present, because of higher cost and most equipment does not allow examination in the sitting position.[83,104] Further investigation is needed to determine whether an open-magnet unit of MRI may solve this postural problem.

5. CLINICAL NEUROPHYSIOLOGIC TESTING

a) Introduction

The clinical use of neurophysiologic testing in patients presenting with incontinence has a long history, but appears to be diminishing in practice because of improvements in clinical sphincter imaging and as a result of the understanding that some neurophysiologic parameters have only minimal influence on decision-making.[105,106] Despite the rise of sacral neuromodulation (SNS) in the selective management of incontinent patients, there is no clear guideline for specific predictive neurophysiologic testing.[107,108] Relegating its specific use in complicated cases of incontinence secondary to particular neurological diseases and following spinal injury.

b) Types of neurophysiologic testing for faecal incontinence

Neurophysiologic testing for faecal incontinence incorporates a range of different testing modalities, including somatic motor testing, somatosensory testing, determination of clinical reflexes, and autonomic nervous system (ANS) testing. Somatic
motor testing assesses the somatic nervous system responsible for skeletal muscle motor innervation plus sensory innervation from cutaneous sites to the muscle spindles. This testing incorporates all forms of electromyography (EMG), including pudendal terminal motor latency studies (PNTML), motor nerve conduction studies, and motor evoked potentials. Somatosensory testing includes somatosensory evoked potentials and sensory neurography. ANS testing: assesses the ANS which provides motor innervation to the viscera and other end-organs and which assess its visceral afferent pathways at peripheral, spinal, and supraspinal levels

c) Electromyography

The specific use of this EMG technology in faecal incontinence in the past was for the differentiation of those patients with potential voluntary sphincter defects from those without sphincter defects thought to be reparable but who had an attendant presumptive neurological cause for their incontinence. Concentric needle electromyography (CN-EMG) is performed with single-use needles used at multiple sites. Inherent differences exist at rest in sphincter musculature when compared with peripheral (non-sphincteric) musculature showing basal resting activity whereas non-sphincter musculature is electrically silent. Denervation is diagnosed as a reduction in the number of continuously firing low-threshold MUPs. CN-EMG has disappeared with improved accurate sphincter imaging; however, it may have a specific place in those patients where ultrasonography and/or MR imaging is equivocal. Single Fibre EMG (SF-EMG) has a smaller recording surface with a pickup of activity from a smaller muscle volume than that recorded with CN-EMG, recording generally 1-3 single muscle fibres from the same MU.

d) Pudendal nerve conduction testing

Pudendal nerve conduction testing measures the nerve conduction velocity in the pudendal nerve. There is a customized (Dantec Electronic Tonsbaakken 16-18 DK-2740 Skovlunde, Denmark) St. Mark’s electrode that has been designed. Prolongation of the pudendal nerve terminal motor latency (PNTML) is common after vaginal delivery and with aging. It has been suggested that the delay in PNTML is associated with a worse overall prognosis of external anal sphincter repair for patients presenting with faecal incontinence, although there is little available evidence to suggest that PNTML measurement alters specific surgical decision-making. There is little available evidence that the presence or extent of a pudendal neuropathy correlates with objective incontinence or with the specific response to biofeedback therapy with or without the presence of an external anal sphincter defect.

e) Sensory system testing

Anorectal sensitivity plays a significant role in the defecation process and in maintaining faecal continence. Variation in anorectal sensibility is also important in pain disorders and in irritable bowel syndrome. Basic sensory testing of light touch and pinprick and sensation of bladder filling is standard. The ano-cutaneous sensation of the perianal area and in the anal canal below the dentate line is conveyed by the efferent fibers of the pudendal nerve (S2-S4).

f) Anal mucosal electrosensitivity

Anal mucosal electrosensitivity (MES) testing was originally described independently by Roe et al. and Siegel using two electrodes with a constant square wave of current with variable intensity. It is unknown precisely which receptors are involved in this standardized and reproducible response. Incontinent patients invariably have a high MES whereas patients with anal sphincter defects, (with or without faecal incontinence), show an increased MES with the highest values found in patients with a combined internal anal sphincter and external anal sphincter defect.

g) Recommendations for practice

- Neurophysiologic testing is of limited value in the assessment of patients with faecal incontinence. (Recommendation Grade C)
- PNTML may be useful in the preoperative assessment of patients before sphincteroplasty or sacral nerve stimulation. (Recommendation Grade C)
- PNTML may be useful in the assessment of patients with possible pudendal neuralgia. (Recommendation Grade D)
- CN-EMG may have a specific role when ultrasonography and/or MR imaging is equivocal. (Recommendation Grade D)

h) Recommendations for research

- Assess reproducibility of testing of anorectal sensation on predicting outcome of surgical and medical treatment for faecal incontinence in large patient samples

IV. EDUCATION AND LIFESTYLE INTERVENTIONS

1. BACKGROUND

Most patients with faecal incontinence do not know how the bowel works and what might improve bowel function. Many patients also have attitudes toward defaecation that are influenced by stigma and taboos present in their particular family and their wider cultural group within a society. Expert opinion supports the use of general health education, patient teaching about bowel function and advice on lifestyle modification, but the evidence...
base is small. Little is known about whether interventions designed to modify lifestyle factors might improve faecal incontinence.

2. SEARCH

Because a small number of studies on these topics were identified in past reviews, two independent searches using their own search strategy were conducted to maximize yield. The following databases were searched: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008- Nov, 2011 and EMBASE 2008- Nov, 2011. The Cochrane Library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence was also reviewed.[123]

Searches included both Medical Subjects Heading (MeSH) terms that were exploded and text searches. The following terms were searched: anal, ano-rectal, bowel, faecal, faecal, f?ecal, feces, rectal, stool and continent$ or incontinent$, or diarrhea, diarrhoea, diarrh?a; and the relevant lifestyle or intervention term: education, educat*, health education; exercise, exercise*, exercis*, exercise therapy, exercise movement techniques, physical exertion; primary prevention, prevent*, preventive health services, preventive health services for older people; weight loss, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free, diet reducing; irrigat$ and rectal, rectum, anal, transanal; smoking, tobacco smoke pollution, tobacco use disorder, tobacco, tobacco$, cigarette$, smok$, smoking cessation; toileting, toilet$, toilet facilities; herbal medicine, plant extracts, drugs, Chinese herbal, plant preparations, plants, medicinal, medicine, Chinese traditional; carer, caregiver, spouse, family, families, familial*, parent$, caregiver burden, caregiver support, and nursing or care. All seemingly relevant abstracts were reviewed, then salient articles were retrieved and reviewed, and the reference lists searched for further studies. Results of the two searches were virtually identical.

3. REVIEW OF EVIDENCE ON THE EFFECT OF EDUCATION AND LIFESTYLE CHANGES ON FAECAL INCONTINENCE

a) Weight loss

Obesity has been proposed as a risk factor for faecal incontinence but the evidence is inconsistent. In 2008, one study of the effect of weight loss after bariatric surgery on faecal incontinence was identified with positive results. In the current review, results of two new studies are included, one using surgery; neither showed a benefit for decreasing faecal incontinence. The effect of a weight loss (i.e., dieting) versus a control (i.e., education) intervention, on reducing faecal incontinence, was compared in a subgroup analysis of 80 women with dual (faecal and urinary) incontinence who participated in a study examining the ability of weight loss to improve UI.[124]

There was no significant difference in the Faecal Incontinence Severity Index (faecal incontinenceSI) or faecal incontinence type (i.e., consistency) between the weight loss and control groups. The 6 month intervention focusing on dietary intake was not correlated with a decrease in faecal incontinence. Women who showed improvement in faecal incontinence had a lower weight at baseline (89 kg) than those with no improvement in faecal incontinence or no faecal incontinence (97 kg). In one study of women who underwent bariatric surgery for morbid obesity (mean (sd) body mass index (BMI) = 48.9 (7.2) kg/m2), there was a decrease in the prevalence of faecal incontinence of solid or liquid stool from 19.4% preoperatively to 8.6% at 12 months (p=.018; 95% CI= 2.1–19.4%).[125] In a later study of 193 morbidly obese patients, bariatric surgery was not beneficial in reducing faecal incontinence.[126]

Faecal incontinence was worse two years after gastric bypass or gastric banding surgery than before surgery despite an average 48 kg weight loss in more than half of the patients. Worsened faecal incontinence was attributed to diarrhoea that occurred postoperatively. When men and women were analyzed together, liquid stool was significantly more common after gastric bypass than gastric banding surgery, a finding not seen when either gender was analyzed separately.

b) Smoking

Nicotine is thought to slow upper gut motility and increase total transit time.[127] but it seems that it can speed recto-sigmoid transit.[128] and this simulation of distal colonic motility may exacerbate a tendency to faecal urgency. This fits with many anecdotal reports that smoking a cigarette facilitates initiation of defaecation. No association has been found between antenatal smoking and postnatal faecal incontinence.[129] In a survey of 271 pairs of identical twin sisters, smoking was not significantly related to faecal incontinence or flatus incontinence.[130] In a longitudinal observational study of community-living elderly men and women, smoking was not predictive of prevalent or incident faecal incontinence.[131] No new or intervention studies were identified in the current literature search.

c) Medication side-effects

Medication used specifically to treat faecal incontinence is covered in section 6 below. A vast number of drugs have direct or indirect effects on the gastrointestinal system, tending to cause constipation, diarrhoea, or either in different people. A case report was found reporting that a combination of olestra in the diet and orlistat given to treat obesity led to symptoms of faecal incontinence, which resolved when the olestra was stopped.[132] Patients reporting soiling while on treatment with orlistat for obesity
have been found to have pre-existing impaired ano-
rectal function, thus predisposing them to symptom
development.[133] It is beyond the scope of this
chapter to review drug effects in detail, and pre-
scribers should be aware of the possible unintend-
ed side-effect of faecal incontinence. A careful drug
history (including all over the counter or “herbal"
preparations) should be taken in each person with
faecal incontinence. No studies were identified that
evaluated the benefits of patient or provider edu-
cation regarding the gastrointestinal side-effects of
medications in the past or current literature search.

d) Toilet facilities

An environment with physical or social obstacles
may impair the ability to maintain continence. This is
particularly relevant to individuals who have physi-
cal or mental disabilities. Environmental obstacles
include toilet facilities that are physically inacces-
able, too few, or distant, require obtaining a key or
money to access, or are restricted to the public alto-
gether; they also include clothes that are difficult to
manipulate in a hurry and a variety of other fac¬tors
which vary with abilities of the individual. The toilet
itself may be too high, leaving the feet dangling and
thus making abdominal straining difficult. The toilet
may be too low, making sitting and rising difficult
for those with immobile hips. Commode use is re-
viewed in by Committee 20.

Public laws, such as those in some U.S. states that
require businesses in public spaces that have toi-
let facilities to make them accessible for public use,
reduce environmental obstacles to continence.[134]

There are many adaptations that can be made to a
bathroom to facilitate access and stability in use.[135]
Effective bowel evacuation is helped by sitting well-
supported, with feet slightly raised upon a small
step stool if needed to enable appropriate use of
abdominal effort, and leaning forward slightly.[136]
Horizontal grab rails assist pushing up from a seat-
ed position, while vertical ones can enable pulling
up. A raised seat or foot blocks can adjust the height
as needed. For lateral transfer from a wheelchair,
both seats need to be at the same height. Where
it proves impossible for a person to use the toilet,
an alternative commode or chemical toilets are avail-
able with appropriate features for the individual’s
needs. No studies were found examining the effect
of modifying the physical or social environment for
bathroom to manage faecal incontinence in the previ-
ous or current literature search.

e) Patient and care-giver education and attitudes

The strongest data on education and lifestyle comes
from a single RCT identified in the previous review.
The study compared nurse-led education and advice
about conservative faecal incontinence management
(e.g., advice on diet, medication titration, and bowel
retraining) alone or as part of a combined intervention
that added exercises and/or biofeedback.[137] The
education and advice group showed reduced frequen-
cy of faecal incontinence and was as effective as the
combination therapies.[137] Other support for the ben-
efits of patient education comes from a study reported
in abstract form[138] which showed that education
and standard medical care, when provided systemati-
cally to a group of faecal incontinence patients, who
had failed prior attempts at medical management, led
to a successful outcome in 38%. Success in this trial
was defined as a patient’s report that they had experi-
enced adequate relief of bowel symptoms.

An RCT of a nurse-led education-focused inter-
vention for bowel problems, in 146 stroke patients
found that a single educational visit with a detailed
information booklet increased patients’ help-seeking
from their family practitioner for bowel problems,
demonstrating a heightened awareness of the pos-
sibility of treatment.[139] Education also changed
diet and fluid behaviour, up to one year later, com-
pared to controls who received routine care. How-
ever, there was no difference in the rates of faecal
incontinence between the intervention and control
groups. No new studies using an education focused
intervention to reduce faecal incontinence were
identified in the current literature search.

For people with dementia or other severe intellectual
impairments, expert opinion holds that the attitude
and management methods adopted by care provid-
ers are as important as bowel function in maintaining
continence.[139] An assessment checklist of toileting
difficulties in individuals with intellectual disabilities,
has been developed to identify the need for inter-
vension, and guide its focus, was identified in the
current literature search.[140] No controlled studies
on managing faecal incontinence in this population
were found. One quasi-experimental study examined
care-givers’ knowledge and compliance before and
after an educational intervention.[141]

Forty home care-givers of people with dementia,
over half of whom had some degree of faecal in-
continence, completed a study-specific question-
naire before and after receiving a videotape and
information booklet entitled, “A practical approach
to maintaining bowel control in people with demen-
tia.” Ninety percent of the care-givers accessed
the information and there was an improvement in
post-intervention knowledge scores, measured on a
55-point scale, with the mean score increasing from
23 pre-test to 32 post-test (p<0.001). However, it
is not known if this improved knowledge translates
into improved care or reduced faecal incontinence.

f) Complementary therapies

There have been no studies of the use of acu-
puncture, reflexology, homeopathy or any other
complimentary therapeutic approach identified in
the previous or current literature search. The use
of cognitive therapy for managing incontinence has
been proposed but not studied.[142]
g) Summary of evidence on education and lifestyle interventions in faecal incontinence

There is at present limited evidence for any lifestyle intervention for faecal incontinence.

• Educating patients and caregivers about their bowel function and faecal incontinence can improve faecal incontinence (Evidence Level 5)

• Obesity: no benefit from weight loss without surgery (Evidence Level 5) and conflicting evidence about the effect of weight loss after bariatric surgery for morbid obesity (Evidence Level 3)

• Smoking: No association with faecal incontinence (Evidence Level 3); no studies of effects of smoking cessation on faecal incontinence

• Medication side effects may cause faecal incontinence related to diarrhoea (Evidence Level 4)

• Environmental modifications in public facilities or private homes to reduce faecal incontinence (Evidence Level 4)

h) Recommendations for practice

• Medication side effects: consider alternatives if causing diarrhoea (Recommendation Grade C)

• Ensure appropriate toilet facilities and convenient access especially for people with disabilities (Recommendation Grade C)

• Improvement in education of patient (Recommendation Grade B/C), and of carer (Recommendation Grade C)

• Complementary therapies cannot be recommended: no evidence (Recommendation Grade D)

There is insufficient evidence to recommend or discourage most lifestyle modifications either for the prevention or treatment of faecal incontinence. The committee recommends patient education about the causes of faecal incontinence and a systematic effort to remove barriers to effective toileting, as an intervention that is likely to be beneficial, based on the consensus of experts (Evidence Level 3 evidence). This may be provided at relatively low cost and involves no significant risk to the patient.

i) Recommendations for research

• Based on encouraging preliminary reports that patient education, combined with conservative management, can reduce the frequency of faecal incontinence, we recommend further research. An RCT may not be possible, due to the challenge of identifying a suitable control for expectancy and attention, but a study which demonstrates a sustained benefit from a limited educational intervention (provided to patients or caregivers), would provide useful guidance for clinical management.

• Further investigation of the benefits for faecal incontinence of weight reduction, especially in moderately obese patients, using non-surgical interventions

• Exercise programmes, when incorporated into a multi-component intervention, have produced promising preliminary results and should be tested further. Such trials should differentiate between constipation-associated faecal incontinence and diarrhoea-associated faecal incontinence, as exercise may be more beneficial to the former group.

• Evaluation of the incremental or additive value of different lifestyle interventions in the patient pathway.

• Research on the contribution of complementary therapies.

V. DIET AND FLUIDS

1. INTRODUCTION

Community-living adults and elderly individuals, especially women, report that they manipulate their diet and eating patterns as a strategy for managing their faecal incontinence.[143-145] Dietary manipulation is employed by the approximately 20% of patients with irritable bowel syndrome (IBS) who also have faecal incontinence [122,146] and by the approximately 19% to 40% of patients with inflammatory bowel disease who have faecal incontinence.[122,147-151] Empirical observations of a suspected relationship between diet and changes in bowel pattern are not limited to faecal incontinence but have been reported by, individuals with constipation, those with IBS with constipation (IBS-C) and some healthy individuals, and together with physiological principles of gastrointestinal (GI) function, supported an investigation of the evidence and discussion of possible mechanisms.

2. LITERATURE SEARCH

The following databases were searched for studies to include in this review of dietary interventions for faecal incontinence management: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, 2011 MEDLINE 2008-Nov, 2011, and EMBASE 2008-Nov, 2011. The Cochrane library and a recent systematic review of the epidemiology and prevention of urinary and faecal incontinence [140] was also reviewed.

The following terms were searched: anal, anorectal, bowel, faecal, faecal, rectal, stool, continent or
incontinent, with diarrhea, diarrhoea, digestive or digestive disease with: alcohol, ethanol, alcoholism, alcoholic beverages, ethanol, drinking; beverages, fluid, fluid intake; liquid, water; coffee, caffeine, cola; diet, dietary therapy, diet, eat, intake, consume and fat or lipid, diet+, diet low carbohydrate, diet fat-restricted, diabetic diet, macrobiotic diet, restricted diet+, diet gluten-free; dietary fibre, fibre, fibre and also with constipation; lactose, lactose intolerance, lactose tolerance, lactose tolerance test, lactose factors, lactose synthase, dairy, dairy products, milk; prebiotic, probiotic, symbiotic; oligofructose, oligofructose, oligosaccharides, fructans, fructose, fos, fructooligosaccharide; sorbitol, glucitol, isosorbide, meglumine; spice, spicy, hot; yogurt, bifidibacteria, Bifidobacterium, Lactobacillus acidophilus, acidophil. All seemingly relevant abstracts were reviewed; then salient articles were retrieved and reviewed, and the reference lists of these articles searched for further studies.

a) Criteria for considering studies for this review

• Types of studies

Only studies in the English language were reviewed. Systematic reviews and meta-analyses of randomised controlled trials and full-length manuscripts reporting individual studies published in a peer-reviewed journal were considered.

• Types of study participants

Studies that involved people who were 18 years or older, had faecal incontinence, and received a dietary intervention were included. People who were tube-fed or had an intestinal ostomy of any type were ineligible.

• Types of dietary interventions

A dietary intervention was defined as any type of food, supplement, dietary product, or fluid that is purposefully consumed or restricted, limited or avoided to manage faecal incontinence. Studies were excluded if it was not possible to distinguish any direct effect of the dietary intervention from other interventions introduced simultaneously. For example, a study was excluded if it combined pelvic floor muscle training and a dietary intervention and compared it to another intervention such as drug therapy making it impossible to determine the effect of the dietary intervention alone.

• Types of outcome measures

A change in faecal incontinence was required to be a primary outcome measure of the studies. Studies which focused primarily on the outcomes of stool consistency or form, stool amount, volume or bulk, defaecation frequency, diarrhoea, or constipation, without including any measure of faecal incontinence, were excluded.

b) Method of review

The reviewers examined the list of citations and abstracts yielded from the electronic search strategy. Potentially relevant papers were retrieved in full text. The reviewers were not blind to the journal titles, authors’ names or their institutional affiliations.

3. REVIEW OF EVIDENCE ON DIET AND FLUIDS

a) Diet modification

Studies of diet modification primarily used observational survey or qualitative research methods and provide background and rationale for examining the effects of diet. One new descriptive study with a large sample size was identified in the current literature search. Findings support those of earlier studies. A survey about faecal incontinence and self-care practices, administered to 1,352 community-living elderly people, showed that many of the respondents changed their diet and skipped meals as a management strategy for faecal incontinence. Changing diet was a significantly more common practice among women (35.4%) compared to men (12.5%). [144]

A qualitative interview of 10 women with faecal incontinence revealed that some avoided eating anything on days they were going to be away from home or restricted the amount eaten while out in public. [145] Many also restricted foods that they thought worsened faecal incontinence (for example, fried or spicy foods or caffeinated beverages and chocolate), or foods that increased flatus (for example, cabbage, onions); a few purposely ate certain foods as a therapy to decrease faecal incontinence (for example, yogurt). Using a trial and error approach, women with faecal incontinence often modified their diet based on recommendations for other gastrointestinal problems (e.g., lactose intolerance and IBS) that were available in the professional or lay literature. [145] Interviews of 189 community-living men and women showed similarities with previous reports regarding aggravating types of foods that are restricted to lessen faecal incontinence. [152] In order of frequency these were: vegetables, spicy foods, fruits, fatty or greasy foods, caffeine containing foods, and dairy. More women (40%) than men (18%, p= .008) avoided foods. There were also differences by age. Younger adults were likely to report that fatty foods and alcohol worsened their faecal incontinence. Individuals with faecal incontinence also modified how they prepared food preferring blander and baked foods.

The effectiveness of these diet modifications was unmeasured and described as variable. Concerns of diet manipulation are nutritional deficiencies and subsequent poor health. However, Bliss et al. [7] found few significant differences in the nutritional composition of usual diets of persons with faecal incontinence compared to the usual diets of age and gender matched controls with normal bowel function.
Those faecal incontinence had a greater intake of carbohydrates, manganese, and vitamin B1.

b) Fluids

Faecal incontinence occurs in association with faecal impaction or constipation, mainly in elderly residents in long-term care institutions.[153,154] General clinical recommendations for faecal incontinence management in these cases are for an adequate intake of fluid to prevent hard stool consistency and constipation (See Chapter 11). Some community-living individuals report increasing fluid intake especially when faecal incontinence is loose or liquid to replace additional fluid lost.[145] However, there are no research-based data to support the recommendation of increased fluids either for constipation or for faecal incontinence, and there is no evidence that the diets of patients with faecal incontinence or constipation are deficient in fluids.

c) Lactose, yogurt, sorbitol, fructose, caffeine, and alcohol

Certain dietary components such as lactose, sorbitol, fructose, caffeine, and alcohol may cause loose stools that can potentially aggravate faecal incontinence. A deficiency of the intestinal enzyme, lactase, prevents hydrolysis of the disaccharide lactose and its absorption. The presence of lactose creates an osmotic shift of intestinal water into the small intestine and speeds transit. In the large intestine, fermentation of lactose by colonic bacteria may result in flatulence, distension, diarrhea, and cramps. However, the majority of adults who have lactase deficiency can tolerate a small amount of lactose in foods.[155] Yogurt is usually well tolerated by lactose maldigesting individuals because the lactose is partially digested by the beta-galactosidase of the bacteria used to ferment the yogurt. However, yogurt has not been found to aid the digestion or tolerance for additional lactose simultaneously consumed with it.[156]

Due to its prevalence in approximately two-thirds of the world’s population, hypolactasia is currently regarded as a normal physiological pattern rather than a disease.[157] The prevalence ranges from highs of nearly 100% in some Asian countries and 70% in Italy to lows of 2% in Scandinavia and 15% in U.S. Whites.[158] Malabsorption of fructose and sorbitol results in osmotic diarrhea and adverse symptoms, similar to lactose. A diet, reduced in fructose and sorbitol content, is suggested for some patients with irritable bowel syndrome to reduce adverse GI symptoms.[159] No studies in the current literature search on the effect of modification of intake of lactose, sorbitol, or fructose, on faecal incontinence were found.

Caffeine, of which coffee is a popular source, induces a desire to defecate.[160-164] Caffeine has also been observed to stimulate defaecation urgency in some patients with faecal incontinence.[131] However, regular consumption of coffee was not associated with prevalent or incident faecal incontinence in elderly men and women.[131] No studies were found on caffeine restriction to improve faecal incontinence.

Chronic consumption of alcohol has been associated with accelerated gastric emptying and small bowel transit in animal studies whereas a single large dose has an inhibitory effect on these parameters.[165-167] Excessive alcohol consumption leads to damage to the duodenal and upper jejunal mucosa and inhibition of sodium and water absorption. There is an increased prevalence of bacterial overgrowth in the small intestine of alcoholics, which may contribute to loose stools, diarrhoea, incontinence, and other GI symptoms.[168] No studies were found in which alcohol restriction was reported to reduce faecal incontinence.

d) Prebiotics, probiotics, and synbiotics

A prebiotic is a general term describing a food ingredient that is not digested in the human small intestine and thus stimulates the growth and/or activity of one or more types of bacteria in the colon that have the potential to improve the health of the host. Because of its ability to stimulate growth of bacteria in the colon, dietary fibre can be considered a prebiotic. Fructooligosaccharides and galacto-oligosaccharides are popular prebiotics. A probiotic is a food supplement containing live non-pathogenic and non-toxic microbes that have the potential to affect the balance of colonic microbes and thereby improve the host’s health. Bifidobacteria and lactobacilli are the most commonly used probiotics, and yogurt which has active microbial cultures can be considered a probiotic. A symbiotic refers to a product that combines a prebiotic and probiotic. Probiotics have been investigated for their ability to prevent or reduce diarrhoea associated with antibiotics, Clostridium difficile infection, ulcerative colitis, acute infant dehydration due to diarrhea and in treating Helicobacter pylori infections.[169,170] However, there are no published data on the use of probiotics or synbiotics to treat faecal incontinence.

e) Dietary fibre

1. BACKGROUND

Dietary fibre is the non-starch, polysaccharide component of plant cell walls and lignin that resists digestion by human intestinal enzymes.[171] In a recent study of weight loss for incontinent and overweight women, analysis of a subsample of 55 women with faecal incontinence showed that those with faecal incontinence were 2.5 times as likely to have a low fibre intake (≤ 10 g/d) than those without faecal incontinence.[124] Moreover, persons with normal bowel function, who had diarrhea induced by administration of phenolphthalein, reported that they had fewer days with urgency to defaecate, or fear of faecal incontinence, when they ingested the soluble fibre psyllium compared to wheat bran, cal-
Evidence Level 1 evidence suggesting that dietary fibre can reduce the percentage of incontinent stools. The percentage of stools that had a loose/liquid consistency was also significantly lower in the fibre groups.[178]

Lauti et al.[177] investigated two combination treatments consisting of an antimitoty medication, a diet advice sheet for a high or low fibre diet, and a fibre supplement or placebo in an RCT design. Subjects were outpatients of a colorectal service in Australia who were incontinent of mucus, liquid, or solid stools (i.e., this study was not limited to patients with faecal incontinence of loose or liquid stools). Results showed no additional benefit of a dietary fibre supplement and advice for a high vs. low fibre diet, over use of the antimitoty medication, loperamide, for reducing incontinence of faecal, mucus or solid or liquid stool.[177] This study had a low level of control of threats to internal validity and intervention fidelity.

Two studies included dietary fibre as part of a staged intervention and used a non-randomized design.[179,180] In one study using a tailored staged intervention,[179] female outpatients with faecal incontinence of either liquid or solid faeces, who agreed to follow the intervention, were instructed to consume one heaped tablespoon of methylcellulose twice per day that could be increased up to two heaped tablespoons as needed. If faecal incontinence did not cease within two weeks, the women were instructed to add one capsule of loperamide twice a day that could be increased up to two capsules three times per day as needed. Fluid intake was also regulated by subgroups: those with solid stool were instructed to drink 60 ml per day (doesn’t seem much!) and those with liquid stool were to avoid drinking 30 minutes before and after every meal. The control group was comprised of women who did not agree to follow the intervention but who agreed to report follow-up data. faecal incontinence was cured in 46% of women in the intervention group and none in the control group.[179]

In another study, 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited from two clinics in the Netherlands, and 47 completed the protocol.180 For two months, patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water daily for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily. Faecal soiling resolved completely in 79% (37/47) of patients. In 12 patients (24%), soiling resolved after psyllium supplementation alone. Of the 37 who added rectal irrigation to psyllium supplementation, 24 (48% of 50) resolved soiling. Of the remaining 11 who added cholestyramine to psyllium supplementation, rectal irrigation, 2 (2% of 50) resolved soiling.

One study of institutionalized frail elderly showed that treating faecal impaction or constipation using...

</table>
lactulose, a nondigestible sugar with osmotic properties, and a laxative or enema did not reduce faecal incontinence, [181] but no studies were found treating faecal incontinence associated with constipation in non-institutionalized adults.

3. SUMMARY OF EVIDENCE

Patients consider diet a factor affecting the severity of their faecal incontinence and they use diet modification as a self-care strategy (Evidence Level 3). Dietary fibre supplementation appears to be a safe and tolerable intervention that reduces faecal incontinence of loose stools (Evidence Level 1). However, findings about its effectiveness when added to an anti-motility medication differ (Evidence Level 2). Dietary fibre as an adjuvant to rectal irrigation can reduce faecal incontinence (Evidence Level 3).

4. RECOMMENDATIONS FOR PRACTICE

- Soluble dietary fibre is recommended for the management of faecal incontinence especially when stool consistency is loose or liquid. (Recommendation Grade B).

- Soluble dietary fibre is recommended as part of a combination therapy involving rectal irrigation (Recommendation Grade B).

- No recommendations about the use of dietary fibre as an adjuvant to antimotility medications can be made because evidence is conflicting and study methods vary in quality. (Recommendation Grade B)

- The effectiveness of food restrictions, timing of eating schedules, and modifications of eating patterns and food preparation on reducing faecal incontinence should be evaluated for their usefulness. (Recommendation Grade C)

- Patients should be asked about dietary restrictions and meal skipping to assess nutritional impact especially in groups who may be at higher risk for malnutrition. (Recommendation Grade C)

5. RECOMMENDATIONS FOR RESEARCH

Further studies on the effect of dietary fibre and other diet modifications on faecal incontinence are encouraged to build a greater body of evidence:

- Determine the optimal type and amount of fibre to use for faecal incontinence as dietary fibres differ in their chemical composition and properties

- Determine the extent to which a dietary intervention can augment other behavioural interventions, such as pelvic floor muscle exercises or bowel training, needs further study.

- Assess the effect of modifying usual diet and eating pattern as a management strategy for faecal incontinence

There are several recommendations for methodological rigour in future studies. Theory-based, adequately powered, controlled trials are sought. Studies should control for variability in an individual’s baseline severity of incontinence and any adjuvant therapies. In staged interventions, the effect of the order of dietary fibre and other components, should be assessed. Monitoring adherence to the dietary intervention and intervention fidelity are recommended. A common set of outcome measures that includes tolerance to diet interventions is recommended. Reporting outcomes of faecal incontinence in addition to those of anal incontinence (which incorporates flatus incontinence) is recommended.

VI. BOWEL MANAGEMENT AND RE-TRAINING PROGRAMMES

1. BACKGROUND

Bowel management programmes are used by individuals with constipation and although constipation is a risk factor for faecal incontinence in children and older people, it has not been found to be a consistent risk factor for faecal incontinence in adults of other ages. Committees 9 and 11 have reviewed the evidence for bowel retraining programmes in children and older adults, respectively. Bowel management after spinal cord injury also involves other bowel problems in addition to faecal incontinence, such as constipation or incomplete evacuation; therefore, combinations of therapies for both faecal incontinence and constipation are common. Few bowel management approaches have been tested for their effectiveness for faecal incontinence only in adults with non-neurogenic faecal incontinence. Any studies found which addressed bowel management or training for multiple bowel problems in adults with non-neurogenic faecal incontinence that did not separate results for faecal incontinence, were excluded from this review.

2. SEARCH

The following keywords were searched: anal, ano-rectal, bowel, faecal, faecal, rectal, stool and continence or incontinent, or diarrhoea, diarrhoea and the relevant lifestyle or intervention term: bowel and train or retrain; digital and stimulat); crede or massage; enema; and suppository, toileting, toilet, toilet facilities. The following databases were searched: EBSCOhost® databases including Academic Search Premier, Alt HealthWatch, Health Source: Nursing/Academic Edition, CINAHL 2008-November, and 2011 MEDLINE 2008- Nov, 2011 The Cochrane library and a recent systematic review of the epidemiology
and prevention of urinary and faecal incontinence was also reviewed.\[123\]

All seemingly relevant abstracts were reviewed, after which salient articles were retrieved and reviewed, and the reference lists searched for further studies. Studies that included patients with a variety of bowel disorders, but did not report results of bowel management/retraining for patients with faecal incontinence separately, were excluded. Studies in which results of retrograde irrigation were not reported separately from those of antegrade irrigation were also excluded.

3. REVIEW OF EVIDENCE ON BOWEL MANAGEMENT AND RETRAINING PROGRAMMES

a) Bowel habit and toileting

Expert opinion supports the importance of attempting to establish a regular, predictable pattern of bowel evacuation by patient teaching and adherence to a routine.\[121,182\] Because peristaltic contractions of the colon, that are associated with defaecation, in increase in frequency following awakening from sleep and following meals,\[183,184\] the period after breakfast is the best time for scheduled defaecation. No studies of bowel habit training or regular toileting in non-institutionalised adults with mobility or cognitive limitations, or with normal cognitive function, were found in the current literature search.

b) Resisting urgency

The strong sensation of urgency to defecate is frequently associated with diarrhoea, and it is a recognised risk factor for faecal incontinence in adults.\[185\] In contrast to urinary incontinence, particularly the overactive bladder syndrome (Committee 14), for which a body of knowledge has developed on the efficacy of bladder training techniques (i.e., voiding at specific intervals rather than in response to urge and deferment techniques), the possibility of bowel retraining for resisting urgency to defaecate is relatively unexplored. Some biofeedback protocols focus on altering rectal sensory thresholds as discussed below.

In the previous review, one RCT\[173\] that compared patients who received education, including urgency resistance techniques and dietary advice, to a group of patients who received the same training plus anal sphincter exercises with or without home or clinic biofeedback showed no significant difference in outcomes.\[137\] No new studies of resisting urgency to reduce faecal incontinence were identified in the current search.

c) Evacuation training

A common factor in the genesis of pelvic floor problems may be chronic straining with perineal descent from constipation; this may lead to pelvic floor damage (direct or neurological),\[186,187\] and may be associated with pelvic organ prolapse or UI or faecal incontinence. In one small study, women who reported straining were more likely to develop urogynaecologic symptoms such as prolapse and stress urinary incontinence.\[188\] However, straining has not been shown to be a risk factor for faecal incontinence. No studies were identified in the previous or current search that examined the effect of decreasing straining on preventing or treating faecal incontinence in non-institutionalised adults.

Clinically, many patients with faecal incontinence are taught evacuation techniques or are encouraged to use laxatives, suppositories or enemas in an attempt to ensure that the rectum remains empty most of the time, thus giving less chance of faecal incontinence. This is known to improve continence in children (Committee 9) and elderly patients (Committee 11). One RCT of a combination treatment package for faecal incontinence in adults included training on evacuation techniques and noted that patients reported improved ease of evacuation after treatment.\[137\] No separate data on faecal incontinence were presented. No new studies were found utilising specific evacuation training to treat faecal incontinence in younger adults in the current literature search.

Committee 10 has reviewed the evidence for digital rectal stimulation and manual evacuation in patients with neurogenic faecal incontinence. The use of these techniques to assist complete evacuation in non-neurological populations has not been evaluated.

d) Rectal irrigation

Irrigation of the lower bowel has been used for many years to manage both faecal incontinence and constipation by patients with spinal cord damage (Committee 10). Surgical construction of a portal for antegrade irrigation is covered by Committee 17. Various equipment has been used for retrograde irrigation, including a stoma irrigation cone held in place manually against the anus,\[189,190\] a mechanical pump\[191\] and specifically designed anal irrigation equipment.\[192,193\] Rectal irrigation for faecal incontinence secondary to spina bifida is common.\[192\]

Five studies that investigated rectal irrigation for faecal incontinence and met the criteria were found in the current literature review. Three of the studies examined the effect of rectal irrigation in patients whose faecal incontinence did not improve after using other conservative therapies.\[194-196\] Three studies had an observational design\[180,194,197\] and two studies reported results of one group before and after using rectal irrigation.\[196,198\] One study included rectal irrigation as part of a staged intervention along with dietary fibre,\[180\] and two studies allowed addition of other therapies such as laxatives or dietary fibre on an uncontrolled basis.\[196,198\] Sample sizes were small in all studies and none used a randomised between groups design.
The effects of rectal irrigation using tap water for a mean duration of 18 months to treat faecal incontinence were reported in one study of 32 patients who had faecal soiling (n=16) or faecal incontinence (n=16) (the distinction between the two conditions was not defined).[197] Overall, approximately half (57%) of subjects reported improvement of faecal incontinence on a questionnaire; improvement was less in those with faecal incontinence (38%) compared to those with faecal soiling (79%). Ten patients discontinued rectal irrigation after 1 month due to lack of benefit, adverse symptoms or time required.

In a survey of patients with a variety of different bowel disorders, retrograde colonic irrigation was observed as being effective in reducing soiling in 41% of 32 individuals and reducing faecal incontinence in 47% of 71 persons.[194] However, irrigation was discontinued by 67% of those with soiling and 17% of those with faecal incontinence despite a benefit. Reasons for discontinuation included the time required, difficulties with the irrigating procedure, and incontinence of irrigation fluid later in the day.

One prospective study followed 18 patients with faecal incontinence who used a rectal irrigation pump and tap water. Subjects could add soap to the irrigation fluid and take laxatives or dietary fibre as needed.[198] Six patients added psyllium dietary fibre and three added medications. Compared to baseline Parks incontinence scores (3.6 (0.50 SD)), faecal incontinence significantly decreased at 3 months (2.3 (1.03)), 6 months (2.7 (1.3)) and one year (1.6 (.92)). Eleven patients (61%) were considered “pseudo” continent at 3 months.

A prospective study of a nurse practitioner-led rectal irrigation program for adult and pediatric patients (age = 52 (5-85 mean (range) years)) with functional bowel disorders included 51 adult patients with predominant faecal incontinence.[196] Faecal incontinence symptoms were reported on a non-validated linear analogue scale at the start and after an average of 42 months using rectal irrigation with water, plus laxatives if needed. Faecal incontinence symptom scores improved in the faecal incontinence only group from 7.5 (6.5-8.5 range) before to 4.9 (3.5-6.4) after the rectal irrigation program.

Rectal irrigation was included as part of a staged intervention for faecal incontinence in an already mentioned, study of 50 consecutive patients (41 men) who had faecal soiling and normal sphincter function were recruited.[180] For two months, all patients consumed 3.25 g psyllium fibre per day and a fibre rich diet. Patients with persistent faecal soiling added rectal irrigation using 500 ml of tap water for two months. Patients whose faecal soiling continued added 4 g of cholestyramine daily; 47 patients completed the protocol. Faecal soiling resolved in 12 patients (24% of 50) consuming psyllium alone, 24 of 37 (48% of 50 patients) who added rectal irrigation to psyllium supplementation, and 2 of 11 (2% of 50 patients) who added cholestyramine to psyllium supplementation rectal irrigation.

e) Combinations of therapies

It is recognised that in many people, the symptom of faecal incontinence is the result of a complex combination of disordered anatomy and physiology, stool consistency and gut motility, emotional and psychological status and restricted access to toilet facilities, amongst other factors (see Committee 5). Hence in clinical practice many patients use a combined approach, for example, adjusting diet, medications, lifestyle, muscle function and bowel habit simultaneously, depending on the result of an initial assessment. [199,200] Studies of combinations of education, diet or fluid, and behavioural therapies, which have been identified in this review, are included by topic of the intervention in the respective section above. A limitation of these studies is that the contribution of the individual components to the overall effect, or the effect of the order of components, has not been determined and remains unknown.

f) Summary of evidence on bowel management and retraining programs

There is limited evidence on many topics in this area. In particular there are no studies on effects of bowel habit training, scheduled toileting, resisting urgency, and rectal evacuation in adults with faecal incontinence. However, rectal irrigation can reduce faecal incontinence when first-line conservative therapies fail (Evidence Level 2).

g) Recommendations for practice

- Rectal irrigation is recommended for patients who do not respond to other conservative therapies and as part of a combined approach of therapies (Recommendation Grade C)
- Attempt to establish a bowel routine (Recommendation Grade C)
- Urgency resistance training is possibly useful for urgency. (Recommendation Grade D)
- No recommendation on toileting methods is given due to lack of evidence. (Recommendation Grade D)

h) Recommendations for research

- Randomized clinical trials of rectal irrigation are needed.
- Research is needed in all other areas of bowel training.

VII. TREATMENT WITH MEDICATION

1. GOALS

With the recognition that severity is subjective, treatment should be allocated according to symptom
profile and patient lifestyle. The goals of this section are to identify the drugs and other medical interventions that have been used to treat faecal incontinence and to evaluate the evidence regarding their efficacy (See Table 2). Drugs can be combined for synergistic effect, helping reduce individual doses; loperamide plus codeine phosphate, and loperamide plus amitriptyline are examples. Conservative management of faecal incontinence has focused exclusively on three mechanisms:

- Reduction of diarrhoea. Diarrhoea is consistently found to be a strong risk factor for faecal incontinence.
- Increasing resting anal canal pressure. Low resting anal canal pressure is a risk factor for passive faecal incontinence, and is commonly seen following some types of anorectal surgery (e.g., ileal pouch procedures, sphincterotomy, abdominoperineal pull-through for imperforate anus).
- Treatment or prevention of constipation. Constipation is frequently found to be a risk factor for faecal incontinence, especially in children and the elderly.

2. SEARCH METHODS

The Medline database and the Cochrane reviews [201,202] were searched for studies in any language and any year through October 2011 which matched the following search terms: “Faecal incontinence” OR “anal incontinence” AND “drug” OR “medical management” OR “medical treatment;” “Faecal incontinence” OR “anal incontinence” AND “loperamide” OR “diphenoxylate;” “Faecal incontinence” OR “anal incontinence” AND “laxative;” “Polyethylene;” “Faecal incontinence” OR “anal incontinence” AND “phenylephrine gel.” Additional articles were identified by examining systematic reviews.[202-204]

3. REVIEW OF EVIDENCE ON MEDICATIONS FOR FAECAL INCONTINENCE

a) Treatment of diarrhoea-associated faecal incontinence with antidiarrhoal drugs

1. LOPERAMIDE AND DIPHENOXYLATE

The most extensively tested drug treatment for diarrhoea-associated faecal incontinence is loperamide. We identified 7 studies in adult subjects [177,205-209] and 3 studies in children.[210-212] These studies all have methodological weaknesses including small sample sizes, use of crossover designs, or they are case series. Loperamide is a synthetic opioid with μ-agonist activity and coincidental calcium channel blocking actions. By slowing gut transit, increasing fluid reabsorption and reducing secretion, loperamide thickens stool consistency and reduces stool frequency. It also has direct sphincter actions, attenuating the anorectal inhibitory reflex and increasing resting anal pressure. It is at least as effective as codeine, and superior to diphenoxylate in chronic diarrhoea, with a tendency to reduce faecal incontinence more effectively than the other agents. The availability of a syrup formulation offers the opportunity of titrating the dose more finely to avoid the side-effect of constipation. Some authors advocate using the drug before meals to reduce postprandial bowel urgency. Tolerance does not seem to develop with chronic administration, and the safety profile is excellent with both regular and as-required use.

Diphenoxylate, a natural opioid, is usually combined with atropine to reduce abuse potential. It crosses the blood–brain barrier to produce central nervous system side-effects and, when combined with atropine, can cause anticholinergic effects. It is less effective than loperamide. Codeine phosphate is another opiate derivative, with side-effects of nausea, tolerance and dependence. Its clinical effects are similar to those of loperamide, but it is harder to titrate and adverse effects become prominent with time.

Studies generally support the efficacy of loperamide for decreasing diarrhoea-associated faecal incontinence. The most important of these studies are briefly summarized below: Palmer and colleagues[205] compared loperamide (average of 4.6 mg per day) to codeine (average of 103 mg per day) and diphenoxylate (average of 12.5 mg per day) in 30 patients with diarrhoea, of whom 19 had faecal incontinence prior to treatment. However, change in faecal incontinence was not the primary outcome measure. Loperamide was superior to diphenoxylate and similar to codeine with respect to decreased stool frequency, improved stool consistency, and reduced side-effects. Although not statistically significant, there was a trend for less faecal incontinence while taking loperamide compared to diphenoxylate.

Fox and colleagues [209] tested different doses of loperamide against placebo in a double-blind crossover study of 10 obese subjects who were soiling as a result of taking orlistat for weight control. These 10 subjects were selected for study because they had previously been found to soil while taking orlistat. In this study, loperamide decreased soiling and faecal incontinence and increased resting anal canal pressure. Lauti’s group [177] compared loperamide plus fibre supplementation to loperamide with a low fibre diet and placebo fibre supplement in the first adequately powered study. This was a double-blind crossover study with order of treatments counterbalanced. Results showed a significant improvement in continence relative to baseline in both groups, but the addition of fibre to loperamide did not increase benefit.

Sze and Hobbs [179] investigated the additional benefit of loperamide over methylcellulose in an unblended study of 69 patients. Forty-six percent of patients were “cured” by the combined treatment, although loperamide had a tendency to cause constipation, which

was modified by dose reduction. Taken together, these studies suggest that loperamide may be more effective than fibre supplementation alone for the treatment of diarrhoea-associated faecal incontinence. An earlier study by Bliss et al.[178] which is reviewed in Section 16.5, showed that fibre supplementation with either psyllium or gum arabic improved diarrhoea associated faecal incontinence, more than placebo.

2. Other antidiarrhoeal drugs

Santoro and colleagues [213] carried out an uncontrolled study of the tricyclic antidepressant, amitriptyline, given 20 mg at bedtime, in 18 patients with faecal incontinence; diarrhoea was not required. Thirteen of 18 became continent and 3 reported improvement. The authors attributed the benefits to increased anal resting pressure and decreased numbers of “rectal motor complexes.” This study suggests that amitriptyline and other tricyclic antidepressants are of possible benefit for treating faecal incontinence. Sucralfate is a formulation of aluminium hydroxide used primarily for the treatment of duodenal ulcers; it has the property of coating the stomach lining. An early study suggested that sucralfate might reduce diarrhoea secondary to radiation proctitis in patients receiving radiotherapy for pelvic cancer.[214] However, subsequent large randomized controlled trials have shown no significant benefit for diarrhoea [215] and a worsening of faecal incontinence [216] in this patient population. Bharucha et al.[217] undertook a 4 week trial of a clonidine patch. There was a modest reduction of stool frequency and improvement of continence.

3. Mechanism of action

Three possible mechanisms of action have been identified in these studies of the drug treatment of diarrhoea-related faecal incontinence: loperamide, diphenoxylate, amitriptyline and clonidine appear to work in part by decreasing bowel movement frequency through an effect on motility and absorption. Fibre supplements (reviewed in Section 4 above), on the other hand, work by binding more water into the stools. Resting anal canal pressures were reported to be increased in response to loperamide [206,207] and amitriptyline.[213]

b) Drugs for increasing anal canal pressure in patients with passive faecal incontinence

A subgroup of patients with faecal incontinence has passive incontinence, defined as faecal incontinence that is not preceded by a sensation of urgency to defecate and that occurs without awareness. This is believed to be related to decreased resting pressure in the anal canal, due to an impaired internal anal sphincter and/or to decreased sensation for rectal distension. A specific aetiology for passive faecal incontinence is the patient with a colectomy (usually for ulcerative colitis) with a surgically constructed ileal reservoir connected to the anal canal.[218]

1. Phenylephrine gel

Phenylephrine gel, an alpha-1 adrenergic agonist, has been investigated for the treatment of passive faecal incontinence in several studies.[219-223] In an initial study of 36 patients with intact sphincters, no significant benefit was seen.[223] Two subsequent studies [219,222] suggested a benefit of phenylephrine gel, but a recent randomized controlled trial in 35 patients with passive incontinence secondary to low anterior resection failed to show a benefit.[221] Thus, the clinical utility of phenylephrine gel (if any) may be limited to patients with passive incontinence associated with ileal pouches. L-erythro methoxamine gel, an alpha-1 adrenoreceptor agonist similar to phenylephrine, has also been shown in two proof-of-concept studies to increase internal anal sphincter resting pressure,[224,225] although no clinical trial data are available as yet.

2. Valproate sodium

The gamma-aminobutyric acid transaminase inhibitor, valproate sodium, also increases anal canal resting pressure. It was compared to placebo in a double-blind, randomised crossover study [226] in 17 patients with diarrhoea-related faecal incontinence secondary to colectomy and ileoanal anastomosis. The drug decreased faecal incontinence episodes and stool frequency relative to baseline and increased anal canal pressure, whereas placebo did not have these effects. In a second randomized controlled trial by the same investigators [227] patients with ileal pouches were treated with valproate sodium or placebo. There was a significant improvement in anal canal pressures, pouch capacity, and continence. Therefore, valproate sodium is of possible benefit in this population.

c) Drug treatment of constipation-associated faecal incontinence

Constipation-associated faecal incontinence, sometimes referred to as “overflow incontinence.” It is more common in children, nursing home residents, and in patients with spinal cord injury. The proportion of faecally incontinent nursing home residents whose faecal incontinence is attributable to “overflow constipation” is not known. No studies of treating constipation-associated faecal incontinence in adults, outside these groups, were found.

1. Summary of evidence on medication and faecal incontinence

- Loperamide is useful for diarrhoea-associated faecal incontinence. There is some evidence that the loperamide may be superior to diphenoxylate (Evidence Level 2).

2. Recommendations for practice

- Treat faecal incontinence with diarrhoea with anti-diarrhoeal medication (Recommendation
3. RECOMMENDATIONS FOR RESEARCH

- Additional, well-designed studies are needed to validate the common clinical practice of using laxatives to treat constipation-associated faecal incontinence.
- There is a need for further research on preparations, doses and combination therapies for all types of faecal incontinence and all patient subgroups.
- The potential for topical treatments is high, but there will need to be formal clinical trials of such agents.

VIII. PELVIC FLOOR MUSCLE EXERCISES, BIOFEEDBACK, AND ELECTRICAL STIMULATION

Pelvic floor muscle training (PFMT), biofeedback, and electrical stimulation are distinctly different therapeutic techniques for treating faecal incontinence; see descriptions below. These techniques are compared to each other or combined in some studies (e.g., biofeedback combined with electrical stimulation).

1. PELVIC FLOOR MUSCLE TRAINING

Pelvic floor muscle training (PFMT) is also called Kegel exercise training, after its developer. [231] The patient is instructed to contract the pelvic floor muscles including the external anal sphincter and puborectalis while keeping abdominal wall muscles relaxed and to do this multiple times each day with the goal of strengthening pelvic floor muscles. In a typical protocol, the patient may be instructed to squeeze for 10 seconds while continuing to breathe deeply so that the abdominal wall muscles do not also contract. Ten to 20 such 10-sec squeezes are separated by 20 second periods of pelvic floor relaxation. Often patients are instructed to squeeze 10-20 times in a block and to repeat this block of exercises 3-5 times a day. The patient may be taught how to perform this exercise using only verbal or written instructions,[232] or they may be given verbal feedback on their performance by the therapist during a digital rectal examination.[233,234] However, electronic or mechanical devices are not often used to amplify the sensory information available to the patient on how well they are performing the exercises.

2. BIOFEEDBACK

Biofeedback training is distinguished from PFMT by the use of electronic or mechanical devices to augment the intrinsic sensory information available to the patient on how well they are contracting their pelvic floor muscles. The purpose of this type of training is to ensure that patients learn the appropriate way to contract the pelvic floor muscles while keeping abdominal wall muscles relaxed. Such training is intended to strengthen pelvic floor muscles and it is usually combined with instructions to practice PFMT at home between clinic visits. Another feature of many biofeedback training protocols is sensory training or coordination training. As a consequence of neurological injuries, many patients lose the ability to recognize sensations associated with the movement of stool into the rectum and may fail to contract the pelvic floor muscles in order to avoid stool leakage. In sensory training, a balloon-tipped catheter is introduced into the rectum and distended with varying volumes of air to help the patient learn to recognize weaker distensions. Coordination training is a variant of sensory training and refers to having the patient practice contracting pelvic floor muscles in response to any sensation of rectal distention until this becomes a well-practiced habit.[138]

3. ELECTRICAL STIMULATION

Electrical stimulation from probes placed in the anal canal or from electrodes on the perineum adjacent to the anus has also been used to treat faecal incontinence. In typical applications, stimulation is performed daily at home using a battery operated electrical pulse generator connected to the anal electrodes. [234] Different theories have been advanced to account for how this might facilitate continence. [234] In the earliest applications, electrical stimulation was used at intensities that triggered a contraction of the pelvic floor muscles, and patients were encouraged to try to augment the contractions produced by electrical stimulation or to try to reproduce these contractions. [234] Others have suggested that the stimulation of afferent nerves by lower intensities of electrical stimulation may help by increasing the sprouting of synapses peripherally or the size of the receptive fields for these nerves in the brain. [235] Electrical stimulation is sometimes combined with biofeedback. [236]

4. METHODS

The effectiveness of PFMT, biofeedback, and electrical stimulation was assessed by this committee in 2008. In this review, we summarize the recommendations made in the Fourth International Consultation on Incontinence [173] and update the recommendations for PFMT, biofeedback, and electrical stimulation from non-implanted devices by reviewing in detail articles published between January 2008 and January 2012. The faecal incontinence surgery committee (Committee 17) updated the review on electrical stimulation. Databases searched were PubMed, Web of Science,
In the last International Consultation on Incontinence [173] the working committee concluded that, improvements, but only one RCT which attempted the addition of biofeedback to PFMT yielded greater benefits. The review of the literature in the previous ICI report [173] identified several RCTs in which PFMT was used as a control condition to determine whether the addition of biofeedback to PFMT yielded greater improvements, but only one RCT which attempted to isolate the contribution of PFMT by comparing education and advice alone to education and advice plus PFMT. [137] This study (described above) was well designed and adequately powered. No greater benefit was observed for PFMT compared to advice. Based on this evidence, the reviewers in 2008 concluded that PFMT may be as effective as biofeedback and that advice alone may be as effective as PFMT.

b) ICI 2008 assessment of biofeedback therapy [173]

In the last International Consultation on Incontinence [173] the working committee concluded that, “In contrast to the mostly favourable outcomes reported in uncontrolled studies, randomized controlled trials have generally found no additional benefit when biofeedback was added to either a comprehensive behavioural and medical management program, or to digitally taught sphincter exercises” [page 1358]. The reviewers noted that very few studies have reported process measures, such as pre-post changes in sphincter strength or rectal sensory thresholds, which are targeted by biofeedback therapy, and presumed to account for any improvements in continence, and they questioned whether this should be required, before a biofeedback treatment protocol can be said to be responsible for an improvement in faecal continence. The committee concluded that biofeedback “...is possibly effective but currently unproven” [page 1359]. Only the following three RCTs were available for review in 2008:

Heymen et al. [237] randomized 40 patients with faecal incontinence to one of 4 groups: (a) EMG biofeedback during clinic visits, (b) EMG biofeedback plus sensory training with a balloon during clinic visits, (c) EMG biofeedback in the clinic plus use of an EMG biofeedback trainer at home, and (d) EMG biofeedback plus sensory training in the clinic plus daily use of an EMG biofeedback trainer at home. There were no significant differences between groups, but the study was underpowered with only 10 patients per group.

Norton et al. [137] randomized 171 patients to one of 4 groups: (a) education and management advice provided by a nurse clinical specialist; (b) advice plus PFMT taught verbally and by digital rectal exam; (c) advice, PFMT, and instrumented biofeedback which included both sensory and strength training; and (d) advice, PFMT, biofeedback, and daily home practice with an EMG biofeedback unit. There were up to nine 40-60 minute sessions in each group (median number of sessions completed was 5). There were no significant differences between groups in subjective rating of improvement, change in Vaisey Continence Scale scores, or change in frequency of faecal incontinence. Specifically, there was no greater rate of improvement in the biofeedback group (53% improved) compared to the advice and education only group (54% improved). A limitation of the study was that 49% of patients rated their incontinence severity as “minor” at baseline, and the median frequency of incontinence before treatment was only once per week.

Solomon et al. [233] randomized 120 patients with mild to moderate faecal incontinence to one of three groups: (a) manometric biofeedback, (b) trans-anal ultrasound biofeedback in which the ultrasound image was visible to the patient in real time, and (c) PFMT taught by a therapist who provided verbal feedback during digital rectal exami-
nation. There were no differences between groups on the Pescatori or St. Mark’s incontinence severity scales, subjective ratings of improvement, quality of life, or manometrically measured squeeze pressures. However, there were significant differences from pre-treatment to post-treatment on most outcome measures.

c) ICI 2008 assessment of tibial nerve transcutaneous electrical stimulation from non-implantable devices

In the previous ICI report, [173] studies of tibial nerve transcutaneous electrical stimulation were reviewed by the faecal incontinence surgery committee. [238] In the absence of any controlled studies, this committee concluded that tibial nerve stimulation was an investigational technique and did not endorse it for clinical use.

6. UPDATE: REVIEW OF EVIDENCE FOR 2008-2012

Five studies published between January 2008 and January 2012 met criteria for review (Table 3). Two studies were RCTs comparing manometric biofeedback to PFMT, [232,239] a third RCT compared different methods of performing PFMT, [240] and the last evaluated the effects of PFMT vs. no PFMT on the prevention of anal incontinence (i.e., inclusion of flatus incontinence) during pregnancy and post-partum. [241] Another large cohort study [242] was included because it addresses the duration of biofeedback effects by following subjects until 60 months.

The Heymen et al. study [232] is important because of its novel design: All patients were first treated for 4 weeks with a conservative treatment protocol that emphasized patient education and normalization of stool consistency with fibre or non-prescription medication. This run-in protocol included only what is considered standard care for faecal incontinence, but the educational component was enhanced by (a) using schematics of the anatomy of the pelvic floor and images from defaecography to teach them why they were incontinent, and (b) having patients keep diaries of bowel accidents and stool consistency. At the end of 4 weeks, patients were asked whether they had experienced “adequate relief” of faecal incontinence, and the 21% who answered affirmatively were excluded from the rest of the trial. The remaining patients who did not report adequate relief had been randomly assigned before the run-in period to either biofeedback plus PFMT or PFMT alone. These interventions were presented in such a way that there were no differences between groups in the expectation of benefit. The biofeedback intervention combined strength training with sensory and coordination training, and was delivered in 5 one-hour sessions spaced approximately 2 weeks apart. PFMT was taught by verbal instruction, not

An intent-to-treat analysis at 3 months showed that significantly more patients in the biofeedback group reported adequate relief compared to the PFMT-only group (76% vs. 41%). Continence (zero faecal incontinence episodes in the previous month) was achieved by 44% of biofeedback-treated patients compared to 21% of PFMT-only patients. Scores on the validated Faecal Incontinence Severity Index [243] confirmed significantly greater improvement in the biofeedback patients compared to the PFMT-only patients at 3 months and again at 12 months follow-up. Heymen et al. [232] also showed that biofeedback-treated patients increased their anal canal squeeze pressures and decreased their abdominal wall tension during pelvic floor contractions significantly more than PFMT-treated patients, but changes in sensory thresholds were not significantly different.

The results of Heymen et al. [232] suggest that biofeedback plus PFMT is superior to PFMT alone in patients with moderate to severe faecal incontinence. They also show that treatment benefits of both biofeedback and PFMT are not explained by nonspecific treatment effects of conservative management such as education and normalization of stool consistency. Furthermore, these data provide evidence that PFMT is more effective than conservative management alone.

Bols et al. [239] reported an RCT which also compared manometric biofeedback plus PFMT to PFMT alone. Eighty patients with moderate to severe faecal incontinence were randomized to these two conditions. Up to 12, 35-minute training sessions were provided, and the primary outcome was the Vaizey Incontinence Severity Score. There was no significant difference between groups, although there was a trend favouring manometric biofeedback: 82.5% of the manometric group vs. 66% of the PFMT-only group improved by more than one point on the Vaizey scale. Limitations of this study were lack of power, only 75% of the numbers calculated beforehand as needed for adequate power were enrolled, and the fact that the intervention was provided by 25 different physiotherapists in private practice settings.

Bartlett et al.[240] compared exercise regimens, i.e., whether the patients were trained to perform fast twitch exercises (1 sec duration contractions) in addition to slow contractions (10 second squeezes) or they only performed slow contractions (10 second squeezes). The 72 patients enrolled in this
| Reference          | Country          | Population                                                                 | Intervention                                                                 | Control                                                                                                                                                                                                                                                                                                                                                                                                   | Outcome                                                                                                                                                                                                                                                                  | Comments                                                                                                                                                                                                                                                                                                                                 |
|--------------------|------------------|-----------------------------------------------------------------------------|------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Heymen et al. 232  | USA              | 108 patients with faecal incontinence, Mean age=59.6 years, 77% females.  | Manometric biofeedback (BF) taught in 6 biweekly sessions of 60 min each. Patients taught to coordinate pelvic floor muscle contractions with sensation of balloon distention. Also performed pelvic floor muscle exercises (PFME) daily. Only difference from control was BF. | BF group verbal instruction. Instructed to squeeze 100X/day. Returned for biweekly sessions to review diary and receive further instructions. Matched to BF group on therapist contact time and expectancy. | Groups comparable at baseline. At 3 mo. follow-up, BF showed greater decrease in FISI than PFME. 76% of BF reported adequate relief at 3 mo vs. 41% PFME. Greater improvement maintained at 12 mo follow-up. Complete continence in 44% of BF vs. 21% of PFE. | Strengths: Exclusion of subjects responding to medical management and use of intent to treat analysis. Weakness: Most assessments not performed by blinded assessor. No differences in quality of life improvement. |
| Bols et al. 239    | Netherlands      | 80 FI patients with Vaizey severity score >12 (possible range 0-24).        | Rectal balloon training (RBT) + PFME. RBT was individualized: For insensitive rectum, patient was trained to respond to smaller volumes; for hypersensitive rectum, patient was trained to tolerate larger volumes using progressive distension and urge resistance. All patients received coordination training. PFME training was individualized with goal of improving strength and duration of squeeze. Sessions were 45 min. | PFME training was individualized with goal of improving strength and duration of squeeze. In both arms patients received up to 12 sessions in 9-week period. Sessions were 35 min. long. | Primary outcome was Vaizey severity score which was not significantly different between groups. 82.5% of RBT group and 66% of PFME-only group improved >1 on Vaizey scale. Some secondary outcomes favoured RBT. | Limitations: Lack of power: only 75% of required sample size for adequate power was included. The use of 25 different physiotherapists from private practice may have resulted in inconsistent treatment. |
| Bartlett et al. 240| Australia        | 72 patients with onset of faecal incontinence following colorectal cancer surgery were randomized to two groups. Mean age 62 years; 73.6% female. | All patients received 4 weekly manometric BF sessions plus PFME training in sustained, 10 sec squeezes. The experimental group received additional practice of 1/sec rapid maximal contractions. | Equivalent number and type of BF sessions combined with PFME training of sustained, 10 sec contractions. The only difference was no rapid exercises. | Both groups improved with no difference between groups. Attrition rate was 22-29%. | Major limitation: Heterogeneity of population and small sample sizes (type 2 error) |
| Bo et al. 241      | Norway           | 105 sedentary primiporous women without history of faecal incontinence     | PFME taught as part of group exercise class 2X/week for 12 wks. Patients performed 3 sets of 12 maximal contractions per class. Only group verbal instructions provided. | Controls received usual care. | No difference in number of women reporting flatus or faecal incontinence during pregnancy or at 6 wks. post-partum. | Study was underpowered. |
| Lacima et al. 242  | Spain            | Cohort of 95 patients continent of solid stool referred for BF. Mean age 61 years; 85% females. Excluded patients with recent obstetric injury, cloaca defect, and rectal prolapse. | Manometric BF combined strength training, sensory training, and coordination training for five 45-min.sessions. Daily PFME were also prescribed. | No treatment. Cohort of 40 patients referred to the same clinic for evaluation but BF was not recommended and no treatment for faecal incontinence was prescribed. | At 60 months follow-up 86% of the BF group were continent or had >75% reduction in faecal incontinence frequency compared to 26% of untreated controls. | Strength: 60 month follow-up. Weakness: patients were not randomized to treatment. The BF group had greater average faecal incontinence severity than controls at baseline. |
study had an onset of faecal incontinence following colorectal cancer therapy. Both groups improved with no difference between groups.

Lacima et al. [242] followed a cohort of 95 patients whom he treated with biofeedback and PFMT and followed up 60 months later. What makes this study worth including is that the authors showed that even at 60 months following training, 86% of the biofeedback/PFMT group were continent or had at least a 75% reduction in the frequency of faecal incontinence.

7. TIBIAL NERVE PERCUTANEOUS STIMULATION

There has been persisting interest in the use of tibial nerve stimulation for the treatment of faecal incontinence, reflected by the publication of several uncontrolled case series. [244,245] The theory behind this treatment derives from traditional Chinese medicine which identifies the posterior tibial nerve as an acupuncture point where stimulation can inhibit bladder contraction. Stimulation is done either using surface electrodes applied over the tibial nerve at the level of the ankle or by inserting a needle electrode into the region of the tibial nerve. Published case series [244,245] show a modest benefit for approximately half of patients tested, and in the absence of controlled studies, this technique must still be regarded as investigational.

Another variation of electrical stimulation is trans-abdominal electrical stimulation accomplished by passing electric current between an electrode on the abdominal wall and one on the back. This has so far been used only in children with slow transit constipation, [246] many of whom have encopresis. Reports show improved transit time, [247] improved quality of life, [244] and reduced encopresis. [245] This technique may find application in adults with overflow faecal incontinence but is currently regarded as investigational.

8. SUMMARY OF EVIDENCE

- Manometric biofeedback training is possibly effective. A new high quality study provides support for the hypothesis that biofeedback, when provided by an experienced therapist, is more effective than pelvic floor exercises alone, but the variability between studies suggests that results may be dependent on the training and experience of the therapist. (Evidence Level 1)

- PFMT is possibly effective for the treatment of faecal incontinence. New evidence shows that PFMT alone significantly improves outcomes for patients who have not responded to conservative management. [232] (Evidence Level 2)

- There is no support for the hypothesis that adding “fast twitch” contractions to PFMT improves continence outcomes. (Evidence Level 2)

- There is no support for the addition of electric stimulation from non-implanted devices in the treatment of faecal incontinence. (Evidence Level 2)

9. RECOMMENDATIONS FOR PRACTICE

- PFM exercises are recommended as an early intervention in the treatment of faecal incontinence as part of a conservative management bundle of interventions, based upon low cost and morbidity and weak evidence suggesting efficacy. (Recommendation Grade B).

- The use of biofeedback as a treatment for faecal incontinence is recommended after other behavioural and medical management has been tried, if adequate symptom relief is not obtained, given the numerous positive outcomes from uncontrolled trials, limitations in the current RCTs and low morbidity associated with its application. (Recommendation Grade B).

- Based on currently available evidence it is not possible to recommended electrical stimulation for faecal incontinence. (Recommendation Grade C)

10. RECOMMENDATIONS FOR RESEARCH

- There is a need to conduct further RCTs to determine whether specific biofeedback and pelvic floor muscle exercise protocols can alter physiological parameters of ano-rectal function with concomitant changes in bowel control.

- Clear description of modalities and evaluation of different elements of biofeedback

- Adherence monitoring

- Standardisation of outcome measures

- Long term follow up

- Robust patient-focused outcome measures

- Understanding of physiological effect and relationship to symptom change

- Work on clinically meaningful improvement and distinguishing cure from improvement rates

- The exploration of possible synergies between urinary and faecal incontinence interventions and evaluations should be considered in study designs.

IX. QUALITATIVE RESEARCH ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

1. BACKGROUND

The experience of faecal incontinence has been studied from a qualitative perspective since 1999 and tied with quality of life. Qualitative methods focus on
the intensive investigation of the particular, and the meaning of a phenomenon, in this case, faecal incontinence. Because qualitative studies generate large amounts of quality text data small purposeful sample sizes are used to accomplish their aims. These studies focus on studying the context or experience of a phenomena rather than measurement of variables. Sample sizes in the 14 studies included in this review ranged from 9 to 100 for qualitative phenomenological, grounded theory and descriptive studies, to 186 participants in an open ended questionnaire interview, for a total of 462 participants. Three studies received a grade of C but were included in the review because the evidence was relevant and substantiated by other quality studies.

The studies below have used a number of qualitative methods to explore the experiences of quality of life using phenomenological, grounded theory and qualitative descriptive designs using in-depth interviews, one study used one question with a rating scale, and one study used a semi-structured interview questionnaire. A thematic analysis was completed on the content of the quality of life studies, and the following five themes were derived and used as categories for the review of content: issues relating to relationships, time, body, sexuality and diet. Of the twelve studies reviewed on faecal incontinence, 4 studies focused on community living women, one study of women in a nursing home with pelvic floor dysfunction, one study of community living men, 4 studies of community living adults, and studies of specific diseases causing faecal incontinence including spinal bifida and multiple sclerosis.

2. CRITERIA FOR EVALUATION

Over the last 25 years there has been an extensive debate about the best methods and criteria to evaluate qualitative research studies. Criteria for the evaluation of qualitative research was synthesized using the most recent literature on quality and rigor, and is included here. These criteria were used to critique studies, strengths and limitations were noted, and a grade was given for practice recommendation.

In the last 10 years new ideas and criteria have been designed and are now being applied to evaluate qualitative studies.[248-257] The qualitative research studies on faecal incontinence (faecal incontinence) and quality of life, related to faecal incontinence, will be analyzed according to these new criteria summarized below. The strength of the evidence provided by an individual study depends upon the individual study design to maximize application to practice. A grading procedure has been developed here to rate studies for their applicability to practice from A to C.

a) Type of study – The qualitative evidence pyramid

1) Qualitative metasynthesis

2) Interpretive designs including phenomenology, grounded theory, ethnography.

3) Descriptive qualitative designs using content analysis (including inductive and deductive content analysis approaches, analysis of focus group data, photovoice, participatory action research, single or multiple case studies).

4) Surveys with semi-structured open-ended questions.

b) Criteria for evaluation of qualitative studies

1) There is a set of discernable research purposes or questions that are suitable for qualitative inquiry.

2) The purpose or questions are linked with a critical review of the literature and key studies are included identifying a gap or misunderstanding of the phenomenon.

3) There is a guiding frame of reference for the study that fits the target phenomenon.

4) There is congruence between the method and the research purpose.

5) The sampling plan is purposeful and fits the purpose and method.

6) The sample size and configuration fit the purpose and sampling strategy.

7) Inclusion and exclusion criteria are described and appropriate for the purpose.

8) Data collection techniques and sources fit the purpose, method and sample.

9) The analysis plan fits the purpose and method.

10) Data are sufficiently analyzed and interpreted, data is re-represented and category or thematic meaning is apparent. The interpretation or description is distinguishable from the original data collected.

11) The participants’ voices are heard through examples highlighting the categories or themes of the findings.

12) Concepts and ideas are well developed and linked to each other and to the data.

13) The results offer new insight into the phenomenon studied and transferability of findings is evident.

14) Reflexivity is addressed within the context of the study.

15) Evidence of an audit trail of how key decisions were made is clear. Strategies to achieve rigor are described.

16) Study specific limitations are summarized.

17) Ethical considerations are attended to and described.
c) Levels of evidence

Level 1: A study would include all criteria. Excellent evidence leads to a practice recommendation.

Level 2: A study should include criteria numbered 1, 4 - 13, 17. Moderate evidence leads to a possible practice recommendation (more evidence is needed).

Level 3: A study does not include the majority of criteria for evaluation. Poor evidence that does not lead to a practice recommendation.

d) Grades of recommendation

Grade A recommendation: Grade A recommendation includes studies with evidence levels 1-2 (the qualitative evidence pyramid).

Grade B. Grade B recommendation includes studies with evidence levels 2-3.

Grade C. Grade C recommendation includes studies with evidence levels 3 or lesser quality.

3. SEARCH METHOD

In order to gain a deeper understanding of the experience of having faecal incontinence from the perspective of the client, the PUBMED database (from 2000 to 2011) was searched using the following subject headings and key words: qualitative research; anal, bowel, faecal and incontinence; quality of life and faecal incontinence; and quality and rigor in qualitative research. Additional articles were identified by examining reference lists from articles, articles in press by the authors and other systematic reviews. This search yielded over 600 studies of which only 16 used qualitative methods and 11 were used for evaluation of qualitative methods. These articles included topics on the experience of faecal incontinence from the perspectives of men and women, faecal incontinence and colorectal cancer, incontinence and sexuality, quality of life and faecal incontinence, and quality and rigor in qualitative research. Additional articles were identified by examining reference lists from articles, articles in press by the authors and other systematic reviews. This search yielded over 600 studies of which only 16 used qualitative methods and 11 were used for evaluation of qualitative methods. These articles included topics on the experience of faecal incontinence from the perspectives of men and women, faecal incontinence and colorectal cancer, incontinence and sexuality, quality of life and faecal incontinence, pelvic floor dysfunctions and frail elderly women, diet strategies to manage faecal incontinence, goals of faecal incontinence management, life with post-natal faecal incontinence, and spina bifida.

4. REVIEW OF EVIDENCE ON THE EXPERIENCE OF FAECAL INCONTINENCE AND QUALITY OF LIFE

The review of the evidence on the experience of faecal incontinence and quality of life begins with a study review including the study purpose, design and critique of the design and the evidence level. The findings were overlapping for most studies so that the study findings are summarized in a following section using five categories of experience/quality of life that were identified: relationships, time, bodily symptoms, sexuality, and diet.

A descriptive qualitative study conducting unstructured interviews of 20 women’s experiences of faecal incontinence from Britain focused on the assessment of symptoms of incontinence, coping strategies and the provision of continence aids.[258] The quality of the study was fair to good. Details of the analysis procedure were not clear and participant’s voices were not included in the report. Additionally reflexivity concerns were not addressed.

The purpose of a descriptive qualitative study in the United Kingdom was to identify question items for a quality symptom and quality of life assessment for individuals with anal incontinence.[259] Three sub-studies addressed the purpose. First, seven clinical experts were asked to characterize symptom items of anal incontinence, second,[284] free text comments from patients involved in a treatment intervention trial were collected, and third, 31 qualitative interviews were conducted with people with anal incontinence. The study design was strong and inclusive of clinicians and patients. A grounded study method was mentioned as the study design but no substantive theory was developed and reflexivity was not addressed.

Another descriptive qualitative study in Sweden explored faecal incontinence in adults with spina bifida.[260] Using semi-structured interviews with 11 subjects, themes were generated using content analysis. The rigor of this study was good with insightful findings and powerful quotations used to illustrate the interpretations of the participants’ experiences. Specifics of the analysis process were not given which was a weakness. The concept of reflexivity was not addressed.

A phenomenological study using 10 community dwelling women was conducted on dietary issues in the US.[145] The study was a secondary analysis of the dataset collected in a larger study by Peden-McAlpine, Bliss, and Hill.[261] Content focused specifically on diet and the meaning of the role of diet and food related to faecal incontinence. Narrative interviews were conducted with the women and the design of the study was strong with few limitations although reflexivity was not mentioned.

A descriptive qualitative study, conducted in the US on frail elderly women, with pelvic floor dysfunction, in nursing homes, interviewed 25 women ages 65-96.[262] The purpose of the study was to increase understanding of the views of frail elderly women in residential care related to quality of life, and values and preferences for pelvic floor care. The study design was strong and used NVIVO as a tool to identify representative categories. The categories derived were not specifically related to the aims. One limitation was that the criterion of reflexivity was not addressed.

A study in the U.S.[263] interviewed clients about their goals for faecal incontinence management as part of a RCT on dietary fibre. The main purpose and source of data in this study was not an interpretive qualitative
exploration. A semi-structured interview questionnaire was used to elicit goals from 189 people with faecal incontinence. The study design was methodologically sound and the overall quality was excellent.

A phenomenological study on community living women was conducted in the USA to investigate the lived experience of women managing faecal incontinence.261 The study used in-depth narrative interviews with women between the ages of 37 and 78. The study design was excellent although issues of reflexivity were not mentioned.

A phenomenological study on 11 community living men, between the ages of 48-85, was conducted in the USA to investigate the lived experience of men managing faecal incontinence.264 The study used in-depth narrative interviews with men between the ages of 37-78. The study design was excellent although issues of reflexivity were not mentioned.

A study from England was conducted to explore the impact of incontinence on an individual’s sexuality and to identify the impact of health interventions for the management of incontinence on sexuality.265 A quota sample of 27 subjects who were being successfully managed and those being unsuccessfully managed were interviewed. The study design was strong although the inclusion/exclusion criteria used for quota sampling was not specific and reflexivity and limitations were not addressed.

One study from Denmark explored how post-partum women experience and cope with faecal incontinence.266 In-depth unstructured interviews were conducted with 9 women ages 28-50 and analyzed with a grounded theory analysis technique for analysis. This study was of good quality however reflexivity, ethical considerations, and limitations were not noted.

A qualitative analysis was conducted on letters sent to the Multiple Sclerosis Society in the UK after a letter regarding constipation was printed in the Society’s newsletter.267 More than 100 letters and emails were received from Society members discussing their bowel problems and were analyzed using a qualitative approach. The study quality was good however the detail of the analysis was lacking.

A study in the UK investigated aspects of distress, expressed by colorectal cancer patients, to produce a more detailed account of the illnesses’ impact on their identities and self-understanding.268 Thirty-nine men and women participated in in-depth interviews from across the UK. The sample included 19 men and 20 women ranging from 33 to 87 at the time of the interview. The study design was strong and the findings portrayed a powerful experience of these participants. No report of reflexivity was noted.

A qualitative descriptive study conducted unstructured interviews with 10 women who had flatual or faecal incontinence, post-vaginal delivery, with a view to improve an existing quality of life scale for faecal incontinence.269 The authors came to interesting conclusions about relevant parameters to measure in younger women with faecal incontinence, but it is not clear if these concepts are reflective of the participants’ voices. The collection technique, analysis and concept development were not explained.

A qualitative descriptive study completed guided interviews with 22 community living adults with faecal incontinence.270 The aims of the study were to explore the participants’ experiences of faecal incontinence on lifestyle, quality of life and how they adapted management strategies. Another aim was to learn about their disclosures and reasons for seeking help from health professionals. Grounded theory was stated as the method although a substantive theory was not produced in the findings. The findings were not well interpreted and linked together. Some insightful information was learned from the study, about faecal incontinence, that was corroborated by other quality studies.

A descriptive qualitative study was conducted in Britain to validate a draft questionnaire measuring quality of life issues with community living women with faecal incontinence.271 Twenty-seven women with longstanding faecal incontinence problems were invited to participate in one of 2 focus groups. The mean age of the women was 51. No specific procedures for data analysis were included and reflexivity and ethical issues were not mentioned. Study findings were similar to those of other quality studies.

5. LIVING WITH FAECAL INCONTINENCE AND RELATIONSHIPS – SUMMARY OF EVIDENCE

- Men and women found that faecal incontinence was a perceived threat to their social acceptability, privacy and relationships. [258, 261, 262, 264, 265, 269] (Evidence Level 1)
- Who to tell about the faecal incontinence problem and when was a matter of great concern. Usually family, close trusted friends and co-workers were told because it could not be kept a total secret. [258, 261, 264] (Evidence Level 1)
- Discussing the problems with others who suffered from faecal incontinence was comforting and allowed conversation about how to manage the problem. [261, 264] (Evidence Level 1)
- Humor was used as a resource to avoid humiliation and embarrassment in dealing with daily symptoms of faecal incontinence and relationships, even though feelings of shame and humiliation persisted. [259, 261, 264] (Evidence Level 1)
- Men and women spoke about their discomfort in being with ‘mixed company’ and their concerns about a possible accident. Gender was an issue in relation to perceived social risk [261, 264] (Evidence Level 1)
Men and women described trying to protect themselves from the unpredictability of their symptoms and kept up a façade to keep the secret of faecal incontinence from others. [259] (Evidence Level 2)

Support from spouses was noted to be very important for men and women. [258, 261, 264, 266] (Evidence Level 1)

Relationships with healthcare providers were not helpful in providing advice concerning symptom management and control. Misinformation or no information was commonly given. [258-261, 264] (Evidence Level 2)

Women reported feeling embarrassed and humiliated by having their faecal incontinence problem minimized or trivialized by rude or blaming health care providers leading, to the feeling of marginalization. [259, 261] (Evidence Level 1)

Women had concerns about entering into new relationships and there was an expressed concern about fear and shame of having to disclose their bowel problems. [259] (Evidence Level 2)

Anxiety was present in both men and women who suffered from the uncertainty of social isolation because of faecal incontinence. [145, 258-261, 264, 266] (Evidence Level 2)

6. LIVING WITH Faecal INCONTINENCE AND TIME AND PLANNING – SUMMARY OF EVIDENCE

• Participants describe spending a significant amount of time planning for and worrying about accidents. [261, 264] (Evidence Level 1)

• Men and women perceived that their symptoms of faecal incontinence grew worse with aging in relationship to severity, onset and duration. [261, 264] (Evidence Level 1)

• Men and women had symptoms for months or years before seeking help for the condition. [261, 264] (Evidence Level 1)

• Women reported that the frequency of stool leakage was unpredictable and because of this, they needed to be vigilant and prepared for the unexpected. [259, 261] (Evidence Level 2)

• Planning and management strategies of faecal incontinence to avoid an accident included: morning bathroom rituals, changing the location of their workstation (relative to the bathroom), altering eating habits (foods and timing), taking a fibre supplement, or using anti-diarrheal products. [258-261, 264] (Evidence Level 2)

• Many women discussed packing ‘kits’ of absorbent products, cleansing supplies, extra clothing as a routine part of planning to leave their home. [258, 261] (Evidence Level 2)

• Women postponed business meetings because of the faecal incontinence. [261] (Evidence Level 2)

• Women reported the frequency of stool leakage was unpredictable and because of this they needed to be vigilant and prepared for the unexpected. [258, 261] (Evidence Level 2)

• Space was experienced as a measure of risk exposure for faecal incontinence and personal space shrank inward or expanded related to perceived comfort or lack of perceived social safety. [258, 260, 261, 264, 265, 268, 272] (Evidence Level 2)

• Seeking out the location and availability of a bathroom was a major consideration in all dimensions of space outside the home. [258-262, 264, 267] (Evidence Level 2)

• Travel was limited to places that felt comfortable and significant planning was done to prevent an accident. faecal incontinence limited travel for the family. [254, 261, 264, 266] (Evidence Level 2)

• Women and men experienced heightened anxiety about faecal incontinence symptoms

a) Recommendations for practice

• Health care providers need to acknowledge the problem of faecal incontinence compassionately, and initiate the assessment and discussion of faecal incontinence symptoms, so they can be properly managed. The stigma, embarrassment and sensitivity associated with faecal incontinence compel clinicians to refrain from giving dismissive or blaming responses that may retard future care seeking and contribute to the under reporting of faecal incontinence. (Recommendation Grade A)

• Health care professionals can facilitate gender sensitive support groups and sharing of practical knowledge of faecal incontinence symptom management. (Recommendation Grade A)

• Primary care/generalists should refer patients to incontinence specialists when unable to provide therapeutic advice or treatment. (Grade B)

b) Recommendations for research

• Investigate the use of humour as a therapeutic coping strategy for dealing personally with the symptoms of faecal incontinence

• Defining the attitudes and treatment goals of health professionals treating faecal incontinence would be helpful to the identify some of the barriers to effective treatment.
and the risk of accidents in public spaces. [258,260,261,264] (Evidence Level 2)

• Work life presented complicated situations for both men and women and limited some people’s ability to engage in productive work outside the home.[261,264,268] (Evidence Level 2)

• Symptoms related to faecal incontinence were a common reason for early retirement for both men and women.[268,261,264] (Evidence Level 2)

a) Recommendations for practice

• Recommend that clinicians share findings of practical management strategies, such as preparing cleansing kits and locating public restrooms, with other patients who have faecal incontinence to help them self-manage their experiences better. (Recommendation Grade A)

• Recommend coaching clients on how to plan for and reduce unpredictable incontinence accidents and/or their embarrassment; teach patients strategies to go to social situations and into public more confidently by supporting self-efficacy (this could include education on products, packing a change of clothes, disposable wipes, using a bowel diary to plan schedules, etc.). (Recommendation Grade B)

b) Recommendations for research

• Study interventions that promote enhanced self-efficacy

• Evaluate effectiveness of using a bowel diary or keeping a routine schedule to reduce incontinence accidents in public

• Evaluate effect of public education campaigns on normalizing elimination and raising awareness that incontinence is a treatable condition

7. LIFE LIVING WITH FAECAL INCONTINENCE AND BODILY SYMPTOMS, SELF ESTEEM AND BODY IMAGE – SUMMARY OF EVIDENCE

• Across all studies feelings of shame and embarrassment related to faecal incontinence were noted. (Evidence Level 1)

• Women felt stigmatized because of the faecal incontinence problem and stigmatized themselves.[258,261,266] (Evidence Level 2)

• Men and women reported that their emotional life and self-confidence was undermined because of the faecal incontinence and embarrassment.[258,261,264,266] (Evidence Level 2)

• Men and women reported changes in body image and self esteem as a result of their inability to control the symptoms of faecal incontinence. [259,261,264] (Evidence Level 2)

• Not talking about the problem and denying the faecal incontinence was a coping mechanism used to protect themselves from a threat to self-esteem and to prevent public embarrassment.[266] (Evidence Level 2)

• faecal incontinence caused women to view themselves as shameful, impure, or unworthy. [260,266] (Evidence Level 2)

• Some women reported the need for psychological consultations because of the feeling of being insufficient and vulnerable.[259,266] (Evidence Level 2)

• Unpredictability of the type and timing of a faecal incontinence event and its magnitude were key issues discussed by men and women.[145,261] (Evidence Level 2)

• faecal incontinence was a consequence of exercise, heavy chores, and lifting.[260] (Evidence Level 2)

• Bodily sensations associated with the symptoms included sensations in the intestines, itching, burning, cramping, feelings of incomplete bowel movements, and odour associated with flatus. Other symptoms discussed included leaking stool without feeling the need to defecate and false abrupt and urgent sensations usually indicative of defecation. Men lost confidence in symptoms to alert them to faecal incontinence due to the unpredictability of faecal incontinence.[260,261,264] (Evidence Level 2)

• Skin excoriation around the anus was reported, because of frequent bowel movements, soiling and excessive cleaning.[261] (Evidence Level 2)

• Women were attentive to their body image and dressed carefully to conceal pads and wore dark clothing when outside the home to hide stains if an accident should happen. [259,261,265] (Evidence Level 2)

• Men and women wore only small disposable pads that were not obvious through their clothing. Large diaper like, pads were avoided because of their visibility beneath clothing. [259,261,264] (Evidence Level 2)

• The essential theme in the phenomenological study of men managing faecal incontinence was ‘secret resignation’ where men came to accept that the consequences of faecal incontinence were normal for them.[264] (Evidence Level 1)

• The essential theme in the phenomenological study of women managing faecal incontinence was ‘controlling the body out of control’ as women tried to control all aspects of their life in relationship to the faecal incontinence and avoiding accidents.[264] (Evidence Level 2)
Major goals of people experiencing faecal incontinence were to have fewer dietary restrictions, eliminate faecal leakage especially during exercise, less reliance on public toilet accessibility, more confidence in controlling faecal incontinence symptoms and a normal daily routine.[263] (Evidence Level 2)

A sense of mastery and new self-confidence was perceived by some after years of successfully dealing with the symptoms of faecal incontinence.[270] (Evidence Level 2)

a) Recommendations for practice

• Acknowledge and provide empathy for the common feelings of shame and embarrassment (Recommendation Grade B)

• Raise awareness with clients and general public that faecal incontinence can often improve with conservative treatment and is not something that must be “put up with” in private (Recommendation Grade A)

• Recommend that conservative symptom management for faecal incontinence includes education about causes of faecal incontinence, diet modifications including fibre supplements, behavioural strategies such as pelvic floor muscles exercises and biofeedback, anti-motility medications, and use of absorbent products such as pads and briefs. (Recommendation Grade A)

• Recommend that health care professionals share positive coping strategies identified by participants, with other people managing the symptoms of faecal incontinence, that include privacy issues in the bathroom, counseling, restricting activity, carrying a change of clothes, humour, knowing the location of toilets when out, care of diet, choosing clothes carefully, careful cleansing and use of pads. (Recommendation Grade B)

• Recommend that clinicians consider patient’s goals when developing a plan for faecal incontinence. (Recommendation Grade A)

• Requesting that people complete a daily stool diary is recommended when accurate information of faecal incontinence severity is important. (Recommendation Grade A)

• Appropriate referral to psychologists should be made to manage issues of self-efficacy, self-esteem and depression. (Recommendation Grade B)

b) Recommendations for research

• Determine how goal setting and tailoring interventions for faecal incontinence is effective in promoting adherence to a management plan.

• Evaluate whether training to pay attention to body sensations might reduce incontinence accidents.

• Studies of the effectiveness of interventions to promote a positive body image and increase self-esteem despite faecal incontinence are needed.

• Future studies should focus on the phenomenon of secret resignation as a method of coping by men, and effective techniques for treating these attitudes to assist them with improved communication with healthcare providers and care seeking.

• Studies are needed on approaches to educate and support men and women in adopting practices for managing faecal incontinence, the associated odour and urgency symptoms as well as to evaluate the successfulness of their practices.[264]

8. LIVING WITH FAECAL INCONTINENCE AND SEXUALITY – SUMMARY OF EVIDENCE

• Although asked about sexuality and intimacy women were reticent to discuss their sexuality or the effect of their symptoms on their sexual functioning.[259,261] (Evidence Level 2)

• Some women felt there were no changes in their sexual drive.[266] (Evidence Level 2)

• Women arranged timing of sex to meet their needs and the needs of their husbands in relation to the symptoms of faecal incontinence. [266] (Evidence Level 2)

• Women reported a range of psychosocial issues including lack of sexual arousal or a desire for abstinence.[259,260,265] (Evidence Level 2)

• Choice of clothing was an outward expression of sexuality and faecal incontinence and UI restricted clothing to wearing patterned materials in order to avoid people detecting an accident. [265] (Evidence Level 2)

• Men and women reported continually washing themselves to avoid smelling.[272] (Evidence Level 2)

• There was a lack of discussion of sexual concerns by health care providers after surgeries that affected sexual functioning.[265,268] (Evidence Level 2)

a) Recommendations for practice

• Recommend that clinicians ask directly about the impact of faecal incontinence on clients’ sexuality. (Recommendation Grade B)

• Recommend that clinicians establish a comfortable, stigma-free climate in order to elucidate
the impact on sexuality and teach practical strategies. *(Recommendation Grade A)*

**b) Recommendations for research**

- Interventions that minimize stool leakage during intercourse, such as pelvic floor muscle therapy
- Develop and test interventions to improve sexuality altered by faecal incontinence

### 9. LIVING WITH FAECAL INCONTINENCE AND DIET ISSUES – SUMMARY OF EVIDENCE

**a) Recommendations for practice**

- Diet is an important self-care strategy for faecal incontinence. Recommend that clinicians include teaching of successful strategies including timing of food intake, restricting food amounts to minimize leakage, avoiding aggravating foods, increasing water intake, and increasing the consumption of yogurt, high fibre foods or a fibre supplement. *(Recommendation Grade B)*

**b) Recommendations for research**

- Determine the effectiveness of diet restrictions and supplementation and modifications in food preparation in reducing faecal incontinence
- Assess the effect of timing of food intake in a bowel management program

### X. ALGORITHM

A revised algorithm for the initial management of faecal incontinence has been developed based on a review of new evidence in the literature within the context of previous evidence and consensus of an international group of experts on faecal incontinence. (See summary of the recommendations and algorithms at the end of this book.)

### REFERENCES
Therapy for faecal incontinence is readily divided into non-surgical and surgical therapy. Selection of specific therapy is based upon a number of considerations, including the severity of incontinence and structural integrity of the anal sphincter.

Conservative therapy is most applicable to relatively mild cases of incontinence. Biofeedback retraining can be attempted for incontinence of any cause or severity, as the therapy is painless and risk-free. These treatments are discussed in detail elsewhere in this monograph.

The most widely accepted surgical therapy for faecal incontinence is overlapping sphincteroplasty. Typical of other well-established therapies, the evidence base supporting this approach is paradoxically less robust than that supporting more recent treatment options. Sphincteroplasty is useful only in cases in which there is an anatomic sphincter defect, and it has been reported to provide satisfactory results in many case series. However, several recent studies have now shown that results of sphincteroplasty deteriorate with time [1,2].

A number of operations were developed in the early to mid 20th century to provide a treatment option for patients whose native sphincter was either intact but weak or not reparable. Muscle transposition procedures using either gluteus maximus or gracilis were devised to create a functional biological neosphincter, but the approach did not gain widespread popularity. The Parks postanal repair was devised in 1975 to treat patients with incontinence due to pelvic neuropathy [3].

Dissatisfaction with available operations for faecal incontinence led to development of a variety of novel procedures during the last 20 years. The stimulated (dynamic) graciloplasty and the artificial anal sphincter were devised as salvage procedures for patients who had failed or were not candidates for standard therapy. A more recent approach is the use of sacral nerve stimulation, which was adopted for this purpose from its previously better-defined role in detrusor overactivity incontinence and idiopathic urinary retention. Moreover, there has also been a trend towards development of minimally invasive approaches to faecal incontinence, such as the use of injectable biomaterials.

Several important caveats apply to interpretation of the results of surgery for faecal incontinence reported in the literature. First, the vast majority of reports are uncontrolled case series. Randomised controlled studies are rare, and those reported include only small numbers of patients [4]. Second, numerous quantitative measures have been used to report outcomes, but only recently have any of these been validated, such as the Faecal Incontinence Quality of Life (FIQL) instrument. Third, criteria for “successful” outcomes have been variable and often arbitrary. Fourth, the quality of data reported is variable, though it has generally improved with the passage of time. Chart review has been supplanted by patient questionnaires and interviews by independent data auditors; daily continence diaries, the most stringent form of data collection, have become increasingly commonplace (though not routine). Despite the fact that studies using lax data collection are certain to report better results than those using methodology that is more stringent, of necessity, composite reviews of surgical results include studies using various methods of data collection. Finally, results are not always reported on an intention to treat basis, particularly in the implantable device literature.

Search Methods

Pubmed search was conducted to identify studies published on the use of surgery for faecal incontinence in children and adults. Keywords used were faecal incontinence and surgery. Full text copies of studies deemed to be potentially relevant were obtained. Priority was given to systematic reviews, randomised controlled trials, and controlled clinical trials; if those were unavailable or inadequate, comparative observational studies, case series, case reports and narrative reviews were also included. Reviewers were not blinded to the names of studies’ authors, institutions or publications. In view of the nature of the guideline, priority was given to the
reports with large number of patients and long follow-ups assessing efficacy of surgical interventions. Particular emphasis was placed on those reporting techniques and functional outcome including quality of life after an operation.

Non-English language papers were noted but excluded from the review unless they contained an English-language abstract providing sufficient information.

II. SURGERY FOR ADULT FAECAL INCONTINENCE

1. SPHINCTER REPAIR

Anal sphincter repair is the term used to describe primary repair of the anal sphincter mechanism following direct trauma. The most common indication is following childbirth and repair in this situation is usually performed by the attending obstetrician. Colorectal surgeons are more commonly involved in primary repair of injury that is the result of blunt or penetrating trauma. Occasionally, the anal sphincter mechanism is damaged during anorectal surgery for other anal pathology particularly surgery for anal fistula.

In Western obstetric practice, the incidence of overt anal sphincter injury (grade 3 or 4 tear) is low, 3-5% following primiparous delivery and 0.5-1% following second and subsequent deliveries [5]. When prospectively looked for with endoanal ultrasound, the actual incidence of anal sphincter injury is higher [6,7]. A meta-analysis of 717 vaginal deliveries found an incidence of new anal sphincter defects of 27% in primiparous and 9% in multiparous women using 2D endoanal ultrasound [8]. 3D ultrasonography suggests that the incidence is somewhat less, perhaps 11%, following primiparous delivery [9]. The risk factors for sphincter injury include instrumental vaginal delivery, prolonged second stage of labor, fetal macromelia, and a persistent occipital position of the fetal head [7,10-12]. Midline episiotomy is associated with higher incidence of anal sphincter injury and the angle of mediolateral episiotomy may also influence perineal outcome [13]. A policy of restrictive use of episiotomy may reduce the incidence of anal sphincter injury [14].

Obstetric injury of the perineum is classified as a first degree tear if confined to vaginal epithelium and skin, second degree if the perineal muscles are torn, third degree if the anal sphincter muscles (external: EAS; internal: IAS) are torn, (3a: less than 50% EAS torn; 3b: more than 50% EAS torn; 3c: IAS torn) or fourth degree if both EAS and IAS and rectal or anal mucosa are torn [15]. Primary repair of an obstetrical tear is correctly termed anal sphincter repair and is usually performed by the obstetrician immediately after delivery, most commonly in the delivery room under local or epidural anaesthetic.

However recent guidelines issued by the Royal College of Obstetricians and Gynaecologists in the UK recommend that all such repairs should be performed in an operating room with adequate exposure, lighting and adequate anaesthesia [16]. By tradition, the technique of repair has been a direct oppositional repair of the severed EAS, however an overlapping technique, as commonly used in secondary repair (vide infra), has been recommended as it obligates identification and adequate mobilization of the severed ends of the EAS [17]. The IAS, if damaged, is difficult to identify separately and is usually repaired en block with the anal canal mucosa in a complete or 4th degree tear. Mahoney et al [18] however have shown that persistence of an IAS defect is adversely associated with continence outcome following repair of a 3rd or 4th degree tear, while Roos et al [19] have found that women with major tears (grade 3c or 4) were significantly more likely to have ultrasound evidence of a persisting IAS or combined IAS and EAS defect following obstetric repair. Such women were more likely to have poor functional outcomes. Separate repair of the IAS has been advocated [17]; however as with overlapping EAS repair, separate repair of the IAS requires good anatomical knowledge and meticulous technique and it is probable that these factors are reflected in the improved outcomes reported, rather than the actual technique used. Thus, McNicol et al [20] have reported full continence in 39/45 (86%) women who underwent primary repair using a standardized overlapping repair without separate identification and repair of the IAS.

There have been six randomised clinical trials [17,21-25], one meta-analysis [26], and a systematic review [27] that have investigated different techniques of immediate primary anal sphincter repair following obstetric injury. Four trials have found no difference between the overlapping and end-to-end repairs. One trial found the overlapping procedure superior and one found the end-to-end procedure to be superior. Thus it appears inappropriate to favor one type of repair over another [26]. [LEVEL OF EVIDENCE: 1] However, all studies were small and it is difficult to control for the skill of the individual obstetrician performing the repair. With regard to the suture material used in repair, a randomised trial found no difference in outcomes between braided and monofilament absorbable sutures with 12 months follow-up [22], while Parnell et al [28] found no difference in outcome in a case series of patients between absorbable and permanent sutures. [LEVEL OF EVIDENCE: 2]

As colorectal surgeons are in general more familiar with the anatomy of the anal canal, it has been suggested that primary anal sphincter repair might be best performed by a colorectal surgeon than an obstetrician [29]. Nordenstam et al [30] concluded, in a single institution study of 165 women, that technique and expertise impact on the outcome of pri-
mary repair and that if needed, the repair could be safely delayed until such expertise was available. In a similar study, Soerensen et al [31] found no adverse outcome with delayed primary repair; thus, repair can be safely delayed until adequate expertise is available. Co-operation between obstetric and colorectal surgical colleagues can result in much improved outcomes [20], while a structured training programme for obstetric trainees also improves clinical outcomes [32]. [LEVEL OF EVIDENCE: 2]

There have been two randomised trials of post-operative management of the bowel after primary anal sphincter repair. These have shown benefit in use of a laxative rather than a constipating regimen but no advantage to the addition of a stool bulking agent [33,34]. [LEVEL OF EVIDENCE: 1]

Alteration in faecal continence occurs in approximately 13 - 17% of women following primiparous vaginal delivery, even in the absence of a recognised sphincter tear [6,35,36]. The prevalence is greater if urgency of defaecation is included as a symptom [7]. MacArthur et al [37] found flatal incontinence in 27% of 7,879 women surveyed 12 weeks after delivery. [LEVEL OF EVIDENCE: 2] Fenner et al [38] found that women who had sustained third and fourth degree tears were more likely to have bowel incontinence than women without anal sphincter injury 6 months following delivery. This was more pronounced in women with a history of 4th degree tear. Samarasekera et al [39] have found long-term effects on anal continence and quality of life following postpartum anal sphincter injury. Oom et al [40] have suggested that concomitant injury to the pelvic floor may be an associated determinant of outcome in addition to adequacy of sphincter repair. [LEVEL OF EVIDENCE: 2]

Management of subsequent labor following a previous anal sphincter tear must take account of obstetric risk factors, symptoms of incontinence and patient preferences. Harkin et al [12] found an approximately 5 fold increase in the incidence of recurrent sphincter tear compared to the incidence of first sphincter injury during second labor. Fynes et al [41] found that women with altered continence after first vaginal delivery were at risk of deterioration if delivered vaginally on their second pregnancy. Cesarean delivery before the onset of the second stage of labor was found to be protective [42]; however, Nelson et al [43] in a systematic review found that pregnancy rather than delivery was a more important in predicting post partum continence. Recently, Scheer et al [44] have confirmed that subsequent vaginal delivery is reasonable in asymptomatic women after a previously repaired third degree tear. [LEVEL OF EVIDENCE: 3]

A number of studies have looked at long-term outcomes after repair of a 3rd or 4th degree tears and all have shown an increasing prevalence of continence disorders with age. These findings parallel those of the general population of parous women who have not had a recognised tear [45-47]. Eogan et al [48] found in a study of women, 10, 20 and 30 years following delivery that onset of menopause was the most significant determinant of symptoms, whereas Mous et al [49] found the incidence of incontinence increased with age irrespective of menopausal status. Fornell et al [50] found that subjective and objective anal function after anal sphincter injury deteriorates with time and subsequent deliveries. A persistent defect in the IAS was also found to be an important determinant, an observation supported by Mahony et al [18]. [LEVEL OF EVIDENCE: 3] There is some evidence that hormone replacement therapy may be of value in women who develop symptoms post menopause [51]. [LEVEL OF EVIDENCE: 2]

2. SPHINCTEROPLASTY

The term anal sphincteroplasty is used to describe secondary or delayed reconstruction of the anal sphincter musculature, injury to which has either not been recognised at the time of injury or the outcome of primary repair has been unsatisfactory. Anterior sphincteroplasty is the most common type of reconstruction performed because of the association with obstetric injury. In this situation, the anal sphincter muscles and perineal body have separated leaving a horseshoe type configuration to the anal sphincter mechanism, with a large defect in the anterior quadrant. Occasionally, the defect is such that the anal and vaginal mucosa have healed to form a cloacal defect. Anal sphincter defects related to previous anal fistula surgery or direct trauma are usually less complex and are not associated with a deficient perineum.

The decision to perform anal sphincteroplasty is based on an assessment of symptoms and the anatomical extent of the sphincter defect [52]. In assessing symptoms one of several continence scores should be used. The two most commonly applied are the Cleveland Clinic Continence Score [53] and the St Mark's Continence Score [54]. In addition a quality of life instrument should be applied [55]. Endoanal ultrasound is helpful in defining the extent of anal sphincter injury. 3D endo anal ultrasonography may provide further information [9]. Pelvic floor assessment using fMRI [56] or multiple contrast defaecating proctography [57] are valuable in the assessment of a more global pelvic floor injury. The American Society of Colon and Rectal Surgeons considers as surgical indication those symptomatic patients with localized defects, without defining exactly the minimum size of the injury detected as indication for this surgery [58]. [LEVEL OF EVIDENCE: 4]

Other causes of disordered continence should be excluded e.g. inflammatory bowel disease, colorectal cancer and neurological lesions. Patients with background IBS are more likely to be symptomatic.
than those more predictable bowel habit and equivalent anal sphincter defects [59]. Pelvic floor electrophysiological assessment, while not essential, if performed, should be comprehensive and not confined to measurement of pudendal nerve terminal motor latency [60].

For symptomatic patients with a less than one quadrant anal sphincter defect, a trial of dietary modification, stool regulating drugs and physiotherapy is appropriate. There are limited data regarding the role of biofeedback with or without electrical augmentation [61,62], however a recent Cochrane review concluded there were insufficient data to allow definitive assessment [63]. [LEVEL OF EVIDENCE: 2]

For patients with a more than one quadrant anal sphincter defect, anal sphincteroplasty is appropriate [4,15,52]. Preoperative counseling should identify post operative wound healing as the most common difficulty. The majority of patients can expect significant improvement in continence after the procedure with a mean of 66% reporting excellent of good results in the short term [52]. Concomitant repair of a cloacal defect or vaginal fistula should be undertaken [64-66]. There is no evidence that a defunctioning colostomy improves outcome. The results of anal sphincteroplasty in recent series reporting more than 50 patients are given in Table 1 [1,2,52,67-84].

Anal sphincteroplasty is usually performed in the lithotomy position although adequate exposure can be obtained in the prone jack-knife position. Full bowel preparation is not needed, although most would give a cleansing enema pre-operatively. The conventional incision is an inverted ‘V’ that may be closed as an inverted ‘Y’ as described by Parks [85]. If anterior levatorplasty or rectocele repair is contemplated, a posterior fourchette incision with the patient in lithotomy may have advantages [76]. The external anal sphincter is usually repaired using an overlapping technique without separate identification and repair of the IAS [15], however, Maslekar et al [82] attribute their good long term results to a selective policy of separate repair of the IAS. There has been one small randomised trial of direct versus overlapping sphincteroplasty which showed similar outcomes [86]. Occasionally the EAS defect is not full thickness and overlapping repair in such circum-

$ defined as “successful”
stances would require division of the residual intact fibres to facilitate overlap. Oberwalder et al [87] have found in a small series of patients that imbrication of the EAS in such cases is associated with outcomes similar to formal overlapping sphincteroplasty.

Initial success of sphincteroplasty is related to whether the anal sphincter defect is corrected [68,88]. Early failure is usually associated with a persisting defect identifiable using endoanal ultrasound [89]. This may be amenable to a further attempt at repair [88,90,91]. There is however increasing evidence that continence outcomes deteriorate with long-term follow-up [15,52,92]. Early failure is usually associated with a persisting defect identifiable using endoanal ultrasound [89]. This may be amenable to a further attempt at repair [88,90,91]. There is however increasing evidence that continence outcomes deteriorate with long-term follow-up [15,97]. [LEVEL OF EVIDENCE: 3]

Pre-operative physiologic testing is helpful in the overall management of patients with faecal incontinence, however the value of anal manometry and pelvic floor electrophysiological assessment as prognostic indicators for outcome following sphincteroplasty is controversial [98]. There are no established parameters that reliably predict outcome following sphincteroplasty [82,99]. Patients with an unsatisfactory clinical outcome follow sphincteroplasty may be considered, if sufficiently symptomatic, for adjunctive sacral neuromodulation (vide infra) [100]. [LEVEL OF EVIDENCE: 4]

3. POST-ANAL REPAIR

Post-anal repair was first reported by Sir Alan Parks in 1975 [3]. This procedure was designed to increase the length of the anal canal, restore the ano-rectal angle and re-create the flap valve mechanism, which at the time was thought essential for maintaining faecal continence. Success rates ranged from 15% to 83%, depending on the definition of the success, the length of follow-up, and possibly the cause of incontinence. The published studies regarding post-anal repair include three systematic reviews of randomised controlled trials (level 1) [4,101,102], two randomised controlled trials (level 1 [103] and 2 [104]), two non-randomised cohort studies (level 2) [105,106], 8 case series of good quality (level 3) [107-114] and 11 case series of poor quality (level 4) [3,115-124]. The results of post-anal repair are shown in Table 2 [3,103-124].

ns: not stated; PAR: postanal repair; ALP: anterior levatorplasty; TPFR: total pelvic floor repair
Subsequent observational studies with a median follow-up of more than 5 years revealed that continence deteriorated with time. Despite 60% to 80% of patients reporting persistent symptomatic improvement, only one-third were actually continent to liquid or solid stool [109,112,114,123]. Even in the most recent study reporting the long-term outcome of post-anal repair [124], only 26% reported none to minimal incontinence, with the Cleveland Clinic incontinence score being between 0 and 5, while 79% improved symptomatically with a mean follow-up of 9.1 years. Possible explanations for deterioration of continence following initial improvement included unrecognised denervation and/or muscular injury of the sphincter and pelvic floor musculature, and the presence of occult anal sphincter disruption, particularly in the studies reported before endoanal ultrasonography or magnetic resonance imaging were available. Moreover, physiological and radiological evaluations before and after postanal repair have not demonstrated consistent changes in anal canal length, resting pressure, voluntary contraction pressure, anorectal sensitivity and movement of the ano-rectal angle [104-107,125]. These reports of increasingly poor outcomes have diminished the popularity of this procedure significantly.

Deen et al [103] in a randomised controlled trial, comparing three procedures in 36 women with neuropathic faecal incontinence, found that complete continence was achieved in 42% of patients after post-anal repair, 33% after anterior levatorplasty and 67% after total pelvic floor repair. In contrast, van Tets et al [104] conducted a randomised controlled trial comparing post-anal repair and total pelvic floor repair in 20 women with neurogenic faecal incontinence. Complete continence to solid or liquid stool was achieved in 27% of patients after post-anal repair and in 22% after total pelvic floor repair.

4. NON-STIMULATED MUSCLE TRANSPOSITION

A variety of muscle transposition procedures have been devised for the treatment of faecal incontinence. Early efforts focused upon the use of transposed skeletal muscle to supplement the function of a weak or disrupted anal sphincter. Early in the 20th century, a number of surgeons utilized gluteus maximus muscle, transposed in a variety of configurations, to create a neosphincter [126,127]. In 1952, Pickrell et al [128] described the use of transposed gracilis muscle to create a neosphincter for incontinent children.

Published series of gracilis transposition are uncontrolled and demonstrate variable success rates [129-138]. [LEVEL OF EVIDENCE: 3] One study reviewed the functional results of graciloplasty longitudinally in 22 patients followed for a median 63 months [139]. 18 patients (81%) were improved at 6 months, though only one regained normal continence. Results deteriorated in 5 patients during subsequent follow up. Bilateral gracilis transposition has been used successfully in several small series [130,140].

Success rates following gluteus transposition have likewise been variable [141-145]. [LEVEL OF EVIDENCE: 3] A prospective randomised trial in women with post-obstetric neuropathic incontinence showed similar significant degrees of improvement following both gluteus maximus transposition and total pelvic floor repair [146]. A recent retrospective review of 25 gluteoplasty patients reported restoration of continence in 18 patients (72%) and partial restoration in an additional 4 patients (16%). Donor-site and peri-rectal complications occurred in 16 patients (64%) [147].

5. STIMULATED MUSCLE TRANSPOSITION

The transposition of the gracilis muscle to reconstruct the anal sphincter was first performed in children in 1952 [128]. The blood supply is primarily from a single proximal artery that allows excellent mobility for transposition [148]. Successful electrical stimulation of a previously transposed gracilis muscle was first reported in 1988 [149], and case series from 2 independent centers were simultaneously reported in 1991 [150,151]. Baeten et al [150] showed improved continence in 8 of 10 patients; Williams et al [151] in 12 of 20.

Even after successful muscle transposition, functional outcomes are limited by two physiological factors. First, patients are unable to consciously maintain tonic contraction of their neosphincters over long periods of time. Furthermore, even if patient volition were not a problem, gracilis muscle is poorly suited to tonic contraction. While the external anal sphincter comprises predominantly slow-twitch, fatigue-resistant type I fibres, the gracilis muscle comprises predominantly type II, fast-twitch fibres that are rapidly fatigable [152]. Graded electrical stimulation transforms type II into type I muscles fibres [153], and use of an implantable electrical pulse generator has been shown to convert transposed gracilis to a muscle with predominantly type I fibres [150-152]. The gracilis muscle is well suited to electrical stimulation due to the relatively constant proximal location of the neurovascular bundle, which is easily identified at surgery [154].

The results of stimulated graciloplasty are shown in Table 3 [155-165]. [LEVEL OF EVIDENCE: 2] In 1995, Baeten reported his results in 52 patients, with 38 (72%) becoming continent after surgery [155]. In a subsequent paper by this group published in 2003, 200 patients followed for a median of 261 weeks were reported [163].
The overall success rate was 72%. Patients with incontinence due to trauma had the best results (82% success), while patients with incontinence due to congenital anorectal malformation had the worst results (52% success). 138 complications were reported, including disturbed evacuation in 32 patients (16%), infection in 24 (12%), pain in 16 (8%) and pulse generator displacement in 12 (6%). Ten patients (5%) had anorectal perforations, 7 of whom eventually obtained a successful outcome. Rosen et al [166] reported restoration of continence in 9 of 10 patients treated by dynamic graciloplasty using a “split-sling” wrap configuration. Sielezneff et al [167] treated 16 patients and 13 had improved continence. However, 8 patients suffered morbidity, resulting in 33 subsequent admissions and 23 reoperations.

Three multicenter prospective trials of dynamic muscle plasty have been performed to date [158-160]. In each of these studies, patients served as their own controls. No randomised prospective trials have been performed.

Madoff et al [158] studied 139 patients from 12 centers, 128 of whom had gracilis wraps and 11 gluteus wraps. Of those patients, 104 were treated for faecal incontinence, and 35 underwent total anorectal reconstruction following abdominoperineal resection for cancer. Success rates for graciloplasty were 71% for patients with acquired incontinence and 50% for those with incontinence due to a congenital abnormality. There were a total of 138 complications for the entire group. Wound complications (41 major and 35 minor) were both the most prevalent and the most consequential. Other complications included pain in 28 patients (22%), hardware problems in 14 (11%) and tendon detachment in 4 (3%). Centers with significant prior experience with the procedure had substantially fewer major wound complications (17.4 vs. 33.1%) and significantly higher success rates (80% vs. 47%).

Mander et al [159] reported the results of dynamic graciloplasty in 64 patients with refractory faecal incontinence treated at 7 centers. There were 24 infectious complications, 5 of which involved perineal wound breakdown and 3 of which required reoperation. 44 (69%) patients became continent to solid stool 1 month following stoma closure. Evacuation problems developed in 16 patients (25%), and this lead to failure in 14. At a median of 10 months follow-up, 29 patients had a good functional result.

Baeten et al [160] reported the results of dynamic graciloplasty in 123 patients treated at 20 centers as part of the Dynamic Graciloplasty Therapy Study Group (DGTSG). The aims of this study were

* variable definitions; does not necessarily denote perfect continence. Issues of divergence in technique arose from these studies, each of which has seen increasing consensus in the literature despite a lack of randomised trial data. Thus, intramuscular (vs. epineural) electrodes are now universally employed, and diverting stomas and ‘vascular delay’ prior to muscle transposition are no longer utilized.
to assess both the safety and efficacy of this treatment; 189 adverse events occurred in 91 patients, including one death due to pulmonary embolism. There were 18 major and 31 minor infectious complications. There were 42 instances of therapy-associated pain, occurring variably in the donor leg, at the anal canal, or at the device site. There were 11 lead dislodgements but no problems with lead breakage or pulse generator malfunction. A follow-up study showed full or partial recovery from these complications in 87% of patients. [161] This study, in contrast to others, was based upon data from daily continence diaries. A successful result (defined as a 50% or greater decrease in incontinent events in patients without pre-existing stomas) was achieved in 63% of patients after one year. Another follow-up of this patient cohort demonstrated stable success rates at 18 months (55%) and 24 months (56%) [162]. Statistically significant improvements in the physical and social function scales of the SF-36 were also recorded at 12 months.

A multicenter retrospective trial from Belgium using dynamic graciloplasty treated 60 patients with 27 failures [164]. Continence was achieved in 78% of the group. However, more than half (26 patients) required the use of antegrade continence enemas or other measures to maintain continence. Seven patients had a permanent stoma constructed. Seventy-five complications occurred with 61 total reoperations. Loss of muscle stimulation occurred in 22 patients; 10 were due to issues specific to the stimulator and leads, 4 were due to technical failure of the muscle wrap. Functional outcome was directly associated with a maintenance of stimulation and initiation of stimulation within 50 days of surgery.

Very few studies have examined the long term results with dynamic muscle wraps. Thornton et al [168] reported on the 5-year follow up of 38 patients who had undergone dynamic graciloplasty. Of the 33 patients available for follow-up by telephone interview, obstructive defaecation was a problem for 11% of the cohort and 16% had been converted to a permanent colostomy. Of those with a functioning graciloplasty (22 patients) who reported a faecal incontinence score of less than 12 (range 0-24), 50% reported problems with obstructive defaecation and 64% felt their bowel habits had negatively impacted their quality of life. Long-term complications were primarily related to stimulator issues; ten patients required 15 operations to replace stimulator components. However, 72% of patients reported pain, swelling or paresthesias of the donor leg and 27% reported sexual dysfunction. Hassan et al [169] reported follow-up of 31 patients who underwent gracilis muscle transposition with periodic electrical stimulation and postoperative supplement of biofeedback. Twenty-two patients (71%) reported improvement at five-years. Nine patients (29%) were deemed failure requiring further surgical intervention (colostomy formation, contralateral dynamic gracilis muscle transposition, implantation of artificial bowel sphincter).

Six patients developed perineal wound infections (5 resolved with antibiotics, 1 required surgical drainage), and 2 patients had evacuation difficulties requiring regular enemas. Those who underwent operation due to traumatic injury to sphincters had better outcome (82% improvement) compared to patients with congenital faecal incontinence (55%).

Tillin et al [165] performed a prospective case-comparison study of 49 patients who had a dynamic graciloplasty and 87 patients who either refused the surgery or were not offered the surgery. The primary outcomes evaluated were symptoms, quality of life, anxiety, and depression. Of the treated group, the procedure failed completely in 15 patients. At two year follow-up, two-thirds of patients were either never or rarely incontinent to liquid or solid stool. Up to 50% of patients with a satisfactory outcome reported disorders evacuation and 8 other patients were deemed failures due to this problem. However, in comparison to the 87 patients who did not undergo treatment, there were significantly more patients in the dynamic graciloplasty group who reported a greater than 20% improvement in their incontinence scores. However, the treated group also had a significantly worse pain as assessed on a validated pain scale.

Chapman et al [170] performed a systematic review of dynamic graciloplasty for faecal incontinence on behalf of the Australian Safety and Efficacy Register of New Interventional Procedures- Surgical (ASERNIP-S). The authors reviewed 37 original articles published between 1991 and October 2000. All of the papers were judged to be of low-evidence quality, as all but one paper were case series, and the sole comparative study utilized historical controls. Mortality excluding cancer deaths was 1% (95% confidence interval 1-3%) and morbidity 1.12 (95% CI 0.14 - 2.08) events per patient. Success was variably defined between studies, but was reported as ranging from 42-58%. The ASERNIP-S Review Group determined that “the safety of the procedure cannot be determined at the present time due to an incomplete and/or poor-quality evidence base” and that “efficacy is established.” Tan et al [171] examined three treatments for faecal incontinence including dynamic graciloplasty, artificial bowel sphincter and end stoma. They concluded that the most cost effective intervention was an end stoma, the artificial bowel sphincter was most cost-effective after 10 years and that dynamic graciloplasty should only be considered as an alternative in highly specialized centers.

6. ARTIFICIAL ANAL SPHINCTER

Artificial sphincters can be defined as any kind of implanted device intending to replace or reinforce the sphincteric mechanism that normally closes the bowel end. They aim to be a substitute to the normal sphincters. As such, it is necessary that they be efficient for both terminal bowel functions: continence and evacuation; that their implantation be safe and reproducible, with a limited need for patient/medical
intervention and follow-up after implantation; and finally that they be cost effective.

There is active laboratory research at a preclinical phase for new artificial devices. Different parts of the world are involved, including China with a novel electro-magnetic anal sphincter with sensor feedback currently tested on animals [172-174], US with bioengineered tissue designed to mimic the function of the internal anal sphincter [175,176], and Germany with a new version of the previously described “German artificial sphincter system” (GASS), now consisting of an inflatable cuff connected to a combined implantable micropump, fluid reservoir and microprocessor [177]. These various prototypes have not been implanted yet in humans but clinicians have to be aware of any development of these innovations.

Artificial sphincters currently used in humans are silicone-made, pressure-regulated devices restoring continence through an inflatable cuff placed around the lower rectum or upper anal canal. Three models have been proposed on the market. Over the 5 last years, no publication has reported any results from the implantation of two of them: the prosthetic bowel sphincter (PBS) developed by Finlay in UK and the Agency for Medical Innovations (AMI) soft anal band system once popular in Germany and Austria. The only currently available data concern the Acticon Neosphincter® (American Medical Systems, AMS) artificial bowel sphincter (ABS).

The ABS, a modified model of the AMS 800 artificial urinary sphincter has been in use since 1996 for faecal incontinence management. In short, it comprises a fluid-filled cuff that encircles and compresses the anal canal. A pressure-regulating balloon is implanted in the retropubic space of Retzius. The system is controlled by a pump placed in the labia majora or scrotum which is accessible to the patient. To initiate defaecation, squeezing the pump empties the cuff by a fluid transfer into the balloon, allowing for the passage of stool. The cuff then refills automatically from pressure built up in the balloon.

The role of the ABS in the treatment of faecal incontinence has been confirmed in reports from different groups [178-182]. [LEVEL OF EVIDENCE: 2] ABS use has been supported in the current recommendations of both the United Kingdom’s National Institute for Health and Clinical Excellence (NICE) and the American Society of Colon and Rectal Surgeons (ASCRS) [58,183]. The ABS is especially indicated for patients with “severe end-stage faecal incontinence,” especially those with major sphincter disruptions that preclude direct sphincter repair, or those in whom sphincter repair has failed. For many of these patients, creation of a permanent end colostomy is the only remaining therapeutic alternative. However, generalizability of the published results remains doubtful as the majority of the series come from expert centers that have developed particular expertise in the implantation of artificial sphincters.

a) Functional Results of ABS

The artificial bowel sphincter provides good restoration of continence for solid and liquid stool in patients who retain the device, with all studies reporting almost similar data (Table 4) [179-181,184,185]. Implantation of an ABS was successful in 27 out of 33 patients in a Dutch series with a significant improvement in Williams faecal continence score at 17 month follow-up [180]. In a series from France, a new transvaginal approach to implant the cuff has been tested [178]. It was successful in 23 out of 32 patients (71.9%), with a device that remained activated for a mean follow-up of 41 (range 18-75) months, resulting in a significant decrease in Wexner incontinence score from 18.4 to 6.8 and no dyspareunia in sexually active patients [179]. Long term data from Spain reported a final success with an activated ABS in 9 out of 17 cases (53%) allowing for a decrease in CCF score from a median of 17.5 preoperatively to 10 at 66 month follow-up and a significant improvement in QOL [184]. In the report of a large single-center experience of ABS implantations, including 52 patients (46 women) implanted over the past 10 years, no publication has reported any results from the implantation of two of them: the prosthetic bowel sphincter (PBS) developed by Finlay in UK and the Agency for Medical Innovations (AMI) soft anal band system once popular in Germany and Austria. The only currently available data concern the Acticon Neosphincter® (American Medical Systems, AMS) artificial bowel sphincter (ABS).

CCF-FI: Cleveland Clinic Florida Fecal Incontinence (0: full continence - 20: worst incontinence); ns: not stated.

“Success” is defined as “continence to solid and liquid stool without significant obstructed defaecation, otherwise defined in each study”
years with 85 devices and a mean follow-up of 64.3 ± 46.5 months, 35 patients (67.3%) had a functioning device at review. A significant improvement in both CCF (P < 0.0001) and FIQL (P = 0.0286) was observed [185]. Some patients of this study with an activated ABS were matched to a group of successful SNS patients to compare their respective functional outcomes. Although this study had several limitations, it showed that the ABS achieved significantly better control of incontinence, albeit at the expense of more symptoms of outlet obstruction postoperatively and a similar quality of life for the 2 groups of 15 patients each [186]. [LEVEL OF EVIDENCE: 2] This risk of constipation after implantation of an ABS is a real concern as the cuff, even when opened, can narrow enough the anal canal to prevent a complete and easy evacuation. It has been well measured in a series of 44 patients with 55% of them expressing some sort of constipation or outlet obstruction [187].

b) Surgical Risks and Postoperative Complications of ABS

Besides an evident beneficial effect in treating severe faecal incontinence, the above-mentioned studies have confirmed the high risk of failure after implantation due to infection and mechanical failure. However severe morbidity is rare and no mortality has been ever reported. Explantation of the device generally solves the problems without long term sequelae.

The primary concern with ABS implantation is infection. In the report from the Cleveland Clinic 23 of 51 (41.2%) implantations became infected [181]. Among these, 18 (35.3%) developed as an early-stage (before ABS activation) and 5 (5.9%) a late-stage infection. On multivariable analysis the authors found that the time between ABS implantation and first bowel movement and a history of perineal sepsis were independent risk factors for early-stage infection. This may explain some variations in infection rate when compared to European reports where great care is taken in bowel preparation before device implantation. Series from France and Holland each reported a 21% infection rate [179,180].

Mechanical failure is now a well-recognised complication after ABS implantation. The most common cause is microperforation at the folds of the cuff membrane, which leads to a loss of fluid and pressurization of the system. Cuff perforation is easily perceived by the patient as both a return to incontinence and development of a non-functioning control pump. Cuff perforation reflects intrinsic wear-and-tear of the device components over time and contributes to the number of revision procedures, especially in patients with satisfactory functional ABS results. Revision rate is directly proportional to the length of follow up. With a mean follow-up of more than 5 years, half of a series of 52 patients required revision surgery after a mean of 57.7 ± 35.0 months, with 73.1% due to a leaking cuff [185]. Although ABS reimplantation is usually easy in the encapsulated area of the previous device, the risks of infection and impaired function are real and account for some long-term failures. Furthermore, the need for reimplantation increases the overall treatment costs. These concerns suggest that an appropriate component upgrade by the manufacturer might lead to improved long term results and a lower cost basis for this therapy.

Cost issues have been assessed in a complex health economics study [188]. The authors aimed to assess cost-effectiveness of ABS, dynamic graciloplasty and end-stoma in the treatment of faecal incontinence. Based on an assessment of incremental cost-effectiveness ratio (ICER), they concluded from published data and expert opinion that the all three procedures were cost-effective with the end-stoma most cost-effective over a 5-year period (ICER GBE4,719 /QALY) and the ABS most cost-effective over a 10 year period (GB£5,387/QALY).

Careful patient selection and sound operative technique are critical components of success for artificial sphincter implantation. Exclusion criteria include morbid obesity, insulin-dependent diabetes mellitus, Crohn’s disease, pelvic sepsis and radiation proctitis. Individuals who practice anoreceptive intercourse are not candidates for the procedure. It is also vital to ensure that all patients are adequately motivated and have sufficient manual dexterity to operate the device independently.

At present, ABS is not commercially available due to a manufacturing hold by the FDA. This situation is especially difficult for those waiting for revision surgery.

Studied in small trials, but not yet clinically available, the magnetic anal sphincter (MAS) (FENIX™; Torax Medical, Inc., Shoreview, MN - US) is a novel device designed to augment the native anal sphincter. It consists of a series of titanium beads with magnetic cores hermetically sealed inside. The beads are interlinked with independent titanium wires to form a flexible ring that rests around the external anal sphincter in a circular fashion. The device is manufactured in different lengths based on the number of beads (14 to 20) necessary to accommodate the variation in anal canal circumferences.

One of the advantages of this still investigational device over the previous artificial sphincters is that it begins working immediately once implanted, without the need for further manipulation by either the patient or surgeon. The procedure for implantation is also substantially simpler than the ABS because access to the perineum alone is required. The device is place under fluoroscopic guidance.

A recent multicenter feasibility study demonstrated good short-term restoration of continence with limited complications [189]. In a subsequent non-randomised comparative cohort study assessing results of the magnetic anal sphincter and the ABS,
it was shown that the 2 devices were similarly effective in restoring continence and quality of life, without any difference in morbidity [190]. **LEVEL OF EVIDENCE: 3** Further comparative studies with other innovative treatments of faecal incontinence such as SNS are getting underway.

Based on these results, FENIX™ has been granted CE mark on November 2011 and its commercial use has started in selected centers in Europe. Further reports from more centers are expected.

Presently the place of the magnetic anal sphincter in the treatment algorithm of faecal incontinence remains to be determined. It appears to be a promising innovation as it offers a less invasive and simpler alternative of anal reinforcement than the ABS. However, with only short-term follow-up available, it remains to be seen if the MAS can withstand the test of time.

7. SACRAL NERVE STIMULATION

Sacral nerve stimulation (SNS) was first applied for the treatment of faecal incontinence in 1994 by Matzel et al [191] in patients with functional deficits of the anal sphincter but no morphologic defect. The concept of recruiting residual function of an inadequate anorectal continence organ by electrostimulation of its peripheral nerve supply, i.e. the sacral spinal nerves, was adapted from the field of urology in the early 1990s [192], where it has been used since 1981 [193]. The rationale for applying SNS to faecal incontinence was based on both clinical observations and anatomic considerations (from the former, the beneficial effect on bowel habits and anorectal continence function and increased anorectal angulation and anal canal closure pressure seen in urologic patients; from the latter, the demonstration by dissection of a dual peripheral nerve supply of the striated pelvic floor muscles that govern these functions [192], with the sacral spinal nerves being the most distal common location of this dual nerve supply). It was hypothesized that stimulating the sacral spinal nerves could both enhance physiologic function and improve the symptoms of faecal incontinence.

**a) Technique**

SNS has become a minimally invasive technique with low morbidity. The surgical technique can be divided into two stages:

As no other predictors of SNS outcome exist at present, patients are uniformly selected for operative implantation of a permanent neurostimulation device on the basis of clinical improvement during test stimulation. This first stage, termed percutaneous nerve evaluation (PNE), is used to confirm a satisfactory neural response and then to evaluate the clinical effect of stimulation before implantation of a permanent device. Therapeutic trial stimulation is performed for one to three weeks, a period sufficient to prove its therapeutic effect—commonly considered a decrease in the frequency of incontinence episodes (documented by bowel-habit diary) by at least 50% and reversibility after discontinuation. Two technical options are used for PNE: a temporary, percutaneously placed, unipolar test stimulation lead (or multiple leads) that will be removed at the end of this phase; or operative placement of a quadripolar lead, the so-called “foramen electrode,” close to a target nerve. This electrode can stay in place and be used for permanent stimulation if the trial is effective. Today most commonly a minimally invasive technique places this foramen electrode with a modified anchoring device, the so-called “tined lead,” through a trochar. For screening, both types of leads are connected to an external pulse, the tined lead with a percutaneous extension cable.

The second stage is implantation of a permanent electrode and neurostimulator if screening is successful. Patients with a temporary lead require simultaneous implantation of the pulse generator and the quadripolar lead, most commonly as a tined lead procedure. Those with a foramen electrode already in place for screening will undergo removal of the percutaneous extension before placement of the pulse generator (so-called “two-stage implant”) [194]. Bilateral placement of foramen electrodes remains the exception, based either on improved outcome of bilateral stimulation during the screening phase [195] or on conceptual considerations [196]. The pulse generator is placed subcutaneously, usually in the gluteal area or under certain circumstances in the abdominal wall. It is activated and stimulation parameters are set early after surgery by telemetry; it can be deactivated by the patient with a small, handheld device commonly referred to as a “patient programmer.”

A small retrospective study, comparing the earlier use of an open electrode placement technique to the current tined lead placement demonstrated no difference in outcome [197]. The infection rate was slightly higher in patients undergoing open electrode placement (11% vs. 8%). Although responses to temporary stimulation and the permanent device are comparable, therapeutic outcome for permanent SNS appears to be best when both sensory/anal motor and toe flexion responses are achieved during test stimulation [198].

**b) Patient Selection and Indications**

Today, a variety of causes leading to faecal incontinence can be treated with SNS. During the initial SNS experience, only patients presenting with deficient function but no morphologic defect of the striated anal sphincter and levator ani were eligible [192,199,200]. However, because of the high predictive value of the test stimulation, a more pragmatic, trial-and-error approach to patient selection evolved. Patients are now selected for SNS based upon PNE results rather than conceptual considerations of the potential mechanism of action. Test stimulation is in-
dicated, not by an underlying physiologic condition, but by the existence of an anal sphincter with reduced or absent voluntary squeeze function and existing reflex activity, indicating an intact nerve-muscle connection (confirmed by intact anocutaneous reflex activity or by muscular response to pudendal stimulation with the St. Mark’s electrode) [199].

At present, the test stimulation is the only reliable mode for selecting patients who will likely benefit from permanent therapeutic stimulation. Various studies have focused on potential predictors of success of SNS. In a study by Gourcerol et al [201], age was the only variable related to success of temporary stimulation. In patients with a permanent implant, neurologic disorders, delay of the left bulbocavernous reflex and a prolonged or absent bulbocavernous reflex were more frequent in patients with successful outcome. In another cohort analysis, the need for repeated temporary procedures was associated with failure during the screening in univariate and multivariate analysis [202]. A low threshold to obtain motor response during temporary lead placement was revealed to be associated with improved outcome only in univariate, but not in multivariate, analysis. Evidence of anal sphincter injury was related to a greater risk of failure during temporary testing, but not with permanent implant.

In a large single-center study comprising 245 patients with test stimulation and 169 patients with permanent implant, Govaert et al [203] determined in univariate analysis that older age (>70 years), presence (but not size) of an external sphincter defect, and the need for repeated procedures after initial failure were significantly related to failure of test stimulation. In multivariate regression analysis presence of an external sphincter defect and need for repeated procedures remained significant. The permanent implant was successful in 76.9% of the patients, but no predictor was found to be significantly related. In a cohort of 55 patients with permanent SNS, Brouwer and Duthie [100] demonstrated that continence scores did not differ significantly in those with a defect, pudendal neuropathy, or previous sphincter repair. Melenhorst et al [204] found no difference in outcome with chronic SNS in patients after sphincter repair and those with an external sphincter lesion of up to 33% of the circumference; they concluded that a morphologically intact sphincter is not a prerequisite for successful SNS. In 244 patients undergoing test stimulation with a success rate of 78.3%, Maeda et al [205] determined that low amplitude of the sensory threshold during PNE and lead placement anterior to the sacral cortex are positive predictors of PNE outcome. No other demographic, physiologic or morphologic variable was a negative predictive factor. In a cohort of 200 patients with permanent SNS from 6 centers [206] only loose stool consistency, a history of diarrhoea management by medical treatment, and low stimulation intensity were associated with improved medium-term outcome. Multivariate regression analysis confirmed that stool consistency and stimulation intensity were independent predictive factors of success or failure of SNS.

In a cohort of 45 consecutive patients, temporary stimulation was successful in 32 (71%). At a median follow-up of 33 months, the neurostimulator remained in place in 25 (55%) and active in 23 (51%). No statistically significant differences were found in the characteristics (including anorectal physiologic workup) of the 32 patients who underwent implantation and the 13 who did not or in those 23 with a functioning stimulator [207].

Altomare et al [208] in a comparative study of 48 patients demonstrated in univariate and multivariate analysis that quadripolar electrode use for test stimulation leads to better clinical outcome than a unipolar electrode.

In summary, none of the variables usually considered in a preoperative workup are of any help in selecting the appropriate patient for chronic SNS.

**[LEVEL OF EVIDENCE: 3]**

Contraindications to SNS include pathologic conditions of the sacrum preventing adequate electrode placement (such as spina bifida), skin disease at the area of implantation, anal sphincter damage requiring a sphincter substitute (e.g. artificial bowel sphincter, dynamic graciloplasty), trauma sequelae with micturition disorders or low bladder capacity, pregnancy, bleeding complications, psychological instability, low mental capacity, limited cognitive function that interferes with the operation of the neurostimulation device, need for magnetic resonance imaging, and the presence of an implantable defibrillator or a cardiac pacemaker. A case series has shown the relative safety of the use of SNS in the presence of a cardiac pacemaker when monitored intraoperatively. If the distance between the devices is greater than eight inches, interference is unlikely [209].

**c) Mechanism of Action**

The mechanism of action of SNS remains uncertain. Clinical outcome has been seen to correlate with results of anorectal physiology studies, but the effect of chronic stimulation varies greatly among published reports [199,200]. Data are in part contradictory and inconclusive and sometimes not reproducible. The effect appears to be somatomotor [210-217], somatosensory [210], autonomic nervous system-based [210,212,218], and mediated by somatovisceral reflexes [219,220]. The effects appear not to be limited to the continence organ per se, but also to the central nervous system: corticoanal excitability in patients with faecal incontinence was found to be reduced with SNS [221]; in successfully treated
patients cerebral somatosensory evoked potential (SEP) latencies were higher at baseline than in the normal population, whereas they were normal in patients with SNS failure. Success was also associated with a fall of the SEP latency to the normal range after one month of SNS at 40 Hz [222]. SNS induces changes in anal representation on the primary somatosensory cortex [223]. The central nervous effect induced by SNS changes during its course: at its initiation, changes are seen in the contralateral frontal cortex, reflecting focus attention; subsequent changes are found in the ipsilateral caudate nucleus, an area related to learning [224].

Qualitative (or quantitative?) changes are seen in anal, rectal and colonic motility, such as reduction of spontaneous rectal motility complexes [225,226], spontaneous anal sphincter relaxation [225], reduction of antegrade transport from the ascending colon and increased retrograde transport from the descending colon at defaecation [227], increase rectal perception thresholds [228,229] and improve pelvic floor contraction during SNS [229]. The findings on rectal capacity with SNS have been inconsistent: unaltered [230-232] or increased [225,233]. No changes in gastric retention, gastric emptying, small bowel transit or colonic passage were seen with scintigraphic measurements during SNS [234].

An effect on mucosal neurochemistry during SNS has also been shown, with elevation of Substance P and TRPV1 levels [235], although the relevance of each of these has not been proven in specific pathophysiological conditions. The mechanism of action is most likely multifactorial and dependent on the underlying condition. [LEVEL OF EVIDENCE: 4]

d) Outcome

The results of permanent SNS after pragmatic, trial-and-error, patient selection are shown in Table 5 [100,206,207,210-213,235-251]. Most studies have encompassed patients with heterogeneous pathophysiologic conditions, and they vary with regard to design and patient number, but there is general agreement regarding the test stimulation for selection for permanent implant. Most commonly, clinical outcome is reported as an improvement in the number of incontinence episodes or days with incontinence during the period of observation, changes in the Cleveland Clinic Incontinence Score, and quality of life.

In a first multicenter prospective trial of SNS adherent to the initial, confined spectrum of indications, Matzel et al [238] reported 37 patients, 34 of whom underwent a permanent implant. Not only were the frequency of incontinence episodes and the CCIS score improved significantly, so too was the ability to postpone defaecation. These effects were attained immediately.

Leroy et al [240] reported a double-blind, cross-over multicenter study in 34 patients with faecal incontinence treated with SNS. Three months after implantation, patients were randomised in a double-blind manner to on- or off-stimulation for a 2-month period, with reversal of the activation mode after 1 month. Of these, 24 of 27 randomised patients completed the 2-month trial. A significant decrease in median frequency of faecal incontinence episodes was noted during the on-stimulation period. No significant change was observed between on- and off-stimulation for frequency of urgency episodes, delay in postponing defaecation, or median number of bowel movements per week (10.2 and 11.1 for on and off, respectively). There was a trend towards greater improvement in the Cleveland Clinic Incontinence Score during on-stimulation (8.5 vs. 10.5; ns). A total of 24 patients (89%) considered that they had improved during the on period compared with 17 (63%) during the off period.

Melenhorst et al [213] published the largest mid-term follow-up, single-center study, with 100 patients undergoing permanent SNS. Late failure occurred in 21 patients as defined by a relapse of symptoms to less than 50% improvement over baseline, implementation of another therapy for faecal incontinence, or patient dissatisfaction. The mean time for definitive failure was 13.6 months (range 3-42.4). There was no evidence of technical failure such as lead migration or lead breakage.

A report by Rosen et al [210] highlights the effect of SNS in a cohort of patients of whom 75% suffered from faecal incontinence of neurologic origin. Frequency of incontinence episodes/week was reduced from 6 to 2 at 15 months’ follow-up.

In a recent larger multicenter study Wexner et al [247] confirmed the efficacy of SNS in reducing symptoms of faecal incontinence: of 112 patients with permanent SNS followed for a mean of 28 months (2-69), 83% experienced a ≥50% improvement, including 41% who gained complete continence (at 12 months).

Mellgren et al [251] reported the same cohort after a mean follow-up of 3.1 years (0.2 – 6.1 years). With a complete or partial data set available in 64% of the patients, a ≥50% reduction of incontinence episodes was seen in 86%, with 40% achieving perfect continence. Symptom improvement resulted in improved quality of life, which was stable over follow-up. If a “last observation carried forward analysis” is performed, the 50% reduction of symptoms at 3 years is a 78% success rate; in a “modified worst-case analysis”—with all missing data classified as failure—the success rate at 3 years is 59%.

The findings of sustained symptomatic improvement with extended follow-up are in accordance with several other series focusing on long-term outcome: a sustained effect was seen in 74% of 52 patients after 5 years [245]; in 84% after a median follow-up of 7.1 years (5.6-8.7) [252]; and in 6/9 with follow-up of 7 – 14 years [253].

*CCIS: Cleveland Clinic Faecal Incontinence Score: 0 = fully continent, 20 = worst incontinence; †Limited to studies reporting incontinence episodes/week and/or CCIS at last follow-up; ‡Denotes median; otherwise all data are presented as mean. ns: not stated; FU, follow-up.
In most studies, quantitative measures are used to describe the clinical benefit, such as days with incontinence episodes or absolute numbers of incontinence episodes per period of observation, ability to postpone defaecation (in minutes), and percentage of improvement. Even though published reports differ with regard to patient population, a general pattern of outcome can be observed: when compared with baseline status, the clinical outcome is significantly improved. The majority of studies report the outcome based on a per protocol approach (PP): the outcome reporting is limited to those patients with a permanent implant after successful testing. The infrequently used intention-to-treat protocol (ITT) approach analyses all patients considered for the therapy and undergoing PNE test. Thus, those are included who failed PNE, who are lost for follow-up or who died. In one study with 245 patients undergoing PNE and 176 patients subsequently being implanted, 132 patients were treated with SNS for a median follow-up of 33 months (ITT 53.9%, PP 75.0%). Outcome was good or acceptable in 103 patients (ITT: 42.1%, PP: 58.5%), limited or reduced requiring additional or alternative treatment in 20 patients (ITT: 11.8%, PP: 16.5%) [254].

In a meta-analysis of publications from 2000-2008 comprising 790 patients, 28 studies compared incontinence episodes per week before and after PNE, and 14 studies compared incontinence scores. Both outcome criteria were significantly decreased. Another study documented the ability to postpone defaecation, and this criterion also was significantly improved [255]. [LEVEL OF EVIDENCE: 2]

An increasing body of evidence indicates that SNS may also be a treatment option for patients with sphincter defects, unrepaired or after attempted anatomic reconstruction. The presence of an internal anal sphincter defect on endoanal sonography is reportedly unrelated to the success of permanent SNS [202]. Since the first report that three of five patients with ultrasound evidence of sphincter disruption measuring 25–33% of the circumference benefited from chronic SNS [256], several studies have been published (Table 5) [100,204,257-262]. The origins and morphologic findings regarding the extent of the sphincter gap differ in these studies, but lesions up to 180° have been treated. It appears that outcome is not dependent on the radial extent [257,260]. A significant improvement in clinical function, measured either as frequency of incontinence episodes or Cleveland Clinic Incontinence Score, has been seen in a substantial number of patients in all studies [100,204,257-262]. Follow-up is still limited.

Melenhorst et al showed that the primary use of SNS in patients with a sphincter gap 17-33% of the circumference appeared to result in an outcome similar to its use after failed sphincter repair [204]. In another study, SNS in 6 of 8 patients with faecal incontinence related to obstetric full-thickness anal sphincter lesions of >30-150º resulted in improved frequency of incontinence episodes (from 5.5 to 1.5 per week), improved ability to postpone bowel emptying, and improved FIQL quality-of-life scores at a median follow-up of 26.5 months [257]. No correlation between improvement and the radial extent of the sphincter defect was seen. In patients with internal and external sphincter disruption owing to Crohn’s disease SNS was demonstrated to be beneficial in one study [258].

In a comparative cohort study [259], the effect of permanent SNS was reported in 53 patients with either an intact external anal sphincter (N=32 (37.5% after sphincter repair)) or an external anal sphincter lesion (N=21 (81% after sphincter repair)) of <90° (N=11) or 90-120° (N=10). Improvement in symptoms and quality of life was achieved, and outcome after 12 months was not statistically significantly different between both groups. [LEVEL OF EVIDENCE: 3]

The therapeutic potential of SNS has also been demonstrated in some, mostly small, case series and individual case reports of patients with distinct pathological conditions or well defined anorectal physiology findings (Table 5) [196,242,263-268]: e.g. muscular dystrophy [269], proctocolectomy with ileoanal J-Pouch reconstruction for colitis [270], neurologic dysfunction including spinal disc prolapse [267], rectal prolapse repair [265,266], and rectal resection for cancer [263] with or without neoadjuvant chemoradiation [196,264,271], and after neoadjuvant and adjuvant chemoradiotherapy for endometrial and anorectal cancer [272,273]. [LEVEL OF EVIDENCE: 4]

In a randomised controlled trial Tjandra et al [274] compared the effect of SNS for severe faecal incontinence with supervised optimal medical therapy that comprised pelvic floor exercises, bulking agents, and dietary manipulation. Permanent SNS in 53 patients was significantly better than conservative treatment in 60 patients: Cleveland Clinic Continence Score 1.2 vs. 14.1; incontinence episodes/week 3.1 vs. 9.4; days with incontinence/week 1 vs. 3.3; lifestyle 3.31 vs. 2.31; coping/behavior 2.68 vs. 1.86; depression/self-perception 3.25 vs. 2.64; embarrassment 2.76 vs. 1.78. [LEVEL OF EVIDENCE: 2]

e) Quality of Life

As with indications, outcome assessment has also evolved, and aspects of quality of life have been added to the evaluation (Cleveland Clinic Continence Scoring System, SF-36 and FIQL Score.) The therapeutic impact of SNS is most evident when a disease-specific quality-of-life instrument, the FIQL scale, is applied.

In the first study to apply this instrument, the multicenter clinical trial by Matzel et al [238], FIQL score was significantly increased in all 4 scales; SF-36
scores improved in 7 of 8 scales, the greatest being social functioning and mental health, but only the former reached statistical significance. A similar result was published by Leroi et al [240] with the French version of the FIQL: at the final follow-up visit, improvements in lifestyle, coping behavior, depression, and self-perception and embarrassment were significant. Hetzer et al [243] demonstrated a significant improvement of the median Gastrointestinal Quality of Life Index score with permanent SNS from a baseline of 96 (range 47–128) to 107 (range: 36–128) at 6 months post-implantation.

In most studies on outcome, quality-of-life evaluation is a secondary endpoint [196, 200, 210, 238, 240, 242, 243, 249-252, 259, 263, 265, 267, 274, 275]. When used, the finding of improved quality of life is consistently related to symptom relief and remains stable with longer follow-up [245, 251, 252, 276].

In a meta-analysis [255] of 34 studies with 790 patients, SF-36 score data were analysed from 7 studies with 98 to 102 patients and ASCRS FIQL data from 9 studies comprising 199 patients: SF-36 outcome was significantly increased in all categories (physical functioning, social functioning, role physical, role emotional, mental health, vitality, general health) with one exception (bodily pain). FIQL outcome was significantly increased in all categories (lifestyle, coping/behavior, depression/self-perception, embarrassment).

In a two-center study of patients with permanent SNS for a median of 46 months (11-122), 108 of 127 patients responded to questionnaires regarding bowel habits and quality of life. Using a non-validated score, 75.8% reported satisfaction, which in most was related to clinical improvement. However, at last follow-up 11 of 23 patients who had failed to achieve a 50% reduction in incontinence episodes reported satisfaction, and 6 of these had more incontinence episodes than at baseline [268]. [LEVEL OF EVIDENCE: 2]

f) Cost Benefit

Permanent SNS is expensive; however, its cost-effectiveness has been demonstrated in several European nations. Hetzer et al [277] compared the costs of SNS with those of conservative treatment, anterior sphincteroplasty, dynamic graciloplasty, and stoma creation in 34 consecutive patients. The 5-year cumulative cost for SNS was €19,333, compared with €35,965 for a stoma (with annual costs of €5,339) and €34,953 for dynamic graciloplasty (annual costs €1,659). The equivalent cost for conservative treatment was €3,895, and the overall median real cost for an anterior sphincteroplasty was €5,327. Muñoz-Duyos et al [276] analysed the direct medical costs of SNS in a series of 47 patients undergoing 57 PNEs and the consequent 29 patients with a permanent unilateral implant for a median follow-up of 34.7 (2.3-81.2) months. The cost totaled €371,434, including €31,7791 for the devices. In patients without anal sphincter damage SNS provided 0.34 incontinence-free life-years and entailed additional costs of €1,054, which generates a cost-effectiveness ratio of €16,181 per quality-adjusted life-year (QALY). The nationally accepted threshold is around €30,000/QALY. The economic impact of the introduction of SNS would be to add 0.07-0.1% to the care of these patients.

In a decision-analysis model based on prospectively collected data in 70 patients undergoing test stimulation and implantation of the permanent SNS device, incontinence episodes/week were reduced from 6 at baseline to 0.5. Dudding et al [278], based on direct medical and non-medical costs, found an incremental cost-effectiveness ratio (ICER) for SNS of GB£25,070 per QALY gained. It cost GB£1,038 per year to achieve a median reduction of 238 incontinence episodes, equal to GB£3.61 per reduced episode. The ICER of GB£25,070 per QALY was within the nationally accepted GB£30,000 per QALY threshold.

In a similarly designed study based on published reports and expert opinion, Indinnimeo et al [279] found that the ICER is £28,285 per QALY gained in patients with a structurally deficient anal sphincter and €30,662 per QALY in patients with an intact anal sphincter. Both are below the national threshold of €40,000 per QALY gained. Budget-impact analysis demonstrated that the implementation of SNS would have an estimated impact of 0.56% over a 5-year period on the budget allocated for faecal incontinence treatment. [LEVEL OF EVIDENCE: 3]

g) Safety

SNS is a relatively safe procedure [247,280]. A recent meta-analysis [255] is in accordance with earlier reports, which describe a relatively low late of complications [199,200] and a need for device removal in only approximately 5% because of loss of effect, symptom deterioration, pain from lead dislocation, or infection. The results of the meta-analysis, which covered the period 2000 – 2008 and included patients undergoing the more invasive, open-approach electrode placement technique, found a complication rate of less than 15% in 665 patients with a permanently implanted device. In only 3% did the device need to be removed. In patients in whom infection has necessitated removal, re-implantation at a later date has reportedly been successful [274]. In a recent FDA study with strict monitoring of adverse events, 334 were reported in 99 patients at three-year follow-up; 67% occurred in the first year, and most required no or minimal intervention. The adverse events included pain at the implant site (28%), paresthesia (15%), change in the sensation of stimulation (12%), implant site infection (10%) [247], urinary incontinence (6%), diarrhoea (6%), and leg pain (6%). Half of the infections required surgical intervention with removal of the device in 5 of 6 patients [251]. A single report with a consecutive series of 87 patients over a mean follow-up of 48.5
months describes the need for revisional surgery in 41%, one-third for device-related failure, including 24% for removal [281]. In a French multicenter study comprising 200 consecutive patients with a mean follow-up of 12 months, the rate of device-related adverse events was 24.5% [206].

Major complications are rare: one case report of a life-threatening haemorrhage after elective tined lead electrode removal has been published [282].

A recent review of 48 cohort studies (45 for faecal incontinence and 3 for constipation) documented the postoperative issues in the 1661 patients with test stimulation and 1600 patients with a permanent SNS implant [283]: it found that the incidence of suboptimal outcome was 12.1%, pain 13%, and infection 3.9%. The most common problem during test stimulation was lead dislodgement (5.3%). The reported incidence rate for suboptimal outcome – loss of efficacy or lack of efficacy – ranged between 0% and 27%. Systematic literature review suggests a possible underreporting of suboptimal outcome and adverse events. In one single study, the rate of adverse event reached up to 85.2% in patients with a median follow-up of 11 months: loss or lack of efficacy and pain or discomfort accounting for 88.5% of these [254]. [LEVEL OF EVIDENCE: 3]

8. POSTERIOR TIBIAL NERVE STIMULATION

a) Introduction

Posterior tibial nerve stimulation has its origin in pain treatment as transcutaneous electrical stimulation (TENS). Its use for the treatment of faecal incontinence (first published in 2003 [284]) is an adaptation of its successful application in the field of urology, stemming from the early 1980s [285-287]. Only recently, based on the therapeutic success of sacral nerve stimulation, has there been an increasing interest in this alternative approach of neuromodulation. The number of publications is still limited and the evidence low; however, several clinical trials are currently ongoing. Larger patient studies are awaited.

b) Techniques

Two different techniques are used: percutaneous stimulation with a needle electrode [288] and transcutaneous stimulation with surface adhesive electrodes [289]. In both techniques current is delivered by positioning the active electrode close to the posterior tibial nerve proximal to the medial malleolus. Adequate placement is confirmed by inducing digital plantar flexion, and the ground pad is placed in the proximity. Both systems are powered by a portable pulse generator. The stimulation parameter are set arbitrarily, mostly to 0.2 ms, a current below the threshold for motor response ranging between 0.5-9.0 mA, and a frequency usually to 10 – 20 Hz.

Although the stimulation parameters themselves are fairly uniform, there is no general agreement regarding the protocol: duration and pattern of stimulation; interval between sessions; basic or “top-up” treatment (Table 6) [289-295].

c) Patient Selection and Indications

Indications vary substantially among the proof-of-principle studies. A prospective observational design

CCIS: Cleveland Clinic Faecal Incontinence Score: 0 = fully continence, 20 = worst incontinence
predominates, with mostly single-center trials and a limited number of patients. Inclusion criteria range from idiopathic faecal incontinence [289,290,292] and incontinence owing to inflammatory bowel disease [294], to faecal incontinence with internal or external sphincter lesions or a combination of both, some after obstetric trauma [290,292,296]. PTNS has been applied for passive, urgency, and mixed incontinence [293]. Symptom improvement has been demonstrated with PTNS for faecal incontinence after partial spinal injury in two cases [297].

**d) Mechanism of Action**

No studies have been performed to elucidate distinctly the effect of PTNS on symptoms of faecal incontinence. Several hypotheses of a potential mechanism of action have evolved based on the experience of the use of PTNS in urology and on an analogy drawn from findings of physiological changes with sacral nerve stimulation, but none of these hypotheses has been systematically explored. In one study significant changes in maximal squeeze pressure only was seen after 6 months [290]; others demonstrated no changes in physiological measurements [289]. An improvement in rectal sensory threshold and resting and squeeze pressures was reported in two patients after partial spinal injury [297]. In another study the clinical efficacy of PTNS was found to be independent of damage to the anal sphincter [298]. [LEVEL OF EVIDENCE: 4]

**e) Outcome**

All studies demonstrate an improvement in outcome measures, although outcome is not described uniformly (Table 6). Most commonly, clinical efficacy is monitored with the Wexner Incontinence Score and/or the recording of faecal incontinence episodes. Where incontinence episodes per month were reported and differentiated by stool consistency, in a study of 13 patients, reduction at 3 months was significant for all categories: wind, baseline 6 (0-17.5) vs. 0 (0-0) episodes/month; liquid, 10 (5-29.5) vs. 0 (0-4); and solid, 18 (0-30) vs. 0 (0-0) [290].

In all studies outcome reporting is limited to short-term follow-up. Postponement of defaecation was found to be significantly increased at 6 weeks and sustained at 12 months [291]. In one study the median increase in the ability to defer was 3 minutes (0-26) in patients suffering from urge incontinence [292]. [LEVEL OF EVIDENCE: 4]

**f) Quality of Life.**

If measured, instruments of quality-of-life recording also demonstrate an improvement with therapy [291]. Comparisons between success and failure, however, have not depicted conditions predictive of symptomatic improvement [291,295]. In patients with subjective improvement, quality of life was significantly better after 3 and 6 months' follow-up [295,296]. [LEVEL OF EVIDENCE: 4]

**g) Safety**

Reports on safety are limited, but none of the studies found relevant side effects. Mild, procedure-related reversible adverse events, such as gastrodynia and numbness in the leg for 2 hours, were reported in one study [291]. [LEVEL OF EVIDENCE: 4]

9. **INJECTABLE BIOMATERIALS**

Injection of bulk-enhancing agents into the anal canal to treat faecal incontinence has continued to gain popularity since the last review. Although injectable agents for urinary incontinence (UI) have had variable success, they offer the benefit of performing an outpatient procedure without anaesthesia and with minimal morbidity. This has resulted in their continued use for urinary incontinence [299,300], as well as in more research on different injectable agents for use in faecal incontinence. The ideal agent for injection should be biocompatible, non-allergenic, non-immunogenic, easy to inject, and should not migrate within the tissues. No agent currently has all these properties. Agents that have a diameter of 80 mm are felt to be less prone to migration, but agents with a larger particle size require a larger bore needle to inject, which put them at a higher risk for leakage from the injection site. The results of all injectable biomaterials used for faecal incontinence to date are shown in Table 7 [301-324].

Injectable agents for faecal incontinence were first used in 1993 when Shafik [301] treated 11 patients with injections of polytetrafluoroethylene paste into the anal submucosa. After 18-24 months of follow-up, 64% reported complete cure and 36% had partial improvement. Shafik [302] subsequently treated 14 patients with autologous fat injections with a reported 100% success rate at 2-3 months and all patients who lost continence to gas or stool became continent after repeat injections. There were no complications using either agent. However, other reports of autologous fat injection have resulted in death from pulmonary fat embolism [325], and a randomised clinical trial using fat for UI demonstrated no efficacy over placebo; thus, it is currently not used for faecal incontinence [325].

Other agents used for injection in the past, that have not achieved widespread use include micro balloons, bovine dermal collagen, and polyacrylamide hydrogel (Bulkamid). A series of six patients injected with self-detaching cross-linked silicone micro balloons with a biocompatible filler material demonstrated fairly good results, with Browning-Parks incontinence scores for the group decreasing from 16 to 5 (range 0-20) [305]. However, sterilisation issues have prevented the ongoing use of this product.

The first reported injections of glutaraldehyde cross-linked synthetic bovine dermal collagen (Contigen) for faecal incontinence included 17 patients [303]. 11 (65%) of whom showed marked

symptomatic improvement at 8 months. A much larger series of 73 patients was then reported [308] in which subjects received injections of 1.7 ml of collagen transanally into the rectal submucosa in three separate areas just proximal to the anal canal. Overall, 63% reported an improvement in their incontinence and the 49 patients with idiopathic incontinence (no sphincter defect and no pudendal neuropathy) had a significant decrease in their Wexner Faecal Incontinence Score (CCF-FIS, range 0-20). The disadvantages of using synthetic collagen are its potential to be allergenic and degrade over time. Furthermore, its success in urinary incontinence has been limited [299].

A pilot study conducted in 2008 examined two other products, cross-linked porcine dermal collagen (Permacol), and polyacrylamide hydrogel (Bulkamid) [313]. Ten patients with passive faecal incontinence to liquid or solid stool who had failed conventional treatments were prospectively randomised to receive either of the two products. The needle was first inserted into the skin 2 cm from the anal margin and the product was then injected trans-sphincterically. The median volume to achieve closure of the anal canal under direct vision was 9 ml for Bulkamid and 15 ml for Permacol. The St Mark’s incontinence score decreased at 6 weeks for both groups, but this decrease was sustained at 6 months only for the Bulkamid group. This pilot study lacked power to determine if these two treatments for faecal incontinence differed significantly. Unfortunately, no other follow-up studies have been reported.

Several other injectables have been used for faecal incontinence with variable results. In one of the few adequately powered, randomised controlled trials using injectables, 44 patients were randomised to receive transdermal injections of polydimethylsiloxane elastomer silicone biomaterial (PDMS) or saline into the intersphincteric space [310]. Three 2.5ml injections were performed using local anesthesia. Only the patients were blinded to the treatment. There was no difference in the percentage of patients in the two groups who had a successful treatment, defined as having a CCF-FIS score <8 or the decrease in CCF-FIS scores post treatment. The saline group tolerated treatment better and had fewer adverse effects overall. Thus, the study concluded that the use of PDMS should not be recommended.

Three smaller studies using other products have shown some promise although the testing was much less rigorous. In one of these studies, calcium hydroxyapatite ceramic microspheres (Coaptite) were injected transanally to four submucosal sites using 1ml at each site with the patient under local anesthesia. The average Faecal Incontinence Scoring System (FISS) score for 10 patients decreased from 85.6 to 28 at 12 months (p=0.008) and the lifestyle, coping and behavior/embarrassment subscales of the Faecal Incontinence Quality of Life Scale (FIQL) showed improvements (p<0.05). Anorectal manometry also showed better resting pressures (40 to 47 mmHg, p=0.018). There were no complications, but one patient experienced leakage of product from the injection site that required another injection [314]. In the second of these smaller studies, 21 patients received ethylene vinyl alcohol (EVOH) injections with 1-2 ml in up to 8 sites in the intersphincteric space under general or local anesthesia. At 12 months, Faecal Incontinence Severity Index (FISI) scores dropped from 32.8 to 22 and CCF-FIS scores decreased from 11 to 6.9. Two subscales of the FISI improved significantly and repeat anorectal manometry demonstrated some increase in anal canal length and resting pressures [302]. The third and most recent of these small studies reported on 14 patients who received transdermal injections of polyacrylonitrile cylinders (Gatekeeper prosthesis) into the intersphincteric space. The CCF-FIS score decreased from 12.7 to 5.1 (<0.01) and there were no complications. Location of the prostheses was documented by ultrasound and no dislodgement was seen at 1 year [323].

The two most common injectables used to treat faecal incontinence are silicone biomaterial (Macrolaste, Bioplastique, PTQ implants) and pyrolytic carbon-coated zirconium oxide beads (Durasphere). Injectable silicone biomaterial has been used extensively for urinary incontinence. It consists of polydimethylsiloxane particles suspended in a bioexcretable carrier hydrogel of polyvinylpyrrolidone. Two pilot studies using Bioplastique for faecal incontinence in 2001 and 2002 [304,326] led to increased use of this product in Europe and it was renamed PTQ implants (PTP implants in Australia). Malouf et al [304] studied 10 patients with passive incontinence who received circumferential or single site injections of Bioplastique. At six weeks, six patients showed either marked improvement or complete cessation of leakage and an additional patient improved after a second injection. However, after six months, only two of seven patients had maintained marked improvement. Complications included anal pain and ulceration at the injection site. In the largest study of PTQ injection to date [307] 82 patients with severe faecal incontinence were randomised to receive PTP implants either with or without endoanal ultrasound guidance for injection. All patients had a significant improvement in their CCF-FIS. At 12 months, this score decreased from 14.5 to 3 in the ultrasound guidance group and from 14.5 to 11 in the non-ultrasound group. Six patients, two from the ultrasound guidance group, complained of pain at the injection sites. There were no other complications. The ultrasound guidance group had more significant improvement in resting pressures and quality of life scores. The same investigators injected PTQ into seven patients with passive incontinence after haemorrhoidectomy and found significant improvement CCF-FIS and quality of life scores in all patients [327].
Several other series have been reported PTQ use for faecal incontinence [311,315,317,319]. In all of them, 2.5ml of product was injected into 3-4 sites in the intersphincteric space and CCF-FIS decreased significantly. In one study of 20 patients, the CCF-FIS decreased significantly from 13.5 to 4.5 at one month and slowly increased to 9.4 at two years, which was a still a significant improvement from the baseline score. Quality of life scores also improved, but there was no effect on resting and squeeze pressures measured at baseline and 3 months after injection. Seventy percent of patients experienced pruritus ani and one patient developed an infection at an injection site [311]. In a study of 33 patients, CCF-FIS decreased from 12.7 to 10.4 at one year, yet quality of life was not improved [315]. Both of these studies examined implant migration and 63-84% of patients had detectable implants at the site of injection by ultrasound, though this did not seem to affect clinical response. The largest of these studies is notable for its sample size of 74 patients and that half of these subjects were men. It found that 70% of patients reported complete satisfaction with their continence (post-treatment CCF-FIS =0) and in the remaining 30%, CCF-FIS decreased from 12 to 3.5 at 33 months with associated improvements in quality of life measures. All patients, but especially those who became continent, had significant improvements in mean resting pressures, squeeze pressure and mean anal canal length. Worse results were seen in women with pudendal neuropathy or those for whom biofeedback had already failed [317]. Another study specifically compared the anorectal manometry of patients injected with PTQ with that of normal controls and found that after injection in the symptomatic patients there was a similar decrease in CCF-FIS with associated improvements in FIQL scores. The symptomatic patients had lower resting and squeeze pressures than controls at baseline and these pressures did not improve with injection. However, these patients did have elongation of their high pressure zone, as well as improvements in the asymmetry index, indicating that morphologic but not physiologic changes had occurred with injection [319]. The only report of long-term results for injectable agents was for Bioplastique [328]. The 5-year outcome for 6 patients injected with Bioplastique in 1999 included a median St. Mark's incontinence score that was essentially unchanged from 11 to 13 (range 9-20). One patient had undergone a colostomy, but four of the five remaining patients reported subjective improvement in their incontinence and better quality of life scores.

The other commonly used injectable, Durasphere, is non-reactive and not biodegradable. However, the beads are known to migrate within the tissues and require a large bore needle to inject the substance. The injected substance is placed in the submucosal plane using either a transanal or intersphincteric approach. The initial trial [306] assessed the short and long-term efficacy in 18 patients with an internal anal sphincter defect refractory to conservative management. About 1.3ml was injected in the submucosal plane at the site of the sphincter defect in 1-4 sites until adequate anal sphincter symmetry was restored. At 12 months, CCF-FIS and patient satisfaction scores were significantly improved. Fifteen of 18 patients reported improvement in their incontinence. An abstract presented by Weiss et al [329] also demonstrated improvement in ten patients who were only followed for 3 months. In a larger study, 33 patients with minor or medium severity faecal incontinence (CCF-FIS < 14 and/or American Medical Systems (AMS) score < 89) received injections (mean of 8.8 ml (range 2-19 ml) of Durasphere into the submucosa at the level of the dentate line using an 18-gauge needle at four different sites [312]. After a mean follow-up period of 21 months, the CCF-FIS for the group decreased significantly from 12 to 8 and the AMS score from 89 to 73 but the faecal incontinence specific quality of life measures did not change. Resting and squeeze pressures also increased 12 months after injection. Adverse events included anal pain in two patients, asymptomatic leakage of material in one patient, and distal migration of product in two patients. A study of 11 patients in which about 2.8ml of Durasphere was injected into 3-4 sites in the submucosal space reported a decrease in CCF-FIS from 12.7 to 4.9 at 2 years with improvements in the coping and embarrassment subscales of the FIQL at 6 months. Although manometry pressures did not change initially, the resting and cough pressures were higher at 2 years than at 1 year [318].

The most recent study using Durasphere injected the product using a slightly different approach. In all 23 subjects, the product was injected into the intersphincteric space in four sites. Again, about 2.8ml of product was injected at each site. At 12 months, patients had a decrease in the CCF-FIS from 18.7 to 10.9 and an increase in FIQL score from 46 to 55.8. Mean squeeze pressures on anorectal manometry increased significantly at 12 months. Adverse complications included prolonged pain in one patient and a sterile perianal fluid collection in another [321].

Only one trial compared the safety and efficacy of PTQ and Durasphere [316]. Sample size was calculated to detect a 50% reduction in the CCF-FIS post injection. Thus, 40 patients with faecal incontinence (mean CCF-FIS 11.45) were randomised to receive either PTQ or Durasphere. Both groups were similar in terms of age, medical history, faecal incontinence severity and quality of life scores, as well as anorectal manometry results. Although the Durasphere group had a more significant reduction in CCF-FIS at 2 weeks (11.45 to 8.25 vs. 11.45 to 10.9), the PTQ group had a greater reduction in CCF-FIS at 6 weeks, 6 months and 12 months (4.6, 2.95 and 3.8 vs. 7.65, 6.2 and 7), and had no complications. The Durasphere group had several complications including anal pain (5%), mucosal erosion (10%),...
arthritis and skin rashes (5%). Furthermore, the PTQ group demonstrated significant improvements in general and faecal-incontinence-specific quality of life scores that were not seen in the Duraphere group. Thus, the conclusion was that PTQ was safer and more effective than Duraphere for the treatment of faecal incontinence [316].

The newest injectable agent to be used for faecal incontinence is dextranomer- hyaluronic acid co-polymer (Zuidex, NASHA Dx). Dextranomer microspheres are suspended in non-animal stabilized hyaluronic acid. As with other injectable agents, Zuidex has been used to treat urinary incontinence [330] and a pilot study of four patients reported no adverse events and a median decrease in St Marks incontinence score of 3.5 points (19.25 to 15.75) [309].

In a subsequent study of 34 patients who received transanal injections into the submucosa just above the dentate line (about 1ml of product was injected into four sites), the median number of incontinent episodes in a four-week period dropped from 22 to 9 [320]. When response was defined as a 50% or greater decrease in number of incontinent episodes, 56% of patients were defined as responders at 12 months. No adverse events were reported. These findings led to a randomised double-blinded sham-controlled trial of 206 patients randomised in a 2:1 fashion to receive NASHA Dx or placebo injection [324]. The patients and the evaluating investigators were blinded to the treatment. More patients in the treatment group had 50% or greater reduction in the number of incontinence episodes (52% versus 31% of controls; p=0.009), but the change in CCF-FIS did not differ after treatment between groups (14 to 2.5 in the treatment group vs. 13 to 1.7 in placebo group). The FIQIQL was only significantly improved compared to placebo for the coping and behavior subscale. Both groups had a high retreatment rates: 82% of patients in the NASHA Dx group received reinjection of product and 87% of patients in the control group had repeat sham injection. The NASHA Dx group had significantly more adverse events, including proctalgia, rectal bleeding, pruritus, diarrhoea, constipation, fever, and two serious complications of rectal abscess and prostatic abscess. The control group had more injection site bleeding [324]. The most recent study of NASHA Dx was reported in an abstract of 21 patients who received injections of 1ml of product in four sites of submucosa. There were no adverse events and 61% of patients had a significant decrease in incontinence episodes at 3 months and 56% had a sustained improvement at 22 months. The CCF-FIS decreased from 16.8 to 12.3 but was not significant. Improvement in FIQIQL scores were noted [331].

In summary, studies of injectable biomaterials comprise several small case series that in general show short-term efficacy and only three randomised trials, two of which compared PMDS and NASHA Dx to placebo, and a third that compared PTQ to Duraphere. These trials indicated that PMDS should not be used, PTQ appears to be better than Duraphere in terms of both safety and efficacy, and that NASHA Dx has some evidence of efficacy compared to placebo. Two systematic reviews [332,333] and a Cochrane review [334] have been published recently that review the data for all injectable agents for faecal incontinence. Due to the poor methodology and small sample sizes of most of these studies, none of these reviews could establish adequate evidence to support the efficacy of any of these agents. However, one review did find that in a multivariate analysis, use of the intersphincteric, instead of transanal or trans sphincteric routes of injection, was associated with a higher complication rate. Furthermore, PTQ and Coaptite were significant predictors of short-term outcome and use of local anesthesia was associated with a lower likelihood of success [332]. LEVEL OF EVIDENCE: 3

10. COLOSTOMY

A permanent colostomy is usually formed as a last resort for severe faecal incontinence when all other interventions have failed. Because colostomy is generally regarded as a failure of treatment, its effectiveness, perioperative complications, and impact on the quality of life have never been properly evaluated except for patients with functional bowel disorders after spinal cord injury [335,336]. For a specific role of colostomy for these patients, please refer to the specific chapter. Not only for patients with spinal cord injury, but also for general population with severe faecal incontinence, colostomy is a frequently successful management strategy that restores dignity and allows them to regain social function.

No randomised controlled trials or non-randomised cohort studies have been reported regarding colostomy for faecal incontinence, and only one systematic review (level 4) [188], one case control study (level 4) [337] and two case series (level 4) [338,339] were identified.

Colquhoun et al [337] conducted a cross-sectional postal survey, comparing quality of life between 71 patients with faecal incontinence and 39 with a colostomy created for rectal cancer, complicated colonic diverticular disease or faecal incontinence. Analysis of the Short Form 36 General Quality of Life Assessment revealed significantly higher social function score in the colostomy group than in the faecal incontinence group (0 vs. -0.6, p=0.022). An age- and gender-adjusted regression analysis of the Faecal Incontinence Quality of Life score revealed significantly higher scores in the coping (2.7 vs. 2.0, p=0.005), embarrassment (2.7 vs. 2.2, p=0.014), and lifestyle scales (3.2 vs. 2.7, p=0.14) in the colostomy group compared to the faecal incontinence group. The authors concluded that a colostomy is a viable option for patients who suffer from severe faecal incontinence and offers a definitive cure with improved quality of life.

Tan et al [188] performed a systematic review, specifically comparing the cost-effectiveness between end stoma (ES), artificial anal sphincter (AAS) and
dynamic graciloplasty (DG). The quality-adjusted life years (QALYs) and the incremental cost-effectiveness ratio (ICER) were compared between the three procedures, by obtaining the probability estimates for patients with faecal incontinence from published data, with being supplemented by expert opinion. The end stoma was the most cost-effective therapy at 5 years, with a QALY gain of 3.45 for GB£16,280 and an ICER of GB£24,719/QALY, compared to AAS (4.38 for GB£23,569; GB£5,387/QALY) and DG (4.00 for GB£25,035; GB£6,257/QALY). After 10 years, AAS became the most cost-effective surgical intervention, with a QALY gain of 8.384 for GB£32,397 and an ICER of GB£3,864/QALY, compared to ES (6.9 for GB£27,910; GB£4,046/QALY) and DG (7.678 for GB£35,165; GB£4,580/QALY). The results of this study, however, must be interpreted with great caution, because it is not an interventional study but a systematic review with a rather complicated methodology and a variety of possible biases.

Norton et al [338] examined patients’ view of a colostomy by conducting a questionnaire study of patients who had a colostomy created to manage their faecal incontinence. Sixty-nine people (58 women) responded. When patients were asked to rate their ability to live with their stoma now on a scale of 0-10, the median score was 8 (range 0 – 10). The majority (83%) felt that the stoma, within the past month, restricted their life “a little” or “not at all”. Eighty-four percent answered that they would “probably” or “definitely” choose to have the stoma again. When they were asked the question “compared to when you were incontinent, how much change has having a stoma made to your overall quality of life?” on the scale of -5 (much worse) to +5 (much better), the median rating was +4.5 (range -5 to +5). The authors concluded that health care professionals should discuss the option of a stoma with incontinent patients because of the overwhelming positive outcomes.

An end sigmoid colostomy without proctectomy is usually recommended as a procedure of choice for patients who elect colostomy for the management of their refractory faecal incontinence. Creating such a colostomy, however, does not always solve all the problems of patients with faecal incontinence. Catena et al [339] reported a retrospective chart review of 44 patients (35 women) who underwent elective end sigmoid colostomy for faecal incontinence of various etiologies. After colostomy formation 19 patients (43%) were asymptomatic, while the other 25 experienced such problems with their rectal stump as diversion colitis and mucus leakage. Of the 25 patients, 12 (27% of the total) underwent a secondary proctectomy due to the rectal stump problems sufficient to warrant the operation. Histological examination revealed diversion colitis in 6 patients. The factor associated with proctectomy was age, with younger patients being more likely to require rectal excision. The authors concluded that data are insufficient to recommend primary proctectomy in patients with severe faecal incontinence warranting permanent end sigmoid colostomy.

### 11. PUBORECTAL SLING

The puborectal sling operation was first reported by O’Rourke in 1974 [340]. In this procedure, an artificial sling is routed behind the anorectal junction and its two ends are fixed to the pubic bone, pulling the anorectal junction up forward with some tension. Similar to the postanal repair, the rationale of this operation is the restoration of the anorectal angle normally maintained by puborectal muscle. For the treatment of female urinary stress incontinence, a similar procedure, called tension free vaginal tape (TVT), has been performed with a reasonable success rate of 81-93% [341].

No systematic reviews, non-randomised cohort studies or case control studies have been reported regarding puborectal sling operation for faecal incontinence, whilst one prospective comparative study (level 2) [342], one case series of good quality (level 3) [343] and three case series of low quality (level 4) [340,344,345] were identified. Results of the puborectal sling operation are shown in Table 8 [340,342-345].

O’Rourke [340] first reported the sling operation using Dacron mesh for the treatment of 3 patients with full rectal prolapse as well as 4 with mucosal partial rectal prolapse and faecal incontinence. Two patients developed a sinus or sinus discharge at the site of the insertion of the sling, and the sling was removed in one. Out of the 4 patients with faecal incontinence and partial prolapse, 3 were reported to have “benefited considerably” from the procedure although a formal evaluation of the faecal incontinence was not performed and the follow-up period was not documented.

PCS: prospective comparative study; ns: not stated
O’Rourke and Egerton [344] reviewed 24 patients in whom the sling operation was performed using a strip of rolled mersilene mesh. This procedure, however, was performed mainly for the treatment of rectal prolapse, while it was conducted because of faecal incontinence alone only in two out of the 24 patients, and the outcomes regarding the continence were not formally evaluated.

Shafik [345] reported another sling operation called puborectoplasty utilizing a Teflon sling for faecal incontinence. Out of the 31 patients who had been incontinent to solid stool and underwent this procedure, “good results” were achieved in 26 patients (84%) after a follow-up period of between 2 and 4 years: 20 became continent to solid and liquid stool as well as flatus; 6 to solid and liquid stool but not to flatus; 4 to solid stool only; and only one remained incontinent to solid stool. Postoperative complications included a wound infection only in one patient, which responded to antibiotics without requiring the sling removal.

Shafik and Shafik [342] conducted a prospective study comparing two fascia lata slings (double loop) in 22 patients and one fascia lata sling (single loop) in 22 for the treatment of faecal incontinence. After 12 months follow-up, “good results” were achieved in 14 (63%) and 8 (36%) by the double loop and the single loop, respectively, and its difference was statistically significant. Postoperative complications included superficial infection in two patients of single loop, which responded to antibiotics without requiring the sling removal.

Yamana et al [343] performed the perineal puborectalis sling operation in 8 patients with passive faecal incontinence using polyester mesh sling. A wound infection developed in one patient which responded to antibiotics, while a rectal ulcer developed in one requiring the sling removal. In the 6 month evaluation of the remaining 7 patients, all reported some extent of improvement of their faecal incontinence. Both the Faecal Incontinence Severity Index and the Cleveland Clinic Faecal Incontinence Score significantly improved from 27 to 9 and from 13 to 5, respectively. Moreover, all parameters in Faecal Incontinence Quality of Life Scale significantly improved: lifestyle from 2.1 to 3.6; coping/behavior from 1.5 to 3.4; depression/self perception from 2.3 to 3.7; and embarrassment from 2 to 3.6.

### III. SURGERY FOR PAEDIATRIC Fecal INCONTINENCE

Faecal incontinence is common in children who have anorectal malformations, spinal problems and surgery for Hirschsprung’s disease. Despite advances in technique for anatomic corrective surgeries, many patients continue to suffer from persistent incontinence. This guideline mainly focuses on anorectal malformations and corrective surgeries along with their results and subsequent management in case of persistent incontinence. Other surgical interventions used less frequently were also reviewed.

1. ANORECTAL MALFORMATIONS

Anorectal malformations occur once in every 3000-5000 live births. Although the severity of malformation varies, it is invariably associated with defaecatory problems including incontinence. The surgical advances have been most prominent in last few decades, particularly with the advent of posterior sagittal approach. [LEVEL OF EVIDENCE: 3] This technique has enabled surgeons to visualise the anatomy under direct vision and perform corrective surgeries more accurately [346, 347]. In brief, a mid-sagittal incision is performed and the sphincter mechanism is completely divided in the midline. The rectum is separated from the genitourinary tract and moved down to the perineum. The most challenging aspect of the operation is the separation of the rectum from the vaginal or urinary tract, which effectively requires creating two walls out of one septum without damaging each structure. This approach can also be used for reoperation in anorectal malformations [348] and can also be applied for reconstruction of severe perineal trauma [349].

For both male and female babies, urethral-perineal fistula is the simplest fistula to correct. These require the so-called ‘minimal posterior sagittal approach’ which enlarges the stenotic orifice and relocates the rectal orifice posteriorly within the limits of the sphincter complex. For males with recto-urethral-bulbar fistula or recto-urethral-prostatic fistula and females with recto-vestibular fistula or cloaca with short (less than 3cm) common channel, posterior sagittal approach is the main operation performed. For males with higher fistulas such as recto-bladder neck fistula and other complex and unusual defects and females with cloaca with long (greater than 3cm) common channel and complex defects, the posterior sagittal approach needs to be coupled with abdominal access which can be either laparoscopy or laparotomy [350]. There has been no robust evidence to suggest superiority of laparoscopy in terms of outcome [351, 352] though better visualisation and assessment of fistula have been advocated as an advantage of this approach [353, 354].

Cloacal repair is the most challenging amongst the corrective surgeries for anorectal malformations. A recent operative advance in cloacal repair is a maneuver called total urogenital mobilization whereby the rectum is separated from the vagina and both vagina and urethra are then mobilized together. The advantage of this technique is to avoid separating rectum, vagina and urethra completely which is not feasible all the time and risks damaging these structures during the procedure. This technique avoids the risk of urethrovaginal fistula and vaginal stricture previously reported as complications in 10% of the cloacal repair and also gives enough mobilization to allow more than 50% of all cloacal repairs without opening the abdomen [355, 356].

Functional outcomes depend on the severity of the malformations. A review of more than 1000 anorec-
tal malformation cases showed 100% of babies who had perineal fistula repair achieved continence. Approximately 55% of patients who had been operated for recto-vestibular fistula had bowel control. Any malformations more complicated resulted in only up to 30% achieving continence. All patients who had recto-bladder neck fistula repair were incontinent. In cloacal repair the length of the common channel, shorter or longer than 3cm, appears to be the distinct prognostic factor in terms of functional outcome [357]. Overall it is estimated that nearly 40% will have voluntary bowel movement and no soiling but some of them may still lose bowel control in case of severe diarrhoea and 25% of all repairs will result in total incontinence [358].

For the group of patients with persistent incontinence following the corrective surgery, the next aim will be to keep the colon clean to avoid unpleasant accidents and improve quality of their life. A good option is implementation of a bowel management programme whereby the patient and family are instructed in the use of daily enema, manipulation of diet and medication to remain clean [359]. This is also a good treatment for constipation, which is the most common difficulty after corrective surgery [360].

Although most young children accept their parents administering enemas, when they get older they want privacy and rectal enemas on daily basis becomes an unpleasant routine. In such cases, continent appendicostomy is a feasible option, whereby a conduit for the administration of an antegrade continence enema (ACE) is created. First described by Malone [361] it has become an important option in paediatric surgery for functional bowel disorder.

According to the initial description by Malone, appendicostomy was created by dividing the appendix at its base and reimplanting by a reverse manner into the cecum, which was then exteriorized through the right lower quadrant. Malone later revised it and the reimplantation of appendix is no longer considered necessary [362]. Levitt et al [363] introduced utilizing the appendix in situ and added caecal plication to prevent reflux of stool and exteriorizing through umbilicus fold rendering it less noticeable. This appears to yield good long-term results [364] though a recent study has shown that caecal fixation and wrap may be unnecessary for appendicostomy [365]. The benefit of a variation called orthotopic continent appendicostomy is not clear [366]. However, construction of appendicostomy with burial of the appendiceal tip appears to help avoid problems of exposed mucosa such as bleeding and mucus discharge. From this perspective, a few techniques have been suggested such as V-Y flap [362] and Y-appendicoplasty [367]. For patients without an appendix, a neoappendix could be formed from ileum or cecum [368-370]. Laparoscopic antegrade continence enema procedure has been reported to yield as good result as open procedure [371-374].

This procedure is not a cure to the problem but a more acceptable method for many children to engage in a bowel management programme without the need for rectal enemas. Success rate is variable between 61-96% [362,368,375-379] with older children benefiting more [380]. Satisfaction with the treatment is reported to be as high as 93% [363,381,382]. [LEVEL OF EVIDENCE 3]

As with any operation, there are known complications associated with antegrade continence enema. Stomal stenosis is the most common complication and the use of ACE stopper will prevent it in the short-term [383]. Leakage of stool from appendicostomy is another common complication. These complications cause 10-33% of patients to undergo revision of the appendicostomy [358,384]. Stoma prolapse, pressure sore, wound infection, anastomotic leak, stomal granulation, caecal-flap necrosis and caecal volvulus are less common complications reported after ACE [385-387].

2. OTHER CAUSES OF FAECAL INCONTINENCE

Some children with Hirschsprung’s disease following pull-through operations and severe constipation may also present with symptoms of incontinence [388]. Patients with spinal problems often lack bowel control due to paralysis and absence of sensation; 50% of the children with spina bifida suffer from incontinence [389]. The majority of these cases can be successfully managed with above mentioned bowel management programme including appendicostomy although wheelchair-bound children with spinal neuropathy is a predictive factor for poorer outcome with ACE [377].

The mechanism of incontinence after an operation for Hirschsprung’s disease, anorectal malformations and severe constipation is thought to be due to impaired bowel motility. Impaired bowel motility causes faecal impaction, which can lead to development of a dilated segment of bowel called ‘megarectosigmoid’. This can subsequently lead to overflow incontinence due to incomplete evacuation [390]. Once the rectum is dilated it is refractory to conservative management, and resection of megarectum or megasigmoid has been associated with improvement [390-392]. A small minority of patients (5%) who fail these options may need colostomy [393].

3. OTHER OPERATIONS

Sphincter augmentation by either palmaris longus transposition, gluteus muscle transposition, graciloplasty or levatorplasty has been used for children with faecal incontinence albeit in small series [394-403]. Dynamic graciloplasty has also been piloted and 50% of patients achieved complete continence although the study only contained four patients [404]. Sacral nerve stimulation has been used in a small open label study with nearly 80% of positive response [405]. [LEVEL OF EVIDENCE: 4]
Data regarding the surgical treatment of faecal incontinence are generally weak. Randomised, controlled studies are few, and practical considerations make the likelihood of such studies improbable. The quality of data reported in older studies was often poor. Problems included heterogeneous patient populations; variable definitions of “continence,” “incontinence,” “success,” and “failure”; non-standardized and non-validated continence scales; underreporting of validated symptom-specific quality of life measures; variable patient follow up and lack of independent assessment of continence outcomes. However, there has been a notable improvement in the quality of studies reported in the past decade.

The spectrum of surgery for faecal incontinence is broad and expanding. Interventions range from simple outpatient procedures to major reconstructive surgery. As the reported outcomes of these various operations are often similar, a sound general principle is to proceed first with the simplest and least invasive procedure. Major operations associated with more profound morbidity should be restricted to patients who have failed simpler measures.

1. SPHINCTER REPAIR (GRADE B)

Sphincter repair is indicated for patients with acute traumatic sphincter disruption, such as following obstetrical injury, but many patients experience persisting symptoms.

2. SPHINCTEROPLASTY (GRADE B)

Overlapping sphincteroplasty can be offered to patients with significant faecal incontinence and a documented sphincter defect. Most patients improve after sphincteroplasty, but outcomes deteriorate over time.

3. POST-ANAL REPAIR (GRADE C)

Post-anal repair can be performed with modest success in carefully selected patients. However, this procedure is now rarely performed due to the advent of newer treatments.

4. NON-STIMULATED MUSCLE TRANSPOSITION (GRADE C)

Non-stimulated muscle transposition repair can be performed with modest success in carefully selected patients, notably in children. However, this procedure is now rarely performed due to the advent of newer treatments.

5. STIMULATED MUSCLE TRANSPOSITION (GRADE C)

Stimulated muscle transposition has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in selected patients with significant perineal tissue loss or in those who have failed other treatments.

6. ARTIFICIAL ANAL SPHINCTER (GRADE B)

Artificial anal sphincter has been shown to have reasonable success but is associated with significant morbidity. It remains a useful technique in carefully selected patients, particularly those who have failed other treatments.

7. SACRAL NERVE STIMULATION (GRADE B)

SNS is an effective therapy for most patients with clinically significant incontinence who fail conservative management. The technique is safe, minimally invasive, and has the unique advantage of allowing a therapeutic trial prior to permanent stimulator implantation.

8. POSTERIOR Tibial NERVE STIMULATION (GRADE D)

Posterior tibial nerve stimulation is an investigational technique with few available data regarding efficacy and outcome.

9. INJECTABLE BIOMATERIALS (GRADE C)

Most series of injectable biomaterials report reasonable success rates. However, the optimal injectable bulking agent and the technique for its insertion have not been established.

10. COLOSTOMY (GRADE C)

Formation of an end colostomy is a reasonable treatment option for patients with refractory faecal incontinence who are able to accept the associated alteration in body image. Colostomy provides restoration of a more normal lifestyle and improves quality of life. It also could be the most cost-effective in the short to medium term, compared to more complicated surgical procedures such as artificial anal sphincter and dynamic graciloplasty. Colostomy should not be regarded as a treatment failure but rather a reasonable treatment option for patients whose lives are restricted by faecal incontinence that is not amenable to other therapies. An end sigmoid colostomy alone, without proctectomy, is recommended. The minority of patients who develop significant symptoms from their retained rectal stump may eventually require proctectomy as a secondary procedure.

11. PUBORECTAL SLING (GRADE D)

The puborectal sling operation seems promising because it is a simple procedure and yielded reasonably good results so far with low complication rate, although the number of patients was small with a short follow-up period. More prospective studies of larger number of patients with a longer follow-up period are warranted. They are expected to closely evaluate complications such as sling infection, erosion and rectal ulcer that might require the removal of the sling.

12. SURGERY FOR PAEDIATRIC FAECAL INCONTINENCE (GRADE C)

Anorectal malformations should undergo surgical repair, most commonly by a posterior sagittal repair.
An antegrade continence enema procedure can be considered for children with persistent or refractory faecal incontinence.

V. RESEARCH PRIORITIES

Despite steady progress in the clinical management of faecal incontinence, including the development of novel treatment methods since the last International Consultation, there remain numerous areas where additional research is needed.

1. BASIC SCIENCE AND PATHOPHYSIOLOGY

Several animal models of faecal incontinence have now been developed that are capable of providing interesting insights into the physiology of normal continence and the pathophysiology of faecal incontinence [223,406-412]. Further use of these and other animal models can be expected to yield valuable information about pathophysiology and treatment, and is strongly encouraged.

2. CELLULAR THERAPY

There is a body of basic research on the use of stem or precursor cells of different tissue of origin (muscle, fat, bone marrow) in supplementation of urinary continence [413]. Recently, Frudinger and colleagues [414] have reported successful treatment of faecal incontinence using autologous myoblasts cultured from a pectoralis muscle biopsy, harvested, and injected into the external anal sphincter defect using ultrasound guidance. Further research relating to the tissue of origin, harvesting and processing of graft cells, the technique of implantation and clinical outcomes is urgently needed.

3. OUTCOME MEASURES

While there is general agreement that patient-based outcome measures are most appropriate for studies of faecal incontinence, standardization of the optimal instrument or combination of instruments remains a central challenge in clinical incontinence research. These instruments should be selected based upon eight general criteria and applied to the specific field of faecal incontinence: appropriateness, reliability, validity, responsiveness, precision, interpretability, acceptability and feasibility [415].

It is unknown if the main outcome measure following incontinence treatment ought to be incontinence severity, incontinence-related quality of life, or a combination of these factors. The FIQL is a well-validated quality outcome measure but it yields separate scores on 4 individual scales. It is desirable that a single score outcome be developed. Furthermore, quantitative changes in FIQL have not been anchored to the corresponding impact on patient quality of life and thus remain rather abstract. Additional studies, for example using time trade-off techniques, are needed to understand the clinical meaning of a given change in FIQL.

The FISI severity score is not as broadly used as the FIQL, and it appears to require additional validation work. Continence diaries have been considered to be the gold standard measurement, but these are highly influenced by the patient’s willingness to stray from a nearby toilet. Standard definitions are needed for such terms as seepage and leakage, and a standardized measure of faecal urgency should be developed. Additional validation work is needed to assess the potential effect of recall bias in recall-based scoring systems such as the Wexner and Vaizey scales. The International Consultation on Incontinence Bowel module (ICIQ-B) has recently been developed, but additional experience with this instrument is required [416].

4. CLINICAL TRIALS

There remains a paucity of randomized, controlled trials in the field of faecal incontinence. Proof of efficacy of novel therapies, numerous in the field of faecal incontinence therapy, is best demonstrated using a randomized trial design, and these types of studies are strongly encouraged.

Long-term outcomes following sphincteroplasty have demonstrated a substantial fall-off in function over many years. Similar long-term data are not available for other therapies, including especially the more recently developed ones such as SNS and injection therapies. Prospective trials funded for long-term follow-up and creation of treatment specific registries are needed.

Much recent research has been industry funded and designed to assess the efficacy of a specific novel therapy. There have been very few studies prospectively comparing different treatments, and randomized comparative treatment trials are urgently needed. The Committee has in particular noted the need for a randomized trial of SNS versus sphincteroplasty for individuals with faecal incontinence associated with a sphincter injury.

5. DECISION AND COST-BENEFIT ANALYSIS

Given the broad range of potential treatments for faecal incontinence and the usual costly proposed devices, additional research is needed in the areas of decision analysis and cost-benefit analysis. In severe faecal incontinence a comparison against stoma care cost would be appropriate.

6. TREATMENT DELIVERY

While there is ongoing research on the epidemiology of faecal incontinence, little is known about the true number of patients who have had treatment, who have access to treatment, or who have adequate knowledge to seek treatment. Research should be directed to identify current treatment needs, improve the accessibility of treatment, and improve the transmission and distribution of information about acceptable treatment options.

GENERAL INTRODUCTION

In the developing world fistula are often a consequence of poor peri-natal care. The epidemiology, aetiology, diagnosis, treatment and prevention have been described in detail during the recent International Consultations on Incontinence.[1, 2]

In contrast to the field of obstetrical fistula where the numbers of patients are high, the prevalence of non-obstetrical fistula seems to be much lower. The published series deal with small numbers, are usually retrospective and have a low level of evidence. The published obstetrical series show impressive numbers and demonstrate the level of skill that many of the fistula surgeons have obtained while working in difficult and isolated situations.

In this consultation the main focus has been put on iatrogenic fistula in the developed world. An entirely new chapter was compiled on this subject.

Despite the fact that the main focus was to write a chapter on iatrogenic fistula, in this edition the scientific summary of the International Consultation on Vesico-Vaginal fistula in the developing world, which was held in Marrakech, Morocco in 2010 was added to the text.

Both committees are convinced that obstetric fistula surgeons in the developing world and reconstructive pelvic surgeons in the developed countries can learn a lot from each other. Combining the obstetrical and iatrogenic fistula into one chapter will facilitate interaction and exchange of knowledge and ideas in this difficult field of fistula repair.

A. Obstetrical fistula

I. INTRODUCTION

The First ICUD-SIU Consultation on Vesico-Vaginal Fistula was held at the SIU meeting in Marrakech, Morocco, October 13th – 16th 2010. The recommendations are evidence-based, following a thorough review of the available literature and the opinion of recognised experts serving on the six committees. The individual committee reports were developed and peer-reviewed by open presentation and comment. Review of the literature showed no Level 1 evidence in that there were no randomised controlled trials. All evidence was confined to case series and observational data: Level 3 and 4 evidence. Hence, all recommendations were Grade B and C.

The Scientific Committee includes the chairmen of the six committees, who refined the final recommendations. These recommendations published in 2011, will be periodically re-evaluated in the light of clinical experience, technological progress and research. These recommendations are taken from the full versions of the six Consultation chapters, from Epidemiology through to Social Reintegration. These chapters provide the full documentation of the existing scientific literature on the six topic areas.

II. WOMEN, FISTULA SURGEONS, NGOS AND GOVERNMENTS

The effect on a woman, in the developing world, of having a VVF resulting from obstructed labour, is disastrous from her point of view, the family perspective and for her society. It is estimated that there are two million women, in developing countries, mainly in sub-Saharan Africa, the Indian sub-continent and South-East Asia, who have either undetected or untreated VVFs. New fistulas are probably occurring at the rate of 82,000 new cases per year, yet only 10,000 operations for fistula closure are being done annually. Hence, this leaves a huge unmet need.

VVF, in itself, is bad enough, but it is also inextricably linked with high maternal mortality rate and high infant death rate. Hence the solution to fistula is similar to the solutions that will drive down the maternal mortality rate and the infant death rate. The solutions are not only medical, but also social and political.

At present, women in developing countries are often dependent on donations that reach their country.
through non-governmental organisations (NGOs) and charities. The relationship between the NGOs and the fistula surgeons are critical. The fistula surgeons are the experts and those to whom fistula women turn for help. Hence, it is vital that the NGOs allow themselves to be guided by the fistula surgeons as to the priorities within their sphere of work. The vital role of the NGOs is to provide financial and logistical support. Support is also essential to allow the fistula surgeons to write up their work. This is often a considerable problem, as their commitment to the women means that their academic time is restricted. Nevertheless, the data the fistula surgeons generate is their intellectual property, and it is vital that they retain primary authorship of all published material.

There are an enormous number of committed and dedicated individuals from both within the developing countries and from developed countries who have committed themselves to the cause of helping women with this dreadful condition. However, the long-term solution must see the responsibilities for women’s and children’s health passing to the governments of the individual countries. Nevertheless, in the meantime, those many dedicated individuals will continue to strive to help as many women as possible return to a life in their own community.

1. EPIDEMIOLOGY OF VVF

Epidemiological studies on obstetric fistula are inadequate.

- They are mainly institutionally-based, retrospective cases series, often written from the perspective of a single fistula surgeon
- The geographical coverage of epidemiological reports is uneven
- However, better and more relevant information is emerging.

The incidence of fistula is expressed per 1,000 deliveries and would appear to be between 0.1% rising to 1.5 per 1,000 pregnancies in rural areas.

The major risk factors appear to be age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment and illiteracy.

The consequences of obstetric fistula include divorce (16-92%), social isolation, worsening poverty, malnutrition, sexual dysfunction and mental illness (including anxiety/depression), insomnia, general ill health and thoughts of worthlessness and suicide.

There are few detailed reports documenting these women’s obstructed labours. The time of onset of labour is rarely recorded and reports from delivery locations may disregard the fact that the woman has laboured at home for days prior to attending the delivery location. The reason for the woman not receiving help rarely differentiates between the absence of health-seeking behaviour and the lack of services. The only observational study showed no substantial difference between VVF patients and women who delivered without fistula, both in terms of their use of orthodox health care services and more traditional forms of support before childbirth.

Recommendations

1. Community-based epidemiological studies using standardised and validated collection tools with acceptable sensitivity and specificity are highly recommended.

2. A validated standardised collection tool should be developed and used in national surveys to facilitate the collection and comparison of data when assessing the regional, continental and global magnitude of VVF and the distribution of fistula world-wide.

3. Prospective longitudinal community-based studies are needed to estimate the incidence of obstetric fistula.

4. Observational studies are needed, utilising advanced epidemiological analyses for:
   - Risk factors (multivariate analysis controlling potential biases)
   - Impacts and consequences of VVF
   - Determining health-seeking behaviour

5. Research that identifies the different profiles of women who manage to overcome the obstacles and successfully access health care, compared to those who do not, is recommended.

6. The contribution of other factors, such as ethnic background and malnutrition, needs to be researched and understood.

7. It is recommended that there is long-term follow up of patients following fistula repair to understand their ongoing quality of life and any long-term sequelae and their ongoing needs.

2. PREVENTION OF VVF

VVF is a characteristic of abject poverty, a clear marker of failure of political, social and health systems to protect and promote women’s health and their rights. Prevention of VVF is ultimately linked to prevention of maternal and infant mortality and is a requirement of MDG5 of 2000.

Prevention, from the medical and public health point of view, mitigates the effect of VVF in the overall burden of pain and suffering the condition imposes, not just on the patient herself, but her family and the entire community. History has shown that improvements in the functioning of local health services dramatically reduce the incidence of maternal death, infant mortality and vesico-vaginal fistula. The following areas of health system improvement and capacity building need to be considered:
• Enhancing professionalism among health care workers to make the system work better.

• Massive infrastructural developments through strengthening existing government health facilities, and advocacy, to maximise the benefits that a political environment sensitive to the needs of these women, is required.

• Ensuring that facilities are properly equipped, monitored and supervised with an emphasis on quality as well as quantity of service provision.

Systematic improvements are required to address the social and economic inequalities, such as the low status of women, lack of education for girls, early marriages and pregnancy, malnutrition, poverty, inadequate health and transportation infrastructure, and harmful traditional practices, such as female genital mutilation.

Health and maternal care are inextricably linked to the availability of financial resources, to the individual in the community and within the country as a whole: as economic conditions improve, the risk of VVF diminishes.

Another key stratagem, in preventing VVF, is the empowerment of women and their spouses, to develop birth preparedness plans, within the context of family planning. Family planning in wealthy regions is available according to the choice of the individual, whilst in other developing areas, such as China, it is actively encouraged, or even enforced. Other components of public health care, such as addressing the special nutritional needs of girl children and the requirements of improving their physical health, in order to improve their physical growth and maturity, are also very important.

Education of the community is vital so that young women understand what VVF is, are made aware of the need to engage in the ante-natal care process, and plan for their delivery, including making transportation plans for use when they go into labour.

Prevention strategies can be considered in public health terms as primary, secondary or tertiary:

• Primary prevention addresses many of the indirect causes which are essential the root causes of fistula. It attempts to reduce or eliminate the risk of the disease and by, amongst other actions, reducing the high levels of illiteracy among women. It also seeks to widen the cadre of care workers by involving, for instance, traditional birth attendants (TBA)

• Secondary prevention attempts to limit the severity of the disease by detecting it at its earliest stages.

• Tertiary prevention aims to mitigate the effects of the existing disease, for example by effective treatment.

The work of Haddon and Maine in the Haddon Matrix and Maine’s Three Delays provide documented approaches to the problems.

Maine’s Three Delays:

• The first delay: the decision to seek care is influenced by the socio-economic and cultural factors in that woman’s environment. These can include the need to obtain permission from a husband or male family member to seek care, or the community perception that only weak women need assistance with delivery and that strong women can manage delivery on their own.

• The second delay is delayed arrival at the health facility. Once the first delay has occurred, the second delay becomes more serious. Road conditions, transportation and communication deficiencies may conspire to delay the woman’s arrival at a hospital or birthing centre.

• The third delay is the delayed provision of adequate care at the facility, and may be due to lack of staff, supplies, or electricity. If the lights are out and there is no back-up generator or fuel, a caesarean section cannot be done. If there is no way to reach a doctor or medical officer because there are no telephones, or if equipment hasn’t been sterilised, then timely surgery cannot be performed.

These three stages of delay disproportionately affect the world’s poor and, in particular, those women living in rural areas.

Recommendations

1. Strong community support is required to develop solidarity groups which include village volunteers working with trained, skilled and traditional birth attendants, depending on the local customs and resources.

2. The components of the three delays need to be identified and targeted in order to minimise the effect of obstructed labour. By this process there will be other benefits for maternal and child health.

3. There should be provision of adequate health facilities and birthing centres to which women move either as soon as they go into labour, or if labour is delayed. Such facilities must provide emergency obstetric care, including caesarean section.

4. National policies for maternity care should be developed for all countries whether or not VVF is a common complication of childbirth.

5. Data collection by local, national and regional bodies should help to define the incidence of birth complications, and factors leading to the “3 Delays”.

6. The components of the “Three Delays” need to be identified and targeted for each community where there is a high prevalence of complications of childbirth.

7. Girls, women and communities should be educated about normal and abnormal labour, and facilities such as waiting houses should be available for pregnant women at risk for complicated deliveries.

8. Solidarity groups including local volunteers and skilled and trained traditional birth attendants should be developed for maternal care.

9. Birthing centres with the capability for caesarean section should be accessible and sufficiently affordable for women to use.

10. Funding should be made available to retain adequate trained staff for waiting houses and birthing centres.

11. Partographs should be employed to track the progress of delivery in order to identify problems and for data collection.

3. UNMET NEEDS IN VVF

There is unmet need at every level of the healthcare service in those developing countries where VVF is a significant problem. These needs span from family planning through obstetric care, the availability of emergency obstetric services and the provision for dealing with maternal and infant post-partum problems.

Unmet need has not clearly been defined, although the increasing gulf between the prevalence and incidence of fistula and its prevention and treatment is exceedingly worrying.

In low resource countries there is a need for stable and enduring collaboration and partnerships between governments and non-governmental organisations (NGOs), such as UNFPA, Engender-health, WHO and MSF. These partnerships will go some way to identifying unmet need and ensuring that unmet need is reduced.

One of the most important aspects of the unmet needs in fistula surgery training has been the lack of standardization. In order that the recommendations below can even be partially met, there has to be a global strategy in developing training, education, and ancillary support for the surgeons and their associated teams. This will be partially met by the creation of the global competency-based fistula surgical training manual, created by the International Federation for Gynaecology and Obstetrics (FIGO) with International Society of Fistula Surgeons (ISOFS). The purpose of this manual is to enable health care providers to acquire the required knowledge, skill and professionalism to prevent fistula and provide holistic care to fistula patients that includes medical, psychosocial and surgical care. A multi-disciplinary team-based approach is encouraged in the training of each doctor and his/her team nurses, physiotherapists and other health professionals. The course is structured at three levels: standard, advanced and expert levels of fistula training.

The manual is made up of several components:

- Curriculum Modules
Each module has an outline of the course content, that the trainee is expected to be aware of. It needs to be used in conjunction with recommended references, and in some cases with specific Performance Based Assessments (PBAs). There are 7 modules that need to be undertaken.

- Logbooks of Competency
These are records of the work carried out by each trainee. Each must be signed off by each trainer, who will determine if the trainee has observed a procedure, has assisted with a procedure or is able to work independently. The trainer will determine if the trainee needs further training in a particular area.

- Performance Based Assessment (PBA)
Each aspect of surgical training will be assessed separately and specifically. The trainees will complete each PBA to a standard, advanced or expert level and ideally need the signature of two or more trainers, from two or more training centres. It is expected that each trainee will undergo a prolonged period of fistula training at one or more centres. There are 15 PBA to be completed before a fistula surgeon would be deemed to be an expert, and will often require the full 24 months of training. However, this is a competency-based training manual and each trainee will require different lengths of time to achieve each level of expertise.

This structured approach of the competency-based manual will attempt to standardise and support surgical training in fistula repair. In the process of achieving this aim, it is envisaged that there will eventually
be an increase in the number of training centres accredited for training and eventually surgeons trained.

**Recommendations**

1. Unmet need has to be defined in each country, and within each country, in each geographical region.
2. The unmet need in ante-natal services needs to be rectified urgently in order to minimise the number of new fistulae occurring.
3. The need for education and training has to be addressed for birth attendants, community nursing and fistula surgeons.
4. Training centres for fistula surgeons need to be identified and new ones established, according to population matrix. Training should be systematic and structured, using assessment tools such as those developed by FIGO with ISFOS.
5. Audit and research must be developed in order to ensure that quality and advances in treatment methods are ensured.
6. National strategies need to be developed to empower individual nations to take charge of the women’s and children’s services in their country.

**4. MANAGEMENT OF NEW AND ESTABLISHED VVFS**

Management of VVF depends on whether the fistula is diagnosed within two or three months of its occurrence or whether the woman presents late with an established fistula. There is evidence that early catheter care will result in the cure of a significant minority of VVFs. Algorithm 1 ([Figure 1](#)) describes the management of women who have both early fistulas, defined as those that have occurred within 75 days of presentation, and established fistulas, that is those that are discovered more than 75 days after obstructed labour.

**5. CLASSIFICATION OF VVF**

The Consultation believes that fistula audit research is considerably hampered by the plethora of VVF classification systems, of which we believe there are 32. The Consultation feels that the fistula system that is able to relate its classification to outcome is the classification that should be used in the next few years. The Waaldijk Classification is the only one that has been used to document sufficient numbers of patients from diagnosis to follow-up ([Figure 2](#)). [Figure 2](#) shows the Waaldijk Classification which involves precise measurements of the distances between the external urinary meatus and the distal edge of the fistula, together with the widest diameter of the fistula. Fistulas are classified into types 1, 2 and 3. Type 3 fistulas are those fistulas other than vesico-vaginal fistulas and include recto-vaginal fistulas and uretero-vaginal fistulas. The Waaldijk Classification of Types 1 and 2 is illustrated in [Figure 3](#) and described below.

If catheter drainage fails, then fistula repair will be necessary. There are certain principles behind fistula repair:

- Necrotic tissue must be removed prior to fistula repair.
- Fistula repair must only be undertaken by a properly trained surgeon.
- Adequate post-operative care is essential.
- Proper follow-up should be arranged.

![Figure 1. Algorithm to describe the management of fistula detected early (less than 75 days after obstructed labour) or later](#)
Table 2 indicates the type of fistula closure that should be used depending on the type of fistula.

<table>
<thead>
<tr>
<th>Bladder / urethra direction of closure</th>
<th>Pubocervical fascia / urethral support</th>
<th>Ant vagina wall closure</th>
</tr>
</thead>
</table>

**Recommendations**

1. The comprehensive use of an indwelling catheter with free urinary drainage should be instituted for all patients who have undergone either an emergency caesarean section or a traumatic vaginal delivery after obstructed labour.

2. When fistula surgery is necessary the woman must be assured of the surgeon’s competence to carry out her procedure.

3. It is recommended that further research is needed into the classification of fistula, not only to further validate the Waaldijk Classification, but also if other classifications are proposed for development.

4. There is a need to compare different surgical approaches to fistula within the context of randomized controlled trials, using the Waaldijk Classification to precisely describe the fistulas.

5. Long-term follow up of fistula patients is recommended in order to study the outcome of both conservative and surgical management and, in particular, to determine its effect on quality of life.

**Figure 2. The Waaldijk Classification for Fistula**

**Figure 3. The Waaldijk Classification for Vesico-Vaginal Fistulas**
6. When reporting the outcome after fistula repair, authors should make a clear distinction between fistula closure rates and post-operative incontinence rates, specifying the time at which follow-up was carried out.

6. MANAGEMENT OF THE COMPLICATIONS OF VVF

The complications of Vesico-vaginal fistula are many but include:

- Persistence or recurrence of urinary incontinence
- Persistence of lower urinary tract symptoms or occurrence of new lower urinary tract symptoms, including overactive bladder
- Urinary tract infections
- Upper urinary tract symptoms, including loin pain
- Dyspareunia and sexual dysfunction
- Infertility
- Neurological symptoms
- Psychological problems and mental illness

Recommendations

1. A care programme for failed repairs with persisting incontinence after a successful repair, needs to be in place.

2. It is recommended that surgical treatment of post-operative stress incontinence should only be considered six months after fistula repair.

3. Autologous material should be used when a graft or sling is required and there is no place for synthetic sling material.

4. In order to prevent new fistulas in women who become pregnant after a fistula repair, waiting homes should be provided to ensure that each woman is able to have an elective caesarean section when she goes into labour.

5. In recurrent identifiable fistula make sure of the size and number and this kind of fistula is better repaired by a well experienced fistula surgeon. It is important to use tissue interposition like a Martius flap or fibrin glue.

6. With urinary tract infections or abscess formation, antibiotics must be given before and after the repair, according to culture and sensitivities.

7. Patients complaining of persistent leakage due to urgency incontinence may try antimuscarinics, botulinum toxin injection or even augmentation cystoplasty in small contracted or poorly compliant bladders.

8. Those with a shortened or disrupted urethra, before or after repair, must be treated with urethral reconstruction, autologous slings or injection of bulking agents, delivered trans or peri-urethrally.

9. In cases with unilateral or bilateral ureteric ligation or injury, the early diagnosis is life saving. Patients must be promptly treated by endoscopic ureteral stenting, PCN or ureteric reimplantation.

10. Patients complaining of contracted vagina and dysparunea with sexual dysfunction may use local estrogen, vaginal dilatation or may require the surgical creation of vaginal flaps to augment the vagina.

11. Patients who develop dropped foot may respond to physiotherapy or require tibialis tendon transfer. Women with neurogenic OAB may benefit from detrusor muscle botulinum injections if antimuscarinic drugs fail.

12. Psychological trauma, social isolation and depression is best treated by counselling and psychological rehabilitation.

Social re-integration is defined as appropriate interventions that help women with obstetric fistula overcome physical, psychological and socio-economic challenges, freely identified by themselves, in order to enhance their return to the communities and social networks of their choosing, such that the risk of them presenting with another fistula is minimized.

The aim of social re-integration is to break the fistula recurrence/occurrence cycle in which the woman’s physical state is inextricably connected to her mental state and her socio-economic situation.

Social re-integration should be seen as happening from the time the leaking of urine becomes manifest, and every subsequent intervention should have the re-integration of the woman, back into her community, as the primary goal. So, social re-integration is the responsibility of everyone who cares for the woman.

Social re-integration can be usefully looked at within a matrix, as shown in Table 3 where the three elements of physical, psychological and socio-economic status are looked at in terms of the facility for treating the patient within her community and the political environment.

**Recommendations**

1. Social re-integration is important for all women with obstetric fistula. It is the process by which women are helped to overcome physical, psychological and socioeconomic challenges, freely identified by themselves, in order to enhance their level of social functioning in communities and social networks of their choosing, so that the risk of will presenting with another fistula is minimised.

2. Social re-integration should be used for all women. However, this series of interventions can be performed by any trained care worker, providing it focuses on making the woman part of her social fabric again, and commences from the time leaking of urine becomes manifest.

3. Social re-integration should be designed to break the fistula recurrence cycle in which the woman’s physical state is inextricably connected to her mental state and her socio-economic situation.

4. Early successful surgical repair or catheter management is highly recommended and is likely to be the only thing needed for social re-integration. Surgery should be performed as soon as possible by a skilled surgeon, and preferably within 3 months of developing the fistula, as this is likely to limit the length of time the woman is seen as abnormal by her family or community and thus perceived as an outcast.

5. Social re-integration should start in a designated space where women can recuperate, perhaps within the repair facility or nearby, rather than going home and encountering the risk of behaviours which may make it likely that a recurrence of fistula occurs, due to an exacerbating physical event such as early sexual intercourse or heavy work. Also, peer counselling is more likely to be available in this space.

6. Surgeons and other care workers should consider social re-integration as not just a social tool but also as a means of ensuring that adequate follow-up of the postsurgical improvement in quality of life is done and reported on. At least, there should be a review of individually defined success of surgery and surgical outcomes, including continence and return to fertility and/or sexual life, as desired by the woman.

7. Appropriate counselling messages about the risk factors and causes associated with fistula should be targeted at family members (including husbands) and the community, as this can help to overcome the stigma, discrimination and misconceptions surrounding the condition and enhance her community inclusion. It is then an opportunity to make changes so that

7. **SOCIAL RE-INTEGRATION OF TREATED WOMEN**

---

---
the woman does not present with another fis-
tula in the future.

8. Counselling should be seen as an opportunity
for health providers to understand the socioeco-
nomic, psychological and physical experiences
that are faced by girls and women living with
fistula, before and after surgery, so that they
may give meaningful help. This will also help to
generate knowledge on social re-integration pro-
cesses and will help in the planning of a broader
range of outcomes for women living with fistula.

9. Social re-integration should include assistance
with education and life skills, and encourage-
ment of private initiatives through vocational
skills development and microcredit support. If
this is freely chosen, it will not keep a woman
away from her community unduly, and will help
her regain or improve her previous economic
status and enhance her self-sufficiency and
community inclusion.

10. Social re-integration should include vocational
skills training with the aim of providing women
with alternative ways to generate income, with-
out jeopardising their recuperation, by teach-
ing them a trade which is economically viable
within their community.

11. Institutional re-integration services should be in-
corporated into existing community activities or
programmes directed to empower women (e.g.
education, skills training, income generation,
self-esteem).

12. Re-integration programmes should develop
criteria to determine where support with so-
cioeconomic interventions should be given, as
funds may be limited and fistula consequences
can vary dramatically by country and region.
They should also be careful not to increase the
burden of stigma and therefore inadvertently
impede re-integration. Of particular concern
should be women who are still incontinent,
those who are deemed incurable, those who
have no children and those who have lived
with fistula for a long period of time.

13. Social re-integration programmes need to con-
sider the potential ethical dilemmas in re-in-
tegration such as providing targeted financial
support or high value goods to women with fis-
tula in poor communities, other than as part of
a community approach.

14. Social re-integration should seek to involve
women who have been successfully re-inte-
grated into their communities. These women
can be termed motivational mobilisers and
can contribute to community mobilisation
movements for safe motherhood, fistula case
mapping and referrals for treatment. Women
should have a choice as to whether they wish
to be involved in such advocacy activities.

15. Social re-integration programmes should be moni-
tored and evaluated in order to collect correlates
of success and failure and to help understand so-
cio-cultural backgrounds, so that a context specific
approach can be used to design and deliver effec-
tive, feasible reintegration programmes.

Below is set out the committee structure for the Con-
sultation, within whose chapters full details of each
committee’s work can be found.

I. INTRODUCTION

Iatrogenic urogenital fistulae are known complications of pelvic surgery and oncological treatments such as radiotherapy. For example, a high quality population-based case-control study from Sweden found that the risk of urogenital fistula was 25 times higher amongst women undergoing hysterectomy (n=180,000) compared to an age matched control population (n=525,826) without hysterectomy. The risk appeared to be highest for laparoscopic hysterectomy and lowest for subtotal hysterectomy but absolute numbers were small with a number needed to harm of 5,700.[3]

This section is based on electronic searches of MEDLINE, EMBASE (from 1980 to November 2011), the Cochrane Database of Systematic Reviews, CENTRAL Register of Controlled Trials (CENTRAL), Database of Abstracts of Reviews of Effects (DARE), Database of Health Technology Assessments, and Database of NHS Economic Evaluations, and the NICE website (all accessed November 2011); references included in identified systematic and non-systematic reviews were evaluated separately. Hand searching of recent (Jan-December 2011) issues of major American, European and British journals in urology, gynaecology and urogynaecology was undertaken, to capture recent publications not yet included in the online databases. ICS, IUGA, AUA, AUGS and SGS conference proceedings for 2011 were also reviewed. It was assumed that studies and trials presented earlier than this would be in press if they were of sufficient quality and maturity to justify inclusion; hence older abstracts have not been considered. Papers offering any relevant data were considered. This included systematic reviews, randomised and quasi-randomised trials, non-randomised cohort studies, case controlled studies, longitudinal studies and case series or reports. Those papers considered for inclusion were assessed for quality where relevant, in terms of sequence generation, allocation concealment, blinding, and handling of incomplete data, selective reporting and freedom from other biases. An evidence level [EL] was then assigned to all included studies according to the ICUD modified version of the Oxford Centre for Evidence-based Medicine system. [4] Where quality was considered to be poor – as in most of the studies included in these sections – the evidence level was reduced accordingly. Recommendations (graded A-D) were made on the basis of consistent or ‘majority evidence’ identified.[4]

II. EPIDEMIOLOGY

1. POST-GYNAECOLOGICAL SURGERY

Fistulae involving the lower urinary tract can occur following any surgical procedure or traumatic event to the female reproductive tract, bladder, or rectum. In developing countries, the most common aetiology of fistulae involving the lower urinary tract is clearly obstetric trauma. [5] In most developed countries in which antenatal and intrapartum care is more readily available, obstetrical fistulae are relatively rare and the majority of fistulae are related to gynaecological surgery. The ratio of obstetric to gynaecological fistula appears to be consistent at about 10:90 in developed countries. [6] In some developing countries, as gynaecological procedures to treat benign and malignant conditions of the female reproductive tract are more commonly performed, the rate of iatrogenic fistulae is increasing (e.g. Pakistan). [7]

The types of fistulae associated with gynaecological procedures may include communication between any reproductive organ (uterus, cervix, Fallopian tube, vagina), intestinal tract (colon, rectum), genitourinary organ (bladder, ureter, urethra), and cutaneous system (abdominal wall, perineum). The combinations, locations, and severity of gynaecological fistulae vary with each patient. In general, vesicovaginal fistulae (VVF) are the most common type. The most common causes of VVF as a consequence of surgery, in developed countries is an injury injury to the urinary tract during hysterectomy for benign conditions (60-75%), followed by hysterectomy for malignant conditions (30%), caesarean section (6%), and obstetric injuries (1%). [8][9] At the Zekai Tahir Burak centre in Turkey 25,998 gynaecologic and obstetric operations were performed over a 3-year period. The bladder was the most frequently injured organ. Urinary tract injury rates were reported to be 0.49% for the bladder and 0.24% for the ureter in gynaecological operations, and 0.18% for the bladder and 0.01% for the ureter in obstetric operations.[10] Overall, the risk of pelvic organ fistula following hysterectomy has been reported to be between 0.1 and 4%. [11] It is important to recognize that most urinary tract injuries do not result in a fistula.

The prevalence of genitourinary injury and fistulae vary slightly from centre to centre. In one US retrospective study from the Mayo clinic, gynaecologic surgery was responsible for 82% of the fistulas, obstetric procedures for 8%, and various forms of irradiation for 6%, and trauma or fulguration for 4%. The majority of fistulae followed treatment for benign conditions. [12] The relative proportions of the types of urinary fistula have changed with urethral fistulae having increased from 6 to 13%, while ureteral, bladder and/or urethral fistulae having dropped from 20 to 16 and 11 to 7%. [2]

Given the various indications for, and types of hysterectomies, it is important to have an understanding of the type of hysterectomy since genitourinary or colonic fistula is reported with all of these procedures. The overall incidence of hysterectomy complications is estimated to be <2%, with bladder injury (1.3%) and ureteral injury (<1%) being most commonly reported. [13] Traditionally, the most common route used to...
remove the uterus for benign and malignant gynaecological conditions is abdominal (open incision, laparotomy); referred to commonly as total abdominal hysterectomy (TAH). The types of hysterectomies also include total vaginal (TVH), laparoscopically-assisted vaginal (LAVH), total laparoscopic (TLH), and subtotal or supracervical abdominal (SCH) or laparoscopic (LSH). Laparoscopic procedures may be done using traditional laparoscopic techniques, robotic assistance, and more recently, the single-site umbilical technique.

Benign and malignant conditions confined to the uterus are usually treated with a simple hysterectomy using any of the methods mentioned above. More advanced malignant conditions are usually treated with a radical hysterectomy in which parametrial and/or vaginal dissection and removal may be involved. In rarer cases, exenterative procedures to remove the bladder or colon may be required if malignant extension to these organs is found. In some centres, robotic radical hysterectomies have been more commonly employed to treat gynaecological malignancies. The rate of urogenital fistula associated with simple abdominal hysterectomy for benign disease is often described as being of the order of 1 in 1000. In a national study from Sweden the rate of women undergoing any fistula surgery was reported as 0.26% in women having had a hysterectomy compared to 0.0007% in those not exposed to hysterectomy, with the 'number needed to harm' being estimated at 5700. From Finland the rate of vesicovaginal fistula associated with simple abdominal hysterectomy for benign disease is often described as being of the order of 1 in 1250 after all hysterectomies, 1 in 455 after laparoscopic, 1 in 1000 after total abdominal, and 1 in 5000 after vaginal hysterectomy. The publicly available tables from the national hospital database in England give similar figures of 1 in 600 after total abdominal hysterectomy, and 1 in 5000 after vaginal hysterectomy. More detailed longitudinal analysis of patient-level information from the same dataset suggests a rate of 1 in 788 for all types of hysterectomy, 1 in 540 for abdominal hysterectomy for benign disease, 1 in 896 following vaginal hysterectomy for benign disease (excluding prolapse), and 1 in 3861 following vaginal hysterectomy for prolapse.

Naturally, caesarean hysterectomy is a recognised cause of fistula, and, with the increase in the number of caesarean deliveries there have been more fistulae related to obstetric-surgical trauma.

The degree of bladder injury appears to be a major factor in iatrogenic fistula formation. In one study, 1,317 benign hysterectomies were reviewed (46% abdominal, 48% vaginal, and 6% laparoscopically assisted vaginal) with reference to risk factors for VVF following intraoperative injury to the urinary tract. In all, 34 cystotomies occurred with 4 (11.7%) developing a VVF. Patients who developed a VVF were more likely to have a large cystotomy and these individuals trended toward greater tobacco use, larger uterine size, and more operative blood loss. Another study involving 3,076 vaginal hysterectomies with or without additional gynaecological procedures, one ureteral injury and 54 bladder lacerations were noted yielding a total of 4 VVF. The bladder lacerations occurred during the hysterectomy portion of the surgery in 61% of cases and during the additional procedures in 39%. (see Table 1)

VVFs associated with hysterectomy may require ureteral reimplantation in as many as one-third of the cases. Ureteric trauma should be considered in any hysterectomy or operative obstetric procedure regardless of the difficulty but certainly in more difficult cases. Iatrogenic ureteric injury may occur after less common procedures such as ureteroscopy, lumbar sympathectomy, abdominal trauma, and iliac vessel ligation.

Altered intraabdominal anatomy such as that due to previous surgery, extensive endometriosis and pelvic inflammatory disease have previously been thought to lead to an altered operative field increasing the risk for genitourinary injury; recent evidence from a cohort of over 300,000 women having hysterectomy for a variety of indications suggests that this may not be the case. The overall rate of ureteric injury from 4998 procedures in these studies was 1.5%; the overall sensitivity was 96.1%, specificity 99.5%, positive predictive value (PPV) 74%, and negative predictive value 99.9%. The modest PPV related to 21 cases in one study where cystoscopic examination revealed abnormal (sluggish or absent) flow of indigo-carmine dye through one or both ureteric

Confidence interval 1% 30%
orifices, but subsequent findings failed to confirm injury. For every 200 cystoscopies undertaken at gynaecological surgery therefore one might expect to diagnose three otherwise unsuspected ureteric injuries but at the expense of one false positive ‘injury’ that would ultimately be shown to be normal.

Visco et al. using a decision analysis model concluded that the cost-effectiveness of routine intraoperative cystoscopy depends on the rate of ureteric injury; if the rate exceeds 1.5% for abdominal hysterectomy and 2% for vaginal or laparoscopically-assisted vaginal hysterectomy, then routine cystoscopy is cost-effective. These data would suggest that whilst the routine cystoscopy might be considered clinically and cost-effective at the time of prolapse and incontinence surgery, its place at hysterectomy is less clear.

2. ONCOLOGICAL FISTULA

This section considers, where the literature permits, the epidemiology of fistula relating to malignant disease and its treatment by surgery, radiotherapy and chemotherapy. The literature relating to fistula of oncological aetiology is limited both in quantity and quality. Seventy-six papers of possible relevance were identified, of which only 52 contained any relevant material. Only one randomised trial was directly identified from the literature searches,[25] although one non-systematic review of relevance,[26] and two systematic reviews were found;[27, 28] each of the latter contained only one further randomised trial. One national cohort study, and one non-randomised cohort study, are included,[18, 29] but all other identified material comprised case series or case reports, and represent level 3 or lower evidence. Two cases of duplicate publication (i.e. the same paper in two journals) were found.

In the oncological context, fistulae may occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.

Traditionally, malignancies involving the uterus, cervix, vagina, or ovaries are often treated with hysterectomy, bilateral oophorectomy, and pelvic lymph node dissection. In many cases, a radical hysterectomy is performed in which the uterus, cervix, and upper vagina are removed. It is generally accepted that the more advanced the cancer, the more radical the surgical dissection will necessarily be. With cervical and uterine carcinoma, oophorectomy is performed when indicated. Pelvic lymphadenectomy is done when invasive carcinoma is suspected or diagnosed. In one study, 536 women underwent a radical hysterectomy for invasive cervical cancer. More advanced stage of disease, obesity, diabetes, and postoperative surgical infection were predisposing factors to urinary tract complications. In this study, ureteral injury occurred in 1.32%, bladder injury in 1.49% with VVF forming in 2.61% and ureterovaginal fistula in 2.43% of cases, respectively. [30] In a similar report, 1,092 women with cervical cancer underwent a radical hysterectomy with obligatory pelvic lymphadenectomy. A VVF occurred in 0.3% and a ureterovaginal fistula occurred in 1.4%. [31] The rate of GU injury likely varies between centres. For example, in one report of 479 women undergoing different methods of radical hysterectomy for cervical cancer over a 15 year period, 52 (10.8 per cent) had urological complications (17 bladder and ureter injuries, 35 fistulae and strictures). [32] In contrast, one institution reported that, with modifications and careful dissection, ureteric and bladder injury have almost been eliminated.[33]

In two recently published case series, one of fistulae specifically associated with gynaecological cancers,[26] and one of urogenital fistula from all causes,[17] those relating directly to primary cancer were uncommon, (2/20=10%)[26] and (2/348=0.6% - 2/66=3% of the oncological cases in this series),[17] respectively. Fistulae associated with cancer surgery (3/20=15% and 30/348=8.6% - 30/66=45% of the oncological cases in this series) or radiotherapy (15/20=75% and 34/348=9.8% - 34/66=52% of the oncological cases in this series) made up a much larger proportion of both series.

Immune-deficiency may be a further contributory factor, and enterovesical fistula has previously been reported in association with non-Hodgkin’s lymphoma in HIV-AIDS,[34] and vesicovaginal fistula has been seen in association with classical Hodgkin’s affecting the vagina in a long-term pessary user.[35]

3. CANCER SURGERY

It is likely that all operations carried out in the pelvis can be complicated by genital tract fistula in some circumstances.[17] Operations carried out with the intention of curing malignant disease will inevitably carry a higher risk of subsequent fistula formation, as compared to those undertaken with less radical intent.

Following radical hysterectomy for cervical cancer (Wertheim-Meigs procedure) the rate of fistula formation reported from case series is between 0.6% and 4.4%.[30, 36-41] It should be noted that these data are very heterogeneous, some reporting all types of fistula together, i.e. intestinogenital plus urogenital fistula, and some reporting these separately; some report all urogenital fistulae together, and some separating vesicovaginal and ureterovaginal. Where they are reported separately, the rates of vesicovaginal and ureterovaginal fistula appear to be of the same magnitude with both being reported in between 0.9% and 2.5% of cases [30, 42, 43] The data from UK
cited above suggests a urogenital fistula rate of 1 in 95 following radical abdominal hysterectomy in women with malignant disease as compared to 1 in 540 for total (simple) abdominal hysterectomy for benign disease, and 1 in 2041 for vaginal hysterectomy for all benign disease (including prolapse).[18] Overall, the rate of urogenital fistula appears to be approximately 9 times higher following radical hysterectomy in women with malignant disease as compared to that following simple hysterectomy (abdominal or vaginal) in women with benign conditions.[18]

The risk of visceral injury or subsequent fistula formation following radical hysterectomy undertaken in pregnancy, or immediately following Caesarean section is not obviously increased over those carried out electively in non-pregnant individuals; Monk &Montz described inadvertent cystotomy followed by vesicovaginal fistula in one of 21 women operated on during or immediately after pregnancy.[44]

Several modifications to the conventional Wertheim-Meig’s procedure of radical hysterectomy have been described in an effort to reduce the associated morbidity. The Miami modification includes vaginal reconstruction and closure using bladder and rectosigmoid serosa, retroperitoneal drainage through abdominal suction catheters, and suspension of the denuded ureters with the ipsilateral obliterated hypogastric artery. One prospective study of 978 women treated by this procedure reported a urinary fistula rate of 1.4% compared to 4.4% from a literature survey following the conventional procedure.[36] The Ohkawa procedure involves peritoneal sheathing of the ureters; Blythe et al. undertook a non-randomised comparison with retroperitoneal suction drainage, and found the conventional method to be associated with fewer ureteric complications (0/34 vs. 4/26 (15.4%)).[45] Similarly, Bostofte&Serup found no benefit in operative or postoperative morbidity following the application of the Okabayashi procedure for radical hysterectomy.[32]

Given the increased risk associated with radical surgery for malignancy, it is intuitive that the risks would increase with the stage of disease and with the extent of the surgery undertaken. There are few published reports of fistula following exenterative surgery. One study noted a 16% vesicovaginal fistula rate in 19 women following exenteration for vulvar carcinoma;[46] while another describes a 15% bowel fistula rate and an 8% urinary fistula rate from a series of 75 exenterations for recurrent cervical cancer.[47] In contrast, Ungar et al. describe only one ureterovaginal fistula and one pouch–vaginal fistula in 212 women undergoing exenteration out of a total of 2540 women treated for cervix cancer in one centre over a 13 year period (0.9%).[48]

Harkki-Siren et al. found the rate of vesicovaginal fistula to be over twice as high following laparoscopic hysterectomy compared to abdominal hysterectomy, and the rate of ureteric injury to be some 35 times higher.[15] The introduction of laparoscopic surgery within oncology is seen to have considerable advantages in terms of patient recovery; the risk of operative injury to bowel and the urinary tract, and subsequent fistula formation may however remain a concern in such cases. Although some studies, both case series and non-randomised cohorts, describe similar rates of injury to those described following open radical surgery,[29, 42, 43, 49, 50] others have reported injury or fistula rates several times higher following laparoscopic radical hysterectomy.[37, 51] A single non-randomised cohort study found that the risks of both injury to the urinary tract and of subsequent fistula formation were higher following laparoscopically-assisted radical hysterectomy as compared to that following laparoscopically-assisted radical trachelectomy (Dargent’s operation).[29]

The risk of urinary tract injury from minor surgical interventions is in general low, although the use of repeat procedures may confer a significant increase in risk. Vesicovaginal fistula has been reported following repeated use of CO2 laser for vapourisation of vaginal condylomata,[52] and following cone biopsy of the cervix.[53] In one personal series of 370 urogenital fistulae, 4 were associated with large loop excision of the transformation zone (LLETZ) of cervix, 3 of which followed a second LLETZ procedure (Hilton, personal communication).

Rarely, localised malignancies have been associated with VVF. One example is a primary mixed mullerian vaginal tumour reported in a 48-year female. [54] The mechanism for fistula formation is likely to be direct invasion into the bladder.

4. RADIATION FISTULA

Pelvic irradiation can be delivered by external beam as well as locally (intracavitary/brachytherapy). Fistula formation appears to be slightly higher for postoperative external radiation (1.9%) compared to intravaginal brachytherapy (0.8%).[55] It does not appear that pre-treatment factors accurately predict those who will develop fistula related to radiotherapy.[56]

The literature in this area is particularly heterogeneous in nature, with wide variation in (and some lack of clarity over) the tumour type and stage being treated, the form of radiation and the site and dose delivered. In a series of urogenital fistulae from the UK, 34/348 or 9.8% were associated with previous radiotherapy; of those related to gynaecological cancer, 34/66 or 52% had undergone radiotherapy.[17] In a further series of cases specifically related to gynaecological malignancy, 15/20 or 75% had undergone previous radiotherapy.[26] In both series most cases followed radiation used
for the treatment of cervical cancer, although, 5/34 or 15% followed treatment of endometrial cancer, and 1/34 or 3% followed treatment of a multifocal gynaecological cancer in one series. [17] Amongst a series of 216 radiation-induced fistulae, the time to diagnosis of the fistula was made between 3 months and 10 years (mean 21 months) following radiation.[57] In other series fistulae have been reported to develop or present up to 30 years after the ‘causative’ influence.[17, 58](Figure 1a and 1b)

The incidence of any deleterious clinical impact on the gastrointestinal and urinary tracts following radiation varies in the literature between 1% and 12%,[28, 59-65] with fistula rates of 1% to 5%.[26, 66]. In a retrospective review of 2096 patients treated for cervical cancer over a 10-year period using unspecified regimen/s of radiotherapy, 38 patients (1.8%) were found to have developed fistulae, all of whom had stage IIIa/b or IV disease at presentation.[62] Of these cases, approximately 3/4 involved the rectum, with 1/3 being combined rectovaginal and vesicovaginal fistulae; 1/4 were vesicovaginal only.[62]

Following a clearly defined regimen of external beam radiation plus brachytherapy for the treatment of primary squamous cell carcinoma of vagina in 91 women, de Crevoisier et al. reported 10.0% grade 2-3 urinary tract toxicity (using the Franco-Italian glossary)[67] and 12.1% grade 2-3 gastrointestinal toxicity.[60] Unsurprisingly, they found anterior tumour location to be correlated with increased risk of bladder toxicity and decreased rectal toxicity. Two women in this series developed rectovaginal fistulae (2%), and one ureterovaginal fistula (1%).[60]

![Figure 1a. Left: Acute radiation fistula; Right: fistula 20 years after radiotherapy, both for cervixcarcinoma](image1a)

![Figure 1b. Supratrigonal vesico-perineal radiation fistula in a small contracted bladder that occurred 22 years after cobalt irradiation for a gynaecological tumour.](image1b)
In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynaecological cancers in one centre over a 22 year period, 133 (1.2%) developed urological complications of which 35 (0.3%) developed fistulae.[64]

In a series of 28 women treated by brachytherapy for recurrent corpus or cervix cancer, four patients developed chronic morbidities related to treatment. Three fistulae were reported in two patients (7.1%): one combined rectovaginal and vesicovaginal fistula and one ureterointestinal fistula; a further patient developed a urogenital stricture and small bowel obstruction requiring resection.[65]

These data tend to suggest a higher rate of fistula formation following the application of radiotherapy in locally recurrent disease than in primary disease. From a small series of urological complications following radiotherapy for gynaecological cancers, 14 had developed vesicovaginal fistula; of these 4 (29%) had evidence of tumour recurrence.[63] In the series reported by Jones et al. 326/1161 (28%) developed urological complications over a 20 year period; 46 developed fistulae (4%), of whom 33 (72%) had evidence of active malignant disease.[39]

When a fistula occurs after radiotherapy, it is considered good clinical practice to exclude tumour recurrence before attempting a fistula closure.

5. CHEMOTHERAPY

There are few reports of fistula formation in association with the use of chemotherapy. One case report described a patient who developed a vesicovaginal fistula having undergone abdominal hysterectomy for atypical endometrial hyperplasia whilst taking tamoxifen following a previous modified radical mastectomy. Surgical repair of the fistula was initially unsuccessful, although after discontinuing the tamoxifen and continued bladder drainage, healing occurred.[68] It was hypothesised that the impaired healing was a result of the administration of the hormone therapy.

6. COMBINATION THERAPIES

Adjuvant or neoadjuvant therapies are used to increase the efficacy of the primary treatment, compared to its use in isolation. It might be anticipated that this would also increase the range and magnitude of adverse effects.

In a case control study examining the urinary tract complications of radical hysterectomy only a single vesicovaginal fistula was seen in 50 patients (2%) – in a patient receiving preoperative irradiation (45-50 Gy).[69] A small case series found 2/20 or a 10% rate of urinary fistulae following preoperative irradiation and radical hysterectomy in a heterogeneous group of ‘high risk’ cervix cancers.[70] A further case series described the impact of combined external whole pelvic irradiation (50 Gy) and intravaginal cone boost (20-26 Gy) following radical hysterectomy in 108 women. The overall rate of fistula formation was 3.7%, 2.2% following ‘prophylactic’ radiation, and 10.5% in ‘salvage’ cases where recurrent disease was present.[71]

Modarress et al. reported a randomised comparison of preoperative combined chemoradiation (cisplatin plus external beam therapy) and neoadjuvant chemotherapy (cisplatin plus vincristine) followed by radical hysterectomy in stage IB-IIB bulky cervical cancer.[25] Four patients developed hydromephrosis (3 in the chemoradiation group – 13.3%) and two vesicovaginal fistula (both in the chemoradiation group – 6.7%).[25] Two further case series reported 2/36 or a 5.6% rate of fistulae following preoperative chemoradiation (cisplatin plus brachytherapy) followed by radical hysterectomy,[72] and 4/46 or 8.7% rate of fistulae following the use of neoadjuvant and postoperative chemotherapy using irinotecan, cisplatin and nedaplatin.[73]

III. URETERIC FISTULA

A large prospective case series from Finland found an incidence of ureteric injury associated with hysterectomy for benign pathology of 0.2% [10/5279] with the lowest rate associated with vaginal hysterectomy and no difference between open and laparoscopic abdominal hysterectomy.[74] The incidence of immediate and delayed ureteric injury during radical hysterectomy was found to be 1.3% [7/536] and 2.4% [13/536] respectively in a series from Serbia; injuries appeared more common after prolonged surgery and in patients with diabetes, obesity or wound infection. [75] A registry study from the United States found an overall incidence of ureteric injury during radical hysterectomy of 0.8%.[76] Case series from referral centres in India, Pakistan, and Egypt showed that the proportion of urinary tract injuries resulting from obstetric or gynaecological surgical trauma that primarily affected the ureter varied from 1% to 23%.[77-80]

IV. FISTULA INVOLVING THE GI TRACT

The literature relating to non-obstetric fistula involving the gastro-intestinal tract is sparse and of poor quality. Although literature searching identified 78 papers of possible relevance, less than half of these contained any useful material; no randomised trials or truly systematic reviews were identified. One case controlled study is included, but all other identified material comprised case series or single case reports, and is considered to represent level 3- evidence.

It should be recognised that, whilst in most papers the term ‘enterovesical’ is used to describe fistulae between small bowel and bladder, and ‘colo/recto-vesical/vaginal’ to describe those between
large bowel and bladder/vagina, in some reports 'enterovesical' appears to be employed generically to include all fistulae involving the gastro-intestinal tract. In this chapter, the term 'intestinovesical' will be used in circumstances where the generic term is clearly more appropriate.

Whilst occasionally reported congenitally,[81] the most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn's disease, and malignant disease or its treatment. There are few data on the incidence of fistula formation in these conditions, although published estimates are in the range 2-6% in Crohn's disease,[82-84] and 20% in diverticular disease.[85]

Intestinal fistulae in Crohn's disease most typically involve the small bowel, although communication with urinary tract and large bowel are also found; involvement of the bladder was reported in 27% and of the colon in 14% in one series.[86] Two large series examining the urological complications in association with Crohn's disease reported that whilst a majority of patients were female, the most serious complications were seen in males; most significantly, 13/14 or 93% of the ileo-vesical fistulae (described in these series were in men,[82, 87]

Whilst clearly diverticular disease involves the large bowel primarily in all cases, diverticular fistulae have been reported to communicate with the bladder in 65% of cases, the vagina or uterus in 28% and small bowel in 7%.[85] Diverticular disease is the most common cause of colovesical fistula in most reports, accounting for up to 75% of cases,[88-95] with colon cancer, bladder cancer, radiotherapy and Crohn's disease accounting for the remainder.

Although there are no direct comparisons between racial groups, the distribution of these causes may vary between populations. Malignancy and/or previous radiotherapy account for 53-93% of cases of colovesical fistula reported from China,[96, 97] presumably reflecting the previously low prevalence of inflammatory bowel disease.[98]

Previous hysterectomy appears to be a significant factor in the incidence of fistula associated with diverticular disease.[99] In a national case controlled study from Sweden, involving a total of 783,245 women over a 30 year period, the risk of undergoing fistula surgery increased four-fold in hysterectomised women without diverticulitis (hazard ratio (HR) 4.0 (95% confidence interval (CI) 3.5 to 4.7)), seven-fold in women with diverticulitis without hysterectomy (HR 7.6 (95% CI 4.8 to 12.1)) and 25-fold in hysterectomised women with diverticulitis (HR 25.2 (95% CI 15.5 to 41.2)).[100] Another study described previous hysterectomy in 50% of colovesical and 83% of colovaginal fistulae associated with diverticular disease.[85]

1544
CLINICAL DIAGNOSIS

Leakage of stool, urine, or possibly both is the hallmark sign of a fistula. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula. In one study, 36% of VVF presented within 1 week of a laparoscopic hysterectomy and 50% in the second week. Most of the patients after trans-abdominal hysterectomies had leakage in the second week (90%). As discussed above, more extensive dissection is a factor when lower urinary tract injury results in a fistula. However, other than a frank injury such as ureteric transection, not all injuries result in the formation of a fistula. With laparoscopic or abdominal dissection, ureteral injury may occur anywhere along the retroperitoneal ureter usually below the pelvic brim. Since the injury may not be recognised during surgery, post-operative pain is a key symptom. The cause of vesicovaginal fistulae after hysterectomy varies with the extent of surgery and the amount of damage that has occurred. In an attempt to determine causative factors of post-operative fistulae, the records of 12 patients who had developeda vesicovaginal fistula after TAH were compared with 12 consecutive TAH patients without fistula formation. Most of the patients who developed VVF had excessive postoperative abdominal pain, distension or paralytic ileus, or both. Haematuria, symptoms of irritability of the bladder, prolonged postoperative fever, and increased white blood cell count were also noted more often in the fistula group. In contrast, the postoperative course was usually uncomplicated in the non-fistula group. The clinical course observed in many of the patients with vesicovaginal fistulas suggests that the patient has an unrecognized or recognized injury to the bladder resulting in urinary extravasation. It may be possible to abort the development of many vesicovaginal fistulae by early recognition and treatment of an unsuspected bladder injury. It is suggested that patients with severe abdominal pain, distension, paralytic ileus, haematuria or symptoms of severe irritability of the bladder after abdominal hysterectomy should be investigated early for a possible genitourinary injury.

Another possible etiology of VVF in the setting of laparoscopic procedures is trocar insertion injury. To prevent this the bladder should be emptied by intermittent or continuous bladder drainage prior to inserting the abdominal and pelvic trocars. During the laparoscopic procedure, gaseous distention of the urinary drainage bag may become evident indicating a hole in the bladder. This intraoperative sign however, has not been associated with fistula formation.

The diagnosis of VVF usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection (office evaluation or exam under anaesthesia) may confirm the presence of a fistula however it may not reveal the extent, location, or course of the fistula. Some fistulae are not readily visible. This is particularly true with iatrogenic fistula in which the fistula may be high in the vagina and may involve the ureter, bladder, or both. Therefore, most physicians rely on adjunctive tools for the diagnosis of VVF. This may include imaging studies in combination with other modalities such as cystoscopy. A simple approach in the office setting to confirm that a fistula is present is to fill the bladder retrograde with a coloured fluid. This could be a milky fluid such as baby formula or vital dye-tinted water or saline (methylene blue, indigo carmine). Direct visualisation of dye extravasation or placement of a tampon into the vagina to identify staining may facilitate the diagnosis of a VVF. (Figure 2) A double-dye test

Figure 2. Methylene blue introduced intravesically, demonstrating complex vesico-vagino-vulval fistula following pelvic fracture (arrows indicate external openings)
to differentiate between an ureterovaginal and VVF may be useful in some cases. The patient is given phenazopyridine orally which will stain the urine orange while the bladder is filled with blue fluid. Blue tinging of the tampon leads to the presumptive diagnosis of a VVF while orange staining is suspicious for an ureterovaginal fistula. [105]

a) The role of cystoscopy in preventing and diagnosing VVF

A number of studies have investigated the role of routine cystoscopy in avoiding/detecting urinary tract injury at pelvic surgery; Indraratna et al. have recently reviewed these.[106]

Gilmour et al. undertook a systematic review of urinary tract injuries at benign gynaecological surgery including all studies of >500 patients reported between 1966 and 1998. [107] The overall rate of ureteric injury from 17 studies where cystoscopy was not undertaken (mostly hysterectomy) was 168/107,068=0.16%. In 10 studies where cystoscopy was undertaken routinely (mainly colposuspension or pelvic floor reconstruction), the rate of ureteric injury was 20/3235=0.62%. The corresponding rates of bladder injury were 0.26% (without cystoscopy) and 1.04% (with cystoscopy). Although the rates of detected urinary tract injury were approximately four-fold higher in those studies where cystoscopy was undertaken as a routine, it should be noted that none of these studies was randomised, and routine cystoscopy was undertaken predominantly during those procedures with intuitively the highest risk of injury. Summary statistics for available studies evaluating the place of routine cystoscopy (with or without intravenous indigo-carmine) at gynaecological surgery are given in Table 2.

Cystourethroscopy may provide direct visualisation of the fistula. In several series using cystoscopy (mostly with IV indigo-carmine) the sensitivity and specificity in detecting ureteric injury intra-operatively were >95%. Depending upon availability, radiologic studies (cystography, urography, intravenous urography, and CT urography) may be useful. Ultrasonography and colour Doppler have been used by some, although their use in routine practice remains to be established. [108][109]

Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared to serum levels. [110]

b) Imaging

An unstructured review by Narayanan et al. suggested that magnetic resonance imaging, particular with T2 weighting, provided optimal diagnostic information regarding fistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative.[111] These newer modalities were considered to be superior to other X-ray contrast techniques and ultrasound.

2. DIAGNOSIS OF GI FISTULA

Pneumaturia, dysuria and/or recurrent UTI’s are symptoms of a colovesical fistula but may be due to other causes as well. Accepting the limitations of small case series in this regard, a number of studies have investigated the value of a range of investigative techniques in the detection and evaluation of enterovesical or colovesical fistulae.[90, 92, 93, 97, 112-116] Since in each study the authors have presented only results on patients known to have fistulae, sensitivity (true positive/true positive + false negative) may be estimated, however, specificity (true negative/true negative + false positive), positive predictive value, (true positive/true positive + false positive) and negative predictive value (true negative/true negative + false negative) cannot (see Table 3). No test was shown to have consistent reliability; excluding those investigations for which only a single report was identified, CT (53%), cystoscopy (48%), and in the case of colovesical fistula, barium enema (38%) were perhaps the most useful; intravenous urography and sigmoidoscopy or colonoscopy appear to have limited utility in the diagnosis of GI fistula.

3. RECOMMENDATIONS

The literature relating to surgical fistula is extensive, but of limited quality. 356 papers of possible relevance were identified, of which only 173 contained any relevant material. Three systematic reviews were identified (albeit one only as a protocol),[117-119] although none contained information of direct relevance. Six randomised trials were identified including one on causation,[120] one on prevention of urinary tract infection at surgery,[121] two on antibiotic prophylaxis at the time of reparative surgery,[122, 123] and two on surgical techniques applied to obstetric fistulae.[124, 125] There was also one quasi-randomised study of relevance.[126] Four non-randomised cohort studies, and one cost-effectiveness study,[131] were also identified. All other identified material comprised case series [99] and individual case reports or procedure descriptions [52], and represent level 3 or 4 evidence. Three examples of duplicate publication were identified.

1. CONSERVATIVE MANAGEMENT

a) Immediate management by catheterisation or defunctionalising

Before epithelialisation is complete an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. Normal continence mechanisms, however, involve the physiological contraction and intermittent relaxation of the sphincter mechanisms, or diverting flow around the fistula, for example by urinary catheterisation, percutaneous nephrostomy or defunctionalising colostomy, may however encourage closure. Bazi reported a non-systematic review of patients including information on the spontaneous repair of vesicovaginal fistulae; whilst the data quality was poor, he identified 30 studies from which 12 could be included; these included cases that were almost exclusively of surgical aetiology; it should be noted that in all but 4 of these 12 studies the sample size was less than 5 patients.[132] Few studies described catheter drainage in large fistulae, although it seemed that 12 of all 25 were included; these included 30 cases from which were identified. In one study of 25 cases which included surgical drainage, the fistulae were closed completely in 11 cases, and in 5 cases a small portion of the fistula remained open. The results of these studies suggest that surgical drainage may be a useful adjunct to conservative management in the treatment of vesicovaginal fistulae.

those of less than 1cm diameter were most likely to heal spontaneously. The time between the insult and institution of drainage in cases of non-surgical closure varied widely, although in most cases this was less than 3 weeks. Similarly, the duration of catheterisation prior to the initiation of conservative treatment was deemed to have been unsuccessful varied considerably, making true estimates of the effectiveness of this approach impossible; generally this varied between 10 days and 3 months.[132] Reported success rates varied between 0% and 100% (although 5 series had a sample size of 1!), although in several series it was difficult to determine how many women had attempted conservative management.[132] In large series of obstetric fistulae where a consistent approach to conservative management has been applied, spontaneous healing has been reported in up to 28% of cases.[133-135] In one series of urogenital fistulae of varying aetiologies, spontaneous closure was seen in 19/238 or 8.0% of surgical cases, 4/38 or 10.5% of obstetric cases, 1/36 or 2.8% of miscellaneous (largely traumatic cases) and 0/34 or 0.0% of radiotherapy related cases.[17] It is likely that in this, and many other reported series, data are an underestimate of the value of this approach to management,[17] nevertheless, combining available data (see Table 4) gives an overall spontaneous closure rate from 348 surgical fistulae treated by initial catheterisation of 13% ± 23%.[8, 17, 21, 136-145]. Patients with ongoing, continuous vaginal leakage despite a functioning indwelling catheter are unlikely to have resolution of the VVF without additional measures such as surgery. Such patients should be spared prolonged catheter drainage and proceed with more definitive repair as soon as medically appropriate. Small epithelialized fistulas may benefit from minimally invasive cystoscopic electrocoagulation of the fistula tract, followed by prolonged catheter drainage. In patients with fistulae less than 3.5mm in diameter, 11/15 had successful fistula tract ablation with cauteterization and catheter drainage in a study by Stovsky et al.[146] In general, conservative measures are successful in small fistulas only, usually less than 2-3mm in diameter.

b) Pharmacotherapies to assist fistula closure

Several case reports describe successful fistula closure following the induction of amenorrhoea by oestrogen, oestrogen/progesterone combinations, or luteinising hormone releasing hormone analogues,[147] in the management of vesicovaginal,[148] and more frequently, uretero- or vesico-uterine fistula following caesarean section.[149-153] The overall closure rate in these studies is 88%±16%. Spontaneous closure of vesico-uterine fistula has also been reported on a number of occasions,[150, 154] with a rate of 41/786 or 5% calculated in one review.[150] Whilst comparison across studies is obviously highly problematic (especially where many are single case reports, with success rates of 0% or 100%), it seems highly likely that the rate of closure following hormone treatment [14/16] is significantly higher than that of spontaneous closure [41/786] (p<0.0005 – Fisher’s exact test).

</table>
In quasi-randomised controlled study (alternate allocation) in patients with continuing urinary leakage following ureteric or pelvi-calyceal surgery, the use of intranasal desmopressin was shown to significantly reduce the duration of leakage compared to ‘watchful waiting’. The use of such treatment should be avoided in patients with complicating factors such as infection.

It should be recognised that some fistulae may be associated with minimal symptoms, and even if persistent these may not require surgical treatment. Small distal urethro-vaginal fistulae, utero-vesical fistulae with menouria, colo-vesical fistulae associated with diverticular disease, and some low recto-vaginal fistulae may fall into this category.

c) Palliation and skin care

During the waiting period between diagnosis and repair, incontinence pads should be provided in generous quantities so that patients can continue to function socially to some extent as well as avoid skin complications related to chronic urinary leakage. Urinary fistula patients usually leak considerably larger quantities of urine than those with urethral incontinence from whatever cause, and this needs to be recognised in their provision of supplies.

The vulvar skin may be at considerable risk from urinary or faecal dermatitis, particularly if there is additional radiation change in the skin; liberal use of silicone barrier cream should be encouraged. Steroid therapy has been advocated in the past as a means of reducing tissue oedema and fibrosis, although these benefits are refuted and there may be a risk of compromise to subsequent healing. Some authors have recommended local oestrogen, and whilst empirically one might expect benefit in post-menopausal women or those obstetric fistula patients with prolonged amenorrhoea, the evidence for this is limited.

d) Nutrition

To maximise the prospects for postoperative healing it is essential, that the general health of the patient should be optimised. This is most relevant to obstetric fistula patients, where social ostracism and the effects of prolonged sepsis, may commonly result in malnutrition and anaemia. Where there is severe inflammatory bowel disease the question of an elemental diet or even total parenteral nutrition may need to be considered. Nutritional support may also be important in patients with malignant or radiotherapy induced fistulae or in those with complications following diversion surgery.

e) Physiotherapy

Obstetric fistulae are commonly associated with lower limb weakness, foot drop and limb contracture. In a group of 479 patients studied prospectively 27% had signs of peroneal nerve weakness at presentation and a further 38%, whilst having no current signs, gave a history of relevant symptoms. Early involvement of the physiotherapist in preoperative management and rehabilitation of such patients is essential. Although nerve injury is rarely seen in association with fistulae of other (non-obstetric) aetiologies, the value of physiotherapist support in the preoperative management and rehabilitation of patients with complex fistulae or with intercurrent pathologies should not be under-emphasised.

f) Antimicrobial therapy

Active infection in the genital or urinary tracts should be treated prior to attempted surgical repair. In tropical countries the treatment of systemic infections such as malaria, typhoid, tuberculosis and parasitic infections are not uncommon and should be rigorously pursued and treatment undertaken before elective surgery. One randomised trial reported no difference in outcome between single dose IV gentamicin and continued postoperative use of amoxicillin, chloramphenicol or cotrimoxazole obstetric fistula patients (although re-analysis suggests that a difference favouring peri-operative gentamicin may be present). A further placebo controlled trial of ampicillin found no evidence of benefit from prophylactic antibiotics in terms of fistula closure or residual incontinence following repair, although the use of postoperative antibiotics was reduced. A recent review of obstetric fistula practices has called for further trials in this aspect of fistula management. Opinions differ on the desirability of prophylactic antibiotic coverage for surgery in the developed world, some avoiding their use other than in the treatment of specific infection, and some advocating broad-spectrum treatment in all cases. A systematic review found only weak evidence that antibiotic prophylaxis (compared to giving antibiotics when clinically indicated) reduced the rate of bacteriuria, pyuria and symptomatic urinary tract infection in female patients undergoing abdominal surgery who had a urethral catheter for at least 24 hours; this limited evidence related to women receiving antibiotics during the first three postoperative days or from postoperative day two until catheter removal.

g) Bowel preparation

Although many surgeons continue to employ mechanical or stimulant laxative bowel preparation prior to recto-vaginal fistula repair, and may even suggest alternative approaches to surgery where this has not been possible, a recent systematic review that included 18 trials (5805 participants), found no evidence that patients benefit from mechanical bowel preparation, nor the use of rectal enemas, and concluded that bowel cleansing can be safely omitted prior to colonic surgery, without increasing the risk of perioperative complications.

h) Counselling

Surgical (non-obstetric) fistula patients are usually previously healthy individuals, who entered hospital
for what was expected to be a routine procedure, and they end up with symptoms infinitely worse than their initial complaint. In contrast, obstetric fistula patients in the developing world are often social outcasts. In both situations therefore these women are invariably devastated by their situation; significant impact on their mental health has been objectively confirmed.[182, 183] It is vital that they understand the nature of the problem, why it has arisen, and the plan for management at all stages. In the setting of an iatrogenic fistula, there may be considerable medico-legal consequences. Confident but realistic counselling by the surgeon is essential and the involvement of nursing staff or counsellors with experience of fistula patients is also highly desirable. The support given by previously treated sufferers can also be of immense value in maintaining patient morale, especially where a delay prior to definitive treatment is required.[184]

2. SURGICAL MANAGEMENT

Whilst most commonly occurring after hysterectomy, virtually any operation undertaken in the pelvis may be complicated by the development of urogenital fistula.[17] In the series from UK recently published by Hilton, 238/348 or 68% were of surgical aetiology, 172 (72% of surgical cases and 49% of the series) followed excision of uterus and/or cervix.[17] It should be borne in mind also that so-called ‘minimally invasive’ procedures may result in fistula formation, including mid-urethral tape procedures,[119] and peri-urethral injections.[185] Minimally invasive procedures are not without risk as ureterovaginal fistula has been reported following a robotically-assisted procedure.[186]

a) Timing of surgery

The most appropriate timing for repair of vesicovaginal fistulae remains one of the more contentious issues in this area. The debate continues between the advocates of early intervention, in order to minimise the distress to the patient from continuing urinary leakage, vs. those in favour of delaying intervention until local inflammatory change has resolved, necrotic tissues have sloughed, and the patient’s recovery from the causative event completed, so as to optimise results.

There is no consensus in the literature as to the definition of ‘early’ in this context, with different studies either failing to specify at all, or giving a broad range of definition. Although some studies have used the terms ‘immediate’,[187] ‘less than two weeks’,[188] or ‘less than 30 days’,[145] most reports have considered either less than 6 weeks,[189-191] or less than 3 months,[130, 188, 192, 193] as their definition of early intervention. Although relatively few studies have reported their outcomes for both early and late approaches to management, overall the results do not appear to be significantly different (see Table 5). The overall results for early management are estimated at 91%±6% and for later management (where provided) 90%±27% (p=1.00; Fisher’s Exact test).

b) Outcomes from treatment and follow-up

Comparing the outcomes of treatment between different reports and different methods is made difficult by the inconsistent and relatively inefficient outcome measures used. These have ranged from the apparent achievement of a water-tight repair based on dye-testing in the operating theatre, to patient reported symptoms at the time of discharge from hospital. Follow-up in obstetric fistula patients is inevitably difficult in many developing world centres, but even amongst surgical or radiotherapy cases in the developed world, relatively few reports describe examination findings or symptoms at later postoperative review. Long-term outcomes and quality of life measures have only rarely been reported.[194, 195]

Table 5. Data from studies examining outcome from vesicovaginal fistula repair using an ‘early’ approach to management; where comparative data from alternative timings are available these are included.

c) Surgical approaches

Despite the fact that there is no universally agreed upon classification of iatrogenic fistula, it is probable that there is a relationship between the complexity of the fistula and the outcome of the fistula repair.

The WHO published a classification on obstetric fistula in 2006 that divided fistula in simple or complex fistula. We adapted that classification by adding the radiation fistula to the complex fistula group. (Figure 3)

1. VAGINAL PROCEEDURES

There are two main types of closure technique applied to the repair of urinary fistulae, the classical saucerization technique described by Sims,[196] and subsequently modified as a partial colpocleisis by Latzko,[142] and the more commonly used dissection and repair in layers or ‘flap-splitting’ technique (variously attributed to Hayward, Collis & Lawson Tait).[197] Individual surgeons inevitably employ these techniques somewhat variably, and in different situations, and there are no data comparing their outcomes.

The conventional dissection and repair in layers is entirely appropriate for the majority of post-surgical fistulae, although modifications may be necessary in specific circumstances. In juxta-cervical fistulae in the anterior fornix, vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilisation of the bladder from the cervix, and the repair should usually be undertaken in such a manner (usually transversely) to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulae, particularly those following hysterectomy, can again usually be managed vaginally. The vault is incised transversely and mobilisation of the fistula is often aided by deliberate opening of the Pouch of Douglas.[198] The peritoneal opening does not require to be closed separately, but is incorporated into the vaginal closure.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by ChassarMoir[199] or Hamlin & Nicholson.[200] A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if any prospect for continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but may also provide additional bladder neck support and improve continence by reducing scarring between bladder neck and vagina. These are indeed technically demanding procedures and outcomes of such complex repairs using robust measures as regards continence or sexual function are lacking.

With very large fistulae extending from bladder neck to vault, the extensive dissection required may produce considerable bleeding. The main surgical difficulty is to avoid injuring the ureters. They are usually situated close to the supero-lateral angles of the fistula, and if they can be identified endoscopically, they should be catheterised. Straight ureteric catheters passed transurethrally, or double pigtail catheters may both be useful in directing the intramural portion of the ureters internally; nevertheless great care must be taken during dissection. In such cases where the ureters cannot be visualized cystoscopically, interventional radiological techniques may be utilized to place antegrade ureteral stents from a percutaneous nephrostomy access tract.
2. ABDOMINAL PROCEDURES

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina; most typically this might be following hysterectomy in nulliparous women, in endometriosis, or in those who have not delivered vaginally. Other indications for transabdominal repair are the need for simultaneous augmentation cystoplasty, or in the setting of a ureteric injury requiring reimplantation or simultaneous VVF and ureterovaginal fistula.

A transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack. The ureters should be catheterised under direct vision either endoscopically prior to skin incision, or following opening of the bladder. The technique of closure is similar to that of the transvaginal flap-splitting repair except that for purposes of haemostasis the bladder mucosa is usually closed with a continuous suture.

A simple transperitoneal repair is relatively uncommonly employed (although this technique does seem to be favoured by some using the laparoscopic approach – see below), although a combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. A midline incision is made in the vault of the bladder; this is extended downwards in a racquet shape around the fistula. The fistulous track is excised and the vaginal or cervical defect closed in a single layer. The bladder is then closed in two layers.

There are no randomised studies comparing abdominal and vaginal approaches; given that those surgeons undertaking both routes for repair would usually see specific indications for the two such a comparison is most unlikely ever to be seen as feasible, ethical or appropriate. Nine non-randomised cohort studies reporting results from both abdominal and vaginal procedures were identified in the current review.[9, 17, 128, 191, 201-205] In all, these series included 388 vaginal repairs and 345 abdominal repairs with overall closure rates at first operation of 89% and 87% respectively (p=0.367; Fisher’s exact test). The same reports included 255 transvesical repairs with a 93% cure rate, and 399 transperitoneal repairs with an 89% success rate (p=0.130; Fisher’s exact test) (see Table 6).

With respect to attempted repair of a previously failed VVF surgery, the law of diminishing returns appears to be as evident in these types of procedures as in many other forms of surgery. Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previously unsuccessful procedures. In a series of 2484 largely obstetric fistulae, the success rate fell from 81% for first procedures to 65% for those requiring 2 or more procedures.[206] Series of surgical cases are rarely large enough for this effect to be evident, although the recent series published by Hilton found successful fistula closure was significantly more likely in the women who had not had attempts at closure before referral (98.2%) than in those who had one or more previous unsuccessful procedures (88.2%) (p=0.003; Fisher’s exact test).[17]

There is only a single randomised trial comparing aspects of surgical technique; Shaker et al. report an RCT comparing trimming of the fistula edge with no trimming.[125] Although there was no statistical difference in success rates between the two groups, in those cases where repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas those where there was no trimming were more likely to be smaller upon recurrence (see Figure 4).[125]

3. LAPAROSCOPIC

Laparoscopic repair of a VVF was first reported by Nezat et al., in 1994.[207] Fifteen series were identified in the current review,[187, 207-220] (plus an additional series in which 2 laparoscopic procedures were undertaken amongst a small series of vaginal and open abdominal operations).[205] All reported series are quite small (1-25 cases, median 6 cases), and in total only 119 patients were included, with an overall cure rate of 92% (confidence interval 4%) (See Table 7). It is not clear from these series whether they include all fistula repairs undertaken in the reporting centres, or whether they were selected in some way; if the latter, it is not clear what selection criteria were used. It is possible that there may be both selection and reporting biases that make it difficult to fully evaluate laparoscopic procedures against alternative surgical approaches.

4. ROBOTIC

The first report of a robotically-assisted repair of vesico-vaginal fistula was from Melamud et al. in 2005.[221] Since that time four additional reports have been identified,[222-225] including a total of 17 cases (see Table 7). The reported cure rate is 100% in all series, although the same comments as above, in relation to possible selection and reporting biases, apply equally here. At this stage, whilst one could state that fistula repair with robotic-assistance appears to be feasible, it is not possible to indicate what its place or potential advantages are over alternative surgical approaches.

5. FIBRIN GLUE

The use of fibrin glue in urological indications was reviewed by Shekarriz and Stoller.[226] They identified nine reports (eight in human subjects) of the use of fibrin glue in fistula repair, including a total of 16 patients.[227-234] A further six more recent reports were identified in the current review, where fibrin glue was used either by endoscopic injection or direct application, making a total of now 53 patients with fistu-
Table 6. Results from series reporting vaginal and abdominal (transvesical or transperitoneal) repairs in exclusively or largely surgical fistulae.

n.b. those studies highlighted in orange give results for vaginal procedures only, those in blue from abdominal (transvesical or transperitoneal), and those in green provide non-randomised data on both surgical approaches.

lae of various aetiologies.[124, 229, 235-239] Several of these publications were individual case reports, although there was also one randomised trial comparing fibrin glue (20 patients) with a Martius graft (20 patients) in obstetric fistula patients.[124] All of the case reports described successful repair (1/1=100% cure); the RCT reported 13/20=65% cure; the overall success rate therefore for the 53 reported patients was 77.4% (confidence interval 7.3%) (See Table 8). In one case successful closure of a radiation induced fistula was reported from the combined use of bovine collagen and fibrin glue.[229] Overall, the indications for, and optimal patient selection for this approach are not defined.

6. ENDOSCOPIC REPAIR

Mackay described a technique for transurethral endoscopic suture repair of vesico-vaginal fistula in 1997.[240]; there have been three further papers using a similar technique on between one and four patients (total 10 cases).[202, 240-242] Although in three of these series the reported cure rate was 100%, overall, fistula closure was found in 80% (confidence interval 24%).

c) Adjuvant Techniques in the Repair of VVF: Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery.[243-247] Most commonly, such flaps are utilized in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistula, large fistula, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high level evidence for the use of such flaps in any of these situations. Furthermore, there is no high level evidence that the use of such flaps improves outcomes in the setting of an uncomplicated VVF.

For those VVF repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap can easily be mobilized. From a transabdominal approach, greater omentum can be used as an interposition flap.

A variety of other flaps including gracilis muscle flaps, labial myocutaneous flaps, seromuscularintestinal flaps, and rectus abdominis flaps as well as free grafts of bladder mucosa have been utilized as adjunctive measures in the repair of complex VVF.[248-255]

3. POST-OPERATIVE MANAGEMENT.

a) Catheter type

No studies were identified comparing different catheter types or duration of drainage following fistula repair. Most reports do not describe their catheterisation practices in any detail; in those that do, the majority have employed urethral catheterisation, with a small number preferring suprapubic drainage or a combination of both. The reason for catheterisation is to ensure free urine drainage until such time as the repair is soundly healed; for this reason some have advocated both suprapubic and urethral drainage, arguing that whilst one catheter might easily become blocked, two are unlikely to do so simultaneously.[17]

b) Duration

There appears to be no obvious consensus over the duration of catheterisation recommended following fistula repair of various types and aetiologies. In a retrospective study of obstetric fistula patients in Ethiopia, approximately equal numbers of patients were catheterised for 10, 12 or 14 days. Patients were not randomised, and there were differences between the groups in terms of the extent of urethral involvement, fistula size, and degree of vaginal scarring, with the more extensively damaged patients being catheterised for longer. Despite this, there was no significant difference in outcome in terms of the rate of repair breakdown, and the authors therefore suggested that postoperative catheterisation for 10 days may be sufficient in the management of less complicated obstetric vesico-vaginal fistulae.[256]

| 53                | 41   | 77.4% |
| Confidence interval | 7.3% |
In a recent review of practices amongst obstetric fistula surgeons, Arrowsmith reported a considerable range of practice. For ‘simple’ fistulae, the average duration of bladder drainage used was 12 days (range 5-21 days); for ‘large’ fistula the average was 17 days (range 0-30 days); and for ‘difficult’ fistulae, the average was 21 days (range 14-42 days).[179]

Studies of non-obstetric fistula management are no more consistent in their description of duration of catheterisation. Most report periods of between seven and 21 days drainage; most typically 10-14 days for surgical fistulae and 14-21 days for radiotherapy-associated fistulae. There is no more than level 3/4 evidence to support any particular practice in these aspects of fistula management.

The summary of the surgical management of VVF can be found in Figure 5-7.

Conclusions & recommendations

- Spontaneous closure of surgical fistulae does occur, although it is not possible to establish the rate with any certainty; if a vesicovaginal fistula is diagnosed within six weeks of surgery, indwelling catheterisation can be considered for a period of up to 9 weeks (i.e. up to 12 weeks after the causative event)
- Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling and support prior to and following fistula repair
- Perioperative antibiotic prophylaxis should follow local policies

<tr>
<td>If a vesico-vaginal fistula is diagnosed within (three to) six weeks of surgery, indwelling catheterisation should be considered for a period of up to (six to) 9 weeks (i.e. up to 12 weeks after the causative event)</td>
<td>Both vaginal and abdominal approaches have an established role in fistula repair</td>
</tr>
<tr>
<td>Retrograde, ureteroscopically-assisted or antegrade ureteric stenting should be considered for immediate management for all uretero-vaginal fistulae</td>
<td>The majority of VVF and all urethro-vaginal fistulae can be repaired vaginally, regardless of aetiology</td>
</tr>
</tbody>
</table>

| **Timing of surgery** | Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal approach is necessary |
| The timing of VVF repair should be tailored to the individual patient requirements, and can be undertaken as soon as any local oedema, inflammation, necrosis & infection resolved | A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting |

| **Bowel preparation** | There is no proven benefit to delayed repair of vesicovaginal fistula; the timing of repair should be tailored to the individual patient and surgeon requirements, but can be undertaken as soon as any oedema, inflammation, tissue necrosis, infection are resolved |
| No benefit from mechanical or laxative bowel preparation prior to colonic surgery; this can be extrapolated to include fistula surgery | There are no high quality data to indicate greater cure rates for any one technique as compared to others; level 3 evidence indicates similar success rates for vaginal and abdominal, and for transvesical and transperitoneal approaches |

| **Antibiotic prophylaxis** | There is no benefit from mechanical or laxative bowel preparation prior to colonic surgery; it is reasonable that this recommendation be extrapolated to apply to fistula surgery |
| Perioperative antibiotic prophylaxis should follow local policies | Surgically involved in fistula surgery should have appropriate training, skills, and experience to select an appropriate procedure for each patient |

| **Counselling & support** | Where concurrent ureteric re-implantation or augmentation cystoplasty are required, the abdominal approach is necessary |
| Realistic counselling by the surgeon, nursing staff and/or counsellors with experience of fistula patients is highly desirable | A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting |
| Support from previously treated patients is appreciated and very valuable | Conventional and robotically-assisted laparoscopic approaches have both been shown to be feasible in selected cases; the place of these techniques is not yet clear |

| **Postoperative drainage** | A period of continuous bladder drainage is crucial to successful fistula repair |
| A period of continuous bladder drainage is crucial to successful fistula repair | 10-14 days for simple and/or surgical |
| 14-21 days for complex and/or radiation |

</tbody>
</table>
| **Repair Procedures** | - Careful selection necessary as results poorer than in non-irradiated cases  
- Colpopexy preferable to ‘flap-splitting’  
- Consider interposition grafts |
| **Urinary/faecal diversion** | - Required more often than in non-irradiated cases, but only after careful consideration of alternatives  
- Avoid irradiated bowel if possible |
| **Intractable incontinence, life expectancy poor** | Consider nephrostomy or ureteric occlusion |

**Investigations:**
- May require several approaches especially CT & cystoscopy

**Diverticular (colo-vesical) fistulae:**
- Frail elderly, limited symptoms of urinary infection or diarrhoea

**Crohn’s fistulae:**
- Consider trial of infliximab, esp. for any external fistulae

**Simple fistulae:**
- Nutritional state good  
- No additional intra-abdominal pathology (e.g. severe inflammation, radiation injury, advanced malignancy, intestinal obstruction)
- No major co-morbidity

**Complex fistulae:**
- Nutritional state poor  
- Severe inflammation  
- Radiation injury  
- Advanced malignancy  
- Intestinal obstruction  
- Major co-morbidity  
- Multiple organ involvement

**One-stage surgery**

**Specialist referral centre for phagedema management:**
- Proximal defunctioning and distal drainage  
- TPN, organ support, radiological planning  
- Joint urological and gastrointestinal surgery

---

**Figure 7. Algorithm for iatrogenic vesicovaginal fistula**

1. Leakage of urine from vagina/perineum
   - Clinical examination
   - Urethro-cystoscopy
   - Imaging (X-ray/CT/ MRI, US)
   - Evaluate upper urinary tract
   - VVF
   - Ureteric fistula (see algorithm)

2. Primary simple
   - Consider catheter 4-12w
   - Vaginal repair  
   - Consider timing  
   - Martius flap optional

3. Primary complex
   - Vaginal or other approach  
   - Consider timing  
   - Use interposition flaps

4. Recurrence
   - If small, consider catheter 4-12w
   - Vaginal repair or other approach  
   - 2-3 months  
   - Martius flap or interposition flaps

5. Post-irradiation
   - Vaginal repair or other approach  
   - 6-12 months  
   - Martius flap

**Assess fistula closure & assess continence status**
4. MANAGEMENT OF RADIATION FISTULA

The literature relating to the management of radiotherapy-associated fistula is again limited in quantity and quality. Forty-nine papers of possible relevance were identified, of which only 35 contained any relevant material. Seven systematic reviews were identified, although none contained information of direct relevance. No randomised trials and only four non-randomised cohort studies of relevance were identified. All other identified material comprised case series or individual case reports or procedure descriptions, and represent level 3 or 4 evidence.

Injury to the gastrointestinal or urinary tracts may arise following therapeutic radiation, with the incidence of complications increasing when the dose exceeds 50 Gy. The obliterator endarteritis associated with ionizing radiation in therapeutic dosages may proceed over many years and may result in fistula formation long after the primary malignancy has been treated.

[17, 58] The associated devascularisation in the adjacent tissues means that conventional surgical repair has a high likelihood of failure, and may also result in re-presentation with several fistulae over a period of many years. In those cases where abdominal repair surgery or urinary diversions are undertaken, a high risk of GI anastomotic leak and progressive sepsis has been reported perhaps related either to inadequate resection of irradiated bowel or to damage to other organs at operation.[59] All these factors often make the management of post-radiation fistulae more challenging than that of post-surgical or even obstetric fistulae. Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer.[203, 257, 258] Spontaneous healing seems rarely if ever to occur,[17, 40] and only one case report was identified, of a radiation fistula presenting 22 years after initial treatment, in which healing occurred following cauterisation (for biopsy) and prolonged catheter drainage.[259]

a) Diversion procedures

Because of the wide field abnormality surrounding many radiotherapy-associated fistulae, several authors have suggested that urinary and/or faecal diversion should be seen as the treatment of choice in such cases.[39, 62, 63, 203] Others have employed a routine policy of preliminary urinary and faecal diversion, with later undiversion in selected cases.[260] In a non-randomised cohort of recto-urethral fistula repairs, Vanni et al. reported 100% closure at first operation in 35 non-irradiated cases, compared to 84% in 39 irradiated cases.[260] Additionally, 97% of the non-irradiated cases subsequently underwent ‘undiversion’, whereas 31% of the irradiated cases required permanent faecal diversion due to a non-compliant rectum or severe sphincter dysfunction.[260]

Some authors have emphasised the place of repair in carefully selected cases of radiotherapy-associated fistulae.[17] Of 36 radiation/malignant fistulae in the series reported by Hilton, although 11 declined surgery or died before treatment, and 6 underwent primary diversion, of the 19 (53%) who underwent repair, 18 (95%) were closed at first operation.[17] Finally, some seem to take the view that diversion has little or no place in the management of radiation-induced vesicovaginal fistula in particular.[57] Of 216 radiation-induced fistula managed over a 47 year period by Pushkar et al., 210 underwent a vaginal and 6 an abdominal repair procedure (although it should be noted that this is a retrospective case series, and whilst not stated in the paper, it is possible that other patients not included in this review actually underwent diversion).[57] It should be noted, however, that with this almost exclusive use of the vaginal repair procedure, whilst a cumulative closure rate of 80% was eventually achieved after 4 or more operations, only 48% were closed after first repair, 40% were closed following a second operation, 52% following a third operation, and 35% following a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favoured over ileum as a conduit in this context, to avoid the risk of employing irradiated bowel and distal ureter.[261-263] Whilst these benefits seem clear, it should be noted that high perioperative morbidity (37%) and re-operation rates (20%) have been reported from this procedure.[262]

As an alternative to the latter operation, where both urinary and faecal diversion are proposed, Hampson et al. described the technique of left colic urinary diversion with distal transverse end colostomy.[264] This technique allows a shorter operation time, and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active following such procedures, the residual bladder or rectal wall may be used to augment the vagina.[265] Where vesicovaginal fistula co-exists with significant bladder contracture following surgery or radiation, an abdominal (transperitoneal) repair might be considered, along with simultaneous ileocystoplasty.[266, 267] or colocystoplasty. [268] Fistula repair concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaey et al.[269] Whilst one might anticipate a very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

b) Repair techniques

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of ‘flap-splitting’ or dissection and repair in layers (variably attributed to Hayward, Collis & Lawson Tait),[197] and partial colpocleisis,[142] have been the most widely advocated in radiation-associated fistulae. Where patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect.[270] In a non-randomised cohort study, Hilton reported anatomical closure by colpocleisis in 94.7% of radiation-associated cases, compared to 96.1%
from a range of repair procedures in fistulae of surgical aetiology.[17]

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colo- or entero-vesical and colo-
or entero-vaginal fistulas.[271, 272] Although the results have generally been good, with the avoidance of a permanent urinary or faecal stoma, Levyenback et al. reported poorer results than following resection of the affected bowel, largely related to bleeding from the isolated segment, and bacterial infection.[272]

c) Interposition grafts

Several techniques have been described to reinforce fistula repair in different sites depending on the type of repair undertaken. These include the Martius bulbocavernous muscle and labial fat graft, a gracilis muscle or myocutaneous graft, omental pedicle grafts, and peritoneal flaps. Whilst there is no high level evidence to support the use of these techniques, the interposed tissue has been presumed to help by creating an additional layer in the repair, to fill in ‘dead space’ and reduce the risk of haematoma formation beneath the repair, to bring in a new blood supply into the area, and to reduce scarring. For each of these hypotheses, interposition grafts might be considered to have their greatest benefit in the repair of radiation-associated fistulae.

At abdominal repair of vesicovaginal or recto-
vaginal fistulae, the use of a pedicled omental graft has been widely advocated.[245, 273] The omentum is dissected from the greater curve of the stomach and rotated down into the pelvis on either the right or left gastro-epiploic arteries; this may be used at any transperitoneal procedure, but has its greatest potential advantage in radiation-associated fistulae.

The role of interposition flaps in trans-abdominal repair procedures was reviewed by Evans et al.[247] They reported 37 patients with fistulae of largely surgical aetiology, of whom 12 of 12 treated employing an omental or peritoneal interposition flap were cured, compared to 16 of 25 managed without interposition (64%); this finding was consistent for fistulae of both benign and malignant aetiology. Although their cases were not randomised, and the authors acknowledge that their overall cure rate (75%) was rather lower than many series, nevertheless, they concluded that an interposition flap should be recommended, when a trans-abdominal repair is undertaken, particularly when the repair is performed by a less experienced surgeon.

Although widely employed in the context of obstetric fistula repair in the past, there is no high level evidence to support the use of the Martius graft in this context and there seems to be a general move away from it amongst obstetric fistula surgeons. One small non-randomised cohort study reported benefit in patients with multiple or recurrent fistulae, based on a univariate analysis.[243] another reported no advantage to the experienced obstetric fistula surgeon.[127] In the series of fistulae of all aetiologies from UK reported by Hilton, the fistula closure rate was not significantly different between those procedures where an interposition graft (omentumal or labial) was (92.0%) or was not (96.1%) used in the repair (p=0.264; Fisher’s Exact test).[17]

In the situation of vaginal repair of radiation-associated fistula Pushkar et al. strongly advocate the use of the labial fat graft interposed at fistula repair;[57] Hilton advocates its use to fill ‘dead space’ in the lower vagina at complete colpocleisis.[17, 270] With the former technique closure at first operation was 48%,[57] with the latter 95% closure at first operation is described.[17]

Labial skin grafts have also been employed in the repair of radiation-associated fistulae, either as an interposition, or replacement for sloughed or indurated vaginal skin. Labia minora flaps, with the outer surface de-epithelialized,[274] and labia majora flaps,[275, 276] have both been described in this context.

Muscle and myocutaneous grafts have also been employed as interposition in fistula repair. These tend to be very bulky grafts, and are perhaps best used therefore in circumstances of extreme tissue loss. The technique of rectus abdominis flap interposition was described in one series of 10 patients, although none of their cases were radiotherapy related.[277] Viennas et al. reported one case of a radiation-induced vesicovaginal fistula repair by this technique.[252] Gracilis muscle along with selective use of a buccal mucosal overlay graft has been used in recto-urethral fistulae, with 84% cure in radiation-associated cases.[260]

d) Other management approaches

In patients with intractable urinary incontinence from radiation-associated fistula, percutaneous nephrostomy or ureterostomy might be considered.[63] This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate. Several methods have been described, including the insertion of coils,[278] coils with gelatin sponge,[279, 280] clips,[281] nylon plugs with injection of polidocanol,[282] Isobutyl-2-cyanoacrylate,[283] and balloons.[283-286] These were reviewed by Avritscher et al. with success rates ranging from 50% to 100% for the different methods, and with an overall success of 77% in 150 cases from nine papers reviewed.[287]
1. LITERATURE REVIEW

The literature relating to the management of urinary fistula involving the gastro-intestinal tract is limited in quantity and quality. Forty-six papers of possible relevance were identified, of which 39 contained any relevant material. One systematic review was identified, albeit of only indirect relevance, and with no mention of fistula.[117] A single non-systematic review of the management of internal fistulae in Crohn’s disease was identified;[288] this included only a single randomised trial,[289] although this did not include patients with urinary fistulae. No further randomised trials or cohort studies of relevance were identified, either from within the review, or independently. One decision analysis model,[290] 26 case series and 10 individual case reports or procedure descriptions were found, including a total of 852 patients.

2. NON-SURGICAL MANAGEMENT

In the context of colo-vesical fistulae associated with diverticular disease, a surgical approach is most commonly advocated. One non-randomised cohort of 30 patients included six who did not undergo surgery, four of whom remained well for periods of up to 14 years; of the 24 who underwent surgical treatment, five (21%) died in the postoperative period.[291]
Ileo-vesical fistula in Crohn’s disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents; in a non-systematic review of the management of internal fistulae in Crohn’s disease, Levy & Tremaine describe the drugs that have been reported to close internal fistulas partially or completely including azathioprine, 6-mercaptopurine, mycophenolate mofetil, cyclosporine A, tacrolimus, and infliximab.\[288\]

One case series of 500 patients with Crohn’s disease included 17 with entero-vesical fistulas; all received sulfasalazine, and most were treated with corticosteroids and antibiotics intermittently, and eight in addition received 6-mercaptopurine. Although it is not clear that their fistulae closed completely, six continued on medical treatment alone for several years.\[84\]

Present et al. reported a placebo-controlled randomised trial of the tumour necrosis factor α (TNFα) neutralising agent infliximab, a murine/human chimeric monoclonal antibody that binds both the soluble subunit and the membrane-bound precursor of TNFα, in patients with externally draining fistulae associated with Crohn’s disease.\[289\] Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5mg infliximab. This latter study did not include intestino-vesical fistulae, although a case of successful use of infliximab in an ileo-vesical fistula has been reported.\[169\]

3. SURGICAL MANAGEMENT

The most frequently advocated surgical approach to colo-vesical fistula in diverticular disease has been sigmoid resection with primary colorectal anastomosis, and closure of the bladder. Dissection of the fistula track followed by closure of the bladder and bowel, with interposition of omentum, but without resection was described in three patients by Lewis & Abercrombie.\[292\] This approach should perhaps be reserved for cases with minimal diverticular disease in otherwise healthy bowel, where, were it not for the presence of the fistula, there would be no indication for colonic surgery.

One series of 74 patients described a technique in which only visible or palpable full-thickness defects in the bladder were repaired; otherwise the bladder was not repaired, but simply drained by indwelling catheter for one week following sigmoid colectomy (in diverticular disease) or small bowel resection (in Crohn’s disease).\[91\] At median 6 month follow-up there was a single recurrence of a colo-cutaneous/vesico-cutaneous fistula, but no recurrence of the colovesical fistulae. Other authors have similarly advocated leaving the bladder unreppaired in patients with Crohn’s ileo-vesical fistulae, to heal by secondary intention with catheter drainage alone.\[87, 293\]

The main contention in the management of intestino-vesical fistulae has been over the feasibility and role of a one-stage management with resection of the affected bowel segment, primary anastomosis, and closure of the bladder, as compared to a two- or three-stage approach.

The authors of many case series have advocated a one-stage approach in the majority of cases, but have indicated that this should be limited to those patients whose nutritional state is good, and where there is no evidence of severe inflammation, radiation injury, advanced malignancy, intestinal obstruction, major medical problem, or advanced age.\[90, 93, 94, 96, 294, 295\] More recent series have tended to imply a greater advocacy of the one-stage approach; Garcea et al. in a series of 90 patients with colo-vesical fistula reported primary anastomosis in 61/65=94% of cases where left colon resection was undertaken.\[92\] Balaguera et al. argue against diverting colostomy or Hartmann’s procedure as being unnecessary, and possibly bringing additional morbidity.\[296\] Several reports have described a laparoscopic approach to one-stage treatment of colo-vesical fistulae, including a total of 30 patients.\[95, 171, 297, 298\] The overall conversion rate was seen to be higher for fistulae involving the duodenum, vagina and sigmoid colon, than those involving the bladder (10%), although a low threshold for conversion to open surgery was advocated in one series.\[95\]

In addition to the above criteria, it is intuitive that the more complex a fistula track, the more relevant a phased approach to treatment becomes. Shackley et al. described a series of 10 patients with highly complex fistulae involving between 3 and 6 separate organs/surfaces.\[172\] They advocate a three-stage multidisciplinary management package, involving: [1] an acute stage involving proximal defunctioning and distal drainage of both the gastrointestinal and urinary tracts to isolate the fistula, together with the eradication of sepsis; [2] a recovery stage consisting of total parenteral nutrition, organ support, radiological planning of surgical reconstruction and intensive nursing; [3] joint urological and gastrointestinal reconstructive surgery, when the patient was stable, nutritionally replenished, and sepsis was controlled. Whilst the mean time to reconstruction was 5 [1-20] months, the fistulae were treated successfully in all patients, with functional restoration in four, and/or diversion of the gastrointestinal and urological tracts in six.\[172\]

VIII. MANAGEMENT OF URETERIC FISTULA

1. GENERAL PRINCIPLES

The relevant clinical principles are related to prevention, diagnosis, management, and after care. [299] Patients at higher risk of ureteric injury such as those undergoing complicated childbirth, radical or repeated pelvic surgery, or surgery following pelvic radiotherapy require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognise injury promptly when it occurs. Immediate repair of any intraoperative injury should be performed observing the principles of debridement, adequate blood supply and tension free anastomosis with internal drainage using stents.[300] Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvi-calyceal system. Fluid should be sent for creatinine determination to differentiate serous from urinary leak. Repair of such cases should be undertaken by an experienced team and may consist of conservative management with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< 3 months) or delayed (> 6 months) surgical repair when required.[301] Surgery should again adhere to the standard principles of tissue repair and safe anastomosis. Functional and anatomical imaging should be used to follow up patients after repair to guard against late deterioration in function of the affected renal unit. These general aspects of care of patients with trauma to the upper tract and subsequent fistula formation are covered in standard textbooks of urology and guideline documents. [300, 301] This review will concentrate on developments in the past six years.

2. EVIDENCE QUALITY

A total of 127 abstracts were screened which were categorised as being not relevant [26], cases reports without useful information [63] and for possible inclusion [38]. After review of full text, 27 were selected for the review and 11 rejected due to duplicate information (n=7) and no relevance (n=4). Four further possible papers were identified from the reference lists of included articles of which two were included in the review. The selected papers [29] included one poor quality randomised trial [302], one poor quality quasi-randomised trial [303], one high-quality population case control study[3], one registry study[76], one systematic review[304], one cost analysis[305], 14 cases series, 8 case reports, and one unstructured review.

3. EVIDENCE SUMMARY

a) Management of Specific Fistula

1. Urinary leak after renal preservation surgery

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days post-operatively, in 4% [45/1118] of patients undergoing partial nephrectomy.[306] This was associated with larger tumours, higher blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic versus open). The majority resolved without intervention but 30% required ureteric stent insertion or percutaneous drainage. A poor quality quasi-randomised study involving 16 patients with persistent leakage after pelvi-calyceal surgery despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared to control.[303]

2. Urinary leak after renal transplantation

A case series from Brazil observed a fistula rate of 2.9% [31/1046] presenting at a mean of 28 [1-131] days following transplantation predominantly due to distal ureteric necrosis and with most cases requiring open repair.[307] Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and two deaths from sepsis. A case se-
ries from China observed fistula development in 3.5% [43/1223] of patients presenting at a mean (range) of 6 [3-20] days following transplantation again primarily due to necrosis of the distal transplanted ureter. [308] Open intervention with re-implantation of the ureter into the bladder or native ureter was required in 34 patients, with one other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series from Serbia found a fistula rate following renal transplantation of 2.2% [5/224] and all required open repair.[309]

3. **Uro-enteral fistula following percutaneous renal surgery**

Case reports of ureterocolic fistulae occurring after renal cryotherapy, and gunshot trauma all resolved with insertion of ureteric stent.[310, 311] This is in line with previous accounts of this complication following percutaneous nephrolithotomy.[312]

4. **Uretero-arterial fistula**

A systematic literature review found reports of 139 cases of uretero-arterial fistula published between 1899 and 2008.[304] All patients presented with haematuria with 25% also having other urinary symptoms or back pain. Virtually all cases had a relevant past surgical history particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The great majority affected the iliac segment and pre-operative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent case series of 20 patients also showed a high mortality of 10 – 20% but did not find any difference in outcome between open or endovascular graft insertion techniques.[313]

5. **Ureterovaginal fistula**

Ureterovaginal fistula occurring in the early post-operative phase predominantly after hysterectomy is the most frequent presentation to urologists of upper urinary tract fistula. A randomised study involving 3,141 women undergoing open or laparoscopic gynaecological surgery lasting > 30 min found that the incidence of ureteric injury after prophylactic insertion of ureteric stents (1.2 % [19/1583]) was similar to control (1.1% (17/1558)).[302] A previous cost analysis from the United States perspective suggested stenting was only worthwhile if the risk of injury was > 3.2%.[305] If injury does occur, many cases, even those with bilateral injury, can be managed by endoscopic techniques. [314](Figure 9)

*Figure 9. Conservative management of bilateral lower ureteric injury. Retrograde ureterogram showing successful cannulation of left ureter by guide wire and successful placement of right ureteric stent.*

Figure 9. Conservative management of bilateral lower ureteric injury. Retrograde ureterogram showing successful cannulation of left ureter by guide wire and successful placement of right ureteric stent.
The use of ureteric stenting in patients with uretero-vaginal fistulae was reported in 11 studies, including 126 patients in total.[315-325] This resulted in closure in 63 cases altogether. Success rates were between 6% and 100%, although the overall closure rate across all series is calculated at 50% ± 18% (see Table 9).

Where retrograde stenting proves impossible, percutaneous nephrostomy and antegrade stenting might be considered if there is some degree of pelvicalyceal dilatation. Ureteroscopy may also be helpful,[320, 324] and a technique for combined antegrade and retrograde ureteroscopic cannulation has been reported.[317] In one report all cases of uretero-vaginal fistula were managed by temporary diversion using a percutaneous nephrostomy followed by delayed repair 4-6 weeks later,[156] and a similar approach was taken in the management of one uretero-uterine fistula.[326]

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if the relevant skills and facilities are available.[327-329] A recent case report has suggested that open repair through the vagina is possible if abdominal access is problematic.[330]

4. RECOMMENDATIONS

Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and repairing the ureter

D

Ureteric stents are not required as prophylaxis against injury during routine gynaecological surgery, while their role in more extensive surgery remains to be established

B

Ureteric injury or fistula may be suspected in patients following pelvic surgery if a fluid leak or pelvi-calyceal dilatation occurs postoperatively

D

Uretero-arterial fistula may be suspected in patients presenting with haematuria with a history of relevant pelvic surgery and indwelling ureteric stent

D

Elevated levels of creatinine in drainage fluid following pelvic surgery are suggestive of a urinary tract injury

D

Most upper urinary tract fistula should be initially managed by conservative or endoluminal techniques where such expertise and facilities exist

B

Persistent ureterovaginal fistula should be repaired by an abdominal approach using open, laparoscopic or robotic techniques according to availability and competence

D

For patients with ureteric fistula associated with advanced pelvic cancer and poor performance status, palliation by nephrostomy takedown and endoluminal distal ureteric occlusion is an option

C

IX. MANAGEMENT OF URETHRO-VAGINAL FISTULA

1. INTRODUCTION

Urethrovaginal fistulas are a rather rare complication of some surgical and medical conditions or treatments. Most of the literature consists of small retrospective series or case reports. There are no randomized prospective trials.

2. AETIOLOGY

Excluding obstetric aetiologies, in the developing world, urethrovaginal fistula may occur as a result of obstructed labor with or without associated VVF. In industrialized countries urethrovaginal fistula in adults mostly have an iatrogenic aetiology. (See Table 10)

In feminizing genital reconstructions in children with ambiguous genitalia and surgical repairs of cloacal malformations, urethrovaginal fistula can occur as early or late complications. [334][335, 336][337, 338] Also in transsexual adults undergoing female to male reconstruction, urethrovaginal fistulae have been reported. [339]

In the surgical treatment of stress incontinence in women with bulking agents [340, 341] or synthetic slings several cases of urethrovaginal fistula have been reported.[342-345] [119] (see Figure 11) Even conservative treatment of prolapse with pessaries can lead to the formation of fistula, if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described.[18, 346](see Figure 12).

Trauma – including inappropriate catheterisation and foreign bodies are obvious causes of fistula. [347-353]

Urethral diverticula and their surgical repair may also lead to urethrovaginal fistula.[354-356]

Urethrovaginal fistula have also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum. [357, 358]

Irradiation complications can also result in the formation of urethrovaginal fistula.[359]

3. DIAGNOSIS

Clinical vaginal examination is often sufficient to diagnose the presence of an urethrovaginal fistula. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistula. In cases of difficult diagnosis, voiding cystourethrography (VCUG) or ultrasound can be useful. [360] Double balloon urethrography is the classic examination to show urethral diverticulum and urethrovaginal fistula, but 3D MRI or CT scan is becoming utilized more widely..[361-363]

4. SURGICAL REPAIR

Several techniques for urethrovaginal fistula closure have been described. A vaginal approach is mostly used. Surgical correction intends to create a continent urethra that permits volitional, painless, and unobstructed passage of urine. Depending on the size, localisation and aetiology of the fistula and the amount of tissue loss urethral reconstruction techniques may be necessary to restore the urethra and to achieve post-operative continence. [347]

a) Vaginal approach

Goodwin described in his series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal

Figure 10. Algorithm for uretero-vaginal fistula

Figure 11. Urethrovaginal fistula following mid-urethral tape procedure for SUI.

Figure 12. Fistula in anterior vaginal fornix following use of shelf pessary for utero-vaginal prolapse.
approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time, had less blood loss and a shorter hospitalisation time.[364]

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: identifying the fistula, creation of a dissection plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall. Primary closure rates of 53%-95.4% have been described (see Table 11). Pushkar et al. described a series of 71 women, treated for urethrovaginal fistula. 90.1% of fistula were closed at the first vaginal intervention. Additionally 7.4% were closed during a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation ororurethrotomy.[365]

Advancement flaps of vaginal wall can be used to cover the urethral suture line. In some cases more advanced methods are used to close or to protect the urethral closure.

In cases of difficult dissection and visualisation, urethral sectioning has been advocated. [366] This technique is also being used in the repair of complex urethral diverticula.[367] Fistulae that are located in the distal third of the urethra may also be marsupialized without compromising the continence mechanism.[368] Distal urethrovaginal fistula may be entirely without symptoms, and in such cases, repair is not mandated.

Blaivas advocates that vaginal flaps are usually the best option in dealing with urethral reconstruction, next to the possibility of offering anterior or posterior bladder flaps. Options for vaginal repair of fistula include primary closure, peninsula flaps, bilateral labial pedicle flaps, and labial island flaps. Outcomes are optimised by using exacting surgical principles during repair and careful postoperative management by an experienced reconstructive surgeon. [347]

1. LABIAL AND VAGINAL FLAPS AND NEOURETHRA

The simplest flap is a vaginal advancement flap. [369] Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra. [370, 371] The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases a transpubic approach has been used. [372] The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernous tissue can be incorporated in the pedicled flap and probably offers a better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome stress incontinence would occur postoperatively. [373, 374]

2. MARTIUS FLAP

While in obstetrical fistula repair, it was not found to have any benefit in a large retrospective study in 440 women, the labial bulbocavernous muscle / fat flap by Martius is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistula where additional bulking with well vascularised tissue is needed. [375] Rangnekar et al. report on 12 patients with urethrovaginal fistula, of whom 8 were treated with a Martius flap and 4 with a conventional repair. Only one out of the 8 had a fistula recurrence, while 3 out of 4 of the conventional repairs broke down; it should be noted however that these cases were not randomised between surgical techniques.[376] Punekar et al. described 15 patients with complex and recurrent fistula, using the skin island flap modification with excellent results.[377] Radopoulus published a small series of 5 recurrent and complex urethrovaginal fistulas that all healed using a Martius flap.[378] The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomized studies.[379, 380] The indications for Martius flap in the repair of all types of fistula remain unclear.

3. RECTUS MUSCLE FLAP

Rectus abdominis muscle flaps have been described by some authors. [381, 382] Transvaginal urethrovaginal fistula closure was performed followed by a pedicled rectus abdominis muscle flap interposed between the fistula closure and vaginal suture line. The muscle flap was based on the inferior epigastric vessels, and provided additional support to the urethra, bladder neck and bladder base. Urethrovaginal fistula repair with the rectus abdominis muscle flap was successful in all cases without recurrence. Of the patients 5 (83%) were continent and able to void to completion at a mean follow-up of 23 months (range 2 to 66).

4. OTHER INTERPOSITION MATERIAL

A range of non-traditional interposition flaps and grafts have been reported by several authors. All of the publications only report on small patient numbers without long-term outcomes or continence data.

Golomb et al. reported the use of a fascial patch, while adding a rectus fascia sling to a urethrovaginal fistula repair.[383] Omentum is extensively used in abdominal approaches to VVF, but Janez et al. used it during a vaginal approach in 3 patients with good results.[384]

The gracilis muscle can be used as well, although the experience is limited. The graciloplasty was described by Ingelman-Sundberg in 1947 and has been adapted by other surgeons in the treatment of fistula. The number of patients reported is low as is the quality of the evidence. [385-387]

Non-autologous material has been used as well. Lowman et al. described the use of porcine dermis interposition and a synthetic sling in an irradiated patient. Other biodegradable materials have been used, although the quality of available data is low and is insufficient to advocate their use. [388] [389] Non-vascularized tissue grafts should be used with caution in such cases as the etiology of the initial tissue damage resulting in fistula is often ischemic.

b) POSTERIOR APPROACH

In cases of high fistula with difficult vaginal access, a perineal pararectal approach has been described. Some variations exist in the incisions and dissection planes. The anterior sagittal transrectal approach (ASTRA technique) and the posterior sagittal pararectal approach only have been reported in small observational series. [390, 391][392-394]

c) ABDOMINAL APPROACH

Female urethral injuries may cause serious morbidity with loss of the entire urethra in some cases. Ahmed et al. reported the results of construction of a neourethra by the flipped anterior bladder-tube technique in five girls aged 3-18 years (mean 8 years). All had pelvic fractures. Three patients came with a supra-pubic cystostomy, one was totally incontinent, and another had an urethrovaginal fistula. Three had an associated vaginal injury. All five patients underwent construction of a neourethra using a flipped anterior bladder-wall tube (FABWT) and have been followed for 18-80 months (mean 44 months). All patients were continent in the daytime and three were voiding spontaneously without the need for catheterization. Two were managed by clean intermittent catheterization (CIC), one per urethram and other via a continent abdominal stoma (Mitrofanoff). [395]

A retropubic urethral technique has been described by Koriatim[396] This approach allows a urethrovaginal flap tube to be fashioned to form a continent neourethra. Urodynamic studies showed that the proximal vesical and distal urethral components of the neourethra contribute to sphincteric function. For larger fistula an enveloping technique has been described as well.[397]

5. COMPLICATIONS

Little information can be found on complications after urethrovaginal fistula repair. A short report on 4 cases by Tehan et al. describes a disappointing experience in the transvaginal repair of these fistulas. These authors advocate a suprapubic bladder flap or bladder tube technique to achieve a functioning urethra. Complications following surgical repair have been fistula recurrence, urethral shortening and retraction, persistent reflux, bladder calculi, and bladder cancer [398].

6. FOLLOW UP

In most series of urogenital fistula repair, follow-up is of very short duration. Dolan et al. investigated urinary and sexual symptoms and quality of life in a group of 31 women 50 months (median) after successful repair of urogenital fistula using the Bristol Female Lower Urinary Tract Symptom questionnaire. [399] All women had undergone urodynamic investigation prior to their repair surgery, and only 36% had normal findings. Almost all women reported one or more symptoms, and for 65%, these caused at least 'a bit of a problem', although 87% said that their urinary symptoms had little or no impact on their quality of life. Symptoms were similar in urethrovaginal and vesicovaginal fistulae and were not significantly associated with prior functional abnormality.

I. INTRODUCTION

1. EVIDENCE ACQUISITION

The unrestricted, fully exploded Medical Subject Heading (MeSH) “interstitial cystitis” (including all related terms as “painful bladder syndrome”, bladder pain syndrome”, or different terms such as “chronic interstitial cystitis”, etc.) were used to thoroughly search the PubMed database (http://www.ncbi.nlm.nih.gov/pubmed) of the United States National Library of Medicine of the National Institutes of Health from the years 2009-2011. Three hundred forty-nine publications in English or with English abstracts were reviewed.

Abstracts if available and titles of the 349 hits were reviewed, focusing on (but not limited to) clinical trials, randomized controlled trials, meta-analyses, scientific guidelines, and core clinical journals. The literature update thus achieved was added to the pre-existing database, covering the time period before and during 2008 (generated for the 2008 International Consultation on Incontinence[1]) that was established according to the same protocol.

Rating of the level of evidence and grade of recommendation was performed according to the Oxford Scale. The committee believes that the Oxford system for categorizing levels of evidence is primarily relevant only for the sections on treatment which follow. While the committee’s opinions will be expressed, where applicable, regarding evidence and conclusions for other areas, including diagnosis, aetiology, and pathophysiology, use of the Oxford system in this context is more open to interpretation.

2. DEFINITION

Bladder Pain Syndrome (BPS) is a clinical diagnosis that relies on symptoms of pain in the bladder and or pelvis and other urinary symptoms like urgency and frequency. Based on the evolving consensus that BPS probably is strongly related to other pain syndromes like Irritable Bowel Syndrome, Fibromyalgia and Chronic Fatigue Syndrome, the European Society for the Study of Bladder Pain Syndrome (ESSIC) published a comprehensive paper on definition and diagnosis of BPS.[2]

BPS was defined as chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusable diseases as the cause of the symptoms must be excluded. Further documentation and classification of BPS might be performed according to findings at cystoscopy with hydrodistension and morphological findings in bladder biopsies. (see Table 2 in section I.1 ) The presence of other organ symptoms as well as cognitive, behavioural, emotional, and sexual symptoms should be addressed.

This definition has been broadly accepted although actual wording differs somewhat[3]. Because omitting the name “Interstitial Cystitis” might cause serious problems in different health systems by affecting reimbursement and disability determinations, the name Bladder Pain Syndrome/Interstitial Cystitis (BPS/IC) could be used in parallel with BPS for the time being. In this chapter, as in the 2008 Consultation, the term Bladder Pain Syndrome largely replaces the older Interstitial Cystitis term, but the two are essentially interchangeable as there is no accepted definition that clearly delineates the interstitial cystitis syndrome from bladder pain syndrome. The Consultation believes the latter term more appropriately describes the disorder.

Historically, definitions of IC have moved from a severe inflammatory bladder disease to a condition described primarily by symptoms (Table 1) [3].

The International Continence Society [13] (ICS) used the term Painful Bladder Syndrome (PBS) defined as “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology”. ICS reserved the diagnosis Interstitial Cystitis (IC) to patients with “typical cystoscopic and histological features”, without further specifying these. It has however been shown,
Table 1: Historical definitions of interstitial cystitis.

1887 Skene [4]: An inflammation that has destroyed the mucous membrane partly or wholly and extended to the muscular parietes.

1915 Hunner [5]: A peculiar form of bladder ulceration whose diagnosis depends ultimately on its resistance to all ordinary forms of treatment in patients with frequency and bladder symptoms (spasms).

1951 Bourque [6]: Patients who suffer chronically from their bladder; and we mean the ones who are distressed, not only periodically but constantly, having to urinate at all moments of the day and of the night suffering pains every time they void.

1978 Messing and Stamey [7]: Nonspecific and highly subjective symptoms of around-the-clock frequency, urgency, and pain somewhat relieved by voiding when associated with glomerulations upon bladder distention under anesthesia.

1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and glomerulations or Hunner’s ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc [8].

1997 NIDDK Interstitial Cystitis Database Entry Criteria [9]: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies.

2008 European Society for the Study of Bladder Pain Syndrome (ESSIC)[10]: Chronic (>6 months) pelvic pain, pressure, or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Confusuable diseases as the cause of the symptoms must be excluded.

2011 American Urological Association [12]: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes.

In the remainder of this chapter the condition will be referred to as bladder pain syndrome (BPS). Some of the older literature may be discussed using the original terminology in the interests of clarity. Logically “interstitial cystitis” should include some form of demonstrable inflammation in the bladder wall, while “bladder pain syndrome” should include pain in the region of the bladder. The diagnosis of BPS is based on exclusion of other diseases in the bladder, urethra, and other pelvic organs including the musculoskeletal system. As with other diseases without clear objective diagnostic criteria or pathophysiological explanation, countless theories have been put forward without adding much to the delineation or understanding of the disease.

In practice, patients with symptoms of BPS are screened to exclude other relevant diagnoses or confusuable diseases[2], and a focused evaluation is performed at the discretion of the physician or centre. This evaluation might include cystoscopy under local or general anaesthesia, bladder distension with registration of bladder capacity and/or the presence of glomerulations and Hunner’s lesion. Bladder wall biopsies might be obtained and evaluated for inflammation, ulcer, fibrosis, mast cells etc. The evaluation might also include urodynamics with registration of bladder capacity, compliance and bladder stability[15]. One view of the relationship of BPS with OAB is graphically depicted in Figure 1 [16]. The 14% incidence of urodynamic detrusor overactivity in the BPS patients is probably close to what one might expect in the general population if studied urodynamically [18].

In the end, these investigations might prove to be normal and the patients are identified as having BPS as a diagnosis of exclusion. The relevance of urodynamic, cystoscopic and histological findings is limited by a lack of consistency in technique, and it is therefore recommended to use the standardisations described by ESSIC [2].

II. HISTORY/NOMENCLATURE/TAXONOMY

1. HISTORICAL NOTES

Recent historical reviews confirm that interstitial cystitis was recognized as a pathologic entity during the 19th century.[19,20] In his textbook Practical Observations on Strangulated Hernia and Some Diseases of the Urinary Organs, Joseph Parrish, a Philadelphia surgeon, described 3 problematic cases of recurrent, severe lower urinary tract symptoms in which he made repeated attempts to locate a bladder stone, which was the most common source for these symptoms in early 19th century America. [21] As Teichman et al have convincingly argued,
these patients displayed all of the clinical hallmarks of IC including chronic frequency, urgency, dysuria and pelvic pain in the absence of demonstrable pathology.[22] Although he used the term repeatedly in his manuscript, Parrish did not elaborate upon the clinical definition of “tic doloureux,” likely because contemporaneous physicians would have been familiar with the concept. However, Parrish attributed the term Tic doloureux to his mentor, Dr. Phillip Syng Physick, who had applied it to patients with severe lower urinary tract symptoms with no discernible etiology, with the most common etiology during the 19th century being bladder stones. A review of archival material from the Philadelphia College of Physicians indicates that by 1808 Physick had developed a concept of bladder inflammation, a “bladder ulcer,” that produced lower urinary tract symptoms in the absence of bladder stone.[19] Tic doloureux at its time represented a neurological irritation, most often associated with the trigeminal nerve but applicable to other sensory distributions as well, which produced pain and discomfort in the absence of injury or other specific physical findings. In applying the concept of tic doloureux to bladder sensation Parrish was ascribing the paroxysmal lower urinary tract symptoms occurring in patients to an idiopathic process affecting the nerves of the bladder. This sophisticated concept continues to be a prominent component of modern theories of BPS pathogenesis. Furthermore, Tic doloureux allowed him to formulate a diagnosis for those patients who chronically manifested the symptoms caused by a stone (severe frequency, urgency, dysuria and pelvic pain) but had no stone that could be detected. That is, he considered a neuropathic etiology in the absence of any other tangible causes of bladder pain. Clearly, this experience strongly resonates with the contemporary diagnosis of BPS.

50 years after Parrish’s first publication on the condition, Skene used the term interstitial cystitis to describe an inflammation that has “destroyed the mucous membrane partly or wholly and extended to the muscular parietes”. [4] Early in the 20th century, at a New England Section meeting of the American Urological Association, Guy Hunner reported on 8 women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years.[5,23] He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to have the pseudonym “Hunner’s ulcer”. As Walsh observed, this has proven to be unfortunate.[24] In the early part of the 20th century,
the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be a focal, rather than a pancystitis.

Hand authored the first comprehensive review about the disease, reporting 223 cases.[25] Many of his epidemiologic findings have held up to this day. His description of the clinical findings bears repeating. “I have frequently observed that what appeared to be a normal mucosa before and during the first bladder distention showed typical interstitial cystitis on subsequent distension”. He notes, “small, discrete, submucosal hemorrhages, showing variations in form…dot-like bleeding points…little or no restriction to bladder capacity.” He portrays three grades of disease, with grade 3 matching the small-capacity, scarred bladder described by Hunner. Sixty-nine percent of patients were grade 1 and only 13% were grade 3. Walsh later coined the term “glomerulations” to describe the petechial haemorrhages that Hand had described.[24] But it was not until Messing and Stamey discussed the “early diagnosis” of IC that attention turned from looking for an ulcer to make the diagnosis to the concepts that 1) symptoms and glomerulations at the time of bladder distention under anesthesia were the disease hallmarks, and 2) the diagnosis was primarily one of exclusion.[7,24] However, this description was not suitable for defining this disease in a manner that would help physicians make the diagnosis and set up research protocols.

The National Institute of Diabetes, Digestive, and Kidney Disorders (NIDDK) held a major meeting in 1987 with researchers and clinicians from around the world[26]. This ultimately resulted in the 1990 Revised NIDDK Criteria: Pain associated with the bladder or urinary urgency, and, glomerulations or Hunner’s ulcer on cystoscopy under anesthesia in patients with 9 months or more of symptoms, at least 8 voids per day, 1 void per night, and cystometric bladder capacity less than 350cc.[8]

In order to validate the criteria, which were designed not for clinical diagnosis, but rather to ensure that patients enrolled in research trials could be agreed upon to have the disease, a database with broad entry criteria was created. The 1997 NIDDKInterstitial Cystitis Database Entry Criteria: Unexplained urgency or frequency (7 or more voids per day), OR pelvic pain of at least 6 months duration in the absence of other definable etiologies[27] Urgency was not defined in the protocol. Participants were given a 10 point scale, and those who scored 2 or higher on self report satisfied the urgency criteria. The protocol was written in 1992, a time when the definition of “urgency” was not a particularly controversial topic.

When a comparison of the NIDDK revised criteria with the database entry criteria was performed, it was apparent that up to 60% of patients clinically believed to have interstitial cystitis by experienced clinicians were being missed when the NIDDK research criteria were used as a definition of the disease. [28] With the demise of the NIDDK criteria as an appropriate clinical definition of the disorder, the last decade became an active one from an international standpoint in terms of wrestling with the issues of nomenclature, taxonomy and diagnosis.[3,29,30]

2. NOMENCLATURE AND TAXONOMY

The literature over the last 170 years has seen numerous changes in description and nomenclature of the disease. The syndrome has variously been referred to as tic doloureux of the bladder, interstitial cystitis, cystitis parenchymatosa, Hunner’s ulcer, panmural ulcerative cystitis, urethral syndrome, and painful bladder syndrome.[4,6,20,22,23,31,32] The term “interstitial cystitis,” which Skene is credited with coining and Hunner for bringing it in to common usage, is a misnomer; in many cases not only is there no interstitial inflammation, but also, histopathologically, there may be no inflammation at all.[33-36] By literally focusing exclusively on the urinary bladder, the term interstitial cystitis furthermore does not do justice to the condition from both the physician’s and the patient’s perspective. The textual exclusiveness ignores the high co-morbidity with various pelvic, extra-pelvic and non-urological symptoms[37] that frequently precede the onset of the bladder condition.[38]

With the formal definition of the term “painful bladder syndrome” by the ICS in 2002, the terminology discussion became an intense international focal point.[13]

- In Kyoto at the ICICJ in March 2003, it was agreed that the term “interstitial cystitis” should be expanded to “interstitial cystitis/chronic pelvic pain syndrome” when pelvic pain is at least of 3 months duration and associated with no obvious treatable condition/pathology[39].

- The European Society for the Study of Interstitial Cystitis (ESSIC) held its first meeting in Copenhagen soon after Kyoto. Nomenclature was discussed, but no decision was reached, as the meeting concentrated on how to evaluate patients for diagnosis[15].

- At the 2003 meeting of the NIDDK titled, “Research Insights into Interstitial Cystitis,” it was concluded that “interstitial cystitis” will inexorably be replaced as a sole name for this syndrome. It will be a gradual process over several years. At the meeting it was referred to as “interstitial cystitis/painful bladder syndrome” in keeping with International Continence Society nomenclature.[40]

- At the 2004 inaugural meeting of the Multinational Interstitial Cystitis Association in Rome, it was...
concluded that the syndrome should be referred to as “painful bladder syndrome/interstitial cystitis” or “PBS/IC” to indicate an intellectual and taxonomic hierarchy within the acronym.[40]

• The International Consultation on Incontinence in 2004, cosponsored by the ICS and Societe Internationale d’Urologie in association with the World Health Organization, included the syndrome as a part of its consultation. The chapter in the report was titled, “painful bladder syndrome (including interstitial cystitis),” suggesting that the IC formed an identifiable subset within the broader syndrome. Because such a distinction is difficult to define, within the body of the chapter, co-authored by nine committee members and five consultants from four continents, it was referred to as PBS/IC (one inclusive entity).[41]

• In June 2006 Abrams and colleagues published an editorial focusing on the nomenclature problem.[42] They noted that: “It is an advantage if the medical term has clear diagnostic features that translate to a known pathophysiologic process so that effective treatment may be given. Unfortunately, the latter is not the case for many of the pain syndromes suffered by patients seen at most pain, gynecological, and urological clinics. For the most part these “diagnoses” describe syndromes that do not have recognized standard definitions, yet imply knowledge of a pathophysiologic cause for the symptoms. Unfortunately the terminology used to describe the condition may promote erroneous thinking about treatment on the part of physicians, surgeons and patients. These organ based diagnoses are mysterious, misleading and unhelpful, and can lead to therapies that are misguided or even dangerous.” The editorial went on to note that a single pathologic descriptive term (interstitial cystitis) for a spectrum of symptom combinations ill serves patients. The umbrella term “painful bladder syndrome” was proposed, with a goal to define and investigate subsets of patients who could be clearly identified within the spectrum of PBS. It would fall within the rubric of chronic pelvic pain syndrome. Sufferers would be identified according to the primary organ that appears to be affected on clinical grounds. Pain not associated with an individual organ would be described in terms of the symptoms.

One can see in this the beginnings of a new paradigm that might be expected to change the emphasis of both clinical and basic science research, and that removes the automatic presumption that the end-organ in the name of the disease should necessarily be the sole or primary target of such research.

• At the major biannual IC research conference in the fall of 2006, held by the National Institute of Diabetes, Digestive, and Kidney Disorders (Frontiers in Painful Bladder Syndrome/Interstitial Cystitis), the ESSIC group was given a block of time in which to present their thoughts and conclusions. Because PBS did not fit into the taxonomy of other pelvic pain syndromes such as urethral or vulvar pain syndromes, and because IC is open to different interpretations, ESSIC suggested that Painful Bladder Syndrome be redesignated as Bladder Pain Syndrome (BPS), followed by a type designation. BPS is indicated by two symbols, the first of which corresponds to cystoscopy with hydrodistention findings (1, 2, or 3, indicating increasing grade of severity) and the second to biopsy (A, B, and C, indicating increasing grade of severity of biopsy findings) (Table 2). Although neither cystoscopy with hydrodistention nor bladder biopsy was prescribed as an

essential part of the evaluation, by categorizing patients as to whether either procedure was done, and if so, the results, it is possible to follow patients with similar findings and study each identified cohort to compare natural history, prognosis, and response to therapy [2].

- As Baranowski et.al. conceived it in early 2008[43], BPS is thus defined as a pain syndrome with a collection of symptoms, the most important of which is pain perceived to be in the bladder. IC is distinguished as an end-organ, visceral-neural pain syndrome, whereas BPS can be considered a pain syndrome that involves the end-organ (bladder) and neuro-visceral (myopathic) mechanisms. In IC, one expects end-organ primary pathology. This is not necessarily the case in the broader BPS.

A didactically very demonstrative way to conceptualize the dawning shift in conception of the condition is with the drawing of a target (Figure 2). There may be many causes of chronic pelvic pain. When an aetiology cannot be determined, it is characterized as pelvic pain syndrome. To the extent that it can be distinguished as urologic, gynecologic, dermatologic, and the like, it is further categorized by organ system. A urologic pain syndrome can sometimes be further differentiated on the site of perceived pain. Bladder, prostate, testicular, and epididymal pain syndromes follow. Finally, types of BPS can be further defined as IC, or simply categorized by ESSIC criteria. Patient groups have expressed their concerns with regard to any nomenclature change that potentially drops the term “interstitial cystitis” because the U.S. Social Security Administration and private insurances recognize IC but not the term BPS, and benefits potentially could be adversely affected. Whether the term “interstitial cystitis”, as difficult as it is to define and as potentially misleading as it is with regard to aetiology and end-organ involvement, should be maintained, is a subject of ongoing controversy.

Taxonomy and nomenclature in Japan, Korea, and Taiwan use the umbrella term of “frequency/urgency syndrome” characterized by frequency (frequent voiding) and urgency (strong desire to void). It is an inclusive term incorporating overactive bladder syndrome (OAB), hypersensitive bladder syndrome (HSB), and other conditions that are associated with frequency and urgency. Urgency in OAB is characterized by sudden onset and/or fear of leakage, while urgency in HSB is of a persistent nature and is associated with the fear of pain. OAB-wet is a subgroup of OAB. Painful bladder syndrome (PBS) is a subgroup of HSB with pain. Interstitial cystitis is one of the diseases manifest by frequency/urgency and overlaps with HSB and PBS.[11,44,45] (Figure 3).

The American Urological Association refers to the syndrome under consideration as “interstitial cystitis/bladder pain syndrome” (IC/BPS) and considers the terms synonymous [12].

The International Association for the Study of Pain (IASP) has dropped the terms interstitial cystitis, painful bladder syndrome, and PBS/IC or BPS/IC and now recognizes the term “bladder pain syndrome” as the occurrence of persistent or recurrent pain perceived in the urinary bladder region accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. www.iasp-pain.org The reader is referred to the IASP website for an in depth discussion of pain taxonomy. This work was spearheaded by Dr. Andrew Baranowski and the Pain of Urogenital Origin (PUGO) group that is associated with IASP and contributed to advancement of nomenclature and taxonomy over the last 5 years [42].

The Consultation will continue to refer to the symptom complex as “bladder pain syndrome”.

III. EPIDEMIOLOGY

Since the clinical diagnosis of BPS remains controversial, epidemiology studies of BPS have been
The lack of an accepted definition, the absence of a validated diagnostic marker, and questions regarding etiology and pathophysiology make much of the literature difficult to interpret. Overlapping patterns of bladder pain, lower urinary tract symptoms and pelvic pain are common and present challenges for clinical practice and research. The other major difficulty in evaluating various prevalence trials is that some are based on unverified self-report, others by physician diagnoses (with or without some type of verification) or by identification of BPS symptoms (with or without exclusion of other confusable conditions). This confusion becomes apparent when one looks at the variation in prevalence reports in the United States and around the world. These range from 4.5 per 100,000 females in Japan [48], to a questionnaire based study that suggests a figure in 20,000 per 100,000 in US women [49]. Studies, however, have consistently shown that bladder pain symptoms are more common than suggested by coded physician diagnoses [50]. Therefore it is important to realize when examining epidemiological data in BPS, that the prevalence of this enigmatic condition can be estimated from patient self-reports, physician diagnoses and/or symptom based surveys, all of which will give a different figure. A Conceptual diagram of the various manifestations of pelvic pain illustrates the problems in determining prevalence data. (Figure 2)

1. EARLY EPIDEMIOLOGICAL STUDIES:

One of the first population-based studies [51] included “almost all the patients with interstitial cystitis in the city of Helsinki”. This superb, brief report from Finland surveyed all diagnosed cases in a population approaching 1 million. The joint prevalence in both sexes was 10.6 cases per 100,000. Ten per cent of cases were in men.

Another early population study, this in the United States, first demonstrated the potential extent of what had been considered a very rare disease [52]. The following population groups were surveyed: 1) random survey of 127 board-certified urologists 2) 64 IC patients selected by the surveyed urologists and divided among the last patient with IC seen, and the last patient with IC diagnosed 3) 904 female patients belonging to the Interstitial Cystitis Association and 4) random phone survey of 119 persons from the US population. This 1987 study reached the following conclusions (interestingly, most of these conclusions have stood the test of time and many further epidemiological studies described later in this section):

1. 43,500 to 90,000 diagnosed cases of IC in the USA (twice the Finnish prevalence)
2. Up to a five-fold increase in IC prevalence if all patients with painful bladder and sterile urine had been given the diagnosis, yielding up to half million possible cases in the USA
3. Median age of onset 40 years
4. Late deterioration in symptoms unusual
5. 50% temporary spontaneous remission rate, mean duration 8 months
6. 10 times higher incidence of childhood bladder problems in IC patients vs controls
7. 2 times the incidence of a history of urinary tract infection vs. controls
8. Lower quality of life than dialysis patients

2. PATIENT SELF REPORT SURVEYS:

As mentioned earlier, the prevalence of BPS can be estimated from patient self-reports, physician diagnoses and/or symptom based surveys. Jones and Nyberg [53] obtained their data from unverified self-report of a previous diagnosis of IC in the 1989 National Household Interview Survey. The survey estimated an overall prevalence of 500 per 100,00 populations (0.5% of the population), or >1,000,000 people in the United States with a self-reported diagnosis of IC. For women this prevalence figure was 865 per 100,000. As part of the third National Health and Nutrition Examination Survey (NHANES III), patients were answered yes to two questions (pain in the bladder/frequent urination and a diagnosis of IC or PBS) and the figures were remarkably similar with an estimated prevalence of 470 per 100,000 (850 per 100,000 women) [54]. These numbers must be viewed with caution because of inaccurate patient recall or confusion with other pain or bladder related conditions. However these patient-reported diagnoses figures certainly suggest that BPS is a common occurrence.

3. PHYSICIAN DIAGNOSES STUDIES

Estimations of prevalence based on physicians’ diagnoses may be thought to produce more accurate estimates, and while they do provide different figures, these are in part based on the local or geographic diagnostic criteria employed. Bade et al [55] used a physician questionnaire-based survey in the Netherlands yielding an overall prevalence of 8-16 per 100,000 females, with diagnosis heavily dependent on pathology and presence of mast cells. The Nurses Health Study I and II [56] showed a prevalence of IC between 52 and 67 per 100,000 in the USA. This report was based on self-reports with validation using data from medical records. The prevalence of a physician based diagnosis of BPS in men and women in a managed care population in the US Northwest[57] was 197 per 100,00 women and 41 per 100,000 men. However these rates decreased to 99 per 100,000 women and 19 per 100,000 men.
Another and possibly more sensitive method to examine prevalence and incidence of BPS is to assess the presence of symptoms that suggest BPS. A follow-up study utilizing the Nurses’ Health Study (NHS) cohort [59] used a mailed questionnaire followed by a detailed supplementary questionnaire if the participant responded “yes” to a bladder or pelvic pain question. They observed that the prevalence of PBS symptoms was 1.7% in women younger than 65 years and increased progressively to 4.0% in women aged 80 years or older. This study suggested that the prevalence of PBS increases with age. Warren, et al [60] combined a mail-in survey with randomly selected telephone surveys to determine the prevalence of PBS amongst first degree relatives in comparison to that of the general population. They concluded that adult female first degree relatives of patients with BPS may have a prevalence of PBS 17 times that found in the general population. This suggests but does not prove a genetic susceptibility to BPS. The Boston Area Community Health (BACH) OSurvey [61], a population based cross-sectional survey of individuals in the Boston area which included an in person interview, determined the prevalence of painful bladder symptoms to be 0.83% to 2.71% in women and 0.25% to 1.22% in men depending on the definition used.

The O’Leary Sant (OLS) and the Pelvic Pain and Urgency/Frequency (PUF) questionnaires were compared by Rosenberg and Hazard [62] in the same general practice population of 1218 patients. The prevalence of PBS with the OLS was determined to be 0.57%, with the PUF the prevalence was determined to be 12.6%. Leppilahti and colleagues [63,64] estimated the prevalence of PBS in the general Population of Finland using a rather robust definition based on the OLS to be 0.68%. However, when a sample of those women was examined by one of the urologists, the more accurate prevalence was 0.3%.

Clemens et al employed [65] 3 different definitions of BPS related symptoms. The first included only self reported pelvic pain with voiding symptoms. The second included increasing pain with bladder filling and relief with urination. The third included a score of 12 or more on the OLS, including 2 episodes of nocturia and a pain score of 2 or greater. The prevalence estimates based on these definitions were 11,200 per 100,000 women and 6,200 per 100,000 men for definition 1; 3,300 per 100,000 women and 1,400 per 100,000 men for definition 2; and 6,200 per 100,000 women and 2,300 per 100,00 men for definition 3. Using a similar methodology, [66] concluded that the prevalence of BPS-like symptoms in South Korean women appear to be lower than in Europe [67] and the United States, similar to Japan and higher than in China [68]. It is conceivable that the acknowledgement by individual patients of these specific IC/BPS symptoms may be influence by cultural differences.

The most comprehensive and probably most accurate estimation of the prevalence of BPS symptoms involved population based symptom prevalence estimate using 2 validated case definitions to identify bladder pain syndrome/interstitial cystitis in 131,691 adult females [69]. Based on a high sensitivity definition, 6.5% (6,500 per 100,000) of women met the symptoms criteria, while 2.7% (2,700 per 100,000) of women met the criteria for a high specificity definition. These percentages translated into 3.3 to 7.9 million US women over 18 years of age with symptoms of bladder pain and/or interstitial cystitis. But only 9.7% of these identified women reported being assigned a bladder pain syndrome or interstitial cystitis diagnosis. A further study compared 3,397 women identified in this RAND Interstitial Cystitis Epidemiology (RICE) survey [46] with urinary symptoms consistent with a diagnosis of IC/BPS to 277 women with an actual BPS diagnosis recruited from specialist practices in the USA [70]. The two cohorts showed remarkably similar demographics, symptoms and quality of life measures, confirming that BPS is a very prevalent condition that is very likely under diagnosed and undertreated in the USA.

**Conclusion:**

Based on these studies, it is impossible to determine an accurate estimation of the prevalence of BPS, but a review of studies done in the US shows that this is a very prevalent medical condition (Figure 4). It is clear that the most inaccurate prevalence figures are derived from patients self-reported recollection, while the prevalence of BPS symptom complexes are more common than those based on physician diagnoses. It is apparent that there has been no standardized method of determining the prevalence of BPS, with wide variation of estimates in the same study employing different definitions or criteria for identifying the condition. Many factors including bias, cultural differences, methodology,
geographic variations in diagnostic criteria and/or possibly real differences in different populations lead to further variations between countries.

**Recommendation:**
A reasonable prevalence estimation for patients diagnosed with BPS would be about 100-200 per 100,000 women with a male prevalence of 10% to 20% of the female estimate. The prevalence of women and men with symptoms suggestive of BPS could be as much as 10 to even a 100 times more. (Figure 4) Level of Evidence: 1 Grade of Recommendation: A

5. INCIDENCE:
Only a few estimates of Incidence have been reported. The annual incidence of new female cases in Oravisto et al, 1975 study[51] was 1.2 per 100,000. The overall age- and sex-adjusted incidence rate of physician assigned diagnoses of BPS in Olmstead county [73] was 1.1 per 100,00 per year (1.6 per 100,00 per year for women and 0.6 per 100,000 for men. Another review of physicians’ diagnoses identified a much higher yearly incidence of 21 per 100,000 women and 4 per 100,000 men [57]. A physician-coded diagnosis supplemented with chart review of the Kaiser Permanente database [74] suggested a BPS incidence rate of 15 per 100,000 women per year. The mean average age of patients was 51 years. With such a wide variation between two similar studies in the same country, it is evident that we really do not have an accurate estimation of BPS incidence.

**Recommendation:**
The available data suggests that the incidence of BPS diagnoses is somewhere between 1 and 15 per 100,000 per year. This does not include the women who have developed symptoms but have not been diagnosed with the condition.

Level of Evidence: 1 Grade of Recommendation: A

6. OTHER CONSIDERATIONS

a) Children
Geist and Antolak [75] reviewed and added to reports of disease occurring in childhood. A childhood presentation of BPS is extremely rare and must be differentiated from the much more common and benign-behaving condition variously called the urinary frequency syndrome of childhood or dysfunctional elimination syndrome, a self-limited condition of unknown etiology. Nevertheless, there is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of BPS. In Close and colleagues’ review [76] of 20 such children, the median age of onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention. Rakow et al [77] assessed 28 women aged 13 to 25 with chronic pelvic pain syndrome and confirmed that 39% had a diagnosis of IC while a further 25% had both IC and endometriosis. The relationship between dysfunctional voiding and bowel symptoms in early life was suggested in a mail based questionnaire study in 215 BPS patients and 823 controls [78]. Another study examining early childhood events [79] showed that early childhood trauma, in particular sexual trauma was more common in IC/BPS patients than asymptomatic control subjects. While not proven in these studies, it may be possible to link early childhood events to the eventual development of BPS symptoms.

**Recommendation:**
C/BPS should be evaluated in young women with complaining of chronic pelvic pain.

Level of Evidence: 1 Grade of Recommendation: A

![Prevalence estimates for BPS/IC in USA](image)

**Figure 4:** Prevalence estimates for BPS/IC in USA

Physician diagnoses: [56,57]
Patient self report:[53,54]
Symptom surveys: [50,59,69,71,72]
b) Men
Most studies show a female to male preponderance of 5:1 or greater [41,57,80]. In the absence of a validated marker, it is often difficult to distinguish BPS from the chronic pelvic pain syndrome (nonbacterial prostatitis, prostatodynia) that affects males [81,82], and the percentage of men with BPS may actually be higher [83,84]. Men tend to be diagnosed at an older age and have a higher percentage of Hunner’s lesion in the case series reported.

 Recommendation:
The Male to Female ratio of BPS cases is 1:5-10
Level of Evidence: 1 Grade of Recommendation: A

c) Overlapping Non-bladder syndromes
Observations have shown that BPS patients are more likely than controls to have syndromes manifesting symptoms beyond the bladder and even the pelvis. In 1997, Clauw, et al [37] reported on the symptom overlap between two cohorts of patients, one with fibromyalgia and one with BPS. In the same year an analysis of a survey by Alagiri, et al [85] of over 6,700 persons who had a physician diagnosis of Interstitial Cystitis reported that individuals with IC were 100 times more likely to have inflammatory bowel disease, and that allergies, irritable bowel syndrome, sensitive skin, and fibromyalgia also have an increased association with IC. The presence of non-bladder syndromes (NBSs) and BPS has further complicated the interpretation of epidemiological studies. Investigators have subsequently compared BPS patients to controls on multiple NBSs. Wu et al. [86] compared 749 cases with BPS them to 1498 randomly selected and matched controls. Significantly more cases had FM, IBS, chronic pelvic pain (CPP), endometriosis, depression, anxiety and vulvodynia. Clemens et al.[87] compared 239 women with ICD-coded BPS to 717 matched controls and showed that cases significantly exceeded controls in myalgias, gastrointestinal symptoms, gynecologic pain, headache, back disorders, depression, and anxiety. Warren et al. [88] demonstrated that significantly more BPS cases than matched controls had 11 antecedent syndromes: FM, CFS, IBS, sicca syndrome, Chronic pelvic pain, migraine, allergies, asthma, depression, panic disorder, and vulvodynia. Nickel et al. [89] found significantly higher prevalence of self-reported FM, CFS, IBS, migraine and tension headaches, vulvodynia, temporomandibular disorder and low back pain in 207 female BPS cases than in 117 controls as well as significantly more with depression and anxiety [90] in a study in several urology practices in 3 continents. A recent review confirmed that fibromyalgia (FM), chronic fatigue syndrome (CFS), and irritable bowel syndrome (IBS) were associated with IC/BPS [91]. The etiological and epidemiological questions that remain unanswered is how are these NBSs associated with BPS, do these NBSs precede or follow IC/BPS and do multiple NBSs increase the risk of BPS. Warren and colleagues [92] have introduced a number of hypotheses, however the studies to validate these have not yet been done.

One other NBS that is sometime neglected or forgotten in these epidemiological associations is the association of BPS with sexual dysfunction. Multiple studies have shown that women with BPS diagnoses or symptoms experience very high levels of sexual dysfunction [93-96].

 Recommendation:
Overlapping Non-bladder syndromes are common in patients with a diagnosis of BPS.
Level of Evidence: 1 Grade of Recommendation: A

d) Progression:
The disease onset is generally described as subacute rather than insidious, and full development of the classic symptom complex occurs over a relatively short time. It appears that BPS does progress continuously, but usually reaches its final stage rapidly (within 5 years) [97] and then continues without significant change in symptomatology. Subsequent major deterioration is unusual[51]. The duration of symptoms before diagnosis was 3-5 years in the Finnish study [51] while a very early American study quoted 7-12 years [25]. The Interstitial Cystitis Database Cohort (ICDB) of patients has been carefully studied, and the findings seem to bear out those of other epidemiologic surveys [98]. Patterns of change in symptoms with time suggest regression to the mean and an intervention effect associated with the increased follow-up and care of cohort participants. Although all symptoms fluctuated, there was no evidence of significant long-term change in overall disease severity. The data suggest that BPS is a chronic disease and no current treatments have a significant impact on symptoms over time in the majority of patients. There is some data [89] to suggest that some patients undergo a phenotypic progression over time from a purely organ specific (eg. bladder) condition to a regional pain syndrome (eg. IBS, vulvodynia) to a more generalized pain syndrome (eg. FM, CFS). Long term longitudinal studies examining progression issues in BPS are lacking.

 Recommendation:
Epidemiological data required to describe progression patterns of BPS is lacking.
Level of Evidence: 1 Grade of Recommendation: A

IV. ETIOLOGY
The etiology of BPS is still an enigma. Quite often hypotheses abound with sparse evidence to support
them and some quickly are found to be untrue. For example disturbed nitric oxide metabolism has been proposed to contribute to BPS, but later controlled studies using L-arginine therapy did not show therapeutic effect and failed to support the hypothesis. It is highly possible that BPS is induced by a variety of causes. Symptoms of urinary frequency and bladder pain are likely the final common presentation of bladder injury resulting from single or a combination of etiologies.

1. MAST CELL ACTIVATION

Mast cells are thought to have a role in the etiology and/or pathogenesis of BPS. They are multifunctional immune cells that contain highly potent inflammatory mediators such as histamine, leukotrienes, serotonin, and cytokines.[99] These cells are the repositories of many potent inflammatory factors. Many of the symptoms and findings in ulcerative BPS such as pain, frequency, oedema, fibrosis, and the production of new vessels in the lamina propria, could possibly be ascribed to the release of mast cell-derived factors. Hence, the mast cell-IgE system and its interaction with other inflammatory cells and the nervous system[100] seems to be of importance when it comes to pathogenesis. There is a ten-fold increase in mast cell count in bladder tissue from patients with ulcerative BPS as compared to controls. In non-ulcer BPS, however, the mast cell count is normal or only slightly increased.[99,101,102]

Other mechanisms have also been put forward. Bouchelouche[103] compared the urinary excretion of leukotrienes E4 and eosinophil protein X in patients in BPS and noted detrusor mastocytosis and both increased urinary leukotrienes E4 and eosinophil protein X.

Level of Evidence: 1 - Grade of Recommendation: A

2. INCREASED PERMEABILITY OF THE UROTHELIAL DYSFUNCTION/GAG-LAYER DEFECTS

The bladder urothelium plays a key barrier to keep low and high molecular weight solutes in the urine from leaking into bladder interstitium. The barrier includes a dense layer of glycosaminoglycans on the luminal surface and intercellular junctions. Intracellular junctions consist of tight junction, adherence junction, desmosome and gap junction in the order of location from the luminal layer to the basal layer. Studies have shown impaired function of intercellular junctions of bladder urothelium of BPS patients. Zhang et al demonstrated significantly increased paracellular permeability, decreased expression of the tight junction proteins ZO-1 and occludin, and increased expression of the adhesion protein E-cadherin from patients with BPS.[104] Shie et al further showed that in the urothelium of the BPS bladder a reduced E-cadherin expression was associated with a higher level of apoptosis.[105] A defect in the glycosaminoglycan (GAG) layer has been proposed by Parsons and co-workers.[106] With such a defect the sub-mucosal nerve filaments might become accessible to noxious substances in the urine and this might explain bladder pain and urinary frequency. In ulcerative BPS there is granulation tissue indicating a reparative process following repeated disruption of the mucosa.[107] Widened tight junctions and increased permeability have been demonstrated by scanning electron microscopy and other techniques.[108,109]

A study by Parsons et al[110] has shown that Tamm-Horsfall protein is qualitatively different in BPS patients as compared to controls. Tamm-Horsfall protein is synthesized in the kidney and excreted into the urine. It has been suggested to have a role in immune defense and in preventing damage to the urothelial cells by injurious urinary constituents.

Level of Evidence: 2 - Grade of Recommendation: B

3. INHIBITION OF UROTHELIAL BLADDER CELL PROLIFERATION

One explanation of the bladder epithelial dysfunction might be the fact that the cells produce an inhibitor of heparin-binding epidermal growth factor-like growth factor in BPS.[111] It was shown that explanted urothelial cells from BPS patients differ from controls not only as to production of epithelial growth factors but also in the rate of proliferation and the production of an antiproliferative factor (APF). Keay and co-workers[112] studied gene expression patterns in normal bladder urothelial cells treated with APF and with mock APF as compared to patterns expressed by BPS urothelial cells. The results indicate that the mechanism of APF inhibition of urotheelial cells may involve both down-regulation of genes that stimulate cell proliferation along with up-regulation of genes that inhibit cell growth. The same group of researchers has indicated that APF seems to be specifically elevated in the urine of patients with BPS but not in normals or patients with confusable diseases. These findings might open up new avenues for identification and development of urine markers for BPS.[113] There has not yet been confirmation of the importance of antiproliferative factor by other laboratories.

Level of Evidence: 2 - Grade of Recommendation: B

4. AUTOIMMUNE MECHANISMS

There are numerous reports on autoantibodies in patients with BPS.[114-117] The precise identity of these of autoantibodies has yet to be determined. Some of the common clinical and histopathological characteristics present in BPS patients show certain similarities with other known autoimmune disturbances. Studies on autoantibodies in BPS have shown that these mainly consist of antinuclear antibodies[118] and these findings are in turn similar to the autoantibody profiles in some systemic diseases like Sjögren syndrome, which is known to be of...
autoimmune origin.[118-120] Only a portion of BPS patients have auto-antibodies. It has been proposed that the presence of auto-antibodies in these patients could be a reflection of disease severity.[121]

Vascular immunopathology with immune deposits in the bladder wall was found by Mattila.[122] Further studies also suggest activation of complement.[123] By means of immunophenotyping and flow cytometric analyses of the bladder mucosa and peripheral blood, differences between ulcerative and non-ulcer BPS patients have been demonstrated. In the former group intense T-cell infiltrates and B-cell nodules were seen, compared to far less T-cell infiltrates in non-ulcer BPS.[124] Involvement of the immune system is one feature found in some individuals with BPS, but findings are conflicting and have not been helpful in explaining the etiology. The lack of thorough descriptions of patients in many published studies has made classification and comparison between series impossible.

**Level of Evidence: 2 - Grade of Recommendation: C**

### 5. INFECTION

No microorganism has ever been revealed as the cause of BPS. Lynnes and coworkers did not find any evidence of recent or remote Gram negative or Gram positive infections in patients with BPS, nor did they find increased urinary IgA and IgG elevation.[125] This makes infection by an untested organism unlikely. Warren et al[126] in a case control study of women with recent onset of BPS symptoms, reported that documented evidence of UTI at symptom onset was found in only a minority of patients. Polymerase chain reaction techniques to amplify bacterial 16S rRNA genes that would be present if there were bacteria in bladder tissue or urine in BPS patients despite negative cultures have been without success.[127] Contrary to what was demonstrated for chronic gastritis, there is no evidence for helicobacter in BPS patients.[128] However, Zhang et al showed that a high prevalence (11 in 27 patients) of nanobacteria (NB) was observed in female BPS patients, and anti-NB treatment effectively improved the symptoms, suggesting that some BPS might be caused by nanobacteria.[129] Nevertheless, the possibility of a microbial contribution to the etiology of BPS remains an open question.

**Level of Evidence: 1 - Grade of Recommendation: C**

### 6. NEUROBIOLOGY/PELVIC CROSS-TALK

Several authors have described autonomic nerve changes[130-132], but the findings are far from uniform. An increase of sympathetic innervation and activation of purinergic neurotransmission has been reported. The S-100 family of proteins appear in Schwann cells of the peripheral nervous system. [133,134] Decreased levels of S-100 protein in the non-ulcer group as compared to controls has been found,[135], which is consistent with a decreased nerve content in patients with non-ulcer BPS, a finding conflicting with the results of Hohenfellner [131] who used polyclonal antihuman protein gene product 9.5 antibody and found the overall nerve content increased in BPS patients as compared to controls. However, their study did not include subtyping of the disease into ulcerative and non-ulcer type. A distinctive ultrastructural appearance of specimens from patients with non-ulcer BPS prompted Elbadawi and Light to propose neurogenic inflammation as a trigger to a cascade of events taking place in this disease.[136] In this context it should be noted that afferent nerves release transmitters like substance P which could activate immune cells, or vasoactive intestinal polypeptide. These events may constitute a link to the immune cell system and promote a decrease of lymphocyte proliferation.

A prominent increase of tyrosine hydroxylase immunoreactivity in bladder tissue of BPS patients, as compared to controls, has been described.[137] This can presumably be interpreted as a sign of generally increased sympathetic outflow. This lends support to the notion of a neurogenic etiology and or pathogenesis.

Malykhina and others[138-142] have demonstrated in innovative animal studies that there is a bidirectional neural cross-sensitization of the colon and lower urinary tract. Acute colitis sensitized lumbar spinal neurons receiving input from the urinary bladder result in spinal neuronal hyperexcitability that may be involved in central cross-organ sensitization of visceral nociception between the colon and urinary bladder. This provides information which not only supports a neurogenic etiology but also may account for the substantial overlap of BPS with other chronic pelvic pain disorders, especially the inflammatory bowel disorders.[85] Rudick and Colleagues have shown in a murine model organ cross talk in pelvic pain and modulation of pain responses by visceral inputs distinct from the inflamed site.[143]

**Level of Evidence: 2 - Grade of Recommendation: B**

### 7. TOXIC AGENTS

There are a few publications which have suggested that toxic substances in the urine may cause injury to the bladder resulting in symptoms consistent with BPS. One published hypothesis is that heat labile, cationic urine components of low molecular weight may exert a cytotoxic effect.[144] Another group of investigators has suggested that defective constituent cytokine production may decrease mucosal defense to toxic agents.[145]

**Level of Evidence: 3 - Grade of Recommendation: D**

### 8. HYPOXIA

Decreased microvascular density has been reported to be a feature of bladders from some individuals with BPS.[146] One group of investigators...
has reported that bladder perfusion decreased with bladder distension in some BPS patients compared to the opposite effect in control subjects.[147] The hypoxic hypothesis is further supported a report by Lee et al, who found an increased expression of hypoxia-inducible factor-1(HIF-1) alpha in bladder tissue obtained from BPS patients.[148] However, it is still unknown why the BPS bladders would become hypoxic.

**Level of Evidence: 4 - Grade of Recommendation: D**

9. THE ROLE OF GENETICS IN BPS

Warren et al[149] report findings from a small cohort of twins which demonstrated a greater concordance of BPS among monozygotic that among dizygotic twins. A later study by the same research group[60] suggested that adult female first-degree relatives of patients with BPS may have a prevalence of IC 17 times that found in the general population. This coupled with the previously reported twin data suggests, but does not prove, a genetic component adds to the susceptibility for BPS. Another study on more than 25,000 twins, Altman et al found that in female twins genetic factors contributed less than one-third of the total variation in susceptibility to BPS, suggesting that there could be a genetic susceptibility to BPS, although environmental factors might also be substantial in the development of BPS. [150]

The report by Weissman et al[151] of the increased frequency of BPS in patients and their first degree relatives with panic disorder and other seemingly disparate disorders, has suggested that there is a familial syndrome consisting of BPS and other disorders of possible autonomic or neuromuscular dysfunction. More recent studies by the same group[152] from a case control study, suggested that this syndrome might include other anxiety disorders as well, and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13.

**Level of Evidence: 1 Grade of Recommendation: B**

10 . CONCLUSIONS:

There have been no significant conclusive advances made in understanding either the etiology or pathogenesis of BPS. It is now believed that the etiology of BPS is more complex than has been previously envisioned.[37,85,87,153-155] The consideration of BPS as a part of a generalized somatic disorder should open new pathways to the study of BPS. Investigators should continue to explore central neurological mechanisms of pathogenesis, as well as genetic/familial, immunological and infectious etiologies of this puzzling, complex disorder.

An algorithm that attempts to illustrate an etiologic schema is presented (Figure 5).

**V. PATHOLOGY**

One can have pathology consistent with the diagnosis of BPS, but there is no histology pathognomonic of this syndrome. The role of histopathology in the diagnosis of BPS is primarily one of excluding other possible diagnoses. One must rule out carcinoma and carcinoma-in-situ, eosinophilic cystitis, tuberculous cystitis, as well as any other entities with a specific tissue diagnosis[107,156,157].

**Level of Evidence: 1 Grade of Recommendation: A**

While earlier reports described a chronic, edematous pancystitis with mast cell infiltration, submucosal ulcerations and involvement of the bladder wall and chronic lymphocytic infiltrate[158,159], these were cases culled from patients with severe disease and not representative of the majority of cases currently diagnosed. The pathologic findings in BPS are not consistent. There has been a great variation in the reported histologic appearance of biopsies from BPS patients, and even variation among biopsies taken from the same patients over time[26].

Lepinard and colleagues[160] reported a pancystitis affecting the 3 layers of bladder wall. In nonulcerative disease the vesical wall was never normal, epithelium being thinned and muscle being affected. Johansson and Fall[107] looked at 64 patients with ulcerative disease and 44 with nonulcerative IC. The former group had mucosal ulceration and hemorrhage, granulation tissue, intense inflammatory infiltrate, elevated mast cell counts and perineural infiltrates. The nonulcer group, despite the same severe symptoms, had a relatively unaltered mucosa with a sparse inflammatory response, the main feature being multiple, small, mucosal ruptures and suburothelial hemorrhages that were noted in a high proportion of patients. As these specimens were almost all taken immediately after hydrodistention, how much of the admittedly minimal findings in the nonulcer group were purely iatrogenic is a matter of speculation.

One can see completely normal biopsies in the nonulcerative BPS group[161]. Transition from nonulcerative to ulcerative BPS is a rare event[101], and pathologically the two types of IC may be completely separate entities. While mast cells are more commonly seen in the detrusor in ulcerative BPS[162], they are also common in patients with idiopathic bladder instability[163]. Mastocytosis in BPS is best documented by tryptase immunocytochemical staining[164]. Larsen and colleagues recommend taking biopsies from the detrusor of patients with suspected BPS and examining them with tryptase stained 3 micron thick sections, with every seventh section used for quantification. They consider 27 mast cells/mm2 indicative of mastocytosis.[165] Despite attempts to develop a diagnostic algorithm based on the detrusor to mucosa mast cell ratio and
Figure 5: Theories of Etiology.
Mast cells could be valuable in clinical phenotyping, but as yet that is unproven. Mast cells trigger inflammation that is associated with local pain, but the mechanisms mediating pain are unclear. In a murine model of neurogenic cystitis, Rudick and colleagues[166] demonstrated that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor respectively. Therefore, pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for the pain of BPS and other chronic pain conditions.

Lynes and coworkers[35] concluded that biopsy specimens are often not helpful in confirming the diagnosis. Although BPS patients in his study had a higher incidence and degree of denuded epithelium, ulceration, and submucosal inflammation, none of these findings was pathognomonic. In addition, these “typical” findings occurred only in BPS patients with pyuria or small bladder capacity. Epithelial and basement membrane thickness, submucosal edema, vascular ectasia, fibrosis, and detrusor muscle inflammation and fibrosis were not significantly different in the BPS and control patients.

Attempts to definitively diagnose BPS by electron microscopy have also been unsuccessful. Collan’s group[167], in the first such study, wrote that the similarity of the ultrastructure of epithelial cells in controls and IC patients makes it improbable that the disease process originates in the epithelium. Other investigators found no differences in the morphologic appearances of the glycocalyx and of urothelial cells in patients with IC when compared with controls[168]. Anderstrom and colleagues[109] saw no surface characteristics specific for IC, but believed that the mucin layer covering the urothelial cells seemed reduced in IC compared with controls, a fact disputed by Nickel in a very elegant paper[169]. Elbadawi and Light[136] observed ultrastructural changes sufficiently distinctive to be diagnostic in specimens submitted for pathologic confirmation of nonulcerative interstitial cystitis. Marked edema of various tissue elements and cells appeared to be a common denominator of many observed changes. The wide-ranging discussion of the etiology of IC in his paper is fascinating, but the pathological findings are potentially marred by the methodology, in that specimens were obtained after diagnostic hydrodistention[170].

So what is the place of pathologic examination of tissue in BPS? Attempts to classify the painful bladder by the pathoanatomical criteria described by Holm-Bentzen[171] are of questionable value. There is a group of patients with what she describes as “nonobstructive detrusor myopathy”[172]. In her series, these patients with degenerative changes in the detrusor muscle often had residual urine, a history of urinary retention, and an absence of sensory urgency on cystometry with bladder capacities over 400cc. Most would not be clinically confused with BPS. A similar English series[173], however, included patients who met NIDDK research criteria and associated detrusor myopathy with diminished detrusor compliance and ultimate bladder contracture.

The Interstitial Cystitis Database (ICDB) study worked backwards from symptoms to pathology, and concluded that certain symptoms are predictive of specific pathologic findings[33,174]. Denson et al.[36] analyzed forceps biopsies from 65 females and 4 males with BPS. Ten per cent of specimens showed vasodilatation or submucosal edema. Inflammation was absent in 30% of patients, and mild in another 41%. Cystoscopic changes did not correlate with degree of inflammation. Hanus and colleagues[175] studied 84 biopsies from 112 BPS patients and reported a linear relationship between the mean bladder capacity under anesthesia and severity of glomerulations. They did not find a correlation between severity of symptoms and histopathological changes observed by light or electron microscopy.

Richter and the Danish group showed studied 349 consecutive BPS patients and concluded that nocturia, detrusor mastocytosis, and detrusor intravesical fibrosis are associated with multiple treatments and presumed failure of standard urological therapy while bladder capacity and glomerulations are not.[176] In a Belgian study, cystoscopic parameters (glomerulations, bleeding, mucosal tears, bladder capacity) showed no correlations with the histological features of bladder biopsies. No correlations were found between inflammatory infiltrate and detrusor mastocytosis. In fact, detrusor mastocytosis was more elevated in biopsies with normal urinary epithelium than in those with damaged epithelium. The study concludes that the clinical significance of pathological findings awaits future research findings. [177]

Rosamilia reviewed the pathology literature pertaining to BPS in 2 recent publications and presented her own data[34,41]. She compared forceps biopsies from 35 control and 34 PBS/IC patients, 6 with bladder capacities less than 400cc under anesthesia. Epithelial denudation, submucosal edema, congestion and ectasia and inflammatory infiltrate were increased in the BPS group. Submucosal hemorrhage did not differentiate the groups, but denuded epithelium was unique to the BPS group and more common in those with severe disease. The most remarkable finding in her study was that histological parameters were normal and indistinguishable from control subjects in 55% of BPS subjects. Method of biopsy can be important in interpreting findings, as transurethral resection biopsies tend to show mucosal ruptures, submucosal hemorrhage and mild inflammation[107], while
histology is normal approximately half the time with cold-cup forceps biopsies [34,35,178].

Histopathology plays a supportive diagnostic role at best[179]. Major reconstructive procedures appear to have better outcomes in patients with pathology consistent with Hunner’s lesions.[180] Inflammatory features can be seen in 24% to 76% of patients without a visible Hunner’s lesion.[181] While recent studies suggest that a severely abnormal pathology may be associated with poor prognosis[182,183], this is not necessarily the case [184].

At this point in time, excluding other diseases that are pathologically identifiable is the primary utility of bladder biopsy in this group of patients.[185,186]

**VI. DIAGNOSIS**

Much work has been put into the attempt to define objective diagnostic criteria based on, among other factors, cystoscopy under local or general anesthesia, bladder distention with registration of bladder capacity and/or possible presence of glomerulations and Hunner’s lesion, bladder wall biopsies evaluated for inflammation, ulcer, fibrosis, mast cells, etc. and urodynamics with registration of bladder capacity, compliance and bladder stability. Results have, however, been frustrating. It is more fruitful to establish a broad clinical diagnosis, mainly on the basis of symptoms and exclusion of other diseases, and then stratify patients by urodynamic, cystoscopic, histological, and other tests on the basis of the significance of these findings for results of treatment and prognosis of disease. Current efforts to phenotype the disorder by the presence or absence of associated syndromes and diseases may also prove useful in the same way.

What follows is based solely on expert opinion.

**Level of Evidence:** 4  **Grade of Recommendation:** C

It is hoped that future Consultations will have the data to base such suggestions on a firmer foundation.

**1. HISTORY**

A general thorough medical history should be taken.

**Special emphasis should be given to:**

- Previous pelvic operations
- Previous UTI
- Bladder history/urological diseases
- Location of pelvic pain (referred pain) and relation to bladder filling/emptying.
- Characteristics of pain: onset, correlation with other events, description of pain
- Previous pelvic radiation treatment
- Autoimmune diseases

**2. PHYSICAL EXAMINATION**

A common physical examination should be performed including palpation of the lower abdomen for bladder fullness and tenderness:

- **Standing:** kyphosis, scars, hernia
- **Supine:** abduction/adduction of the hips, hyperaesthetic areas

In females physical examination should include a vaginal examination with pain mapping of the vulvar region and vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor. Tenderness might be graded as mild, moderate or severe.

**3. PAIN MAPPING**

**Inspection:**

- **Vulva**
  - exclusion of vulvar/vestibular diseases (vulvitis, dermatosis etc.)
  - evaluation of introital area (endometriosis)
  - tenderness of vestibular glands or vulvar skin (Touch Test: use wet cotton stick or finger tip)

- **Vagina**
  - tenderness during insertion and opening of speculum
  - cervical pathology
  - vaginal fornices (endometriosis)

- **Bimanual physical examination**
  - tenderness of urethra, trigone and bladder
  - superficial/deep vaginal tenderness
  - tenderness of pelvic floor muscles (levator, adductor)
  - tenderness in adnexal areas

In males digital rectal examination (DRE) should be performed with pain mapping of the scrotal–anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and the scrotal content.

**4. LABORATORY TESTING**

- Urine dipstick (ABS, pH, leucocytes, nitrate), urine culture in all. If sterile pyuria culture for tuberculosis.
- Urine cytology in risk groups.
- Investigations for vaginal Ureaplasma and Chlamydia in females and prostatitis in men are optional.
5. SYMPTOM EVALUATION

- Voiding diary with volume intake and output for 3 days at initial evaluation. Patient sensation at voiding might be recorded (see chapter outcome assessment, Hanno).

- At follow-up only number of voidings during day and night time is necessary. Morning volume might be recorded as a help to monitor highest functional capacity.

- The O'Leary–Sant Symptom Score supplemented should be used as basic symptom score supplemented with the Quality of Life Score from the International Prostate Symptom Score (see chapter symptom scales, Hanno3).

Pain should be recorded using a Visual Analogue Scale (VAS) for pain during the last 24 hours (to fit with the voiding diary). Separate scores for the average, mildest and worst pain should be obtained (see symptom scales)

6. URODYNAMICS

**Level of Evidence:**4 **Grade of Recommendation:**C

The NIDDK criteria excluded patients with detrusor overactivity at filling cystometry in order not to confuse the picture in clinical trials.[8] This does not however mean that detrusor overactivity can not coexist with bladder pain syndrome. In the interstitial cystitis database approximately 14% of BPS patients had overactive bladders[17]. Whether these patients respond better to antimuscarinics than BPS patients with stable bladders has never been systematically investigated. If so, a rationale for routinely employing urodynamics as a part of the evaluation would follow. In males, infravesical obstruction might be a differential diagnosis[187], and it is recommended to do flowmetry in all males and pressure-flow studies in men with a peak flow rate below 20ml/seconds.

There are no data to support the following recommendations:

In females, flowmetry, post void residual urine volume and pressure-flow study are optional. In males, a flowmetry should be done in all, and if maximum flow rate <20 ml/s a pressure-flow study and measure of residual urine volume should be done. It is recommended to perform filling cystometry with a filling rate of 50 ml/s (to comply with the revised Potassium Test - see below) to look for overactivity, volume at first desire to void and cystometric capacity.

7. POTASSIUM TESTING

**Level of Evidence:**1 **Grade of Recommendation:**A (not recommended)

Parsons has championed an intravesical potassium chloride challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4 M potassium chloride solution. The test has proved controversial [188]. Pain and provocation of symptoms constitutes a positive test. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients, or hypersensitivity of the sensory nerves is unclear. Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small[189]. The concentration of potassium used is 400meq per liter, far exceeding the physiologic urinary concentrations of 20-80meq/liter depending upon dietary intake[190]. Healthy controls can distinguish KCl from sodium chloride, though they don’t experience severe pain[191]. The hope is that this test may stratify patients into those who will respond to certain treatments (perhaps those designed to fortify the glycosaminoglycan layer) [192].

Used as a diagnostic test for bladder pain syndrome, the potassium chloride test is not valid[193]. The gold standard in defining BPS for research purposes has been the NIDDK criteria. These criteria are recognized to constitute a set of patients that virtually all researchers can agree have BPS, though they are far too restrictive to be used in clinical practice[28]. Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test[194]. In the group it should perform the best in, it is lacking in sensitivity. When we look at the specificity side of the equation, in the universe of asymptomatic persons, it performs relatively well and is rarely positive, although a recent study reported a 36% false positive rate in asymptomatic men[195]. It is in the patient population with confounding conditions for which we would want help in sorting out BPS from other disorders. Sixty percent of patients with overactive bladder test positive[196] and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive[194,197]. The results with chronic prostatitis / chronic pelvic pain syndrome in men are variable, but 50-84% of men have been reported to test positive[195,198,199]. In women with pelvic pain results are similar[200], and based on these findings, Parsons has expressed the view that BPS may affect over 20% of the female population of the United States[201]! Others have reported prevalence in unselected female textile workers in Turkey using similar methods at 32.8%,[202]. Another way to interpret the findings would be that the KCl test is very nonspecific, missing a significant number of BPS patients and over-diagnosing much of the population.

Prospective and retrospective studies looking at the KCl test for diagnosis in patients presenting with symptoms of BPS have found no benefit of the test in comparison with standard techniques of diagnosis[193,203,204]. A later modification of the test
using 0.3 molar potassium chloride for potential differentiation between patients with IC and detrusor overactivity (DO) showed that the 0.3 M KCl reduces maximum cystometric capacity in BPS and DO, the effect being more pronounced in DO. Urothelial hyperpermeability was not specific to IC. Comparative cystometry using NS and 0.3 M KCl does not help to differentiate BPS from DO [205,206].

The development of a painless modification of the potassium chloride test[207] using cystometric capacity and a 0.2M solution may improve acceptability among patients. The so-called revised or Comparative Potassium Test has shown prognostic value in bladder irrigation studies[208] but is considered optional by ESSIC. If performed it should be performed according to Daha et al.[207]: A Foley balloon catheter (14F) is inserted and the bladder drained. Instill into the bladder 500 ml saline (0.9%) at a rate of 50 ml/min via an infusion set until the maximum capacity is reached. Drain the bladder and measure the saline filling volume. Repeat the instillation and measurement with 500 ml 0.2 M potassium chloride at a rate of 50 ml/min (taking care that filling lines are emptied of all saline before KCl instillation), and calculate the filling volume difference. A difference in bladder capacity > 30% is considered positive. Besides reduction of bladder capacity with 0.2 M KCl there is a stronger feeling of urgency in IC patients compared to the saline filling, which is also clinically relevant.

8. CYSTOSCOPY AND HYDRODISTENSION

The classic cystoscopic picture of BPS as an “elusive” bladder ulcer with a corresponding cystoscopic appearance of patches of red mucosa exhibiting small vessels radiating to a central pale scar was described by Hunner in 1915 [5]. (Figures 6, 7 & 8) courtesy of Jorgen Nordling)

After 1978, glomerulations, described as punctuate petechial hemorrhages and observed after hydrodistention, became the primary cystoscopic feature of BPS[7]. (Figures 9 and 10, courtesy of Tomohiro Ueda)

But not all patients with symptoms of BPS have glomerulations[9,28,36,176], and not all patients with glomerulations have symptoms of BPS [196,209-212]. Neither presence nor severity of glomerulations correlate with any of the primary symptoms of BPS [33], although the presence of a Hunner’s lesion is significantly associated with bodily pain and urinary urgency [211]. The finding of a Hunner’s lesion or glomerulations has been somewhat subjective. Some researchers find a Hunner’s lesion in 50% of their BPS patients [213], while others rarely see one [214].

No study comparing individual perceptions and variations in reporting or classifying glomerulations has ever been reported. Bladder capacity during hydrodistention has not drawn much attention, although it is strongly associated with increased urgency [215].

Because considerable variation in the duration of distension, repetition of distension, the pressure used for distension, and the measurement of bladder capacity have been described [216], the ESSIC
has suggested a standardized procedure for cystoscopy and hydrodistension [15]:

A rigid cystoscope is preferred to facilitate taking of adequate biopsies. Glycine or corresponding filling fluid should be used to allow for coagulation after biopsies. Infusion height should be approximately 80 cm above the Symphysis Pubis. (note: some would recommend a pressure of only 60cm to minimize risk of bladder perforation and in the absence of data that a higher pressure is beneficial). A dripping chamber is used and the bladder is filled until fluid dribbling stops. If necessary, a digital block is applied around the urethra to prevent leakage. Pre-distension inspection includes observation for radiating vessels, coagulum or fibrine deposits, white spots, hyperaemia, oedema, cracks, scars or any other mucosal changes. Continuous inspection while filling the bladder is advised. When maximum capacity is reached, the distension is maintained for 3 minutes. The bladder is emptied and the colour of the fluid checked for the degree of bleeding. The total volume drained is the measured maximum bladder capacity. During a second filling, the bladder is filled to approximately 1/3rd to 2/3rd of the bladder capacity to achieve optimal vision for inspection and biopsies. The bladder should not be filled to maximum capacity or distended again to avoid further provocation of changes with doubtful reproducibility.

a) Inspection

Describe lesions in anterior wall, posterior wall, lateral quadrants and fundus. At the fundus one should be alert for possible artefacts if there is blind introduction of the scope. Bladder mapping by drawing is mandatory. Photographs are recommended but optional.

b) Classification

Grade 0 = normal mucosa

Grade I = petechiae in at least two quadrants

Grade II = large submucosal bleeding (ecchymosis)

Grade III = diffuse global mucosal bleeding

Grade IV = mucosal disruption, with or without bleeding/oedema

The importance of the finding of the finding of glomerulations after hydrodistension is however as mentioned been questioned since 45% of asymptomatic females, 20% of males with LUTS suggestive of BOO and 85% of females with OAB and no bladder pain demonstrates typical glomerulations after hydrodistension[196,210,212] and 10-34% of patients with BPS do not [9,176]

c) How useful is hydrodistention?

Hydrodistension results fail to identify any statistically significant differences in post-distention objective findings (anesthetic capacity, glomerulations) or therapeutic benefits when patients are categorized according to presenting symptoms[217]. Cystoscopy with hydrodistention may provide little useful information above and beyond the history and physical examination findings. In one study, 56% of 84 patients reported symptom improvement, but the duration was short lived with a mean of 2 months[218]. It is necessary to distinguish between short term hydrodistension (2-10 min.) for classification of BPS and long term hydrodistension (20-30 min.) for treatment[219]. Many reports on the therapeutic effect of hydrodistension are from Asia and from patient material with IC based on the Asian definition[45], where up to 2/3 of the patients have frequency-urgency and no pain.

Lamale and colleagues examined the relationships between symptoms and cystoscopic findings in 12 women newly diagnosed with BPS who had not previously received treatment. Pain symptoms had consistent positive correlations with the cystoscopic findings. An increase in pain with bladder filling was associated with inflammation (P = 0.011), ulceration, and smaller bladder capacity. Pain relief after voiding correlated with smaller bladder capacity (P = 0.019), hematuria, and total cystoscopic score. Pain
intensity in the urethra was related to ulceration and hematuria, and pain in the lower abdomen was related to a smaller bladder capacity \( P = 0.047 \), glomerulations, and a larger total cystoscopic score. Daytime frequency correlated negatively with most cystoscopic findings, and nocturnal frequency had a positive relationship with most cystoscopic findings and was significantly associated with a smaller bladder capacity \( P = 0.010 \). Urgency showed no strong associations with any cystoscopic findings. The results of this study contradict those of previous studies that found no relationship between symptom reports and cystoscopic findings suggesting possible effects of treatment on pain perception and therapeutic influence on cystoscopic findings[220].

It is important to keep in mind that the cystoscopic appearance of the bladder wall after hydrodistention may not be constant over time, and the absence of initial findings of glomerulations or terminal hematuria does not preclude further development of these findings of the disease on subsequent evaluation[221]. Rare cases of hydrodistension induced bladder necrosis have been described[222].

9. MORPHOLOGY

Pathological changes in light microscopic and electron microscopic features in patients with BPS have been described including infiltration with inflammatory cells in all or specific parts of the bladder wall. Although these findings are important in our attempt to understand the disease and perhaps as an aid to stratification of patients, there are at this time no pathognomonic findings on biopsy in terms of diagnosis[33]. Expert opinion as per the ESSIC suggests the following procedures when biopsy is planned for BPS evaluation[15]:

a) Biopsies

During cystoscopy the bladder is distended to full capacity. After draining the bladder, bladder biopsies are taken at roughly half full bladder capacity. Biopsy procedures should be performed by using large forceps and include detrusor muscle; alternatively double punch biopsies or resections of lesions can be used.

b) Number of biopsies

At least 3 biopsies from the two lateral walls and bladder dome should be taken in addition to biopsies from visually abnormal areas. The biopsies are to be immediately fixed in neutral buffered 4% formalin.

c) Biopsy handling

Biopsies are treated conventionally. Six adjacent 3 mm sections are cut and placed with 3 specimens on each of two specimen slides. The first slide is stained with H&E, the next with a connective tissue stain suitable for the individual institute. Twenty-four 10 mm sections are then cut and every third section is mounted on a specimen slide for mast cell counting. The specimens are stained by Lederstain (naphtolesterase) according to routine procedures. Finally, a 3mm section is obtained to ensure the presence of detrusor muscle in the specimens.

d) Mast cell counting

The use of a measuring grid (e.g. Leitz periplan 6F 10_N ocular containing a standardized grid) is necessary. Only mast cells containing nucleus are included. When counting the cells those covering or touching the bottom should be excluded whereas those covering the upper and left line are included. At least 3 biopsies must be the subject of mast cell counting and if possible one including a lesional area. Biopsies for mast cell counting should contain detrusor muscle.

e) The pathology report

- **Epithelium**
  - Not present
  - Present
  - Dysplasia with grading
  - Abnormal but no dysplasia: description is mandatory.

- **Propria**
  - Normal
  - Inflammation: description with a grading
  - Other findings are described

- **Detrusor muscle** Abnormal muscle cells: describe

- **Intrafascicular fibrosis**
  - Not present
  - Present

- **Mast cell count** At least three biopsies should be included in the counting. Only the biopsy with the highest number of mast cells per mm2 should be reported.

The enzymatic (naphtolesterase) staining is, for the time being, recommended since standardized values are available:

- less than 20 mast cells/mm2: no detrusor mastocytosis;
- between 20 and 28 grey zone!
- more than 28 mast cells/mm2: detrusor mastocytosis.

Larsen recommends examining the detrusor biopsies with tryptase-stained 3 micron thick sections, with every seventh section used for quantification; 27 mast cells/mm2 is considered indicative of mastocytosis[165].
These guidelines have been reported to be easy to follow. A statistically significant correlation was found between the cystoscopic aspect and inflammatory infiltration, mast cell count in the detrusor muscle and stromal edema. Maximum bladder capacity was negatively correlated with inflammation, detrusor mast cell count, hemorrhages and the overall cystoscopic aspect[223]. Correlations have also been demonstrated between urothelial damage and inflammatory infiltrates and between normal epithelium and detrusor mastocytosis suggesting either 2 different types of BPS or different stadiums in the pathophysiological process of BPS [177]. Also in a large retrospective study of 349 patients with BPS, it was found that treatment intensity ranging from hydrodistension only to major surgery correlated positively to detrusor mast cell count, detrusor fibrosis and nocturia, but not to maximum bladder capacity or glomerulations after hydrodistension [224].

10. BIOMARKERS

The lack of universally accepted clinical diagnostic criteria for BPS affects all aspects of making progress in understanding this disease. Insights into risk factors, pathogenesis, trials for effective therapy, prognosis, and outcome criteria for treatment are all affected by this lack of diagnostic criteria. A major factor affecting the controversy over accepted clinical diagnostic criteria is that the current criteria are predominantly symptom specific. An objective biomarker would advance the establishment of reproducible diagnostic criteria for BPS and also aid in monitoring effects of treatment.

A biomarker for any disease needs to demonstrate high sensitivity and high specificity. In addition, the marker assay needs to be reproducible in many laboratories and should be suitable for use in a clinical diagnostic laboratory.

Many of the published studies on biomarkers for BPS have been on biomarkers isolated from urine. Erickson et al has published excellent reviews of urine markers for BPS [225,226]. The most thoroughly investigated marker is antiproliferative factor (APF). This factor has been identified and characterized by Dr. Susan Keay and her colleagues at the University of Maryland [227,228]. Control subjects for this study included asymptomatic individuals, patients with bacterial cystitis, and patients with vulvovaginitis. APF is found in urine from the bladder and not from the renal pelvis [229-231]. Treatment of symptomatic BPS by either hydrodistention or neurostimulation normalized the APF levels concurrent with symptom relief [232]. It is not known if other forms of treatment will affect APF levels. Preliminary studies in 58 women with documented BPS demonstrated a sensitivity value of 91.4% and a specificity of 90.6%[233]. A later study with 219 symptomatic BPS patients and 325 controls with and without other urological disorders documented the sensitivity as 94% and the specificity at 95%[234]. APF has been isolated from urine and found to be a frizzled 8 protein-related sialoglycopeptide which interacts with the epithelial cell receptor CKAP4/p63[235,236]. Keay et al have suggested that APF might inhibit cell proliferation by the downregulation of genes that stimulate cell proliferation along with the upregulation of genes that inhibit cell growth[112]. Cell growth inhibition of human urothelial cells appears to be mediated by p53[237]. APF treatment caused significant increases in the paracellular permeability of normal bladder epithelial cell monolayers and the attenuation of tight junctions compared to mock APF, similar to changes seen in IC cells. APF treatment also decreased expression of the tight junction proteins zonula occludens-1 and occluding [236].

APF seems an ideal candidate for a biomarker for symptomatic BPS. There need to be additional studies to determine if it can serve as a BPS marker for patients in remission or for those who have not yet become symptomatic. As of 2008, the findings on symptomatic patients have yet to be replicated by laboratories around the world, and the biologic assay has not proven suitable for commercial development as it currently exists. The ultimate fate of APF as an important biomarker and etiologic factor remains to be determined.

GP-51 is a glycoprotein present in both the transitional epithelium and urine of humans and other mammals. Moskowitz et. al have shown that bladder biopsies of BPS patients had decreased staining for GP-51[238] The same laboratory also demonstrated that although GP-51 demonstrates a high specificity for BPS, it is not as sensitive as APF[239].

There have also been many published studies on heparin-binding epidermal growth factor-like growth factor (HB-EGF)[112,230,231,240,241]. HB-EGF is a growth factor found in normal urine. It has been shown that APF inhibits the production of HB-EGF. There have been no large population studies focusing solely on HB-EGF as a biomarker for BPS.

11. CONFUSABLE DISEASES

Criteria for a diagnosis are needed only if the target disease may be confused with other diseases (confusable diseases) because of overlapping features[242]. For a diagnosis, the target disease has to be recognized in a pool of confusable diseases in one of two ways: by recognition of the specific combination of features of the target disease or by exclusion of confusable diseases. For the diagnosis of BPS both methods might be used because:

- Confusable diseases are more common than BPS, so recognition is mandatory because many can be treated.
- Failure to diagnose a confusable disease would automatically incorrectly yield a diagnosis of BPS.
- Patients may have a confusable disease plus BPS.
The diagnosis of BPS can thus be made on the basis of exclusion of confusable diseases and confirmation by the recognition of the specific combination of symptoms and signs of BPS. If the main urinary symptoms are not explained by a single diagnosis (confusable disease or BPS), the presence of a second diagnosis is possible. Symptoms and signs for use in diagnostic criteria do not need to be specific for the target disease. On the contrary, if a specific symptom or sign existed for the target disease, a diagnosis would only require the presence of the specific feature and diagnostic criteria would not be necessary.

In evidence-based medicine, diagnoses are based on medical history, physical examination, and appropriate clinical investigations to eliminate diseases from a list of differential diagnoses (confusable diseases) and to confirm the final diagnosis. BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. Cystoscopy with hydrodistention and biopsies might in this situation document positive signs of BPS thereby making a double diagnosis more probable. For therapeutic studies it makes sense to exclude patients who also have a confusable disease because symptoms and signs may be caused by BPS, the confusable disease, or by both. For prevalence studies of BPS, on the other hand, all cases with BPS should be included, also those with a confusable disease. This approach eliminates the need for separate diagnostic criteria for clinical practice and scientific studies. Table 3 summarizes confusable diseases related to BPS and their mode of exclusion based upon the aforementioned diagnostic proposals and procedures [15,243].

### VII. CLASSIFICATION

Interstitial cystitis was originally described as bladder disease with severe inflammation of the bladder wall described by Hunner as an ulcer[5]. The lesion is however not an ulcer but an inflammatory infiltrate that can crack upon distention, and the name of the bladder lesion has consequently been changed to “Hunner’s lesion[243]”. The finding of a Hunner’s lesion could therefore originally be regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations as another typical finding for IC and this was included in the NIDDK criteria[8]. Magnus Fall proposed, that patients with Hunner’s lesion (classic IC) and patients with glomerulations (non-ulcer type) represented two different subtypes [101] with different clinical pictures, different outcomes, and different responses to treatment [213] meaning that patients fulfilling the NIDDK criteria represents at least two different patient populations. Moreover up to 60% of patients clinically believed to have BPS by experienced clinicians do not fulfill the NIDDK criteria [28] and whether or not these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally Japanese urologists con-

---

sider that "interstitial cystitis" should be preserved as a disease name for patients with urinary symptoms and cystoscopic findings of glomerulations or Hunner’s lesion as outlined in the NIDDK criteria [45].

In an attempt to unite these different philosophies into a coherent schema, ESSIC proposed a classification of BPS based on findings during cystoscopy with hydrodistension and morphological findings in bladder biopsies[243] (Table 2). The classification includes groups not having had cystoscopy with hydrodistension (group X) as well as groups not having had morphological investigation of bladder biopsies (group XX). By using this classification future research will be able to identify if findings of glomerulations and/or Hunner’s lesion as well as morphological changes in bladder biopsies does have significant importance for disease prognosis and/or treatment outcome.

1. BEHAVIORAL MODIFICATION

Behavioral therapy for BPS includes education, timed voiding (scheduled voiding time and interval), controlled fluid intake, pelvic floor muscle training and bladder training (gradually extending voiding interval).

Chaiken et al [244] reported that when they conducted behavioral therapy consisting of frequency-volume chart, timed voiding, controlled fluid intake and pelvic floor muscle training for the treatment of 24 female patients, 50% of the patients showed improvement in the number of urinations and bladder capacity. At the same time, they considered that as the data was collected from 12 weeks’ intensive therapy conducted by skilled therapists for selected patients whose main symptom was urinary frequency, it should not be generalized. Parsons and Koprowski [245] reported that when 21 patients with the main symptom of urinary frequency underwent bladder training using a frequency-volume chart, 15 patients showed improvement. In 15 patients, the mean voided volume after one month increased by 65cc, whereas a persistent sensation of bladder fullness remained unchanged.

Participants in both arms of a large NIH funded randomized placebo controlled trial evaluating amitriptyline in BPS [246] received a standardized education and behavioral modification program (EBMP). Adherence to the EBMP at 6 weeks was assessed in 4 categories of 1) symptom management, 2) fluid management, 3) diet modification and 4) bladder training. For each of these EBMP categories adherence was defined as the overall percentage of participants who reported adhering to each component of the EBMP at each telephone contact or clinic visit. For the 241 subjects evaluable for EBMP adherence, the rate at 6 weeks was 75% (181 of 241) for symptom management, 83% (201 of 241) for fluid management, 82% (196 of 240) for diet modification and 71% (172 of 241) for bladder training. The overall GRA response rate was approximately 57% for adherers in any of the 4 EBMP categories, whereas it was lower for nonadherers. This rate neared statistical significance for diet modification, which demonstrated only a 41% response rate among nonadherers (p = 0.051).

Recommendation:

Behavioral therapy should be a cornerstone of treatment for patients with BPS.

Level of evidence: 2 Grade of recommendation: B

2. PHYSICAL THERAPY

Women with BPS may have associated pelvic floor dysfunction [247]. Physical therapy for the pelvic floor is said to be effective for genitourinary and anorectal disorders[248]. Biofeedback and soft tissue massage may stimulate the relaxation of the pelvic floor muscles [249,250]. Lukban et al [251] conducted a direct myofascial release treatment on 16 BPS patients with high-tone pelvic floor dysfunction and sacroiliac dysfunction. The treatment was effective for urinary frequency and suprapubic pain. Fifteen patients (94%) showed improvement in the O’Leary & Sant symptom score. Coital pain relief was observed in 15 of 16 patients, with 9 patients becoming able to resume sexual intercourse [252]. Transvaginal Theile massage was also reported to be effective for 9 of 10 patients of the same group [253]. Mendelowitz et al [250] showed a 69% success rate when treating 16 patients using electromyographic biofeedback. However, it was suggested that a placebo effect may have occurred because the effect did not correlate with the improvement in patient’s awareness of the pelvic floor muscle movement and position before and after the therapy. Weiss [254] reported that 70% of 10 patients with IC showed symptomatic improvement, rating from “effective” to “remarkably effective”.

An NIH study[255] to determine the feasibility of conducting a randomized clinical trial was undertaken to compare 2 methods of manual therapy (myofascial physical therapy and global therapeutic massage) in patients with urological chronic pelvic pain syndromes. The global response assessment response rate was 57% in the myofascial physical therapy group compared
patients, that more than half of the patients expe-
Ric nurses are considered to be useful [262,263].

to 21% in the global therapeutic massage treatment
group. This statistically significant difference (P=0.03)
was primarily driven by the response seen in women
(24 women) compared to the men (24 men) enrolled in
this small pilot study. A follow-up randomized trial com-
paring similar treatments [256] but only in women with
BPS and demonstrable pelvic floor pathology showed a
clear benefit of directed myofascial physical therapy.

Recommendation:

Physical therapy of selected and motivated patients
with BPS, particularly those with demonstrable pelvic
floor dysfunction, is indicated.

Level of evidence: 1 Grade of recommendation: A

3. STRESS REDUCTION

It is long been observed that mental stress is one
of the factors which aggravate the symptoms of
BPS. Koziol et al [97] reported, in a survey of 374
patients, that more than half of the patients expe-
rienced intensified pain due to stress. Rothrock
et al [257] reported that when comparing patients
with BPS and healthy people, increased pain and
urgency caused by stress were observed only in
patients with BPS. Case-cohort studies have con-
firmed that patients diagnosed with IC/BPS ex-
perience considerably more stress than patients
without the condition [90]. Stress was shown to
correlate with both the severity of symptoms and
quality of life. In another study of patients with
BPS identified in urology tertiary care clinic popu-
lations [258], mental health disorders were identi-
fied in 23 % of IC/BPS female cases compared to
3% of female control subjects. Medications for
anxiety, depression or stress were taken by 37%
of patients with IC/BPS compared to 13% of fe-
male controls.

It is believed that exercise and bathing favorably
influence the quality of life by reducing stress
[259] however, the effect of such nonspecific
therapies are difficult to assess and have not
been proven in clinical trials. It would seem rea-
sonable to suggest, when possible, to shorten
working hours, choose a job with less stress or
create a less stressful home environment. In-
volvement in patient education programs and
patient support groups are considered by most
practitioners to be beneficial [259,260]. World-
wide patient support groups, including the In-
terstitial Cystitis Association (ICA) [261], http://
www.ichelp.org/ , the International Painful Blad-
er Foundation, http://www.painful-bladder.org/, are
important sources of information for patients
with BPS. Patients with BPS frequently suffer
depression, which may negatively impact upon
the quality of life [90] and perhaps symptoms.
Effective self-care strategies taught by psychi-
tric nurses are considered to be useful [262,263].

Recommendation:

Stress and depression are related to poorer quality
of life and increase in severity of symptoms. Level
of evidence: 1 Grade of recommendation: A.
Reduction of stress and depression may contribute
to an overall improvement in quality of life and per-
haps even symptoms. Level of evidence: 4 Grade
of recommendation: C.

4. DIETARY MANIPULATION

Acidic beverages, coffee, spicy food, and alcohol
may aggravate the symptoms of most patients with
BPS [97,259,264,265]. The symptoms of the major-
ity of BPS patients are generally believed to be im-
proved by dietary manipulation [259,264,266,267].
However this has proven difficult to document and
Ngan et al [268] reported that there was no statisti-
cally significant difference in pain and other symp-
toms, when they evaluated the influence of the
changes in urinary pH on the symptoms of 26 pa-
tients with BPS by instilling pH5.0 and pH7.5 saline
solutions into the bladder. One of the best studies
designed to determine the effect of particular foods,
beverages and/or supplements (comestibles) on
IC/BPS symptoms was undertaken by Shorter et al
[269]. One hundred and four patients with IC/BPS
were asked to indicate on a validated questionnaire
whether each of 175 individual items worsened, im-
proved or had no effect on symptoms. Of the pa-
tients surveyed, 90% indicated that the consump-
tion of certain foods or beverages caused symptom
exacerbation. The comestible items that had the
most effect were caffeinated, carbonated and alco-
holic beverages, certain fruits, artificial sweeteners
and spicy foods.

Dietary manipulation was ranked in the top five
frequently used treatments in a cohort study of
the Interstitial Cystitis Data Base (ICDB).[270]. As
the influence of diet is variable with regard to
food, beverage, and patient, there is no reason
for patients to be uniformly on a strict diet. It is
advised that each patient experiment to find out
the foods that tend to aggravate their symptoms
and avoid them. The ICA home page, (http://www.
ichelp.org/) introduces the foods often avoided by
patients with BPS.

Recommendation:

Personalized dietary manipulation should be part
of the therapeutic strategy for patients with IC/BPS.

Level of evidence:2 Grade of recommendation :B

IX. ORAL THERAPY (TABLE 5)

Several categories of medication have been used in the
management of patients with bladder pain syndrome
including analgesics, antidepressants, antihistamines,
Immunosuppressants, and glycosaminoglycans. Many
of these drugs are used empirically. Only a few of them have been studied in randomized controlled trials and none have a grade A recommendation.

1. ANALGESICS

**Grade of Recommendation: C - Level of Evidence: 4**

The long-term, appropriate use of pain medications is indispensable in the treatment of bladder pain syndrome. Many nonopioid analgesics including acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) and even antispasmodic agents [271] have a place in pain therapy. Patients with more severe symptoms can often be helped with medical pain management using medications commonly used for chronic neuropathic pain syndromes including antidepressants, anticonvulsants, and opioids.

Gabapentin, introduced as an anticonvulsant, has found efficacy in neuropathic pain disorders including diabetic neuropathy [272] and postherpetic neuralgia [273]. It demonstrates synergism with morphine in neuropathic pain [274]. Two patients with IC showed improved functional capacity and received adequate pain control when gabapentin was added to their regimen [275]. Sasaki et al reported that 10 of 21 male and female patients with refractory genitourinary pain had subjective improvement of their pain following treatment with gabapentin [276]. Recently gabapentin was one compound of a triple mix including amitriptyline and etodolac, a NSAID. The interpretation of the observed efficacy in 74 patients is hampered by an uncontrolled open label study protocol that additionally allowed up titration of gabapentin and amitriptyline. The impact and contribution of amitriptyline, whose exclusive efficacy for BPS has been proven better than for any other oral drug, on the reported amelioration was not discussed [277].

Pregabalin has similar structure as gabapentin and also has been shown to reduce the pain of diabetic neuropathy [278]. Pregabalin was proved effective for treating pain associated with fibromyalgia [279]. Pregabalin might be worthwhile to try for bladder pain syndrome, particularly for those with concurrent fibromyalgia, though studies are lacking.
Opioids are seldom the first choice of analgesics in chronic pain states, but they should not be withheld if less powerful analgesics have failed [280]. Chronic opioid therapy can be considered as a last resort in selected patients, who have disabling pain and often receive inadequate doses of short-acting pain medications, which put them on cycles of short-term relief, anxiety, and pain.

The major impediment to the proper use of opioids when they are prescribed for long-term nonmalignant pain is the fear of addiction. Some studies suggest the risk is low [281], but not zero. [282] Using opiates is a difficult decision that requires much thought and discussion between patient and urologist, and a pain specialist. They are best administered in a pain clinic setting, requiring frequent reassessment by both patient and physician [283].

In addition to narcotics, concurrent usage of nonsteroidal anti-inflammatory drugs, cyclooxygenase inhibitors, acetylsalicylic acid, and tricyclic antidepressants may provide better pain control [284]. The common side effects of opioids include sedation, nausea, mild confusion, and pruritis. These are generally transient and easily managed. Respiratory depression is extremely rare if they are used as prescribed. Constipation is common and a mild laxative is generally necessary. The long-acting narcotic formulations that result in steady levels of drug over many hours are preferable.

2. ANTIDEPRESSANTS

a) Amitriptyline

**Grade of Recommendation: B - Level of Evidence: 2**

Amitriptyline is a tricyclic antidepressant with the property of blocking H1-histaminergic receptors [285]. It stabilizes mast cells and inhibits mediator-stimulated vascular leakage. It inhibits synaptic reuptake of serotonin and norepinephrine, thus inhibiting painful nociception from the bladder at the level of the central nervous system. Its nighttime sedation can be therapeutic in the BPS population and its purported beta-adrenergic receptor stimulation in the bladder may facilitate urine storage [286].

Using a dose titration of up to 75mg taken before bed, Hanno and Wein reported success in about half of 20 patients who could tolerate the medication. Twenty percent of the initial 25 patients dropped out because of fatigue, weight-gain, or dry mouth. In a follow-up report [287], 18 of 28 patients who could tolerate the drug had major relief of symptoms within 3 to 6 weeks of onset of therapy with a mean follow-up of 14.4 months. However, about one-third of patients initially placed on the drug could not continue on it because of side effects. Kirkemo et al [288] treated 30 patients and 90% had subjective improvement in 8 weeks. Pranikoff and Constantino [289] reported improvement in 16 of 22 patients with urinary frequency and pain who did not have a diagnosis of interstitial cystitis, noting that 5 of the 22 could not tolerate the drug.

van Ophoven et al performed the first prospective, double-blind, placebo-controlled study of amitriptyline. Fifty patients were randomized to placebo or a titrated dose of amitriptyline up to 100mg daily. Forty-two percent of amitriptyline patients had greater than 30% decrease in O’Leary/Sant symptom and problem scores at 4 months compared to 13% in the placebo group[290]. They subsequently reported a long-term follow-up of amitriptyline for patients who can tolerate the side effects and continued the medication. With a mean follow-up of 19 months, 64% of 94 patients had response [291].

Foster and Hanno reported a second multicenter, randomized, double-blind, placebo controlled clinical trial of amitriptyline in subjects with interstitial cystitis/painful bladder syndrome who were naïve to therapy. Study participants in both treatment arms received a standardized education and behavioral modification program. Only of the subgroup of 207 subjects who achieved a drug dose of at least 50 mg, a significantly higher response rate was observed in the amitriptyline group (66%) compared to placebo (47%) (p = 0.01). When all randomized subjects were considered, amitriptyline plus an education and behavioral modification program did not significantly improve symptoms in treatment-naive patients with interstitial cystitis/painful bladder syndrome. However, amitriptyline may be beneficial in persons who can achieve a daily dose of 50 mg or greater[246].

b) Doxepin, desipramine, duloxetine

Other tricyclic antidepressants that have been used for bladder pain syndrome are doxepin and desipramine. Wammack et al used the combination of doxepin and piroxicam, a cox-2 inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms [292]. One study reported satisfactory outcome with desipramine. [293] Duloxetine, a serotonin-norepinephrine reuptake inhibitor has also been tried but without therapeutic effects [294].

3. ANTIHISTAMINES

**Grade of Recommendation: D - Level of Evidence: 1**

Simmons first proposed use of antihistamines in 1955 [295]. His findings of mast cells in the wall of a normal bladder and the edema and increased vascularity seen in the IC bladder suggested that histamine may be responsible for the development of interstitial cystitis. He reported on 6 patients who had some improvement with pyribenzamine for limited periods [296].

a) Hydroxyzine

Hydroxyzine is the most widely used antihistamine for bladder pain syndrome. Its ability as an H-1 receptor antagonist, to inhibit bladder mast cell activation, along with its anticholinergic and anxiolytic
properties and good safety profile, have made it a reasonable candidate for use as a therapeutic agent for bladder pain syndrome.[297] In 1933, Theoharides first reported significant benefits of hydroxyzine in reducing pain and urinary symptoms.[298] His two subsequent reports of totally uncontrolled series further suggested the therapeutic effects of hydroxyzine.[299] [300] However, in an NIDDK randomized controlled trial, the global response rate for hydroxyzine was only 31% compared to a 20% response to those not treated with hydroxyzine. When looked at by itself the response was 23% vs. 13% on placebo. None of the results in this under-powered trial reached statistical significance [301].

**b) Cimetidine**

**Grade of Recommendation: C - Level of Evidence: 3**

Cimetidine, a H2 histamine receptor antagonist, has been explored for treatment of bladder pain syndrome. In a pilot study [302], 9 patients were treated with a dose of 300mg orally twice daily for one month. At follow-up 26 to 42 months later, 4 patients had complete relief of urinary symptoms and suprapubic pain. Lewi[303] reported 31 patients given 200mg three times daily with mean follow up of 6.6 months. Seventy-one per cent experienced varying degrees of symptomatic relief, 45% were pain free, and 26% went into remission of all symptoms. In a later report [304] of 69 patients treated over a 4 year period, 67% of patients had complete relief of all symptoms.

A small, prospective, placebo-controlled RCT studied 36 patients who either received oral cimetidine or placebo[305]. Median suprapubic pain and frequency scores improved significantly, but the publication does not state exactly how many patients in each group improved.

**4. IMMUNOSUPPRESSANTS**

**a) Cyclosporine**

**Grade of Recommendation: C - Level of Evidence: 3**

Cyclosporine, a widely used immunosuppressive drug in organ transplantation, was the subject of a novel bladder pain syndrome trial. [306] Eleven patients received cyclosporine for 3-6 months at an initial dose of 2.5-5 mg/kg daily and a maintenance dose of 1.5 to 3mg/kg daily. Miciturition frequency decreased, and mean and maximum voided volumes increased significantly. Bladder pain decreased or disappeared in 10 patients. After cessation of treatment, symptoms recurred in the majority of patients.

In a long-term follow-up study, 20 of 23 refractory IC patients on cyclosporine therapy followed for a mean of 60.8 months became free of bladder pain. Bladder capacity more than doubled. Eleven patients subsequently stopped the therapy, and in 9, symptoms recurred within months, but responded to reinitiating cyclosporine [307]. Sairanen et al further found that cyclosporine A was far superior to sodium pentosanpolysulfate in all clinical outcome parameters measured at 6 months. [308] Patients who responded to cyclosporine A had a significant reduction of urinary levels of epidermal growth factor (EGF) [309].

**b) Suplatast Tosilate**

**Grade of Recommendation: D - Level of Evidence: 3**

Suplatast Tosilate (IPD-1151T) is an immunoregulator that selectively suppresses IgE production and eosinophilia via suppression of helper T cells that produce IL-4 and 5. It is used in Japan to treat allergic disorders including asthma, atopic dermatitis, and rhinitis. Ueda et al reported a small study in 14 women with interstitial cystitis. [310] Treatment for one year resulted in a significantly increased bladder capacity and decreased urinary urgency, frequency, and lower abdominal pain in 10 women. Concomitant changes occurred in blood and urine markers suggesting an immune system response. Larger, multicenter, randomized controlled trials in the United States and Japan have been completed and results are unpublished. Further studies with this drug for bladder pain syndrome are not planned and approval for this indication is not expected.

**c) Azathioprine and Chloroquine derivatives**

**Grade of Recommendation: D - Level of Evidence: 4**

In a single report in 1976, Oravisto et al used azathioprine or chloroquine derivatives for BPS patients not responding to other treatments.[311] About 50% patients responded.

**d) Corticosteroids**

Reports on outcome with corticosteroid therapy have been both promising (131) and discouraging (132). Soucy et al. (133) have suggested a trial of prednisone (25 mg daily for 1–2 months, afterwards reduced to the minimum required for symptom relief) in patients with severe ulcerative IC, which is otherwise unresponsive to conventional treatment. The side effects of steroids can be very serious, making it difficult to justify their use[312-314].

**5. SODIUM PENTOSANPOLYSULFATE**

**Grade of Recommendation: D - Level of Evidence: 1**

Sodium pentosanpolysulfate (PPS), a synthetic sulfated polysaccharide, is available in an oral formulation, 3-6% of which is excreted into the urine and theoretically may replenish the damaged glycosaminoglycan (GAG) layer overlying transitional epithelium of the urinary bladder of BPS patients. An intact urothelial GAG layer has been proposed to be essential to keep the urothelium impermeable to urinary components. A defective bladder GAG layer is hypothesized to be one important cause for BPS. [315]
PPS's mechanism of action has been attributed not only to correction of a putative defect in the GAG layer, but also its ability to inhibit histamine release from mast cells, [316] and a possible effect mediated by nonspecific binding of the molecule with the inflammatory stimulants of uro-thelial activation, an action that would occur in the urine rather than at the mucosal membrane [317].

PPS is the most intensively studied treatment ever proposed for BPS. It is the only medication approved by the Food and Drug Administration for the pain of interstitial cystitis. Parsons initially administered the drug at a dosage of 50mg 4 times daily or 150mg twice daily in an open trial involving 24 patients. [318] Twenty-two of 24 patients experienced a good or excellent response within 8 weeks. In a subsequent randomized, placebo-controlled trial using a dose of 100mg three times daily in 62 patients, pain and urgency improved in 44% vs. a placebo response of 15%. Urgency improved by 38% vs. 18% on placebo. The average number of daily voids was unchanged [319].

Five randomized controlled trials for pentosan polysulfate have yielded conflicting results of efficacy. Holm-bentzen et. al[320] reported the first multicenter double-blind placebo controlled trial in 1987 looking at 115 patients with bladder pain syndrome. Patients were randomized to a dose of 200mg twice daily vs. placebo for 4 months. The results showed no difference between pre and post trial values with regard to symptoms, urodynamic parameters, cystoscopic appearance, or mast cell counts in the two groups. The study concluded that the drug had no clinically significant effect.

The first of two pivotal studies for the FDA was performed in the United States in 1990.[321] A total of 110 patients in 5 medical centers were studied for 3 months on a dosage of 100mg three times daily. Twenty-eight per cent of patients on PPS reported “more than slight improvement” versus 13% of those on placebo. Pain and pressure to urinate were the main parameters to show benefit with PPS.

The FDA asked for a second study which was reported 3 years later. [322] In a multicenter, placebo-controlled RCT 148 patients were randomized to 100mg three times daily of pentosan-polysulfate vs. placebo. In the primary endpoint of patient self-evaluation of global improvement, 32% of those on PPS reported 50% or more improvement vs. 16% on placebo at 3 months. Pain, urgency, and pressure showed significant improvement with drug. Frequency, nocturia, and volume voided showed no significant changes between study groups.

The NIDDK performed their own 2 X 2 factorial study to evaluate PPS and hydroxyzine. [301] Each drug was used alone and in combination and compared to a placebo group. Patients were treated for 6 months. There were 121 participants in 7 centers. No statistically significant response to these medications was documented. A non-significant trend was seen in the PPS treatment groups (34%) compared to non-PPS groups (18%). Of the 29 patients on PPS alone, 28% had global response (primary end-point) of moderately or markedly improved vs. 13% on placebo, very similar in this 6-month study to improvement rates in the 3-month pivotal studies, though not reaching statistical significance in the longer study.

In summary

Of 5 RCTs 2 had unfavorable and 3 had favorable results for PPS. Most recent non randomized studies showed a complex heterogeneity in efficacy as well[323-326]. Such conflicting results might suggest that a minority of patients do respond to PPS, but currently there is no reliable method to identify such patients.

Long-term, open-label studies with PPS have been reported. Populations of patients receiving extended treatment for up to 90 months or more in the compassionate use program showed no further improvement in symptoms after 1-2 years, though there seemed to be little tachyphylaxis [301,327]. A total of 2809 patients had begun treatment with a 3 month supply of PPS and 21% continued with treatment beyond this point and reordered medication. This seems to correlate with the 28-32% improvement rate previously reported. The dropout rate in the first 6 months was extraordinarily high with only 178 active patients out of 1742 who initially ordered the drug. There was an overall improvement in symptoms in 62% of the patients who did remain in treatment for 6-35 months.

PPS appears to be a very well-tolerated medication [327] with no common central nervous system side effects, and appears to be beneficial with regard to improving the pain associated with interstitial cystitis in up to one-third of patients, a standard often expected with a placebo. A 3-6 month course is required to see an effect in most patients. Claims suggesting greater efficacy and claims urging its use in patients who do not meet the standard definition of bladder pain syndrome should be regarded with caution.

6. OTHER ORAL MEDICATIONS THAT HAVE BEEN USED FOR BPS

a) L-arginine

Grade of Recommendation: -A - Level of Evidence: 1

Foster and Weiss were the original proponents of L-arginine in the therapy of interstitial cystitis [328]. Eight patients with IC were given 500mg of L-arginine 3 times daily. After one month, urinary nitric oxide synthase activity increased 8-fold and 7 of the 8 patients noticed improvement in IC symptoms. An open-label study of 11 patients showed improvement in all 10 of the patients who remained on L-arginine for 6 months [329].
An open-label study of 9 women in Sweden failed to find any change in symptom scores or in nitric oxide production in the bladder [330]. A placebo-controlled randomized controlled trial of 53 IC patients could find no difference on an intention to treat analysis between drug and placebo-treated patients [331]. A smaller randomized placebo-controlled crossover trial of 16 IC patients found no clinically significant improvement with L-arginine and concluded that it could not be recommended for IC treatment [332].

Data does not support the use of L-arginine for the relief of symptoms of interstitial cystitis.

b) Quercetin

**Grade of Recommendation: D - Level of Evidence: 4**

Quercetin, a bioflavenoid available in many over-the-counter products, may have the anti-inflammatory effects of other members of this class of compounds found in fruits, vegetables, and some spices. Katske et al [333] administered 500mg twice daily to 22 BPS patients for 4 weeks. All but one patient had some improvement in the O’Leary/Sant symptom and problem scores as well as in a global assessment score. Further studies are necessary to determine efficacy.

c) Antibiotics

**Grade of Recommendation: D - Level of Evidence: 4**

Warren et al [334] randomized 50 patients to receive 18 weeks of placebo or antibiotics including rifampin plus a sequence of doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin and ciprofloxacin for 3 weeks each. Intent to treat analysis demonstrated that 12 of 25 patients in the antibiotic and 6 of 25 patients in the placebo group reported overall improvement while 10 and 5 respectively noticed improvement in pain and urgency. The study was complicated by the fact that 16 of the patients in the antibiotic group undertook new BPS therapy during the study as did 13 of the placebo patients. There was no statistical significance reached. What was statistically significant were adverse events in 80% of participants who received antibiotic compared to 40% in the placebo group. Nausea and/or vomiting and diarrhea were the predominant side effects. Most patients on antibiotics correctly guessed what treatment arm they were in, and those that guessed correctly were significantly more likely to note improvement after the study. No duration in improvement after completion of the trial of antibiotics was reported.

Burkhard et al [335] reported a 71% success in 103 women presenting with a history of urinary urgency and frequency and chronic urethral and/or pelvic pain often associated with dyspareunia and/or a history of recurrent urinary tract infection. This was a large, inclusive group and one that is probably broader than the bladder pain syndrome we are focusing on. Nevertheless, he recommended empiric doxycycline in this group. The overwhelming majority of BPS patients have been treated with empiric antibiotics prior to diagnosis. The role of tetracyclines to eradicate nanobacteria in urine of BPS patients has recently been addressed in small Chinese open label study, leaving the significance of nanobacteria as a reasonable pathogen or trigger of the condition open [129,324-326].

At this time there is no evidence to suggest that antibiotics have a place in the therapy of BPS in the absence of a culture-documented infection [336].

d) Methotrexate

**Grade of Recommendation: D - Level of Evidence: 4**

Low dose oral methotrexate significantly improved bladder pain in 4 of 9 women with BPS, but did not change urinary frequency, maximum voided volume, or mean voided volume [337]. No placebo-controlled, RCT has been done with this agent.

e) Montelukast

**Grade of Recommendation: D - Level of Evidence: 4**

Mast cell triggering releases 2 types of proinflammatory mediators, including granule stored pre-formed types such as heparin and histamine, and newly synthesized prostaglandins, and leukotriene B4 and C4. Classic antagonists, such as montelukast, zafirlukast and pranlukast, block cysteinyl leukotriene 1 receptor. In a pilot study,[338] 10 women with IC and detrusor mastocytosis received 10mg of montelukast daily for 3 months. Frequency, nocturia, and pain improved dramatically in 8 of the patients. Further study would seem to be warranted, especially in patients with detrusor mastocytosis, defined as >28 per mm2.

f) Nifedipine

**Grade of Recommendation: D - Level of Evidence: 4**

The calcium channel antagonist nifedipine inhibits smooth muscle contraction and cell-mediated immunity. In a pilot study, [339] 30mg of an extended release preparation was administered to 10 female patients and titrated to 60mg daily in 4 of the patients who did not get symptom relief. Within 4 months five patients showed at least a 50% decrease in symptom scores, and 3 of the 5 were asymptomatic. No further studies have been reported.

g) Misoprostol

**Grade of Recommendation: D - Level of Evidence: 4**

The oral prostaglandin analogue misoprostol was studied in 25 patients at a dose of 600 micrograms daily [340]. At 3 months 14 patients were significantly improved, and at 6 months 12 patients still had a response. A cytoprotective action in the urinary bladder was postulated.
h) Tanezumab

Grade of Recommendation: D - Level of Evidence: 1

A recent randomized, double-blind, placebo controlled phase two 64 patient study investigated tanezumab, a humanized monoclonal antibody that specifically inhibits nerve growth factor as a treatment for BPS pain[341]. At week 6 tanezumab produced a significant reduction from baseline in average daily pain score vs placebo. A significantly higher proportion of patients on tanezumab responded as improved in the global response assessment and tanezumab also significantly reduced urgency episode frequency vs placebo. Studies with this drug have been suspended by the Food and Drug Administration because of the occurrence of osteonecrosis in nonurologic trials.

X. INTRAVESICAL / INTRAMURAL THERAPY (TABLE 5)

Intravesical therapies form one of the staples of BPS therapy, though regulatory approvals and availability throughout the world differ from nation to nation. What follows are treatments that have been reported in the recent literature, some of which are commonly used. Older therapies that are rarely used now include silver nitrate[80,344-347] and chlorpactin WCS90.[7,348-352] These have not been included in this current edition of the Consultation, but have level 3 evidence to support a grade C recommendation based on original reports.

1. DMSO (DIMETHYL SULFOXIDE)

Grade of Recommendation: B - Level of evidence 2

A small number of significant side effects. Not approved in Japan.

DMSO is believed to reduce inflammation, relax muscles, eliminate pain, dissolve collagen, and degranulate mast cells. It has long been used as a therapeutic agent for BPS. Its mechanism of action, however, has not been clarified. Ten articles on DMSO for the treatment of IC were retrieved. Peeker et al[353] reported that in a randomized study, frequency and pain were improved in ulcer-type IC patients, although no improvement was observed in maximum bladder capacity. Perez-Marrero et al[354] reported that in a non-randomized controlled study, 53% of the patients showed remarkable improvement in subjective evaluation (placebo 18%), and 93% in objective evaluation (placebo 35%). Around an 80% improvement rate has been reported in case series and retrospective studies.[355-362]

With regard to side effects after instillation of DMSO, most patients recognize a garlic-like odor, which disappears within a day, and about 10% of patients report bladder irritative symptoms which resolve with or without symptomatic treatment.[363] It is hypothesized that these transient exacerbations occur as the result of mast cell degranulation. The number of significant side effects is considered to be small[362]. Cataracts have been reported in animal studies.[364,365] though not in humans. Negative effects on bladder compliance have been noted in rat detrusor.[366] DMSO may accelerate the absorption of other drugs instilled simultaneously, which could be a source of side effects.

The instillation method has not been standardized. Generally, 50cc of a solution of medical grade 50% DMSO is instilled into the bladder. If pain occurs immediately following instillation, local anesthesia (e.g. 20ml of 2% lidocaine solution) may be instilled. Average retention time is considered to be 10 to 20 minutes.[363] The instillation is performed weekly for 6-8 weeks. After an initial course, treatment is suspended until symptoms recur. If a good result was obtained, another 6 week course (often followed by monthly maintenance) can be initiated. The long-term effect is unknown, although there is no upper limit for the duration of the treatment. DMSO is medically approved in the US, while it has not been approved yet in Japan.

2. HEPARIN

Grade of Recommendation: C - Level of Evidence: 3

Side effects primarily related to effects intravesical catheterization and slight chance of bladder hemorrhage.

The glycosaminoglycan (GAG) layer on the bladder urothelium is a kind of muco-polysaccharide, working as a non-specific defense mechanism. It is believed that a deficiency or abnormality of GAG secondarily causes inflammation of the bladder by increasing the permeability of the bladder mucosa, leading to the pathologic cascade of BPS. Heparin has similarities to the GAG layer of the bladder. When instilled into the bladder, theoretically it might replace the damaged GAG layer. Kuo[367] reported that the International Prostate Symptom Score, as well as bladder capacity at initial desire to void and maximum bladder capacity, improved significantly. According to the report by Parsons et al[368] symptoms were reduced in 56% of patients treated 3 times weekly for 12 weeks. These reports suggest the efficacy of heparin, however, there is no randomized comparative study to give conclusive evidence. One study indicated that intravesical heparin instillations may prolong the response to dimethyl sulfoxide treatment.[369]

No significant side effects have been reported, as it does not affect systemic coagulation parameters. In the case of patients with hematuria, however, it may exacerbate local hemorrhage.

The instillation method has not been standardized. Generally, 10,000-40,000 units of heparin are instilled. It is unusual to have pain or irritation as a
result of instillation, and retention times can be 30 minutes or more. Instillation frequency can be up to every other day and is often administered at home by the patient. Parsons et al [370] recently reported that when 40,000 units of heparin combined with 1 to 2% lidocaine was instilled 3 times a week for 2 weeks, about 80% efficacy was obtained. There is no upper limit for the duration of the treatment, but a long-term effect is unknown. A bleeding tendency may occur. Heparin for intravesical use is not approved by drug regulatory authorities.

4. **CHONDROITIN SULFATE**

**Grade of Recommendation: D - Level of evidence: 4**

Hyaluronic acid, like heparin, is a mucopolysaccharide, that could theoretically repair a damaged GAG layer of the bladder mucosa. Seven reports have indicated efficacy [371-376] In the summer of 2003 Bioniche Life Science Inc http://www.medicalnews-today.com/articles/112053.php and in the spring of 2004 Seikagaku Corporation reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40mg or 200mg per cc respectively) and neither showed significant efficacy of sodium hyaluronate compared to placebo. These negative studies have not been published in peer reviewed literature. Neither preparation has been approved for use for BPS in the United States. At the same time, no significant side effects were observed.

A non-placebo-controlled study has demonstrated a favorable effect of hyaluronic acid on pain reduction [192]. Forty-eight patients with typical symptoms and a positive potassium (0.4 M) sensitivity test were treated with weekly instillations of 40 mg hyaluronic acid for 10 weeks. Visual analogue scale scores showed symptom relief due to hyaluronic acid therapy, irrespective of bladder capacity. The improvement was particularly evident in patients with a reduction in Cmax < 30% compared to patients with a reduction of < 30% with 0.2 M KCl solution (P = 0.003). Long-term effects were investigated in a study of 70 patients previously treated with hyaluronan [377]. Of the initial 70, 48 improved. Of these, 50% reported complete remission with no further therapy. Another 41.7% of patients with symptom recurrence improved after retreatment

A recent interventional study from China suggested a prolonged effect of bladder distension when combined with instillation of hyaluronic acid [378]

4. **CHONDROITIN SULFATE**

**Grade of Recommendation: D - Level of Evidence: 4**

Chondroitin sulfate is another mucopolysaccharide. Its efficacy was suggested for the first time in 2002 when used alone [379] and in another trial when used in combination with hyaluronic acid (364). Intravesical chondroitin sulphate demonstrated beneficial effects in patients with a positive potassium stimulation test in two non-randomised, uncontrolled, open-label pilot studies. Steinhoff (363) treated 18 patients with 40 mL instilled intravesically once weekly for 4 weeks and then once monthly for 12 months. Thirteen of 18 patients were followed for the entire 13-month study. Twelve of these patients responded to treatment within 3–12 weeks. A total of 6/13 (46.2%) showed a good response, 2/13 (15.4%) had a fair response, 4/13 (30.8%) had a partial response, and 1/13 (7.7%) showed no response. In a second trial [380] 24 refractory patients with BPS/IC were treated with high-dose (2.0%) chondroitin sulphate instillations twice weekly for 2 weeks, then weekly with 0.2% solution for 4 weeks, and monthly thereafter for 1 year. The average symptom improvement reported in 20 patients completing the trial was 73.1% (range: 50–95%). The time to optimum response was 4–6 months. A more concentrated 2.0% solution was needed in eight patients to maintain results. Chondroitin sulphate instillation was effective and well tolerated in the therapy of various chronic forms of cystitis associated with a possible GAG layer deficit including BPS in a large multicenter but open study [381].

Sixty-five patients with IC/BPS were treated in a prospective, randomized, double-blind, inactive vehicle-controlled, 12-week study (6 weeks treatment, followed by 6 weeks follow-up) . At the primary endpoint analysis (week 7), 22.6% of the vehicle control group were responders compared with 39.4% of the active therapy group, however, the difference was not significant [382]. A follow up randomized placebo-controlled trial with 98 female patients showed only minor improvements in IC/BPS symptoms and pain and failed to demonstrate a statistically significant drug effect vs. placebo [383]. The authors concluded that the study did not support the use of intravesical chondroitin sulfate as a monotherapy for this condition.

5. **PENTOSAN POLYSUFATE**

**Grade of Recommendation: D - Level of evidence: 4**

No significant side effects are considered to be present.

Pentosan polysulfate (PPS) is a mucopolysaccharide similar to heparin, with a similar postulated mode of action when used locally. Like other mucopolysaccharides, it has not been well-studied clinically. Bade et al in a randomized controlled trial found benefit in 4 patients out of 10 on PPS versus 2 of 10 on placebo.[384] A more recent placebo-controlled study of 41 patients found the addition of a 6 week course of intravesical PPS to a regimen of oral PPS significantly improved results.[385]
6. VANILLOIDS (CAPSAICIN, RESINIFERATOXIN)

**Grade of Recommendation: -A (ineffective) - Level of Evidence: 1**

Significant side effects: local irritation possible

It would seem reasonable that capsaicin, a C-fiber afferent neurotoxin, could alleviate the pain of BPS by desensitizing bladder afferents. Resiniferatoxin (RTX) is considered to have a stronger action than capsaicin, by desensitizing C-fibers more quickly, and causing less initial irritation. Efficacy was indicated in five relatively small clinical trials.[386-390] No severe side effects were reported. A randomized multicenter placebo-controlled clinical trial of RTX failed to demonstrate benefit over placebo.[391]

7. BACILLUS CALMETTE-GUERIN (BCG)

**Grade of Recommendation: -A (ineffective) - Level of Evidence: 1**

Potential serious complications

Seven articles reported on a BCG instillation therapy. Zeidman et al first reported that 5 patients who did not respond to other therapies showed symptomatic improvement.[392] Peters et al conducted a randomized double blind study showing a 60% improvement compared to 27%[393] placebo response with good long-term results at 27 months. [394] Sixty-five percent of the patients experienced burning sensation, 41% irritation of the bladder, and 35% pelvic pain. One patient was reported to have dropped out due to joint pain.

Peeker et al conducted a randomized double blind study comparing intravesical BCG and DMSO and failed to find any efficacy with BCG.[353] A very large, multicenter randomized placebo controlled trial conducted by the National Institute of Diabetes, Digestive, and Kidney Disorders failed to identify benefit from BCG, although the side-effect profile was surprisingly similar to that of placebo.[395]

8. OXYBUTYNIN

**Grade of Recommendation D - Level of Evidence: 4**

Side effect profile is unknown

Barbalias et al observed significant improvement when combining intravesical instillation of oxybutynin with bladder training.[396] Randomized trials are lacking.

9. LIDOCAINE

**Grade of Recommendation: C - Level of Evidence: 2**

No significant side effects.

Lidocaine is a local anesthetic that relieves pain by blocking sensory nerves in the bladder. Four articles[397-400] reported on the electromotive drug administration (EDMA) of lidocaine. Using EMDA, ionized lidocaine is actively introduced into the bladder using an electrical current. Three articles reported that lidocaine and dexamethasone were instilled following hydrodistention. According to the report by Rosamilia et al[400], 85% of the patients had a good result, with the effect persisting for 6 months in 25%. There are two other case reports.[401,402] A report on a pharmacokinetic effect, demonstrated safe levels of lidocaine absorption into the bladder. [403] 102 adult patients (99 women) with a clinical diagnosis of BPS were randomised from 19 centres in the USA and Canada to receive a daily intravesical instillation of alkalinised lidocaine or placebo (double-blind), for 5 consecutive days. Treated patients had significant sustained symptom relief for up to 1 month [404]. However, further randomized, placebo-controlled trials are needed to ascertain efficacy, optimal treatment parameters, and length of response to intravesical lidocaine preparations. [405] Advantages seem to be immediate response, low-cost of generic medication, and ability of patients to self-administer at home.

10. BOTULINUM TOXIN (INTRAMURAL)

**Grade of Recommendation: A - Level of Evidence: 1**

- Side effects include dysuria, incomplete emptying

Botulinum toxin type A (BTX-A) acts by binding to the nerve endings within muscles, blocking the release of acetylcholine, and probably other neurotransmitters, to modulate muscle contraction and reduce the sensitization of sensory nerve endings. There is increasing evidence for an additional, direct effect on the sensory bladder pathways and subsequent modulation of the efferent overactivity or hyperexcitability involved in the pathophysiology of the detrusor and other muscle dysfunction.[406]

Thirteen BPS patients were injected with 100–200 IU of BTX-A (abobotulinumtoxin A or onabotulinumtoxin A) into 20–30 sites submucosally in the trigone and floor of the bladder. Overall, nine (69%) patients noted subjective improvement, and ICSI scores improved by 70% (P< 0.05). There were significant decreases in daytime frequency, nocturia and pain, and a significant increase in first desire to void and maximal cystometric capacity. However dysuria occurred in a majority of patients and persisted in a minority for several months after initial injection. Three patients required clean intermittent catheterization for 2-3 months following therapy.[407]

To ascertain effect of repeat injections a total of 13 patients were followed up for 2 years, while 58 injections were administered with a mean of 4.8 ± 0.8 injections per patient. The mean interval between two consecutive injections was 5.25 ± 0.75 months.

At 1 and 4 months follow-up, 10 patients reported a subjective improvement. Mean VAS scores, mean daytime and night-time urinary frequency decreased significantly. The three non-responders to
the first intravesical treatment session underwent further treatment 3 months later with satisfactory results. At 1 and 2 years follow-up, the beneficial effects persisted in all patients [408].

These results are in contrast with those in another study from Kuo of BTX-A (onabotulinumtoxin A) in 10 patients with BPS. One hundred units were injected suburothelially into 20 sites in five patients, while 100 U were injected into the trigone in the remaining five. None of the patients became symptom-free; two showed only limited improvement in bladder capacity and pain score.[409]

However in an RCT, Kuo and Chancellor analysed the difference between hydrodistension and hydrodistension plus intravesical, sub mucosal BTX-A (onabotulinumtoxin A).[410] Of the 67 patients, 44 were divided in two groups: one received 200 U and the other 100 U, and cystoscopic hydrodistension was performed after 2 weeks. The remaining 23 patients received hydrodistension only. There was symptomatic improvement in all groups. However, in the hydrodistension group, 70% had returned to their previous symptoms after the first month, while in the BTX-A-treated groups, there was improvement of VAS, functional bladder capacity and cystometric bladder capacity at 3 months. At 12 and 24 months, the results in the active group were 55 and 30% versus 26 and 17% in the hydrodistension group.

Trigonal-only injection seems effective and long-lasting since 87% of patients (n = 23) reported improvement after a 3-month follow-up period in a study by Pinto et al.[411] Over 50% referred continuity of the beneficial effect 9 months after the first treatment. When retreatment was needed, similar results were obtained. No cases of urinary retention were reported. The authors concluded that this treatment is safe, effective and can be repeated.

Further studies will be needed to obtain conclusive evidence for its efficacy, duration of effect, and side-effect profile.

**XI. NEUROMODULATION**

**Grade of Recommendation: B - Level of Evidence: 1**

Sacral nerve stimulation (SNS) involves implanting permanent electrode(s) to stimulate S3 or S4 roots. As early as 1989, Tanago et al showed that stimulation of S3 may modulate detrusor and urethral sphincter function [412]. FDA approved the usage of sacral neuromodulation for treating refractory detrusor overactivity in 1997 and for urinary urgency and frequency in 1999. Although the effectiveness of SNS for detrusor overactivity is largely confirmed by a good number of papers, only a few papers report the effect of SNS in treating BPS.

Zerman et. al reported significant improvement in a 60-year-old woman treated for severe BPS pain using sacral nerve stimulation implant. Pain and accompanying bladder dysfunction were improved by temporary and permanent sacral nerve stimulation for up to six months [413]. Maher et al [414] showed that temporary stimulation was effective in 73% of 15 women with refractory BPS. Mean voided volume during treatment increased and mean daytime frequency, nocturia and pain decreased significantly. As indicated by the Short Urinary Distress Inventory and SF-36 Health Survey, the quality of life parameters of social functioning, bodily pain and general health significantly improved during the stimulation period.

Chai et. al[230] found that percutaneous S3 nerve root stimulation improves symptoms and normalizes urinary HB-EGF levels and antiproliferative activity in patients with BPS. In their report in 2003, Comiter et al[415] prospectively investigated the effect of SNS on a series of 17 patients with refractory BPS. At an average of 14 months follow-up mean daytime frequency, nocturia and mean voided volume improved significantly. The average pain decreased from 5.8 to 1.6 points on a scale of 0 to 10 and Interstitial Cystitis Symptom and Problem Index scores (ICSI and ICPI) decreased from 16.5 to 6.8 and 14.5 to 5.4, respectively. Of the 17 patients 16 (94%) with a permanent stimulator demonstrated sustained improvement in all parameters at the last postoperative visit. Whitmore el al [416] applied percutaneous sacral nerve root stimulation on 33 patients with refractory interstitial cystitis. Statistically significant improvements were seen in pain and urinary symptoms. Significant improvements were also seen in ICSI and ICPI scores.

Peters et al [417] reported a reduction of narcotic usage in 18 BPS patients following SNS for a mean of 15.4 months, although the dose reduction was modest (36%) and only 4 of 18 discontinued the narcotics. However, Elhilali and colleagues [418] found that both of two patients with interstitial cystitis reported no improvement following sacral neuromodulation. Zabibi et al [419] more extensively stimulate S2-S4 by implanting electrodes into epidural space through sacral hiatus. 23 of 30 (77%) patients had successful trial stimulation and were permanently implanted. Among these patients, the symptom score was improved by 35% (p=0.005). The pain score improved by 40% (p=0.04). Patients reported an average of 42% improvement in their symptoms.

In the first prospective, single-blind, crossover trial of sacral nerve stimulation (SNS) versus pudendal nerve stimulation (PNS) for patients with BPS (n = 22), PNS gave an overall 59% improvement in symptoms, whereas SNS gave an overall 44% improvement (P = 0.05). Most patients who tested both a sacral and pudendal electrode chose PNS as the better site. Follow-up showed marked improvements in voiding variables.
and validated BPS symptom questionnaires. Over 90% of patients treated with neuromodulation stated that they would undergo implantation again [420].

Long-term results were verified in a retrospective study of 78 patients treated from 1994 to 2008. Permanent sacral neuromodulation implantation was performed in patients who showed at least 50% improvement in their symptoms with a temporary peripheral nerve evaluation test. Median follow-up was 61.5 ± 27.7 months. Good long-term success of sacral neuromodulation was seen in 72% of the patients. The explantation rate was 28%. The most frequent reason for explantation was poor outcome (54% of the failed patients). The revision rate was 50% [421]. In another observational, retrospective, case-controlled review (January 2002–March 2004), 34 female patients underwent permanent device implants. Mean pre-/postoperative pelvic pain and urgency/frequency scores were 21.61 ± 8.6/9.22 ± 6.6 (P < 0.01), and mean pre-/postoperative visual analogue pain scale (VAPS) scores were 6.5 ± 2.9/2.4 ± 1.1 (P < 0.01). Mean follow-up was 86 ± 9.8 months. Sacral neuromodulation showed adequate improvement for the symptoms of refractory BPS. Reoperation rate was 25%.[422]

Sacral nerve modulation is still considered an investigational procedure for BPS by the Consultation. Pudendal nerve stimulation has shown better results. Therapeutic benefits of both appear to be significant in selected cases. Strict patient selection and detailed discussion with patients prior to surgery is mandatory. Long-term results should be collected and reported, and trial results discussed with patients before employing this treatment modality.

XII. PAIN EVALUATION AND TREATMENT

1. EVALUATION OF PAIN:

The first premise that all physicians treating patients diagnosed with BPS is that they deserve to have their chronic pain assessed and treated. It is now recognized that successful management of BPS is only possible using a multidisciplinary and multimodal treatment approach which must include management of the associated chronic pain. This includes evaluation of the whole patient, not just the urology related symptoms. As described in previous sections, this will involve assessment of clinical symptoms, physical signs and history to best define the underlying diagnosis and overlapping conditions, while not ignoring the problems of mood, sleep and sexual problems. The patient’s self report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales and should document the efficacy of pain relief at regular intervals after starting or changing treatment. Systematic evaluation of the pain involves the following:

- Evaluation of severity
- Detailed history of the pain including assessment of pain intensity and character
- Evaluation of the psychological state of the patient, including assessment of mood and coping responses
- Physical examination emphasizing the neurologic examination
- Diagnostic workup to determine the cause of the pain
- Re-evaluation of therapeutic strategy and response.

The initial evaluation of pain should include a description of the pain, PQRST has been described for this purpose:

P: Palliative or Provocative factors, ‘what makes it less intense?’
Q: Quality, ‘what is it like?’
R: Radiation, ‘does it spread anywhere else?’
S: Severity, ‘how severe is it?’
T: Temporal factors, ‘is it there all the time, or does it come and go?’

Pain measurement

A number of different rating scales have been devised to attempt to methodically measure pain and to allow patient follow-up. These have been used in research, audit and in clinical practice. They all rely on a subjective assessment of the pain and therefore make inter-individual comparisons difficult. Additionally, pain is a multidimensional complex phenomenon and is not adequately described by one-dimensional scales, however there is value in making some sort of an assessment to aid clinical practice.

- Categorical scales e.g., verbal rating scales: mild, moderate, severe pain
- Visual analogue, Likert or Numerical Rating scale (VAS)
- Complex pain assessment compendiums e.g., Brief Pain Inventory (BPI), McGill Pain Questionnaire [423-425]

The BPI consists of several visual analogue scales grouped together assessing pain at rest, on movement, and other aspects of the pain including interference with function and effect on work. The McGill Pain Questionnaire measures pain quality by asking patients to rate the intensity of 15 verbal descriptors of pain on a 0 to 3 rating scale. The pain rating index is composed of 2 scores, including a sensory pain score and an affective pain score. Some versions also use a standard pain intensity VAS.

2. PHARMACOLOGIC MANAGEMENT OF CHRONIC PELVIC PAIN

Physicians using pharmacologic measures to control BPS pain must be committed to the following principles [426]:
1. Drugs are prescribed and monitored with knowledge of the patient's history and risks.
2. Patients understand potential benefits and harms and participate in reducing harms.
3. Clinicians assess outcomes for both effectiveness and harms.

**a) Non-acidic antipyretic analgesics**

Acetaminophen (paracetamol) is the main representative of this group. It has antipyretic activity and is a simple analgesic. There is very little evidence about its role in chronic pelvic pain [427,428]. Acetaminophen should be considered for only mild pain. Acetaminophen is a common cause of hepatotoxicity [429,430] and risk increases with alcohol use [431].

**b) Acidic antipyretic analgesics**

The classical non-steroidal anti-inflammatory drugs (NSAIDs) fall into this group and include salicylic acid. They are known to act on the cyclooxygenase (COX) enzyme. The early NSAIDs tended to have little selectivity for COX2 over COX1, and are therefore said to be associated with more side effects than the newer COX2 selective inhibitors [432]. The COX1 enzyme is mainly involved in normal 'housekeeping' functions, such as mediating gastric mucosal integrity, and renal and platelet function. Blocking the COX1 enzyme is the cause of the platelet, gastric and renal complications that can occur with NSAIDs. It has been suggested that the COX2 enzyme is inducible as a result of tissue damage, and that it is the main enzyme involved in inflammation and peripheral sensitization of nociceptors [433]. As a result, the analgesic efficacy of COX2 selective drugs should be as good as that of the nonselective drugs, however the benefit is primarily seen in acute inflammatory type pain. The selective COX2 agents should not be prescribed in patients with increased risk of cardiovascular disease including congestive cardiac failure [434]. There is very little evidence for a role of NSAIDs in the management of chronic pelvic pain and even less evidence for a role for the COX2 selective drugs. Most of the analgesic studies have investigated dysmenorrhoea in which NSAIDs have been found to be superior to placebo and possibly paracetamol [428,435].

For practical purposes the NSAIDs may be divided into:

1. Non-selective, low potency (e.g. salicylic acid, ibuprofen).
2. Non-selective, high potency (e.g. ketoprofen, diclofenac, ketorolac).
3. COX2 selective drugs (e.g celecoxib).

Non-selective, low potency NSAIDs can be used as first-line analgesics [436]. They are most likely to be of help if there is an inflammatory component to the pain. More potent NSAIDs should be reserved for those conditions in which the low potency drugs have been tried and failed to produce significant benefit. COX2 selective drugs should be used with caution as an alternative to the non-selective drugs where there is an increased risk of gastric complications. They should be avoided in patients with known cardiovascular disease. NSAIDs should be taken with food and consideration must be given to the use of gastric protective agents. The benefits of the NSAIDs must be demonstrated to outweigh the risks. All NSAIDs are contraindicated in active gastrointestinal ulceration/bleeding and renal disease. They may seriously exacerbate asthma and produce fluid retention. Even if stronger analgesics such as opioids are added, the NSAIDs can be continued as they are likely to have a synergistic action improving pain control above and beyond that obtained with opioids alone [437].

**c) Neuropathic analgesics**

1. **Tricyclic Antidepressants**

Tricyclics have a definite analgesic effect on neuropathic pain compared with placebo [438]. 30% of patients should obtain more than 50% pain relief; 30% will have minor adverse effects; and 4% will have to stop treatment because of side effects. Tricyclics are said to work in doses that are too low to affect mood. They may work by increasing levels of norepinephrine and/or serotonin. They also have actions at sodium channels. They are extensively used for pelvic pain and good evidence exists to justify their usage [290,439]. A recent randomized placebo controlled study sponsored by the US National Institutes of Health [246] evaluated increasing doses of amitriptyline with or without standardized education and behavioural modification in treatment naïve patients with IC/PBS. While this study did not confirm the overall benefit of amitriptyline plus education and behavior modification was superior to only the education and behavioral changes, they did show that amitriptyline may be beneficial in persons who can achieve a daily dose of 50 mg or greater.

2. **Serotonin Reuptake Inhibitors**

Selective serotonin reuptake inhibitors appear to be less effective for the management of pelvic pain [440]. Fluoxetine can increase plasma levels of amitriptyline and induce toxicity, and therefore care must be exercised if the drugs are combined.

Anticonvulsants have been used in the management of pain for many years.

3. **Anticonvulsants**

Gabapentin and pregabalin have recently been introduced for pain management. There is evidence to show that both compounds are effective in chronic neuropathic pain [441,442]. Whereas...
there is little evidence to support the use of anticonvulsants in the management of genitourinary pain, they should be considered if there is a suggestion of neuropathic pain or central sensitization [275,443-445].

N-methyl-D-aspartate (NMDA) antagonists. Ketamine is thought to act primarily at the NMDA receptor, though it may also have actions at sodium channels, as well as opioid (kappa and mu) receptors [446]. Ketamine has been shown in both human [447] and animal models [448] of neuropathic pain to reduce central sensitization and wind-up. Ketamine has been found to be useful in a number of chronic pain states including: peripheral neuropathies with allodynia, stump and phantom pain, central pain, as well as fibromyalgia [449-453] However it has become evident that ketamine should only be used with caution (or not at all) by an experienced practitioner trained in its use. Ketamine is a street drug of addiction and has recently been associated with disastrous bladder consequences, the so-called ketamine bladder. [454]

4. **Opioids**

There is now a general acceptance that opioids have a role in the management of chronic non-malignant pain [455]. While the use of opioids in urogenital pain is poorly defined, they should be considered for patients with BPS in whom all other treatments to reduce pain have failed. Opioid use does present very real risks and potential harms [284] and include overdose, addiction, and opioid diversion and prescribers have an obligation to assess risks and minimize harms. Unfortunately, not enough is known about the long-term benefits, risks, and side effects of opioid therapy, not only in IC/PS, but other chronic non-cancer pain conditions. More research is needed in this area. The following guidelines for the use of opioids in chronic/non-acute urogenital pain are suggested by the European Association of Urology [436].

1. All other reasonable treatments must have been tried and failed.
2. The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (preferably the patient’s family doctor).
3. Where there is a history or suspicion of drug abuse, a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
4. The patient should undergo a trial of opioids.
5. The dose required needs to be calculated by careful titration.
6. The patient should be made aware (and possibly give written consent): I. that opioids are strong drugs and associated with addiction and dependency
   II. the opioids will normally only be prescribed from one source
   III. the drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period
   IV. the patient will be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed and that non-prescribed drugs are not being taken
   V. inappropriate aggressive behaviour associated with demanding the drug will not be accepted
   VI. hospital specialist review will normally occur at least once a year
   VII. the patient may be requested to attend a psychiatric/psychology review
   VIII. failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic, analgesic opioids being stopped.

- **Morphine.** There is no compelling evidence that one opiate is better than another. Morphine has, however, become the traditional gold standard. Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. The drug should be prescribed in a slow release/modified release form. Short-acting preparations are undesirable and should be avoided where possible. Parenteral dosing is undesirable and should be avoided where possible. In an acute situation, the daily morphine requirement may be calculated by titration of the drug with progressively increasing doses of 4-hourly rapid-release morphine. However, in most cases, starting with a low dose of slow-release morphine and confining the increments to occur at intervals of no less than 3 days to 1 week is adequate. Chronic non-cancer pain can be managed effectively in most patients with dosages at or below 200 mg/day of morphine or equivalent.

- **A fentanyl patch** can be used when oral absorption is restricted or when the patient suffers from nausea and vomiting. Patches are generally changed every 72 hours. The problem with the currently available patches is that the dosing increments between patches are large. Care needs to be exercised when increments in dose are undertaken. Fentanyl has contributed to numerous overdose deaths [456,457].

- **Methadone** is a strong analgesic which has a long track record [458]. While it may have a useful role in the management of urogenital pain, there is very little science to support this. Methadone has the
tendency to accumulate with repeated dosing and cause delayed respiratory arrest. Therefore, whereas it may be a very useful drug, it should only be prescribed by a practitioner familiar with its use as an analgesic. Methadone as an analgesic is usually prescribed 6 hourly as its analgesic action is relatively short-lived compared with the longer benefits seen from using the drug in drug addiction.

- **Meperidine** (Demerol) 300 mg intramuscular (i.m.) is about as effective as morphine 30 mg i.m. (conversion factor 0.1). Its oral bioavailability is, however, poor. Meperidine has a short duration of action, can accumulate with multiple dosing and is therefore not recommended for use in chronic, non-acute pain [459].

- **Oxycodone**, hydromorphone and hydrocodone are available as slow/modified-release preparations. They may be useful for opiate rotation if side effects or tolerance is a problem. They are powerful opioids and should be used with the same caution as morphine. 20 mg of oxycodone and 6 mg hydromorphone is equivalent to 30 mg of Morphine (1.5 and 5 X conversion factor). Oxycodone, hydromorphone and hydrocodone may have a higher abuse liability than morphine [460].

- **Codeine** is a less potent opioid than morphine and the other opioids discussed and could be useful in mild to moderate pain. 20 mg of Codeine is equivalent to 30 mg of morphine (conversion factor 0.15). Tramadol produces analgesia by two mechanisms: an opioid effect; and an enhancement of serotonergic and adrenergic pathways [461,462]. It has fewer of the typical opioid side effects (notably, less respiratory depression, less constipation and less addiction potential) [463]. Morphine dose equivalences with tramadol has not been reliably established. Codeine and tramadol may have a lower abuse risk than more potent opioids [460,464].

**Opioid Recommendation:**

A stepped approach to opioid selection should be based on a patient’s clinical profile and individual characteristics and should proceed in a stepwise fashion. First line therapy for mild to moderate pain would include codeine or tramadol while second line therapy for mild to moderate pain could include morphine, oxycodone or hydromorphone. First line therapy for severe pain would include these same agents, morphine, oxycodone or hydromorphone while second and third line therapy for severe pain could include fentanyl and methadone respectively. It is important to determine the optimal dose, i.e., a dose that will improve function or reduce pain intensity by at least 30% without causing major adverse effects or complications. It is recommended to start the opioid trial with a low dose and increase the dose in small quantities over several days or weeks carefully monitoring for effectiveness (or plateauing of response) and adverse effects or complications. Opioids produce a graded analgesic response: the patient experiences the greatest benefits at lower doses and a plateauing of analgesic response and adverse effects at higher doses.

**Recommendation Pain Treatment**

BPS patients deserve to have their chronic pain treated. There are few well controlled long term pain therapy studies in this area, therefore most of our recommendations must come from studies in other non-cancer pain conditions. As discussed in the previous sections, management of symptoms of BPS, including the chronic pain must start with conservative therapies along with BPS condition-specific treatments. For those whose chronic pain is refractory to these therapies including standard analgesics, therapy for the chronic pain should normally start with a tricyclic and/or gabapentinoid (gabapentin or pregabalin), followed by addition of an opioid such as codeine, tramadol, morphine or oxycodone as a last resort. **Level of Evidence: 4**

**Recommendation: C**

**XIII. SURGICAL THERAPY**

**Bladder Pain Syndrome (BPS) is a chronic and debilitating disease. Major surgical options should be considered only when all conservative treatment has failed** (Table 6) The patient should be informed of all aspects of surgery and understand consequences and potential side effects of surgical intervention. An experienced surgeon familiar with the particular surgical technique should perform the procedure.

**Table 6: surgical therapies rated according to the Oxford System**
1. HYDRODISTENTION

Bladder distention has been used for many years [465] not only as a diagnostic/ classification tool but also for treatment of BPS. In 1957 Franksson reported on a retrospective series of 33 patients, with symptom improvement in all, and lasting up to 1 year in 7 patients[466]. Reports from the seventies were contradictory. Using the Helmstein method [467] Dunn reported complete absence of symptoms in 16 of 25 patients[468], while Badenoch found no improvement in 44 of 56 patients[312]. More recent literature reports poor results with only a minority of patients reporting a small improvement in symptoms for a relatively short period of time[217,218,232,469]. Most studies are retrospective and uncontrolled.

Level of evidence 3; recommendation C

2. TRANSURETHRAL RESECTION

In his first papers Hunner described open resection of the bladder ulcer in the treatment of patients with IC[5]. He later abandoned this treatment due to operative morbidity and recurrence of symptoms. Results of transurethral resection were originally reported by Greenberg et al.[470] and Fall[471]. The retrospective results of this treatment in 116 patients with Hunner’s lesion from Fall’s Swedish clinic was later reported by Peeker et al.[472]. Hunner’s lesion was first recognized by bladder distension under general anesthesia. All lesions were then resected including at least half of the underlying muscular coat. Large areas of the bladder might be treated to resect all diseased tissue. Ninety-two of the 116 patients experienced amelioration of their symptoms. Average duration of symptom alleviation was 23 months ranging from 0-180 months. Up to 16 resections were performed if symptoms recurred. This is the only center having reported a large clinic series of patients with BPS treated in this manner. Shanberg and Malloy reported in 1987 on laser fulguration of 39 patients with BPS[473]. Nineteen of 39 had Hunner’s lesion. Of the 19 patients with Hunner’s lesion 17 reported good pain relief lasting between 6 and 18 months. In the 20 patients without Hunner’s lesion, reddened areas in the bladder were photoagulated with the Neodymium:Yag laser. Thirteen felt marked improvement of symptoms but time to symptom recurrence was not reported. Small bowel perforation in 2 patients was the most important complication in this series. This series was extended to 76 patients [474] where 21 of 27 patients with Hunner’s lesion (BPS ESSIC type 3X) experienced symptom improvement; 12 had relapse within 18 months. Of patients with BPS ESSIC type 1 or 2, 20 of 49 improved but 10 required further therapy within 1 year. Rofeim et al. [475] reported on Nd:YAG laser ablation of Hunner’s lesion in 24 patients with BPS type 3X. All had symptom improvement within days without complications. Pain, urgency, nocturia, and frequency were improved after 23 months, but relapse in 11 patients required up to four additional treatments.

Payne et al. reported on 14 patients with Hunner’s lesion treated by cystoscopic ablation. Eight became symptom free and 4 improved symptomatically more than 50%. Four had symptomatic recurrence with improvement after repeat ablation[476]. Intravesical, submucosal injection of triamcinolone has in uncontrolled studies been reported to have as good symptomatic effect as resection/fulguration[477].

Transurethral resection, coagulation, or laser ablation of Hunner’s lesions is a recommended treatment for patients with BPS type 3X.

Level of Evidence: 3 Grade of Recommendation: C

3. CYSTOLYSIS – PERIPHERAL DENERVATION

Hunner [5] simply dissected bladder from surrounding tissue. Initial results were encouraging, however after 3 years of follow-up, symptoms recurred. Worth and Turner-Warwick [478] attempted to do more formal cystolysis and were more successful with regard to symptoms. Worth [479] followed patients up to 7 years and found bladder areflexia to be a significant complication of this procedure. Patients had to use Credé technique or even be on intermittent self-catheterisation. Albers & Geyer [480] reported symptom recurrence after 4 years in most of the patients.

• Cystolysis – peripheral denervation is not indicated for BPS; Level of Evidence: 3 Grade of Recommendation: -A (not recommended)

4. SYMPATHETIC DENERVATION

Visceral pain is transmitted in most cases by the sympathetic nervous system. Gino Pieri [481] applied this principle to the bladder pathology and suggested resection of the superior hypogastric plexus (presacral nerves), paravertebral sympathetic chain, and gray rami from S1-3 ganglia (Level 4). This was repeated by Douglass [482] a few years later. Immediate results were very good; however Nesbit [483] showed that the long term results were short lived.

• Sympathetic denervation is not indicated for BPS
Level of Evidence: 4 Grade of Recommendation: -A (not recommended)

5. PARASYMPATHETIC DENERVATION

Based on the contribution of S2-S4 segments to bladder innervation, Moulder and Meirowsky [484] used S3 neurectomy in 3 patients with good long term follow-up. Larger series were reported by Miller [485] and Mason[486] but results after five years were not encouraging. To improve results selective dorsal sacral root neurectomy, unilateral or bilateral, was introduced by Bohm and Franksson[487]. The outcomes of this procedure were unclear.
• Parasympathetic denervation is not indicated for BPS;

Level of Evidence: 4 Grade of Recommendation: A (not recommended)

6. BOWEL SURGERY

a) Bladder augmentation-cystoplasty has been commonly used for refractory BPS for 50 years. First reports of ileocystoplasty from 1958 were very promising[488]. Later publications were less sanguine with good results varying from up to 100% [489,490] to 25%[312,491]. Cystoplasty is usually done with or without bladder resection.

Cystoplasty alone was reported as early as 1967 by Turner-Warwick and Ashken[492], advocating augmentation with removal of the diseased tissue. Several subsequent studies indicated that cystoplasty with subtrigonal cystectomy offers better results than without subtrigonal cystectomy[490,493-495]. These were all retrospective studies and conclusions should be taken with reservation. Cystoplasty with partial or total removal of the bladder requires bowel tissue substitution. Different bowel segments are used to enlarge the bladder. It is the general consensus that the intestine segment used for bladder augmentation should be detubularized[496]. Experiences with different bowel segments have been reported in numerous articles with level 4 evidence:

- Ileum [312,489,490,495,497-501]
- Ileocecum [344,490,491,493,502,503]
- Cecum [489,504]
- Right colon [312,490,505]
- Sigmoid colon [493,495,499,502]
- Gastric segments [506,507]

There is no significant different between different bowel segments with regard to outcome except for gastric tissue substitution which is associated with dysuria and persistent pain due to production of acids.

b) Cystoplasty with Supratrigonal Resection (i.e. trigone-sparing) has been reported in various studies. Von Garrelts[489] has described excellent results in eight of 13 patients with a follow-up of 12-72 months. Bruce et. al [495] reported satisfactory relief of BPS symptoms by ileocystoplasty and colocystoplasty in eight patients. Dounis and Gow [508] reported improvement in pain and frequency in seven BPS patients after supratrigonal cystectomy with ileoccecal augmentation. Kontturi et. al [493] used segments of colon and sigmoid colon in 12 cases with 100% symptom-free outcome in five patients augmented with sigmoid colon over 4.7 years of follow-up. Two of seven cases augmented with colon required ileal conduit and cystectomy. Linn et. al [509] followed six BPS patients for 30 months, and reported that all were symptom-free and voided spontaneously. The report by Nielsen et. al [491] was less favorable. Six out of eight patients had good results. Van Ophoven et. al [510] reported the long-term (mean 5 years) results of orthotopic substitution enteroplasty in 18 women with BPS, using ileocecal (n = 10) or ileal (n = 8) segments with only two failures. In the group [511] augmented with ileum, three patients required self-catheterization and one a suprapubic catheter. Peeker et. al [512] found that patients with end-stage ulcerative BPS had excellent results following ileocystoplasty but not so the patients with non-ulcer disease. A follow up on this paper was recently published [180] with the same conclusion for the patients with end stage BPS ESSIC type 3C, while both continent diversion and illocystoplasty were unrewarding in patients with type 2X BPS. Patients with low cystoscopic capacity (<200 ml) under general anaesthetic have achieved better results [7,25,513,514].

There is some weak evidence that cystoplasty with supratrigonal resection may benefit some selected patients with end stage ESSIC type 3C BPS.

Level of Evidence: Level 3; Grade of Recommendation: C

c) Cystoplasty with Subtrigonal Cystectomy — orthotopic continent bladder augmentation (i.e. with trigone removal but preservation of the bladder neck) in the management of BPS has been reported less often[511,515-517]. Because of the need of ureteral reimplantation, it is associated with some risks of urine leakage, urethral stricture and reflux[516]. Linn et. al [509] had three failures in 17 patients and half of the patients with good symptomatic response required self catheterization. Nielsen et. al [491] had better results following orthotopic substitution with low bladder capacity (200 mL versus 525 mL, respectively). Orthotopic continent bladder augmentation, particularly when removing the trigone, may cause incomplete voiding requiring intermittent self-catheterization. Therefore patients considering such procedures should be advised accordingly and must be considered capable of performing, accepting and tolerating self catheterization. Nurse suggested that the decision on whether to due a subtrigonal or supratrigonal cystectomy be based on the results of trigonal biopsy, with the former procedure indicated in the patient with trigonal inflammation[518].

There is no compelling evidence that subtrigonal cystectomy with cystoplasty has any outcome advantage over supratrigonal cystectomy but it tends to be associated with more complications and poorer functional bladder rehabilitation. Level of evidence: 3; Grade of Recommendation: C

7. URINARY DIVERSION WITH OR WITHOUT TOTAL CYSTECTOMY AND URETHRECTOMY

This is the ultimate, final and most invasive option. It should be used as a last therapeutic resort in selected
patients. Techniques include simple or continent urin ary diversion. Continent diversion may be preferable for cosmetic reasons in younger patients.

Simple urinary diversion with formation of an ileal conduit is the most common surgical treatment for BPS [519]. Initially, diversion can be done without cystectomy and only when bladder pain is persistent, cystectomy may be considered. Bladder de-functionalization alone produced symptom-relief in several reports. [7,25,312,520,521]

Often diversion is performed as a next step after unsuccessful bladder augmentation. To avoid further bowel resection, a bowel segment used for cystoplasty can often be converted to a conduit [522] in some patients chronic inflammatory changes have been seen in the cystoplasty pouch resembling interstitial cystitis [7,312,523,524], preventing one from using this technique. Similar bowel changes however have been described when cystoplasty is performed for pathology other than interstitial cystitis, suggesting that these pathologic findings are not a direct result of the exposure of bowel to BPS urine [525]. Relatively good responses to diversion without cystectomy have been reported in small series. [491,526]

Urinary diversion with and without cystectomy may be the ultimate option for refractory patients. Continent diversion may have better cosmetic and lifestyle outcome but recurrence of pain in the pouch is a real possibility. Level of Evidence: 3; Grade of Recommendation: C

XIV. CLINICAL SYMPTOM SCALES

Symptom scales have enabled patients to be categorized by symptom severity and have also served to follow results of treatment in patients with bladder pain syndrome. Their future development may enable a presumptive diagnosis of the syndrome but at this time that is not possible. A brief survey that reliably segregates BPS from other urologic disorders would make the ability to diagnose the syndrome reliable, inexpensive, and available to all healthcare providers. It would aid in epidemiologic studies as well. Currently such work sponsored by NIDDK is ongoing. www.mappnetwork.org

A process for development of a case definition for BPS has been developed by adapting the RAND/University of California, Los Angeles Appropriateness Method. [46] This involves a panel consisting of nine experts with experience in BPS and related diseases, literature review of case definitions of BPS, initial ratings of symptoms as indicators of the BPS diagnosis, and discussion and a second set of ratings to establish criteria for diagnosis through patient reports. Symptom questionnaire development, based on the results of the case definition exercise, and validation have been successful in establishing a population-based estimate for disease prevalence using both high specificity and high sensitivity models. [69] If this could be adapted for use in screening by primary care physicians, the potential benefits in early diagnosis of BPS are evident.

Questionnaires and symptom scales are currently utilized to measure treatment outcome and are especially valuable in clinical research studies as well as for guiding therapy for individual patients.

There are 3 published BPS symptom questionnaires: the University of Wisconsin IC Scale (Figure 11), the O’Leary-Sant IC Symptom Index (ICSI) and IC Problem Index (ICPI) (Figure 12), and the Pelvic Pain and Urgency/Frequency (PUF) Scale (Figure 13).

The University of Wisconsin IC Scale includes 7 BPS symptom items and has not been validated for identification or diagnosis of BPS. It captures severity of symptom expression [527,528]. Unlike the other two instruments, it addresses some quality-of-life issues, and this is an advantage when such issues are subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation.

The O’Leary-Sant indexes are validated questionnaires that were originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to BPS patients and asymptomatic controls [529,530]. The questionnaires center on 3 questions related to urgency/frequency and one on bladder-associated pain. It does not address generalized pelvic pain or symptomatology associated with sexual activity. This is not because these questions were not considered in the formulation of the questionnaire. Of 73 questions in the preliminary instrument covering domains of urinary symptoms, pain, sexual function, menstrual variability, and general health, only the four questions now in the instrument were needed to reliably and validly describe the illness experience of those with IC and distinguish these patients from those without the disorder [531].

The Pelvic Pain, Urgency, Frequency (PUF) questionnaire [201] was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by patients who are affected by this disorder. One-third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum.

The PUF is marred by the fact that patients were not included in its development. If used to monitor outcomes, question 4 regarding sexual activity may worsen the score as the outcome improves. These and other problems make its use highly dubious. [532]

A large study utilizing the PUF questionnaire has concluded that up to 23% of American females have BPS [201]. This makes one wary as to the utility and
The face-validity of the PUF[533]. A total score of 10-14 =74% likelihood of positive potassium test (PST); 15-19=76%; 20+=91%. To the extent that the PST is suspect, the reliability of PUF data comes into question.

Neither the PUF nor O’Leary Sant questionnaires have been shown to be of value in diagnosis of the individual patient[534]. In an interesting epidemiologic study in Finland, Leppilahti and colleagues randomly selected 2000 participants from the Finnish population registry and administered the O’Leary Sant IC symptom and problem index[64]. Women with symptom scores 7 or higher with no history of urinary tract infection in the preceding month were invited to undergo clinical examination. Of these 32 women, 21 underwent examination of whom 3 had probable interstitial cystitis and 4 had possible interstitial cystitis. Based on this specificity, a population prevalence in Finnish women of 230/100,000 probable interstitial cystitis and 530/100,000 possible interstitial cystitis was calculated. Thus, one can get some idea as to O’Leary Sant specificity. For probable BPS it would be about 14% using a parameter of 7 or greater on the symptom index.

The O’Leary-Sant and University of Wisconsin instrument correlate strongly in a large population of patients with BPS.[535] Clemons and co-workers administered the ICSI to 45 patients scheduled to undergo laparoscopy for pelvic pain. Seventeen were diagnosed with BPS based on the finding of glomerulations on bladder distention associated with urgency, frequency, or nocturia. A score of 5 on the ICSI had a 94% sensitivity and a 93% negative predictive value in this enriched population of patients with pelvic pain[536]. However, Clemons and colleagues have found a high degree of overlap in International Prostate Symptom Scores, the O’Leary Sant Symptom Index, and the Chronic Prostatitis Symptom Index in a random sample of over 1400 men and women with urologic symptoms, underscoring that we should be cautious in using these questionnaires as a basis for diagnosis in epidemiologic studies[537].

Rosenberg and Hazzard[62] surveyed 1218 consecutive patients presenting to their primary care office and found 7 (0.6%) who had a 7 ICSI score. Likely BPS was noted in 12.6% of patients on the PUF scale, a Figure 21 times higher, suggesting that either the PUF drastically overestimates BPS, or the ICSI lacks sensitivity. Based on the correlation of the potassium sensitivity test and the PUF questionnaire, Parsons[49] stated that 30.6% of 3rd year female medical students at his California institution had probable BPS. Sahinkanat and co-workers[202] in Turkey administered the PUF questionnaire to all 442 female textile workers in two local factories. Eighty-six per cent of those with a PUF score 7 or greater had an 86% positive rate of PST testing verses 9% positive in the group with PUF less than 7. They extrapolated that bladder epithelial permeability dysfunction was present in 32.8% of these unselected women. The ICSI estimate seems much more in line with current epidemiologic data.

While perhaps not ideally suited for epidemiologic studies, these questionnaires can reveal important
Interstitial Cystitis Symptoms Index During the past month:

How often have you felt the strong need to urinate with little or no warning:
0. __ Not at all
1. __ Less than 1 time in 5
2. __ Less than half the time
3. __ About half the time
4. __ More than half the time
5. __ Almost always

Have you had to urinate less than 2 hours after you finished urinating?
0. __ Not at all
1. __ Less than 1 time in 5
2. __ Less than half the time
3. __ About half the time
4. __ More than half the time
5. __ Almost always

Interstitial Cystitis Symptoms Index During the past month:

How often did you most typically get up at night to urinate?
0. __ Not at all
1. __ Once per night
2. __ 2 times per night
3. __ 3 times per night
4. __ 4 times per night
5. __ 5 or more times per night

Have you experienced pain or burning in your bladder?
0. __ Not at all
1. __ A few times
2. __ Fairly often
3. __ Usually
4. __ Almost always

Interstitial Cystitis Problem Index During the past month how much has each of the following been a problem for you.

Frequent urination during the day?
0. __ No problem
1. __ Very small problem
2. __ Small problem
3. __ Medium problem
4. __ Big problem

Getting up at night to urinate?
0. __ No problem
1. __ Very small problem
2. __ Small problem
3. __ Medium problem
4. __ Big problem

Need to urinate with little warning?
0. __ No problem
1. __ Very small problem
2. __ Small problem
3. __ Medium problem
4. __ Big problem

Burning, pain, discomfort, or pressure in your bladder?
0. __ No problem
1. __ Very small problem
2. __ Small problem
3. __ Medium problem
4. __ Big problem

Add the numerical values of the checked entries:
Total score
epidemiologic data. Porru and colleagues[538] compared University of Wisconsin scores including both urinary and non-urinary symptoms, for 30 BPS female patients and 30 female controls. While the IC group had significantly higher scores for the urinary symptoms, they did not appear to indiscriminately report higher scores than controls for different somatic and general complaints, as might be expected if this disease is a manifestation of a more generalized disorder. Diggs and colleagues[539] used the ICSI to investigate how interstitial cystitis patients interpret urgency. The ICSI question regarding: “the strong need to urinate with little or no warning” consistently underestimated the response to the International Continence Society definition of urgency: “the compelling urge to urinate that is difficult to postpone.”

Treatment outcome studies have also used the Global Response Assessment (Figure 14); a balanced patient self-report on overall response to therapy, developed for NIDDK sponsored multicenter therapeutic trials[301]. The O'Leary Sant and University of Wisconsin questionnaires are responsive to change over time in patients with BPS and have been recommended as secondary endpoints in future clinical trials of the disorder. Propert and colleagues in the Interstitial Cystitis Clinical Trials Group determined that a 1.2 point change in the O'Leary Sant indexes and a 3.1 point change in Wisconsin IC inventory corresponded to a one-category change in the GRA. Individual symptoms were also responsive [540].

A self-report measure that reliably identifies moderate to severe bladder pain syndrome patients for inclusion into clinical trials was recently reported by Pfizer Inc. [532]. Whether it will have value in diagnosis of the syndrome or following patients' clinical course remains to be seen. A quality of life scale for women with BPS has also been developed for use in clinical trials and reportedly can be used to examine the effects of psychosocial and treatment interventions on quality of life.[541]

Conclusions

The three commonly employed clinical symptom scales include the O'Leary Sant, the University of Wisconsin, and the Pelvic Pain, Urgency, Frequency scales. None of the questionnaires have the sensitivity or specificity to be used in the clinical diagnosis of patients. The O'Leary Sant and University of Wisconsin indexes have been validated as reliable instruments for following the course of the disease and results of treatment interventions. All have shown some value in assessing the severity of disease. The Global Response Assessment has become one of several primary endpoints used in judging the response to specific therapies.

**XV. OUTCOME ASSESSMENT**

1. THE PROBLEM

BPS/IC has been a difficult condition for which to assess therapeutic impact. There is a 50% inci-
dence of temporary remission unrelated to therapy, with a mean duration of 8 months [52]. A somewhat surprising finding from the Interstitial Cystitis Database was that although there was initial improvement in symptoms partially due to regression to the mean[542] and the intervention effect, there was no evidence of a long-term change in average symptom severity over the four year course of follow-up[98]. In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, patients are desperate and often seem to respond to any new therapy. A skeptical view of outcomes is essential (Figure 15), as patients can be victims of unorthodox health care providers using unproven forms of therapy, some medical, some homeopathic, and some even surgical.

2. THE PLACEBO ISSUE

Where possible, the results of randomized controlled studies should be used for decision making. Placebo, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy.

Placebo effects influence patient outcomes after any treatment which the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects.[98,543-545] Unfortunately, few BPS treatments have been subjected to a placebo-controlled trial. This is not to say that what seems effective is not, but rather that a high index of skepticism is healthy, even in treatments tested in controlled trials.[546]

While in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value[547], a good case for true placebo comparison can readily be made for BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that it is not life threatening, mean that there is little to lose and much to gain by subjecting new treatments to the vigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (though generally unproved) therapies. It has long been recognized in protocols that use subjective criteria for assessment that “improvement” may be expected in up to 35% of placebo-treated patients[548]. As the spontaneous remission rate (though temporary) for BPS is 11%[311] to 50%[52], combined with the placebo improvement it can be difficult to prove efficacy.

Even in placebo controlled trials, it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over placebo.[549,550] Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials.[551] When occurring late in a study after one would expect onset of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in BPS and any disorder where primary outcomes may be subject to patient-specific psychological and physiological factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also where delay in treatment has been shown to result in disease progression[552-554]. However, there are methodological concerns with equivalence and non-inferiority active agent comparison trials[555]. These include an inability to determine if the treatments are equally good or equally bad, and the possibility that successive non-inferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied[556].

The value of placebo-controlled trials is aptly illustrated by the recent decisions by pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for BPS[557,558] after placebo-controlled trials failed to establish efficacy. These include low concentration hyaluronic acid (Bioniche, Canada), high concentration hyaluronic acid (SKK, Tokyo), and resiniferatoxin (ICOS, Bothell, Washington, USA). Nalmefene, an initially promising oral therapy in the 1990’s,[559] also failed phase 3 trials (IVAX, Miami). Placebo trials are impractical in surgery and it can be difficult to evaluate surgical reports. The many older medications currently used off-label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off-label often requires dependence on the largesse of government agencies like the National Institute of Health [301,395,560].

+2: Moderately improved
+3: Markedly improved

Figure 14: Global Response Assessment (GRA)
Figure 15: Selected reported treatment outcomes in uncontrolled studies in IC literature: Percentage of patients initially improved.
3. OUTCOME INTERPRETATION

As has been discussed with regard to rheumatologic disorders[561], the interpretation of measurements of physical functioning in clinical trials should consider the composition of the study sample, with attention to the stage of disease and the heterogeneity in disease duration. Patients with long-standing disease or compromised bladder capacity or central sensitization can be expected to be less responsive to treatments directed toward the bladder itself. Finally, when considering objective changes, the concept of statistical versus clinical significance is paramount. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement[562]. As Gertrude Stein reportedly stated, “A difference, to be a difference, must make a difference”. An increase in bladder capacity of 30cc may be statistically significant but clinically irrelevant. Number needed to treat and number needed to harm data[563] may be particularly important in BPS and have not typically been included in efficacy analysis.

4. IMMPACT RECOMMENDATIONS

The core outcome domains for chronic pain clinical trials have been published.[423,564] The Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommendations indicate that core outcome domains should be considered in all clinical trials of the efficacy and effectiveness of treatments for chronic pain. These domains include:

1. Pain
2. Physical functioning
3. Emotional functioning
4. Participant ratings of improvement and satisfaction with treatment
5. Symptoms and adverse effects, participant disposition

CONCLUSIONS:

Currently for BPS/IC there are no accepted biologic disease markers that can be used for the assessment of response to therapy. The O'Leary Sant, University of Wisconsin, and Global Response Assessment are well-validated questionnaires to follow disease progression and response to therapy. The IMMPACT recommendations suggest that, as well as symptoms scores, any future study on a pain syndrome must involve more general assessments of psycho-physical functioning. There is limited experience in BPS/IC for the use of well-validated measures available for the study of chronic pain. Future NIDDK research initiatives may help to rectify this. http://www.mappnetwork.org

LEVEL 2 GRADE C RECOMMENDATIONS

XVI. PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline. Different groups of “experts” would undoubtedly create different “best practices”.[565] The compromise approach devised by an experienced cross-section of urologists and gynecologists from around the world at the International Consultation on Continence 2004 meeting in Monaco[41] and subsequently modified at the 2008 meeting in Paris[1] has been reviewed and updated by the committee and allows for significant latitude to reflect varying individual practice patterns and to account for patient preference.

An underlying principle is that, where possible, decisions on the treatment of bladder pain syndrome should be evidence based[566]. Unfortunately, high level evidence of efficacy is lacking for many common treatments, either because such studies have not been done, or were done and failed to demonstrate efficacy.[343,567,568]

Another principle is that we should be guided by patient perceived and driven outcomes for bladder pain syndrome, which is, after all, diagnosed on the basis of symptoms after exclusion of confusable diseases. Many patients prefer noninvasive therapies[569], and it would seem reasonable to start with physical therapy and/or oral therapies if conservative non-medical interventions (i.e. education, diet, behavioral modification, stress reduction) fail to result in significant symptom amelioration. Use of surgical therapies should be approached with some caution. It has been reported that women with BPS have had significantly more pelvic surgeries than controls, and the majority were performed prior to diagnosis of BPS, possibly for pain related to undiagnosed BPS.[570,571]

1. HARMONIZATION

With representatives from Asia, Europe, and North America, the Consultation has attempted to create a document that is harmonious with guidelines developed around the world in the last several years, many since the last meeting of the Consultation. The Canadian Urological Association[572], the International Society for the Study of Bladder Pain Syndrome (ESSIC)[2,15], the European Association of Urology[342], the Japanese Urological Association[45], East Asian countries[11], and the American Urological Association[12] all have published
consensus guidelines, many of which have been reviewed in a recent publication[565].

In the Japanese and Asian view, urinary frequency/urgency is the primary symptom, with overactive bladder (OAB) and hypersensitive bladder (HSB) listed as subgroups (with painful bladder syndrome (PBS) as its extreme form)[44]. (Figure 3)

In the European view as reflected in European Association of Urology and ESSIC guidelines, pain is the key symptom, with frequency being secondary to pain, while urgency basically represents a different pathology. American and Canadian guidelines are concordant with the European view. They emphasize pain, pressure, and discomfort perceived by the patient to be related to the bladder and associated with urinary frequency or urgency.

Pathologic afferent activity is a feature in overactive bladder as well as BPS, making the philosophy of the Asian guidelines conceptually attractive. But the knowledge gaps on lower urinary tract sensory functions are tremendous and from a neurophysiologic point of view it may be premature to link the conditions.

As a disorder based on symptoms, it is remarkable that we do not know if sensations described by the patient as pain, urge, or pressure are physiologically different or identical, if they represent various grades of the same pathology, or if this set of terms merely represents linguistically different ways of presenting the same problem. Do cultural differences play a part? Are Asian patients more reluctant to use the word pain to describe the same symptoms?

Cystoscopic and pathologic findings have a more important role in Asia and Europe than in North America, but nowhere do guidelines now recommend invasive procedures like endoscopy with or without biopsy as essential to make a diagnosis of BPS.

The latest algorithms from the European Association of Urology, American Urological Association, and East Asian nations are presented below and illustrate different approaches to a difficult problem. (Figures 16, 17, 18) Opportunities for future harmonization are apparent.

2.INITIAL TREATMENT

Patient education and support, dietary manipulation, stress reduction, nonprescription analgesics, and pelvic floor relaxation techniques comprise the initial management of BPS. It is important at every stage to address the patient’s pain, and understand that at some point in the progression of treatment, referral to a pain specialty clinic may be desirable. When the conservative approach fails, or symptoms are severe and conservative management unlikely to succeed, oral medication, physical therapy, and/or intravesical treatment can be prescribed.

3.SECONDARY ASSESSMENT

If oral or intravesical therapy fails, or before beginning such therapy at the discretion of the clinician, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia. Laparoscopy may be indicated if there is a suspicion of gynecologic disease. Findings of bladder overactivity suggest a trial of antimuscarinic therapy. Findings of a Hunner’s lesion suggest therapy with transurethral fulguration or resection of the ulcer. Distention itself can have therapeutic benefit in up to one-third of patients, though benefits rarely persist for longer than a few months.

4.REFRACTORY BPS

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. These might include neuromodulation, intradetrusor botulinum toxin, or cyclosporine. At any stage of the treatment algorithm, experimental pharmacologic protocols of promising new treatments are reasonable to consider if symptoms warrant and the risk-benefit ratio is acceptable.

The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urine stream. Augmentation (substitution) cystoplasty and urinary diversion with or without cystectomy have been used with good results in very well selected patients.

A treatment algorithm by the Consultation is presented in Figure 19.

Figure 18: Management Guideline of American Urological Association[12].
Figure 19: Algorithm for Diagnosis and Treatment: 2012 International Consultation on Incontinence.
It is the opinion of the committee that, because of the natural history of the disorder, it is best to cautiously progress through a variety of treatments. Whereas the shotgun approach, starting newly diagnosed patients on a variety of simultaneous medications, seems to have many adherents, employing one treatment at a time makes the natural history of the disease itself an ally in the treatment process. If a treatment has no efficacy, it should be stopped. It a treatment results in modest improvement, it should be continued and another treatment option employed in an attempt to further improve symptoms. The goal is to maximize quality of life and dispense with ineffective treatments in a somewhat controlled fashion. The patient and clinician must remember that “perfect is the enemy of good” and expectations should be realistic. One should encourage patients to maximize their activity and live as normal a life as possible, not becoming a prisoner of the condition. Although some activities or foods may aggravate symptoms, nothing has been shown to negatively affect the disease process itself. Therefore, patients should feel free to experiment and judge for themselves how to modify their lifestyle without the guilt that comes from feeling they have harmed themselves if symptoms flare. Dogmatic restriction and diet are to be avoided unless they are shown to improve symptoms in a particular patient.

Level 4 Grade C

XVIII. FUTURE DIRECTIONS IN RESEARCH

The committee believes that further research is needed in the following broad areas:

1. The recent American Urological Association guideline[12] points out numerous areas for which there was not enough information to allow an evidence basis for recommendations, and these areas require further study.

2. Pathology of BPS

3. Biomarker development

4. Immunology of BPS

5. Neurological aspects with particular attention to the relationship of BPS to overactive bladder

6. The relationship of bladder pain syndrome to chronic pelvic pain syndrome (nonbacterial prostatitis)

The majority of current treatments options are still targeting the bladder. However, as said in the AUA guideline, IC/BPS, which was originally considered to be a bladder disease, has now been recognized as a part of chronic pain syndromes. There is a growing body of literature demonstrating that different visceral pain syndromes, as well as pain syndromes in other body regions, and other systemic diseases often occur together in the same patient. Thus, the efforts to understand the pathophysiology and to design therapeutic modalities have recently shifted from an organ-based approach to a more global approach. Therefore, “phenotyping” of the disease conditions would be important to identify “bladder-related” and “non-bladder” (=outside the bladder) components that contribute to the symptoms for improving the treatment efficacy.

For this purpose, following issues require major research initiatives:

1. To improve symptom-based classification to identify the degree of bladder and non-bladder symptoms, for example, based on the responses to local treatment such as lidocaine intravesical application.

2. To identify bladder-specific pathology (urothelial changes, ulcer, hypervasculization, and the potential role of narrow band imaging[574], Neurometer[575] etc.

3. To identify bladder-specific biomarker (NGF or other neurotrophic factors, angiogenic growth factors, urothelial markers such as antiproliferative factor, cytokines/chemokines profile, uroplakin [antibody, splice variant])

4. To identify bladder-specific or systemic immunological process (cytokines/chemokines profile) Identification of these factors could also identify the difference in the disease process between IC/BPS and OAB (=LUTS with and without pain, respectively)

Finally, if we can identify the “bladder-related” and “non-bladder” (=outside the bladder) components that contribute to the symptoms, we should be able to develop the agent(s) to control bladder pain based on its pathology.

Major recommendations of the last Consultation for future directions in research on BPS still have pertinence today. They include:

A) Epidemiological study

i. Develop a reliable screening tool with adequate sensitivity and specificity to conduct epidemiologic research in the general population to study the incidence, prevalence and identify risk factors for the development of BPS.

ii. Establish patient data bases in different regions and conduct longitudinal follow up to understand the natural history of the disease and to examine the differences in disease natural history among regions.

B) Sub-grouping/phenotyping patients.

Patients who have or develop additional pain syndromes, such as vulvodynia, temporomandibular disorder, irritable bowel syndrome, fibromyalgia and
chronic fatigue syndrome, or autoimmune diseases such as lupus erythematosus and Sjögren’s syndrome might have different pathophysiology, natural history and treatment response from those patients without co-morbidities. Sub-grouping patients not only allows us to develop better treatment strategy but also may answer the question: Is BPS an end-organ disease of the bladder or a systemic condition? [37,576] [87] However, to properly phenotype patients, it is necessary to develop an easy-to-use tool for non-specialists to identify those with co-morbidities. It is also important to validate the concept that categorizes all types of pelvic pain into one “chronic urological pelvic pain syndrome”, as some patients’ symptoms involve multiple pelvic organs, concurrently or sequentially along with other body systems.

C) Developing a simple, non-invasive diagnostic test for BPS.

This will most likely involve urinary markers. Urinary markers may help to sub-classify various types of BPS. This test will determine the diagnosis of BPS in the female population, as well as determine the subset of men currently diagnosed with non-bacterial chronic prostatitis/chronic pelvic pain syndrome who may actually have BPS.

D) Develop a practical multi-disciplinary care model.

In addition to physical morbidity (urinary frequency, pain), many BPS patients have associated psychological co-morbidities. [577] These can often be managed by psychological intervention. BPS patients also need help from dietitians and physiotherapists. A practical multi-disciplinary care model, which includes physicians, dietitians, physiotherapists, pain specialists, psychologists, psychiatrists and patient support groups, should be developed and tested in various settings.

XIX. SUMMARY

1. DEFINITION

Bladder Pain Syndrome (in the absence of a universally agreed definition, the European Society for the Study of Interstitial Cystitis –ESSIC definition is given along with the definition of the American Urological Association)

ESSIC: Chronic pelvic pain, pressure or discomfort of greater than 6 months duration perceived to be related to the urinary bladder accompanied by at least one other urinary symptom like persistent urge to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.

American Urological Association Guideline Definition: An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks duration, in the absence of infection or other identifiable causes.

2. BLADDER PAIN SYNDROME (BPS)

a) Nomenclature

The scientific committee of the International Consultation voted to use the term “bladder pain syndrome” for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome.

Properly defined, the term Bladder Pain Syndrome appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP) (see below), and focuses on the actual symptom complex rather than what appears to be long-held misconception of the underlying pathology.

Bladder Pain Syndrome (XXIII-2) (per IASP)

Bladder pain syndrome is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology. Bladder pain syndrome is often associated with negative cognitive, behavioral, sexual, or emotional consequences as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.

b) History / Initial Assessment

Males or females whose symptoms meet the requirements of the definition of bladder pain syndrome should be evaluated. The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms of bladder pain syndrome also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency/volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology, cystoscopy, and urodynamics evaluation are recommended if clinically indicated and/or the diagnosis is in doubt. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and microscopic or gross hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS. Grade of recommendation: C

c) Initial Treatment

- Patient education,
- dietary manipulation,
• nonprescription analgesics,
• stress reduction,
• pelvic floor relaxation techniques comprise the initial treatment of BPS. In the patient with findings suggesting pelvic floor dysfunction, pelvic floor physical therapy with myofascial trigger point release and intravaginal Thiele massage is often an effective therapeutic intervention. The treatment of pain needs to be addressed directly, and in some instances referral to an anesthesia/pain center can be an appropriate early step in conjunction with ongoing treatment of the syndrome.

When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed,

• oral medication or
• intravesical treatment can be prescribed. It is recommended to initiate a single form of therapy and observe results, adding other modalities or substituting other modalities as indicated by degree of response or lack of response to treatment. Grade of recommendation: C

d) Secondary Assessment

If initial oral or intravesical therapy fails, or before beginning such therapy based on clinician judgment, it is reasonable to consider further evaluation which can include Urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia.

• Findings of bladder overactivity suggest a trial of antimuscarinic therapy.
• The presence of a Hunner’s lesion suggests therapy with transurethral resection, fulguration of the lesion, or direct steroid injection into the lesion.
• Distention itself can have therapeutic benefit in 30-50% of patients, though benefits rarely persist for longer than a few months. Grade of recommendation: C

e) Refractory BPS

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include

• neuromodulation,
• intradetrusor botulinum toxin,
• oral cyclosporine A, or
• clinical trials of newly described pharmacologic management techniques. At this point, most patients will benefit from the expertise of an anesthesia pain clinic.

The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream.

• Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients.
• Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series.

Grade of recommendation: C

• Pain management is a primary consideration at every step of algorithm
• Patient enrollment in appropriate research trial is reasonable option at any point
• Evidence supporting neuromodulation, cyclosporine A, and botulinum toxin for BPS indication is limited. These interventions are appropriate only for practitioners with experience treating BPS and willing to provide long-term care post-intervention.

I. INTRODUCTION

Not all incontinence can be cured completely and even those who are ultimately successfully treated may have to live with incontinence for a time, for example, whilst they wait for surgery or for pelvic floor muscle training to yield its benefits. Still others – depending on their frailty, severity of incontinence and personal priorities – may not be candidates for treatment or may choose management over attempted cure. For all such people, the challenge is to discover how to deal with their incontinence so as to minimise its impact on their quality of life. This usually involves using some kind of continence product(s) to control or contain leakage of urine and/or faeces, and/or to manage urinary retention. In short, the possible role of continence products should be considered at each stage of patient assessment and treatment and, if treatment is not available, appropriate, acceptable or (fully) successful – subsequent management. Managing incontinence successfully with products is often referred to as contained incontinence, managed incontinence or social continence, in recognition of the substantial benefits it can bring to quality of life even though cure has not been achieved [1].

This chapter is aimed primarily at healthcare professionals seeking to make informed decisions as they choose – or help their patients to choose - between continence product categories and then select a specific product within their chosen category. We have also aimed to make this information accessible to the user, particularly in the summary and recommendation sections. The chapter includes a section for each of the major product categories, each section reviewing published data and – where possible - identifying evidence-based recommendations for product selection and use. Products designed to deal with skin and odour problems caused by incontinence are also addressed.

The sections on the major product categories are preceded by two others. The first provides overall guidelines for product selection, describing the key elements of patient assessment and suggesting a classification of people with incontinence into a number of broad groups based on gender, age (adult or child) and the nature and severity of their incontinence. A table is provided for each group summarising the user characteristics, priorities and contexts which commonly favour or discourage the use of each of the major product categories available to them. Following these overall guidelines and preceding the sections on the major product categories, a review is provided of the methodological challenges of conducting continence product evaluations and interpreting the results.

Much of the evidence base for product selection and effective use is patchy and so, where there is little published data to provide confident evidence-based advice on an issue commonly raised by patients and caregivers, an expert opinion is offered as the best advice available. The hope is that highlighting knowledge gaps in this way will help stimulate the research necessary to provide more robust evidence-based advice in the future.

To accompany this chapter, the International Consultation on Incontinence and the International Continence Society have collaborated to make the material more generally available via a new website hosted by the International Continence Society at http://www.continenceproductadvisor.org/. The hope is that this will help people with incontinence and their caregivers to make informed choices in selecting appropriate products, and provide them with accessible, evidence-based advice on how to use them effectively.

The literature search strategy to identify material for this chapter additional to that reviewed for the third consultation [2] was conducted as follows. MEDLINE and CINAHL databases were searched from 2008 – 2011 for English language publications. Detailed search strategies were developed for each electronic database searched. Consideration was given to variations in terms used and spellings of terms in different countries so that studies were not missed. Relevant abstracts were examined and then pertinent articles were retrieved and reviewed, and the reference lists searched for further studies.
For product categories associated with little or no research literature, analysis relied on expert opinion from clinical practice papers.

The following main search terms were used: incontinence AND device*, toilet* AND facilities, female, male, urinal*, commode*, bedpan*, urin* AND sheath, condom AND catheter*, incontinence OR absorbent pad*, urinary AND catheter* (in title), urinary AND leg bag* OR legbag* OR drainage bag, faecal OR fecal AND incontinence AND plug OR pouch OR bag OR device, OR manage* system, incontinence OR perineal AND dermatitis OR inflammation.

Selecting suitable continence products is critical for the well-being and quality of life of patients and carers. The ability to contain and conceal incontinence enables individuals to protect their public identity as a “continent person” and avoid the stigma associated with incontinence [3]. Failure to do so can result in limited social and professional opportunities, place relationships in jeopardy and detrimentally affect emotional and mental well-being [4]. The ability to contain and conceal incontinence enables carers to feel confident that the person(s) they care for will not be embarrassed publicly. It reduces the level of care required in relation to maintaining hygiene, skin care and laundry for the person who is dependent upon continence products [5].

Fortunately there is a diverse range of different products to choose from. However, without comprehensive and current information on the products available, this plethora of choice can be overwhelming and confusing [5]. Furthermore, the range of products actually accessible to users can vary enormously between and within countries, depending on the funding available, healthcare policy and the logistics of supply [5].

The choice of appropriate products for an individual with incontinence is influenced by the resources and care available and patient / carer preference, as well as assessment of specific client characteristics and needs [6] [7].

The stigma associated with incontinence means that another measure by which the success of products is judged is their ability to conceal the problem [8]. Such concealment may involve compromises: for example, in order to prevent leakage from a product, those with a larger capacity than strictly necessary may be preferred but this can in itself introduce issues to do with discretion when the product is worn. The intimate and stigmatised nature of incontinence means that issues relating to self-image can affect some patients’ preferences. This may be especially marked in younger people for whom body-image may be particularly important and for whom disruption to normal social and interpersonal development may result in isolation or lack of access to normal experiences [9] [10].

1. PRODUCT CATEGORIES

The continence products considered in this chapter may be divided into those that are intended to assist with toileting and those to manage urinary retention and / or contain incontinence (urinary and / or faecal) (Figure II-1).

All toileting products can be useful for dealing with urine and / or faeces except for handheld urinals which are just for urine. Containment / control products are subdivided into three overlapping classes: those for urinary retention, urinary incontinence, and faecal incontinence. So, for example, someone with urinary retention is most likely to benefit from one of the products in the red ellipse, while someone with urinary incontinence will most likely benefit from one in the blue ellipse. A patient experiencing both problems will need two products (one from each ellipse) or one product from the intersection of the two ellipses.

2. IDENTIFYING THE NEEDS

The algorithms below (Figures II-2 and II-3) are designed to provide guidance for determining broadly which product(s) is likely to be of benefit to a particular patient. There are three main questions:

**Figure II-1: Products for toileting (top) and for managing incontinence and / or urinary retention (bottom). CIC= Clean intermittent catheterisation; IDC= Indwelling catheter**
Figure II-2: Algorithm to help identify the category(s) of products most likely to help a patient with urinary incontinence and/or urinary retention. (Y = Yes; N = No; U = unsatisfactory ie considered and deemed unsuitable or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence. (CIC = Clean intermittent catheterisation; IDC = Indwelling catheter).
Figure II-3: Algorithm to help identify the category(s) of products most likely to help a patient with faecal incontinence. (Y = Yes; N = No; U = unsatisfactory ie considered and deemed inappropriate or tried and found not to work satisfactorily). * Consideration should be based on assessment of the patient’s physical characteristics, cognitive ability and personal preferences, as well as the nature of their incontinence.

- Is there urinary retention (with or without incontinence)?
- Are there problems with toilet access (e.g. the proximity or design of the toilet; mobility or urgency problems for the patient)?
- Is there urinary incontinence or faecal incontinence or both?
- Answers to these questions will determine which one (or both) of the algorithms is most appropriate for an individual and help identify the category(s) of products most likely to help.

3. PATIENT ASSESSMENT FACTORS

A careful patient assessment is an important part of the process of product selection and Table II-1 summarises the key elements to be considered.

The choice of appropriate products for an individual with incontinence is dependent upon the resources and care available. It must also be influenced by patient and carer preference as well as assessment of specific client characteristics and needs [6] [7].

Assessment of physical characteristics such as anthropometrics, level of independence, mobility and dexterity, mental acuity and the nature of the incontinence will determine which products may be appropriate. In addition to these factors, successful product choice and effective use involves other practical and psychosocial considerations. Product effectiveness depends upon the same factors as any assistive device intended to address a disability or impairment: patient participation in device selection [11] provision of adequate instructions for use [12] and the need for products to fulfil their function reliably and not be difficult to use [12] [9] [13].

While Table II-1 provides general guidance on patient assessment relating to product selection, later sections in the chapter provide further discussion on assessment issues specifically related to the various product categories.

In addition to selection of appropriate and effective products following patient assessment, education and training of users or carers in the correct use of the devices is of importance if product use is to be optimal. This may be a simple matter of instruction in the effective fitting and changing of absorbent products, or may involve more in-depth training in the ongoing care of, for example, a suprapubic catheter.
<table>
<thead>
<tr>
<th>Element</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nature of the continence problem</td>
<td>The frequency, volume and flow rate of the incontinence influences product suitability.</td>
</tr>
<tr>
<td>Gender</td>
<td>Males may consider and prefer sheaths as a more masculine option to pads. Females may be attracted to products that are more feminine in design and presentation. Some ‘unisex’ products such as absorbent pads have different designs that work better for men (or women).</td>
</tr>
<tr>
<td>Physical characteristics</td>
<td>Anthropometrics (e.g. height and waist, thigh, penile circumference) will influence the comfort and effectiveness of a product.</td>
</tr>
<tr>
<td>Mental acuity</td>
<td>Mental impairment can affect the person’s ability to manage the product. Products that resemble usual underwear (e.g. some absorbents) may be easiest to manage. Products which have health implications if used incorrectly (e.g. mechanical devices or catheter valves) should be avoided if mental impairment is likely to preclude correct and safe use.</td>
</tr>
<tr>
<td>Mobility</td>
<td>Impaired mobility may make some product choices impractical or require toilet or clothing modification to allow effective use of the product.</td>
</tr>
<tr>
<td>Dexterity</td>
<td>Problems with hand or finger movement can make it difficult to use some products (e.g. taps on leg bags, straps with buttons).</td>
</tr>
<tr>
<td>Eyesight</td>
<td>Impaired eyesight limits effective application and management of some products.</td>
</tr>
<tr>
<td>Leg abduction problems</td>
<td>Difficulty with abduction can make the use of some products impractical or ineffective.</td>
</tr>
<tr>
<td>Lifestyle and environments</td>
<td>Daily activities and environments can influence the choice of product and a mixture of products may provide optimum management. Different products may be most satisfactory for daytime and going out (when discreetness may be a priority) and night-time or staying in (when comfort may be a priority), for holidays (when laundry and / or large quantities of disposables may be a problem) or for use at work. The proximity and accessibility of a toilet in the various environments may be a key factor.</td>
</tr>
<tr>
<td>Independence / assistance</td>
<td>If a caregiver is required to apply or change the product then it may be important to involve them in the selection of the product and to establish their willingness and ability to use it.</td>
</tr>
<tr>
<td>Laundry facilities</td>
<td>Washable pads and bed linen may be very heavy when wet and take a long time to dry. It is important to check that the person doing the laundry has the ability and facilities to cope.</td>
</tr>
<tr>
<td>Disposal facilities</td>
<td>Ability to appropriately, safely and discreetly dispose of the selected products needs to be considered.</td>
</tr>
<tr>
<td>Storage facilities</td>
<td>Some products - notably, pads for heavy incontinence - can be bulky. Adequate space to store supplies between deliveries / purchases needs to be available.</td>
</tr>
<tr>
<td>Personal preferences</td>
<td>Different people like different products and where possible patients should be given a choice of products with which to experiment to determine the most satisfactory product.</td>
</tr>
<tr>
<td>Personal priorities</td>
<td>Everyone wants to avoid leakage but other factors such as discreetness may be more or less important to individuals.</td>
</tr>
</tbody>
</table>
Incontinence is often a long term condition and so monitoring and periodic reassessment is essential to maintain effective management with products.

4. MAIN USER GROUPS

Although needs, priorities and preferences vary between people with incontinence it is useful to divide patients into major user groups to help identify the category(s) of products most likely to benefit an individual. Seven primary groups are identified in this chapter:

- People with urinary retention.
- People who need help with toileting / toilet access.
- Females with light urinary incontinence.
- Males with light urinary incontinence.
- Females with moderate / heavy urinary incontinence.
- Males with moderate / heavy urinary incontinence.
- People with faecal incontinence.

An individual may belong to more than one group. Each group includes children and young people; the products available for them are broadly similar to those for adults.

5. CHOOSING BETWEEN PRODUCT CATEGORIES

- Figures II-4 to II-9 summarise the user characteristics, priorities and contexts which favour or discourage the use of each of the categories of products available for six of the seven user groups identified in section II.4. Assistance with choosing appropriate products for the first group (people with urinary retention) is given in the section on catheters (Table XII-1) as all the product options for these people are in the same category (catheters).

- The recommendations given in these charts are based on the evidence presented in the sections of the chapter dedicated to different product categories and they are intended to help identify which product category (categories) are most likely to help an individual. However, it should be remembered that the same product will not suit all people, even if they have very similar assessment outcomes on the factors summarised in Table II-1. Different people prefer different products and where possible patients should be given access to a range with which to experiment to determine the most satisfactory product(s) for them. Similarly, the balance of priorities varies between users; for example, some pad users will opt for a bulky and, therefore, less discreet product to achieve an acceptably low risk of leakage while others will see the balance differently. It should also be noted that a mix of products from different categories may provide the best solution; for example, needs may vary between day / night and home / away. Once a product category of interest has been identified the corresponding chapter section should be consulted for further help.

6. SUMMARY

In conclusion, continence products can play an important role in enhancing the quality of life and reducing the stigma of incontinence of those who: are awaiting treatment; are waiting for treatment to take effect; elect not to pursue cure options; are unable to be fully cured and are living with an ongoing bladder / bowel problem.

7. RECOMMENDATIONS

- Incontinence should be actively managed with products to minimise the impact of incontinence on quality of life (Grade of Recommendation C).
- Patients should be carefully assessed (and reassessed periodically) to select the most appropriate products (Grade of Recommendation C).

III. PRODUCT EVALUATION METHODOLOGY

This section aims to assist those planning clinical trials of products. There have been relatively few large clinical trials of continence products (with the exception of urinary catheters) and for most product categories research evidence to guide the selection of individual products / designs / features is limited and in some cases absent.

Measuring the performance of continence products is methodologically challenging. Manufacturers modify and change their products regularly - in terms of both materials and designs - and this limits the long-term validity of research results. There are also complex issues regarding research questions, study design, product representation, blinding and sample size [14] which are discussed below.

It is common for practitioners to be asked (by their employers or by companies) to do a small evaluation or trial – sometimes to ‘test out’ a new product and sometimes to help choose between competing brands for bulk-buying. Such trials should be approached with caution; they can be very demanding but their results may be of very limited value, even for local use. The methodological challenges identified below still apply but are compounded by small sample size and restricted product selection. These studies are likely to be helpful only for identifying gross product short-comings or benefits.

1. RESEARCH QUESTIONS

a) Comparisons

Part of the complexity of product evaluations stems from the sheer number and type of products available, meaning that many different comparisons could be made. Table III-1 illustrates the problem

</table>
using a hierarchy of questions relating to absorbent products. So, in this example, once the decision is made to choose an absorbent product in response to question 1, successive further questions can be used to narrow down the choice to a specific product brand. Questions at any of these levels may form the basis for research projects.

**Table III-1: Levels of questions**

- Which product category (e.g., catheter, sheath, absorbent pad)?
- Which design of product design (e.g., pull-up or diaper design of pad)?
- Which material type (e.g., reusable or disposable)?
- Which features (e.g., with/without elastic gathers)?
- Which product brand?

In the field of absorbent products the practitioner and/or patient wishes to know whether to use an underpad or a bodyworn product, a reusable or a disposable, a diaper or an insert (if they select a bodyworn), a diaper with internal elastication (standing gathers) or without and, finally, which of the many diaper brands is likely to be most effective. Attempting to answer this final question is the most pertinent question for the practitioner (who may already have made decisions about questions 1-4, Table III-1) but is particularly problematic because of the high rate of product change. By the time the results of a clinical trial of product brands are known many of the test products will have been modified and the results will have limited value for product selection. However, these ‘single design’ studies do have value in demonstrating the range of performance within the group of product brands, and where objective measurements can be made (for example, of leakage performance) can allow for comparisons between groups of products. Single design studies are also helpful in promoting product improvement by revealing common problems experienced by patients and exposing particularly poor products or poor product features which are amenable to change by manufacturers.

Basic product designs, features and materials change much less frequently and attempting to answer questions 1-4 (Table III-1) is therefore likely to lead to more long-lasting results. Such studies have been attempted by many researchers, but these have frequently been confounded by problems with product representation.

**b) Product representation**

The single greatest (and most frequently overlooked) threat to the validity of clinical trials of products is the selection of the products entered into the study. Evaluations of a number of product variants of a similar design (e.g., different brands) have shown that patient ‘overall opinion’ scores can vary by as much as 70 percentage points between apparently similar products [15]. Accordingly, in an evaluation to compare different designs, the selection of one or more products to represent each design, is crucial. Studies that have purported to compare different designs or materials have often included a small number (most often just one) of arbitrarily selected product(s). Generalizing the results of such studies to whole product groups (e.g., reusable underpads, or disposable bodyworns) is meaningless and misleading. It is perfectly possible to select (either by accident or design) a particularly ‘good’ product from one group and a particularly ‘poor’ product from another. A well-designed study will therefore be seriously flawed if there is no clear process or pilot study to determine and justify the choice of particular products. Even with a systematic process of product selection (or preferably a pilot study) it is unwise to select a single product to represent a whole group of products and selection of a small group of products (e.g., three) is preferable. This allows for any ‘within group’ differences to be detected and helps to demonstrate the ‘representativeness’ of the products selected. The most controlled method of testing different designs, materials or features of products is to make up experimental batches which differ only in the aspect of interest (e.g., the material or the feature) and a small number of studies have attempted this [15] [16]. However, experimentally made products are not usually identical to those available on the market which impairs the validity of such studies.

**2. RESEARCH DESIGN**

A randomized controlled trial is not possible for clinical trials of products in most categories simply because a ‘control’ product does not usually exist. Nor is there a ‘standard or reference’ product to act as a control and comparisons with ‘standard practice’ (i.e., the product currently in use) are prone to bias.

Although it is methodologically simpler (and more robust) to compare only two different product groups, it is more clinically relevant to compare several competing groups, using a multiple cross-over design, where there are valid comparisons. For example, there are four main design groups of disposable bodyworn pads for moderate/heavy incontinence (inserts, diapers, pull-ups and T-shaped). Evaluation of all four groups together is much faster (and therefore gives more long-lasting results) and more cost-effective than several serial studies. Cross-over trials are vulnerable to order effects and randomization of the order of testing should be carried out using Latin squares [17] to ensure balance.

It is important that clinical trials of single designs of products (which aim to enable selection of particular product brands) are comprehensive (i.e., cover all the available products) because otherwise manufacturers
can justifiably claim that although their product may be similar to one of those tested even subtle distinctions may lead to clinically important differences.

A further problem with research design is the blinding of products. Different products have different appearances and it is impossible to blind subjects or staff to the product in use. Products can be re-packaged to assist anonymising but this may have unwanted effects on the products and is expensive.

Previous product experience can also affect study results, particularly if a substantial proportion of subjects are currently using a product included in the study. It is therefore important to record which products are in current use in order to add this data to the model used in the analysis.

**a) Sample size and study power**

Studies that include more than two products (or two small groups of products) will need to be powered so that multiple comparisons can be made. As the number of products included in the study increases the number of possible comparisons of pairs of products rises. This requires a corresponding reduction in the significance level (e.g. by using the Bonferroni method) for each pair-wise comparison to retain the overall level of significance (usually p<0.05). Thus as the total number of pair-wise comparisons increases the likelihood of a type 2 error (accepting the null hypothesis when it is false) also increases.

Sample sizes therefore need to be calculated to allow for each pair-wise comparison. Sample size requirements rise rapidly if each subject does not test each product and the number of products entered into a study must therefore be limited by subject fatigue. As an example, a clinical trial of four product groups where the primary outcome variable will be binarised (e.g. satisfactory / unsatisfactory) will require a sample size of approximately 80 subjects with an alpha of < 0.05 and d (difference) of 20%.

**b) Outcome variables**

Studies of product performance have most frequently used self-report questionnaires at the end of the product test period to assess participant ratings of product performance. Diaries of product-related events such as leakage, laundry generation and product consumption are also commonly included. Subjects in some absorbent pad studies have been asked to identify and prioritise items of product performance [18] [19] [20] to inform questionnaires and Table III-2 shows the most common items of high priority to women with light urinary incontinence identified by Getliffe and colleagues [19].

Outcome variables in studies designed to compare catheterisation strategies and / or catheter materials or other design features commonly encompass measures of urinary tract infection, tissue trauma and recurrent catheter encrustation leading to blockage (see Section XII-2).

Questionnaire items vary depending on the products being tested and for product groups where few studies have been carried out it is particularly important to tailor questionnaires to patient needs by asking study subjects to prioritise items and to assess final questionnaires for content and face validity. One study [21] has measured the test re-test reliability of a questionnaire to assess sheath performance and found moderately good Kappa scores (around 0.7) when assessing the same sheath twice with four weeks between assessment periods.

Skin health, urinary tract infection, pain or discomfort are the main physical health consequences of containment products and skin health (which can be rated by self-report or by skin inspection) has sometimes been used as the primary outcome variable (e.g. [22]). Urinary tract infection is an important outcome for invasive devices such as catheters.

Although leakage performance is most frequently

rated as the top priority for users, good leakage performance is not adequate as a sole measure of patient satisfaction with performance. A single (or multiple) fatal flaw such as poor comfort, bulkiness, or poor fit may cause a product that performs well for leakage to be unacceptable to the patient. For this reason aggregate measures - which assumes that the overall performance of a product can be calculated using a weighted sum of the scores for specific aspects of performance (like comfort and freedom from leakage) - are ill-advised. Patient overall opinion or satisfaction with the product should therefore be used as the primary outcome variable [21].

There are no quality of life measurement tools specifically designed for clinical trials of products, but there is a need for such tools to measure the impact that good or bad product performance has on people’s lives. Existing incontinence-specific quality of life tools are designed to measure change after interventions to improve incontinence and include urinary symptoms. These tools are therefore likely to be insensitive to changes in quality of life brought about by products which are designed to contain incontinence rather than reduce or prevent it. The first stage in the development of a quality of life tool for absorbent product users has been reported by Getliffe et al. [19] and a similar tool for catheter users is known to be under development.

3. SUMMARY AND RECOMMENDATIONS

There is little published evidence on which to base summary and recommendations regarding methodology and so the following summary points / recommendations are all Level of Evidence 3 / Grade of Recommendation C.

- Evaluation of continence products is methodologically complex and many attempts at providing robust evidence for product selection have been hampered by methodological weaknesses.
- Product representation is critical to providing robust and generalisable data. Selection of products for inclusion in a study needs to be transparent and systematic and several products should preferably be included to represent a product group. In particular, care should be taken not to select a particularly good or a particularly poor product to represent a whole class of products.
- Multiple crossover designs are likely to be more efficient than randomised controlled trials for many products (eg pads) and therefore sample sizes estimation needs to take into account the multiple comparisons that will be made.
- Outcome variables should include patient (or carer) questionnaire including items that have been established as important to patient users.
- Diary data should be included to determine leakage performance, skin health, laundry and product consumption.
- Incidence of urinary tract infection should be included when testing invasive devices such as catheters, but “significant” UTI / bacteriuria needs to be carefully defined (see Section 12.2.8).
- The primary outcome variables should be patient overall opinion / satisfaction and patient preference.
- Health economics should be measured alongside product performance

4. RESEARCH PRIORITIES

- The development of Quality of Life tools for users of continence products.

IV. HANDHELD URINALS

Handheld urinals are portable devices designed to allow a person to empty their bladder when access to a toilet is not possible or convenient, often due to limited mobility, hip abduction or flexibility. They can be especially helpful for those suffering from frequency and / or urgency.

An effective hand held urinal must enable its user to empty his / her bladder in comfort and be confident of no spillage. It should not require excessive physical effort on their part and should be easy to empty without spillage.

General guidelines on patient assessment for product selection are discussed in Section 2. Aspects of patient assessment particularly important for handheld urinals are user postures (in bed, on side of bed, back in chair, on edge of chair, standing / crouching / kneeling), leg abduction, approach of urinal (from front, side, behind, above), ability to initiate void, dexterity and strength to position and remove urinal, level and availability of assistance, user preference.

There has only been one clinical trial [23] of female urinals and there are no published trials of male urinals. However, much helpful guidance and expert opinion has been published [24] [25] [26] [27].

1. FEMALE HANDHELD URINALS

Female handheld urinals come in a variety of shapes and sizes (Figure IV-1). Most are moulded in plastic but they may be made from metal or (for single use items) cardboard. Some are designed for use in particular postures, like standing, sitting or lying down – (see below). Some have handles to facilitate grip and positioning. Some are intended to empty into a drainage bag during or after use.

Although female handheld urinals are often described and discussed in general nursing articles on continence products they have only been the subject of one published (cross-over) evaluation. Fader
et al. [23] carried out a multi-centre study in which each of 37 community-based women (age range 33-89y; mean age 61y) was invited to evaluate all 13 products on the UK market in 1997. No product suited everybody but each was successful for at least some subjects. The key requirements for success were that the user should be able to position the urinal easily and feel confident that it would catch urine without spilling (Level of Evidence 2). Many products were successful when used in the standing / crouching position or when sitting on the edge of a chair / bed / wheelchair. Fewer worked well for users sitting in a chair / wheelchair. Only one worked even reasonably well when users were lying / semi-lying (Subaseal), In general, subjects with higher levels of dependency found fewer urinals to be suitable for their needs.

Recently the development of a powered urinal designed to pump urine into a reservoir has been described [28]. The aim of the device was to provide active removal of urine without leakage and without the need for gravity-assisted drainage. The urinal was tested by 80 women from six countries. Although evaluated as 'good' or 'okay' by more than three-quarters of the women, nearly half the women found the device 'poor' for weight and size. Problems with reliability of the device were also common and the authors concluded that the current device needed further refinement but may have potential as an alternative to conventional urinals. Although this device is not currently on the market, at least one other powered device is available. However, there are no published reports on efficacy.

2. MALE HANDHELD URINALS

Most handheld urinals for men are somewhat similar, involving a narrowed neck opening into which the penis is placed. Some products come with a detachable or integral non-spill adaptor containing a flutter valve to impede back-flow of urine from the urinal. There are no published trials of such products.

A review paper by Vickerman [27] makes recommendations for selecting suitable urinals for men.

A flat bottom urinal may be more stable (and less likely to spill) for those using a urinal in bed. Urinals made from soft plastic (jug-style or with a funnel) may be easier to grip for those with poor manual dexterity. Urinals designed to be attached to a drainage bag (for emptying the urinal) may also be helpful to men living at home with limited support.

Vickerman also suggests that home-made devices (such as empty wide-mouthed containers with a handle and lid (for example, those used for clothes-washing liquid or conditioner) may be a practical (and cheap) option for some men. For those with a retracted penis female urinals may be easier to use than male products.

3. GENERAL POINTS FROM THE LITERATURE, INCLUDING EXPERT OPINION

The literature [24] [25] [26] [27] suggests that successful use of urinals depends on many factors which are summarised below.

- Experimentation is often needed to find the optimum urinal for an individual. A ‘library’ of urinals (i.e. a collection of different types of urinals to be lent out to users for experimentation) has therefore been recommended [26] but rigorous cleaning methods are needed (see below).

- Clothing alterations can aid quick and easy use of a urinal. For men, extending the fly opening of trousers or replacing zips with Velcro can be helpful, as can boxer shorts. For women drop-front pants may be needed, particularly if mobility is limited.

- Disposable and reusable ‘travel’ hand-held urinals are available for both men and women. These urinals fold away to fit into a pocket and may therefore be more discreetly portable than conventional urinals.

- Some disposable urinals include superabsorbent polymer in their reservoirs which turns urine into a gel and help to prevent spillage. Sachets of superabsorbent polymer may also be added to reusable urinals.

- Use of a urinal is not always free from leakage and provision of absorbent chair or bedpads to protect bedding, clothes and furniture (particularly when testing out urinals) may be necessary.

- The limited range of urinal options in acute settings, where often only bedpans are available, has been criticised and the process of introducing hand-held urinals to hospital services has been described and recommended [29].

- When used by one individual in the home, urinals can be cleaned with soap and water between uses. But where urinals are shared (i.e. cleaned and used by others), or if a library of urinals is used then robust methods are necessary. Some urinals can be cleaned in a bedpan washer but cleaning methods vary with different designs and

Figure IV-1: A variety of female handheld urinals.
materials and compliance with local infection control procedures will be needed.

4. RECOMMENDATIONS

- There is a wide range of female urinals and experimentation is likely to be necessary to identify the best one for an individual (dependent on their individual needs and abilities) (Grade of Recommendation C).
- A library of female urinals (used with robust cleaning methods) will help to facilitate experimentation (Grade of Recommendation C).
- Male urinals are less varied than female urinals, but may be supplemented by use of less conventional receptacles (e.g. jugs, home-made devices); experimentation will help to identify best options (Grade of Recommendation C).
- Section IV.3 addresses other more general recommendations regarding urinal use.

5. PRIORITIES FOR RESEARCH

- Further development of female urinals is encouraged, particularly for supine users and those unable to move to the edge of a chair.
- The range of male and travel urinals need to be evaluated to provide guidance for users and carers.

V. COMMODES AND BEDPANS

Toilets can be difficult to use by people with mobility problems and other disabilities. Toilet adaptations such as raised toilet seats, padded seats, and grab rails can be very helpful in enabling individuals to access the toilet easily and comfortably. Bottom wipers and bidets can also be useful. However, if access to the toilet is impossible, commodes and other toileting receptacles should be considered.

Commodes are devices that comprise a frame supporting a toilet seat with a pan (disposable or washable) beneath to receive urine and faeces. They are used independently of a toilet and may be static or mobile. Mostly, they are used by people with reduced mobility who find it difficult to access a conventional toilet. Bedpans are portable receptacles that may be used for passing urine or faeces while in bed or chair. Some female urinals (see section 4) may also be used to collect faeces.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding commodes and bedpans begin with appropriate indications for their use since Matsumoto and Inoue [30] reported that incontinent elderly persons or their caregivers misunderstand indications of commode use for incontinence. Other patient assessment elements include: a) physical characteristics of the person with incontinence (e.g. can an obese person fit on a commode and use its handrails?); b) mental acuity (e.g. will a person with dementia recognize a commode or bedpan as a device to be used for defecation?); c) need for supervision or foot supports whilst on the commode (what is the risk of falling?); d) mobility (e.g. does the person need a commode or bedpan?), ability to transfer and method of transfer to the commode (e.g. hoist, carer help, independent with transfer board), need for static or mobile commode (particularly when considering using commode over a toilet), postural stability and need for supportive commode, e) level of assistance needed and physical burden to caregiver involved; and f) personal preferences (e.g. comfort of bedpan type) including need for ‘non-commode-like’ appearance (e.g., particularly when used in own room, particularly the living room). Patient assessment findings need to be evaluated in terms of the safety and stability properties of a commode. The proximity of the area for waste disposal, storage facilities (i.e., the location / visibility of the commode in the household), the availability of privacy during defaecation, and length of time likely to remain on the commode (is there a need for a pressure-relieving commode cushion?), are additional factors to be considered.

Commodes (or better still toilets) are preferable to bedpans (which are relatively difficult to use and do not permit appropriate posture for passing urine/faeces). Bedpans are generally reserved for people who are confined to bed (e.g. post-operatively) and for whom safety (risk of falling) is an important assessment issue.

1. RESULTS

Fader [31] has reviewed the little work that has been done to evaluate existing commodes and bedpans and to identify the needs of users. An investigation of commode design by Nazarko [32] highlighted the problem of commodes providing poor trunk support for elderly and disabled people. Prolonged periods of sitting alone (for privacy) to enable defecation resulted in a risk of falls. Nazarko worked with a manufacturer to produce a design specification for a commode. Consultation with patients indicated that many would prefer to use a toilet. As a consequence, attention was focused in designing a shower chair which could also be used as a commode or could be wheeled over a toilet.

An evaluation of the four main types of commodes (standard; with adjustable height; with removable / drop-down arm; with adjustable height and removable / drop-down arm combination) was published by the UK Medical Devices Agency [33] [34]. One third of the 150 commodes on the UK market at the time were found to have backwards instability, and most of them scored poorly for aesthetics and comfort. A discussion of the results of this evaluation and its application to nursing was subsequently published by Ballinger et al. [35].
The maintenance of hospital commodes can be a problem and Gillan [36] complained about the poor condition of commodes in wards for elderly people. Commode cleaning has also been found to be poor [47] and a recent audit by Bucior and Cochrane [37] showed visible traces of faecal contamination on cleaned commodes. The authors concluded that it was necessary for ward staff to have clearly defined roles and responsibilities for commode cleaning. New commodes have been designed to overcome such problems by being easier to clean (e.g. design-bugs-out commode www.designcouncil.org.uk/our-work/challenges/Health/Design-Bugs-Out/Case-studies/Commode).

Naylor & Mulley [38] investigated the use of commodes in community-dwelling patients and the attitude of carers and users towards them (115 subjects and 105 carers). The main reasons for commode use were impaired mobility, difficulty climbing stairs and urinary incontinence. Main concerns were lack of privacy and embarrassment about using the commode, unpleasant smells and the poor physical appearance of the commode. Carers tended to view them negatively, particularly with regard to cleaning. Where commodes were used for defecation in a living area the authors highlighted the problem of odour that lingered even after a commode had been emptied, and recommended the use of a chemical toilet.

Thorough cleaning of commodes or bedpans after every use is necessary for hygienic purposes and to eliminate odours. Naylor & Mulley [38] report that typically a caregiver rather than the commode user empties and cleans a commode. No recommendations for cleaning a home commode or bedpan were found in the published literature. In institutional settings, large sinks with spray hoses or special sanitizing equipment are available. The size and shape of a bedpan or commode receptacle may be difficult to fit under a standard sink basin in the home. Whether certain commode cleaning products reduce any residual odour more than others is not known. Toilet bowl cleaning products are suitable for cleaning a commode or bedpan; many contain bleach or antibacterial ingredients but their effect on reducing odour of commodes or bedpans has not been studied. Gel formulations are advertised by manufacturers as being better able to cling to hard-to-reach surfaces than liquid agents. Use of a deodorizer can be considered (Level of evidence 4).

Nelson and colleagues [39] surveyed 147 spinal cord injured patients regarding their satisfaction and safety with the shower chairs (used for bowel care) used in the home. They found that around a half of patients were dissatisfied with their chairs and concerns expressed related to lack of hand access to the perianal area, difficulty in turning and rolling the chair and problems with keeping the chair clean. One third of patients experienced chair related falls and nearly a quarter reported pressure ulcers. Two-thirds of subjects felt that their safety was compromised.

The same group of researchers evaluated three shower chairs using video-taping, photography and questionnaires and produced performance criteria for the design of an optimal shower chair [40]. Pressure mapping devices were used to measure seat pressures on three subjects who tested all three bowl / shower chairs to inform seat design [41].

These researchers [42] then set about designing a more advanced commode-shower chair. It had lockable, swing-away armrests and lever activated brakes to facilitate transfers. To prevent pressure ulcers a chair frame and padding combination was designed to facilitate a seating position that distributed body weight and reduced pressure on pressure points. Cupped edgeless footrests were designed to reduce the risk of heel ulcers. An adapted version of this chair is now commercially available in the USA.

Matsumoto and Inoue [30] examined whether use of a commode in the home might prevent or delay nursing home admission of elderly people who were incontinent. A five-year follow-up of multiple predictors of institutionalization in elderly people in a rural town in Japan showed that 40% of incontinent men and only 17% of incontinent women used a commode. Use of a commode was not associated with institutionalization. The authors suggested several possible reasons: misunderstanding of appropriate indications for a commode based on the type of incontinence; physical burden in assisting a care recipient to use a commode that seemed no different than for cleansing after an incontinence episode; and inadequate muscle strength of the elderly for using either a Japanese-style or Western commode.

Bedpans and other portable receptacles are not well described in the literature. Wells and Brink [43] describe three general shapes of bedpans: concave, cutaway, and shovel. The concave pan has a rounded triangle shape that slopes back to front and a curved seat. The cutaway has a rounded triangle shape with a flatter seat and rolled edges that allow for handgripping. The shovel shape, commonly called a "fracture pan" is a wedge or rectangle shape that has a flattened end that goes under the individual and a handle at the distal end. Generally bedpans are considered to be unsuitable for defecation for safety and acceptability reasons. However, for individuals with specific needs (e.g. frequency and urgency of defecation) a portable receptacle may be beneficial. Although many portable urinals are now available for both men and women, very few are recommended for defecation [44] and they have yet to be formally evaluated.

Privacy and dignity need to be given high priority when patients need to use a bedpan or commode, in particular in institutional settings. Care needs to be taken when transporting patients on a shower...
chair to maintain dignity and avoid revealing the patient’s bottom.

Bottom wiping and cleaning can be difficult for people with disabilities, particularly manual dexterity problems, or caregivers. Simple moist wipes may be helpful and are widely available. Devices designed to assist with bottom wiping problems are on the market and portable bidets are also available, however there are no published trials of these products. Bedpans have other disadvantages including difficulty removing the bedpan from under an individual without spilling (particularly if the individual is obese), risk of spilling and odour when transporting the contents for disposal since none have lids, and lack of privacy during use.

2. SUMMARY

- There are major defects in most of the current designs of commodes, especially: poor aesthetics; poor trunk support; instability (i.e. a tendency to tip over easily); poor comfort; difficult to clean; poor pressure relief (Level of Evidence 3).
- If direct transfer to a toilet is impossible or unsafe a sani-chair / shower chair is usually preferable to a commode (Level of Evidence 3).
- The main concerns of users about commodes and bedpans are: lack of privacy; embarrassment over use; odour; poor aesthetics; poor perineal cleansing accessibility; and inadequate facilities for cleaning the devices in the home (Level of Evidence 2).
- Defecation on a bedpan or other portable receptacle presents problems of safety and unacceptability to users (Level of Evidence 2).

3. RECOMMENDATIONS

- If at all possible, access to a toilet should be made available for defecation (Grade of Recommendation C).
- If direct transfer to a toilet is impossible or unsafe, a sani-chair / shower chair should be offered in preference to a commode wherever possible (Grade of Recommendation C).
- If a commode is used, care should be taken to ensure good trunk support; that the chair is stable; and that methods of reducing noise and odour are offered (Grade of Recommendation C).
- With commodes and sani-chairs / shower chairs, the user’s bottom should never be visible to others and transportation to the toilet and use of the toilet or commode should be carried out with due regard to privacy and dignity (Grade of Recommendation C).
- Bedpans and other portable receptacles should be avoided for defecation purposes (Grade of Recommendation C).
- Patients vulnerable to pressure ulcers should not sit on a commode / sani-chair / shower chair for prolonged periods (Grade of Recommendation C).
- The person should be given a direct method of calling for assistance when left on the toilet / commode / sani-chair / shower chair (Grade of Recommendation C).
- Cleaning of bedpans and commodes should be carried out after each use following local infection control policies (in institutional settings) (Grade of Recommendation C).
- There are no evidence-based published guidelines regarding frequency of cleaning or type of cleaning product. However, thorough cleaning after bowel evacuation (to avoid odour and maintain aesthetics) is important, together with rinsing after urine has been passed. Cleaning needs may vary according to personal hygiene standards and offensiveness of urine/faecal smells (Grade of Recommendation C).

4. PRIORITIES FOR RESEARCH

- Studies are needed to determine how to make toilets accessible to as many users as possible. These may lead to improved designs for toilets and associated equipment and / or strategies for toileting.
- Studies are needed to determine which commode / sani-chair / shower chair designs best meet performance and safety requirements.
- Development of better commodes designed to overcome the limitations identified

VI. ABSORBENT PRODUCTS

1. INTRODUCTION

Absorbent products (commonly known as pads) are available in a wide range of sizes and absorbencies encompassing light through to very heavy incontinence. Most pads are bodyworn but some are used on the bed or chair (underpads, see Section 6.2); in this section the term ‘pad’ refers to bodyworn absorbent products. Broadly speaking, absorbent products can be divided into two main sub-groups: those suitable for light incontinence (usually smaller products) and those suitable for moderate-heavy incontinence (usually larger products). Manufacturers generally indicate the severity of incontinence that each product is designed to accommodate, but see the discussion in Section VI.4. Although absorbent pads are most commonly used for urinary incontinence they are also used by individuals for both faecal and urinary / faecal incontinence; however, there have been no published studies which specifically address this issue.

Incidental findings from evaluations of products indicate that absorption capacity alone does not
determine whether a user will choose to use a product. Some users may have frequent, low flow-rate loss of small volumes of urine ("dribble"), whilst others may be dry for days but then have a higher volume, higher flow-rate incontinence incident ("gush" or "flooding"). Both may prefer to use pads for light incontinence. Mobile and independent community-dwelling women of all levels of incontinence are reported to generally prefer small pads and are often willing to change them frequently rather than use larger products and change them less often [45]. Conversely, dependent, immobile individuals may prefer the security of larger products despite relatively low urine volumes due to their dependence on others for pad changing.

More recently studies have focused on the use of pads by men. Teunissen and Lagro-Jansson [46] interviewed 56 men with UI of which only nine used absorbent pads. They concluded that men use pads less frequently than women, have little knowledge about purpose-built pads, are more likely to construct their own pads out of absorbent materials such as towels and are less satisfied with pads than women. Furthermore there are indications that men may prefer other devices such as urinary sheaths [47] (see Section VII Sheaths).

Studies that have collected and weighed used pads to measure urine volume have found overlap between the quantities contained by pads from different sub-groups of users; thus in a study of insert pads for moderate-heavy incontinence used by older people in residential care around 15% of insert pads for moderate-heavy incontinence contained less than 100g of urine [48] and in a study of older women with light incontinence living in the community about 10% of insert pads for light incontinence were found to contain more than 100g of urine [49].

It might be speculated that the number of pads used per day might be a good measure of degree of urinary incontinence, but this has not been found to be the case in nursing home residents in Norway [50]. Pads were collected and weighed from residents in six homes, but a poor correlation was found between the number of pads used and the mass of leaked urine measured over 48 hours. The authors concluded that this was due to pad changes being carried out at routine times by healthcare assistants.

It is possible that a proportion of patients are simply provided with inappropriate products that exceed or fall short of the absorption capacity they require. One study investigated this issue [51] and found that patients were more satisfied with their products once their urine loss had been determined by pad weighing and appropriately absorbent products were provided. But many of these patients were using inadequate products to start with (such as pads comprising tissue paper) and firm conclusions could not be drawn. In practice, it is probably hard to justify the need for pad weighing to determine which absorbents should be provided and if there is doubt about which group a patient falls into then the patient should be offered small pads for light incontinence in the first instance and the size of pad titrated upwards as necessary.

General guidelines on patient assessment for product selection are discussed in Section II. Aspects of assessment that are particularly important regarding absorbent pads are frequency / severity of leakage, day / night incontinence, gender (some products are designed for, or are better for, men / women than others), ability to change pad independently / need for carer, pad changing position (standing / lying), laundry / drying facilities, individual priorities (e.g. need for discreetness), personal preference for design / materials (washable / disposable), lifestyle (at home / travel / work etc).

Aspects of absorbent pad performance have been identified and prioritised (during interviews) by men and women taking part in a series of clinical trials of such products [19]. There was considerable consistency across patient groups (light / heavy, men / women) with the ability of a product to hold urine without leakage being the top priority, and the following aspects also being considered to be of high priority: discreetness, containment of smell, ability to stay in place, comfort when wet and ability to keep skin dry.

2. ABSORBENT PRODUCT CATEGORIES

Absorbent products may be classified into two broad categories - disposable (single-use) and washable (reusable) - with each category dividing into two sub-categories: bodyworn products (worn on the person) or underpads (placed under the person). Within each sub-category are different designs such as diapers and pull-ups which are subdivided by size (to fit users of different sizes) and / or absorbency (to cater for different severities of incontinence). Some designs are further subdivided into those intended for men, women or children. This classification is shown in Table VI-1:

- **Bodyworn** absorbent products can be divided into four main design groups:
  - **Inserts** (sometimes called liners or, in the case of small pads, shields) are held in place by close-fitting underwear or stretch mesh briefs (Figure VI-1). Some patients experience problems with keeping pads in place using the commonly supplied net pants. As a result, many use more robust stretch pants purchased privately (e.g. cotton / Lycra, etc). Many disposable inserts (Figure VI-2 and Fig VI-3) have an adhesive strip on the back to help secure them and may have an indicator that changes colour when the pad is wet to signal the need for a change. They may have longitudinal, elasticated standing gathers of hydrophobic material intended to impede lateral leakage of urine and faeces. They
are sometimes rectangular but are more usually shaped to fit the body more snugly. Elastica
tion at the legs may also be used to enhance fit. Washable inserts (Figure VI-4) are usually more simply designed than disposable inserts, with no elastication and are either shaped or a simple rectangle. Inserts are made in a wide range of sizes suitable for light through to very heavy urinary incontinence. For light faecal incontinence, the liner may be a small cotton gauze dressing placed against the anus and held in place by the cheeks of the buttocks (Figure VI-5).

**Diapers** (sometimes called all-in-ones or briefs) are adult-size versions of babies’ diapers. Disposable diapers (Figures VI-6) usually have elasticated waist and legs and self-adhesive tabs (usually resealable), and often a wetness indicator and standing gathers. More recently modified diapers have been introduced that fasten round the waist before the front is pulled into position and secured, to enable users to apply the diaper whilst standing (Figure VI-7). Washable diapers are usually elasticated at the waist and legs and are fixed with Velcro or press-studs (Figure VI-8). Diapers are intended for moderate to very-heavy incontinence.

**Pull-ups** are similar in construction to trainer pants for toddlers. The absorbent material is built into a pull-up pant and is either limited to the crotch area or distributed throughout the pants (Figures VI-9 to VI-11). Disposable pull-ups (Figure VI-9) are usually elasticated throughout the pants to give a close fit. Both disposable and washable pull-ups have versions for different levels of incontinence. Washable pull-ups for light incontinence are often known as pants with integral pad (Figure VI-11).

Some people use less conventional or home-made systems either instead of or as well as the designs described above. In particular terry-towelling squares may be used by those with heavy incontinence. These may be formed into briefs by folding into different configurations and fastening with pins and covered with plastic pants as a waterproof barrier. It is known that such pants may also be worn over more conventional designs in an attempt to reduce leakage and/or odour.

“Body” garments (like vests which have a crotch section which opens and closes with snap fasteners, much like those manufactured for babies) may be helpful to hold pads in place well and may reduce the rustling noise from plastic backing materials.

- **Male pouches** (sometimes called shields, guards or leaves) are for lightly incontinent men and are designed to fit around the penis and sometimes the scrotum too (Figures VI-12 and VI-13). All are worn with close-fitting underwear or stretch mesh briefs. An adhesive strip is often provided on the disposable versions to help hold them in place.

- **Underpad** absorbent products are usually simple rectangles of different sizes to be used on the bed or chair (Figure VI-14). Washable underpads (Figure VI-15) may have a high friction backing or have ‘wings’ for tucking beneath the mattress of single beds to help keep them in place. Underpads vary widely in absorbency with less absorbent products being used as ‘back-up’ with bodyworn absorbents and more absorbent products being used as sole protection on the bed at night.

3. ABSORBENT PRODUCT MATERIALS

Absorbent products – disposable or washable – usually comprise three main layers: an absorbent core sandwiched between a water-proof backing beneath and a water-permeable coverstock (or topsheet) next to the wearer’s skin.

The main component in disposable absorbent cores is invariably some kind of fluffed wood pulp fibres, but most also contain some powdered superabsorber (sometimes referred to as SAP (superabsorbent polymer) or AGM (absorbent gelling material)), which is often concentrated in the crotch region. Superabsorbers hold much more urine – weight for weight – than fluff pulp and retain it far more tenaciously under pressure. They are usually based on cross-linked salts of polyacrylic acid whose chemistry can be varied according to the balance of properties such as absorption capacity and absorption speed desired. Some thermoplastic fibres are also sometimes included in absorbent cores to reduce core break up and the collapse of the structure when wet. It is increasingly common for absorbent cores to comprise two or more layers, each designed to perform a different function. For example, an upper layer might comprise low absorbency fibres engineered to receive and distribute urine efficiently and maintain a dry layer next to the skin, while lower layers provide absorption capacity. Some disposable products have ‘breathable’ plastic backings designed to reduce skin occlusion.

Washable absorbent cores are usually made from a needlefelt or knitted fabric comprising rayon and/or polyester fibres. A variety of polymers are used for the water-proofing. In general, the thicker, stiffer materials are more durable (the durability of the plastic backing often determines the lifetime of the product) but less comfortable. Topsheets are usually made from either cotton – which is hydrophilic and intended to have good dry comfort – or polyester – which is hydrophobic and intended to have good wet comfort.

Concern for the environment and also for controlling costs has led to an increase in the number of washable products available on the market. An important consideration in the comparison of washable and disposable designs is the relative environmental cost, particularly disposal (landfill) costs of disposable designs and energy costs associated with laundering the washables. A recent report on baby diapers concluded that there was no significant difference in environmental impact between three diaper systems (disposables, home and commercial laundered washables) although the types of impacts did vary [52].

4. ABSORBENT PRODUCT CAPACITY AND USER REQUIREMENTS

Pads come in a range of absorbencies to cater for users with different levels of urinary incontinence and, understandably, purchasers wish to know how much urine available pads will hold. But there is no simple answer: a pad does not have a volume of urine below which it is guaranteed not to leak; rather, the probability of success decreases as the volume of the urine increases. However, for higher absorbency pads the performance falls away more slowly with increasing urine volume than it does for lower absorbency products.

This is a complex concept to communicate in sales literature and product packaging and so companies commonly quote a simple absorption capacity figure. Some use the volume of fluid a pad will hold in a laboratory test - usually international standard ISO 11948-1[53] - but this figure can be very misleading. Although it has been shown to correlate well with the leakage performance of pads for some groups of users (see Section VI.7.2), the volume of urine which a pad will hold when tested with ISO 11948-1 is enormous compared with how much it will hold in real use. For this reason, some companies prefer to quote a “working capacity”, which might be calculated as some proportion (companies vary in the proportion they use) of the capacity in the laboratory. However, this is still misleading as it implies that the pad will not leak until the working capacity is exceeded. A simple, valid and widely accepted solution to this problem has yet to be devised.

It is equally difficult to determine the needs of users in terms of the volume of urine they need their pads to hold. Not only can different users leak widely differing volumes from each other but also a given user may leak widely differing volumes on different occasions. This means that, like pad performance, users’ needs cannot be easily quantified. However, a number of studies have been published on work with pad users described as being lightly incontinent of urine in which the median and 90th percentile urine volumes in used pads have been of the order of 15ml and 100ml, respectively [54]. Similarly, a number of studies of pad users described as having moderate-heavy urinary incontinence have yielded corresponding figures of about 250ml and 600ml [54]. Accordingly, in this chapter the material is divided – somewhat simplistically – into that which relates to light incontinence and that which relates to moderate-heavy.

But the published work also makes it clear that some products work better for users whose inconti-
nence is towards the lighter or the heavier end of the spectrum within each of these two groups and so, where necessary in the text and tables that follow, these distinctions are made by dividing light incontinence into “light LIGHT” and “heavy LIGHT”; and moderate-heavy incontinence into “light HEAVY” and heavy HEAVY”.

5. ABSORBENT PRODUCTS FOR WOMEN WITH LIGHT URINARY INCONTINENCE

There are four main product designs for women with light incontinence (Table VI-2). In addition menstrual pads are known to be frequently used for light urinary incontinence. The disposable pull-up group are relatively expensive, single-use items and are seldom used for light incontinence except as ‘emergency’ items. Underpads are not commonly used for light incontinence. (Figure VI-16)

Aspects of assessment that are particularly important regarding pads for women with light incontinence include frequency / severity of leakage, day / night incontinence individual priorities (e.g. need for discreetness), personal preference for washables / disposables, lifestyle (home / travel / work).

a) Quality of data

A small number of robust comparative evaluations of absorbent pads for lightly incontinent women have been published and there has been a Cochrane review [55]. A recent study has compared the most common designs: disposable inserts, menstrual pads, washable inserts and washable pants with integral pad. One study has compared a range of disposable inserts and menstrual pads and there have been comprehensive single group studies of disposable inserts and washable pants with integral pads. A further study has compared specially made experimental products that have differed from one another in carefully controlled ways enabling more specific questions about product materials and design to be addressed.

b) Results

Using a crossover design, Fader et al [54] compared disposable inserts, menstrual pads, washable pants with integral pad, and washable inserts. Three products were selected (based on previous study results) to represent each design and each product was tested for one week (three weeks for each design block, total 12 weeks). Order was randomised. Product performance was characterised using a validated questionnaire to evaluate pad performance (leakage, discreetness etc) with a five point scale (very good – very poor) at the end of each week of product testing. A pad change and leakage diary was used to record severity of leakage from pads (three-point scale: a lot, a little, or no leakage), and numbers of laundry items and pads used were recorded to estimate costs. Skin health changes were recorded weekly. At a final interview preferences were ranked (with and without costs), acceptability of the design recorded (highly acceptable – totally unacceptable) and overall opinion marked on a visual analogue scale (VAS) of 0-100 points (worst design – best design). This VAS score was used to estimate cost-effectiveness.

Eighty-five women (mean age 60) completed the study and 8691 used pads were weighed. The disposable insert was significantly better than the other designs on most variables except for discreetness. For leakage prevention, overall acceptability and preference, disposable inserts were found to be significantly better than menstrual pads, which were better than washable pants with integral pad, which were better than washable inserts. There was no clear benefit for skin health using either washable or disposable designs. Most women preferred the disposable insert pad but some preferred the other cheaper designs (6/85 preferred menstrual pads; 20/85 preferred washable pants).

![Figure VI-15: A reusable underpad.](image-url)
Figure VI-16: Designs of pads for women with light urinary incontinence. For definitions of light LIGHT and heavy LIGHT, see Section VI.4. (Grade of recommendation in brackets)
13/85 preferred washable pants), both of which were >50% cheaper to use than disposable inserts. Washable inserts were significantly worse than the other designs (72/85 found them unacceptable). Overall there were generally more practical problems with washables, particularly when away from the home (Level of Evidence 1).

The authors concluded that allowing women to choose their preferred design of absorbent product (or combination of different designs for different circumstances) would be more cost-effective and provide better patient satisfaction than provision of disposable insert pads (the most expensive product) alone.

Clarke-O’Neill et al. [18] compared the range (12 products) of disposable inserts for lightly incontinent women available in the UK in 2000. Products were tested by 60 community-based women aged 50 years or older who currently used products similar to those to be evaluated. Products were evaluated using a pad performance questionnaire and a pad leakage diary. As a group, the products performed well in terms of their ability to hold urine without leakage. However, the ‘overall opinion’ scores of the testers showed large differences between products with 88% of subjects scoring the most successful insert as Good or OK compared with 51% for the least successful product (p<0.001) (Level of Evidence 2).

A similar study by the same research group [56] compared all 10 washable pants with integral pad for lightly incontinent women available in the UK in 1999. Seventy-two community-based women who usually used absorbent products for light incontinence tested each product for one week each. Leakage performance was found to be disappointing with 69% (CI: 59-78) of the best performing product not leaking at all with 10g of urine, compared to 40% (CI: 29-51) for the least successful product. Again subjects’ ‘overall opinion’ scores showed wide differences between products with the best performing product scoring 85% Good or OK compared with 34% for the least successful product (Level of Evidence 2).

Baker and Norton [57] evaluated six small disposable inserts and two menstrual pads (available in the USA in 1991) with 65 community dwelling women. The products were rated using an evaluation questionnaire and daily diary of pad use. The two menstrual pads (which were the least expensive pads in the study) scored significantly higher than many of the incontinence products although neither was the most popular pad. The authors concluded that women should try a ‘maxi’ menstrual pad first and then move onto a higher capacity (incontinence) pad if this was inadequate. However, this study was carried out more than 10 years ago and products have changed considerably since then (Level of Evidence 2).

Thornburn et al. [16] studied ‘wet comfort’ using small disposable pads that had been experimentally made using different combinations of materials in an attempt to reduce ‘wetback’ (the tendency of pads to allow urine to escape back on to the wearer’s skin). Twenty women tested the pads. Whenever differences in wet comfort, absorbency or overall performance were found they were in the expected order but differences were small and few reached statistical significance. The clinical value of including technically superior materials was not strongly supported. However, this was a small study and may have had insufficient power to detect significant differences (Level of Evidence 2).

More recently Erekson and colleagues [58] measured the wet-back performance of a range of 10 different branded products. This was a laboratory experiment involving two patients (of different BMIs) sitting on pre-wetted pads. Results showed that neither size nor price of the pads had any effect on the measured product performance. However it is difficult to determine how much such measurements reflect clinical performance.

c) Summary

There is robust evidence that disposable inserts are more effective in terms of leakage and more acceptable than menstrual pads, washable pants and washable inserts (Level of Evidence 1). Menstrual pads are cheaper and washable pants cheaper still (on a per-use basis) and are acceptable to many, particularly those with lighter incontinence and particularly when used at home. Washable inserts are not acceptable to most women. The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Figure VI-16.

d) Recommendations

- Disposable inserts are recommended as the most effective and preferred absorbent product for women with light incontinence (Grade of Recommendation B).
- Menstrual pads or washable pants may be sufficient for some patients with very light incontinence and are cheaper (Grade of Recommendation B).
- Washable inserts are not recommended (Grade of Recommendation B).
- Combinations of designs for different situations (e.g. disposable inserts for going out, washable pants with integral pad for staying at home) are likely to provide optimum management in terms of patient needs and cost-effectiveness, and product advice and provision (where purchased by institutions / services) should reflect this (Grade of Recommendation B).
- See also the general recommendations relating to pad selection in Section VI.11 and to washable pads in Section VI.12.
e) Research priorities

- Because the performance of washables is generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.
- The use of combinations of designs for different situations needs to be evaluated.

6. ABSORBENT PRODUCTS FOR MEN WITH LIGHT URINARY INCONTINENCE

There are five main product designs for men with light urinary incontinence (Table VI-4). However, disposable and washable insert pads are often unappealing to men as they are frequently marketed specifically at women and bear a strong resemblance to menstrual pads. Anatomical differences are also likely to mean that they are less effective for men. Pouch, shield and leaf products (Figures VI-11 and VI-12) are designed to be more suitable for men by containing the penis or penis and scrotum.

Aspects of assessment that are particularly important regarding pads for men with light incontinence include frequency / severity of leakage, day / night incontinence, retraction of penis, individual priorities (e.g. need for discreetness), personal preference for washables / disposables, and lifestyle (home / travel / work).

Only one study has been published which has evaluated absorbent products for men with light urinary incontinence (59). It compared the four main absorbent designs of products available in the UK in 2003: disposable insert pads, pouches and leafs and washable pants with integral pad. All six leaf products (five disposable and one washable) and all six pouches (all disposable) on the UK market in 2003 were evaluated, together with a selected disposable insert pad and a selected washable pant with integral pouch (chosen to represent their respective designs). Seventy men with light urinary incontinence completed the 14 week study and filled out product performance questionnaires at the end of testing each product for a week. Products were supplied in random order within their design group and the design group order was also randomised. Pad leakage diaries were used to record product performance and used pad weight. At the end of testing each design a design performance questionnaire was completed. ‘Overall opinion’ was used as the primary outcome variable. Results showed that the pouch design performed significantly worse than the leaf and the insert design. The most common problems with the pouch were staying in place and difficulties re-inserting the penis in the pouch once the pouch was wet. The leaf designs had the best leakage scores, but one product was significantly better than the other leafs (Tena). The disposable insert was also effective for leakage prevention and was substantially cheaper than the leaf designs.

The washable leaf was the least successful of the leaf designs. The washable pants with integral pad received polarised overall opinion scores (loved or hated) and scored well for staying in place but poorly for leakage (Level of evidence 2). The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Figure VI-17.

a) Recommendations

- Disposable leafs are recommended as the most acceptable and effective design for men with light incontinence, but some men prefer other designs which should be considered as alternatives (Grade of Recommendation B).
- Simple insert pads are cheaper and may be acceptable to some men (Grade of Recommendation B).
- Washable pants with integral pad are likely to be most suitable for men with very light incontinence who have difficulties keeping an insert or pouch in place (Grade of Recommendation B).
- See also the general recommendations relating to pad selection in Section VI.11 and to washable pads in Section VI.12.

b) Research priorities

Because the performance of washables was generally poor (particularly for leakage) compared to disposables, the development of better washable products is a priority.

7. ABSORBENT PRODUCTS FOR MEN AND WOMEN WITH MODERATE-HEAVY URINARY INCONTINENCE

There are at least 12 absorbent product designs for men and women with moderate-heavy urinary incontinence (Table VI-5). The most commonly used products are disposable bodyworn inserts and diapers (Figures VI-3 and VI-6). More recently, modified diapers (T-shaped diapers, Figure VI-7) have been introduced which can be applied by the wearer whilst standing. Pull-ups are also a relatively new innovation and comprise an absorbent pad integrated into a disposable elasticated pant (Figure VI-9). Washable counterparts to most disposable bodyworn designs are available but they have a much smaller market, where they are available. They are made from a variety of natural and synthetic materials. Disposable and washable bedpads are used on the bed at night with or without the support of a bodyworn product. Disposable and washable chairpads are used either without a bodyworn product (in which case the individual must sit directly on the pad with no underpants on) or in combination with bodyworn products to protect chairs from any leakage from the bodyworn. Both practices place an underpad on display and mark the individual as being incontinent and are therefore to be discouraged.

Aspects of assessment that are particularly important regarding absorbent pads for moderate/heavy UI are frequency/severity of leakage, day/night incontinence, gender (some products are better for men/women than others), ability to change pad independently/need for carer, pad changing position (standing/lying), laundry/drying facilities, individual priorities (e.g., need for discreetness), personal preference for design/materials (washable/disposable) and lifestyle (at home/travel/work etc).

**a) Quality of data**

There have been two recent clinical trials comparing the main designs of disposable bodyworn pads (one also included washable designs) which are included in a Cochrane review [55]. There have been no trials of underpads for the last 15 years. There have also been a large number of comparative studies of absorbent products for moderate-heavy incontinence but most are more than 10 years old and evaluated products that are no longer available. Furthermore, changes in materials and design features mean that it is impossible to generalise any particular findings to products of today. Brink [60] identified 30 studies of absorbent products published between 1965-1990. Some robust multi-centre international studies have examined the correlation between laboratory testing and the leakage performance of products clinically.

**b) Results**

1. **Evaluations comparing different designs of disposable and/or washable bodyworn absorbent products for urinary incontinence**

Fader et al. [54] carried out two clinical trials of absorbent products for moderate-heavy incontinence; one involving subjects in the community and the other subjects in nursing homes. In the community-based trial 85 moderate/heavily incontinent adults (urinary or urinary/faecal) living in their own homes (49 men and 36 women) were enrolled, and tested three (or two) products from each of five design categories (total of 14 test products): disposable inserts (with mesh pants); disposable diapers; disposable pull-ups; disposable T-shape diapers; and washable diapers. All products were provided in a daytime and a (mostly more absorbent) night-time variant. Products were selected based on having similar scores for absorbency across the designs (Rothwell scores, [53] see below) and performance data from pilot studies. In the nursing-home-based trial 100 moderate/heavily incontinent adults (urinary or urinary/faecal) living in a total of 10 nursing homes (27 men and 73 women) evaluated one product from each of the four disposable design categories above. Products were selected on the basis of product performance from the community-based trial and, again, day and night-time variants were provided.

Product performance was characterised using validated questionnaires which asked the participants (in the community-based trial) or carers (in the nursing home based trial) to evaluate various aspects of pad performance (leakage, ease of putting on, discreetness etc) using a five point scale (very good – very poor) at the end of the week (or two weeks for the nursing-home-based trial) of product testing. In addition, participants/carers were asked to save individual used pads in bags for weighing and to indicate the severity of any leakage from them on a three-point scale (none, a little, a lot). These data were used to determine differences in leakage performance. Numbers of laundry items and pads used were recorded to estimate costs, and skin health changes were recorded by the participant or by the researchers. At the end of testing participants were interviewed and ranked their preferences (with and without costs), stated the acceptability of the design (highly acceptable – totally unacceptable) and recorded their overall opinion on a visual analogues scale (VAS) of 0-100 points (worst design – best design). A pad changing experiment was conducted with 12 women from the nursing home based trial to determine any differences between product designs. Under idealised conditions the different designs were applied (by the same carers) in random order for each patient and the speed of pad changing was timed using a stop-watch.

Findings from the community-based and nursing home trials were broadly similar. The leakage performance for the disposable inserts was worse than the other designs for day and night and disposable pull-ups were preferred over inserts for the daytime. The new T-shape diaper was not better overall than the traditional disposable diaper. But there were important differences in performance and preference findings between men and women from both trials.

1681
and the men (in the community) had more severe urinary incontinence than the women - mean daytime urine mass in a pad 375 g for men and 215g for women (difference148g, CI: 80, 218).

Pull-ups (the most expensive design) were better overall than the other designs for women during the day and for community-dwelling women during the night too. Although disposable diapers were better for leakage than disposable inserts (the cheapest), women did not prefer them, but for men (in the nursing homes and the community) the diapers were better both overall and for leakage and were the most cost-effective design. No firm conclusions could be drawn about the performance of designs for faecal incontinence and there was no firm evidence that there were differences in skin health problems between designs (Level of Evidence 1).

In the nursing home trial the carers found pull-ups and inserts significantly easier to apply (in the standing position) and significantly quicker in the pad change experiment (mean time 35.2 and 37.9 seconds for inserts and pull-ups respectively and 53.2 and 62 seconds for diapers and T-shaped diapers respectively) and ability to stand was associated with preference for pull-ups or inserts. Despite being designed for ease of changing the T-shape diaper was not found to be easier or quicker to change than the diaper.

The washable products (used in the community-based trial) gave diverse results. Two of the products were made from cotton terry-towelling (one a simple square, folded and pinned in a diaper shape; the other a shaped diaper-like design, both worn with plastic pants) while the third product had a felt absorbent core, with an integral plastic backing and was fixed by poppers. This third product performed significantly worse for leakage than the other two washables and was therefore excluded from the final data analysis. The terry-towelling washables were better for leakage at night than the disposable designs, but were less popular overall for daytime use than the disposable designs. Three quarters of the women (27/36) found them unacceptable, but nearly two thirds of men (31/49) found them highly acceptable at night. Findings from the community-based trial showed that there were many practical problems dealing with washable products particularly when out of the house, but that they were more acceptable at home.

Macaulay et al. [20] carried out a pilot study of 19 washable products with 14 community dwelling subjects. The products included a mixture of washable insert and brief designs and two disposable body-worn products. Product performances varied widely: the most popular was rated as good (for overall performance) by 78% of testers, while the least popular scored 22%. Although most of the washable products performed poorly for leakage, one washable product made of cotton towelling (used with plastic pants), scored better than both the other washable and disposable products (Level of Evidence 3).

Eight older trials have compared disposable with washable bodyworn products for moderate-heavy incontinence [61] [62] [63] [64] [65] [66] [67] [68]. The trials varied in size and design from a large controlled trial with 276 subjects [61] to a small trial of eleven subjects [64]. In addition some trials have compared disposable and washable bedpads and body-worns. Brown [22] [69] undertook a large trial of this kind. The fact that no systematic method of product selection was used for these studies limits the utility of the results since particularly good or poor products may have been selected to represent the disposable or washable groups.

Skin condition was used as an outcome measure in five of the above trials. However, only three used an experimental design and statistical methods of analysis. Beber [61] and Grant [62] both reported that they did not find statistically significant differences between their washable and disposable products in terms of an adverse change in skin condition. But Hu et al. [70] reported a statistically significant improvement in the skin condition of their disposable product users as compared to their users of washable products (See Section XIV).

Four studies attempted to measure costs [63] [62] [71] and [69]. Of these, three used statistical methods of analysis. Hu et al. [71] and Brown [69] reported that although there were no statistically significantly differences in terms of per-day product costs of washable and disposable products, the laundry costs associated with the disposable product (ie for laundering soiled bed linen and clothes) were significantly lower than those associated with the washable product (ie for laundering the products as well as soiled bed linen and clothes). Brown [69] found no significant differences between daily costs of the washable and disposable products. However, statistically significant differences were found between the groups in terms of incontinence-related laundry, with the disposable group producing less laundry than the washable group. Grant [62] reported that the cost of washable products was significantly lower than that of disposables, but laundry costs were not taken into account.

2. DISPOSABLE ABSORBENT PRODUCTS FOR URINARY INCONTINENCE: STUDIES OF SINGLE DESIGNS, LABORATORY TESTS AND STUDIES OF MATERIALS

Clancy and Malone-Lee [15] compared versions of the same pad experimentally engineered to have differ-
ent combinations of fluff pulp and topsheet materials. Forty-five heavily incontinent older adults participated. The main valuable finding from this study was that pads were more likely to leak if they were not held in place by pants (p<0.0001) and that, if there was any leakage from a pad, this tended to be less severe if the supplied mesh pants were worn than if normal pants were worn (p<0.05) (Level of Evidence 2). The mesh pants probably held pads more firmly to the body.

There have been two single design group studies of bodyworn products for moderate-heavy incontinence [72] [73], both carried out in nursing homes. A study of shaped insert pads involved 228 subjects from 33 nursing / residential homes who tested 20 ranges of insert pads [74 products in total]. A similar study of diapers involved 192 subjects from 37 nursing / residential homes who tested a total of 36 products. These studies showed the wide range of product performance that can exist within single product groups. For example, the least successful diaper (based on 'overall opinion') was found to be unacceptable to 100% of the test subjects while the most successful was unacceptable to only 6% (Level of Evidence 2).

In addition, there have been a number of studies on the impact of wet pads on skin health and these are reviewed in Section XIV.

Because clinical evaluations are expensive and time-consuming, laboratory evaluation procedures are in widespread use. Few have been clinically validated but there is a clinically validated International Standard (ISO 11948-1) relating to the leakage performance of disposable bodyworn pads for moderate-heavily incontinent adults in institutions [53]. It describes a simple method for measuring the absorption capacity of pads in the laboratory that was shown to correlate well with the leakage performance of 18 different products evaluated in an international multi-centre clinical study involving 112 heavily incontinent adults [74]. The strength of the correlation between technical and clinical data depended on the exact parameters being compared, but typically r = 0.9 (Level of Evidence 2). This laboratory test (the Rothwell method) is now in common use in the UK, Sweden and other countries and provides a basis for selecting similar products with which to make direct comparisons (for cost purposes) or to select promising pads for inclusion in clinical trials.

The ability of ISO 11948-1 to predict the leakage performance of more recent bodyworn pads (138 diapers and inserts) for heavy incontinence was investigated by Cottenden et al. [75]. Correlations were poorer than in the original 1993 study (r<0.87 compared with r<0.95) but still strong enough to make the method useful. For a given Rothwell capacity, the leakage performance of diapers was far superior to inserts, but no evidence was found for any other design feature of the test products (inserts and diapers) having a significant impact on their leakage performance (Level of Evidence 2).

The repeatability and reproducibility of the ISO 11948-1 was investigated by Cottenden and co-workers [76] in three laboratories (UK, Spain and Sweden). Repeatability (precision between repeats in the same laboratory) was found to be very good with the co-efficient of variation for five repeats rarely exceeding 5%. However, the reproducibility (precision between laboratories) was poorer, revealing systematic differences: results from the Swedish and Spanish laboratories typically exceeded those from the English laboratory by 13% and 8%, respectively. Efforts to identify the source(s) of this poor reproducibility have so far been unsuccessful but it seems likely that minor variations in interpretation of the standard when constructing the apparatus and / or executing the test are to blame (Level of Evidence 2).

**c) Summary**

Results from these studies indicate that there is no single best design (i.e. one design that is significantly better than all other designs for all users) (Level of Evidence 1).

There is evidence that different designs are better for men and women, and that men leak substantially higher volumes of urine than women (Level of Evidence 1).

Of the disposable designs, the more expensive pull-up and T-shaped diaper designs are not better overall than the cheaper diaper for men, indicating that the diaper is the most cost-effective design for men. For women pull-ups are better overall than the other designs (except for night-use in those living in nursing homes), but they are expensive (Level of Evidence 1).

Unlike men, women in the community do not favour diapers over insert pads and of these cheaper designs, inserts may be preferred for women. There is also evidence that the leakage performance of inserts is worse than other designs, but that they leak significantly less if they are held in place by mesh pants than by ordinary pants, and using no pants at all is associated with significantly more leakage than if either kind of pant is worn (Level of Evidence 3).

There is evidence that pads containing superabsorber leak less, are more comfortable, and keep the skin drier than those without (Level of Evidence 2).

The leakage performance of inserts and diapers for heavy incontinence can be predicted with reasonable precision using an international standard laboratory tests (Level of evidence 2).

This test has been shown to have very good repeatability and adequate reproducibility (Level of Evidence 2).

Washable products are very varied in design and materials, and also in performance. There is evidence that terry-towelling products (used with plastic pants) have good leakage performance, however they have limited acceptability - confined mainly to some men at night. There is no firm evidence regarding the perfor-
mance of different designs for faecal incontinence and no firm evidence that any particular design or type of material (washable or disposable) is better or worse for skin health.

The user characteristics, priorities and contexts which favour or discourage the use of the different product designs are summarised in Figure VI-18.

d) Recommendations

• Gender should be considered when products are prescribed / purchased for users. As men often have substantially higher incontinent urine volumes than women, men may require more products and / or more absorbent products than women (Grade of Recommendation B).

• Gender should also be considered when products are prescribed / purchased for users because men and women are likely to prefer different designs. Men generally prefer disposable diapers to inserts (Grade of Recommendation B).

• Women generally prefer disposable pull-ups to other designs, but these are expensive. Disposable inserts are a cost-effective alternative (Grade of Recommendation B).

• Caution is recommended if washable designs are being considered. Heavy bulk confines their use mainly to the night-time (where they may be particularly useful for users who lie on their side). They are unacceptable for most people during the day-time and for most women at any time and for this reason a blanket policy of health services providing washables alone is not recommended. If washables are being considered refer to points below (Grade of Recommendation B).

• Freedom from leakage: Where possible, international standard laboratory tests should be used to rank the likely leakage performance of different pads for heavy and light incontinence (Grade of Recommendation B). In general, diapers should be selected in preference to inserts to minimise leakage (Grade of Recommendation B).

• Carer application: When products are applied by a carer to a patient who can stand for pad changing, disposable inserts or pull-ups are easier and quicker to change than diapers or T-shaped disposables. If the patient is lying down (e.g. at night) pull-ups should be avoided (Grade of Recommendation B).

• Combinations of designs for different situations (e.g. disposable inserts for staying in, disposable pull-ups for going out, washable diapers at night) are likely to provide optimum management in terms of patient needs and cost-effectiveness (Grade of Recommendation B).

• See also the general recommendations relating to pad selection in Section VI.12 and recommendations specific to washable pads in Section VI.13.

e) Research priorities

• Comparison of absorbent products (disposable and washable) when used by carer-dependent users in the community.

• Development of more effective and aesthetically acceptable washable products, particularly for nighttime use and for women.

• Development of more effective and acceptable disposable designs specifically for men.

8. DISPOSABLE UNDERPADS

There have been no published studies examining the use of bedpads during the last 15 years. This probably reflects the recognition of their limited role in long-term management of incontinence. Disposable underpads on chairs declare their user to be incontinent and require clothes to be pulled up (or absent) which is unacceptable for dignity. In the bed disposable underpads easily become displaced, folded and creased under the patient which inhibits their performance and comfort, and may potentially be a threat to skin health. Large disposable underpads with wings to tuck into the bed may have a role as bed protection ‘back-up’ to bodyworn pads. The main role of disposable underpads should be confined to temporary bed or chair protection such as during clinical procedures (e.g. enemas) or when using a urinal.

Published trials comparing different disposable bedpads are few [77] [78] [22] and it is not possible to draw firm conclusions from them on the effectiveness of different product design features and materials. Some useful work has been done to highlight the risks of infection from disposable bedpads and to validate clinically some laboratory tests to assist with product selection by predicting pad leakage performance.

Bedpads are generally supplied as non-sterile items and Bradbury [79] has drawn attention to the risk of infection, particularly from products containing recycled paper. Leigh and Petch [80] and Sprott et al. [81] have conducted microbiological tests on a range of products. Both studies identified low levels of bacterial contamination but concluded that the risk to patients was minimal unless they were immunocompromised in some way. More recently, Stansfield and Caudle [82] reported an outbreak of wound colonization on a surgical orthopaedic hospital ward which they attributed to the use of disposable underpads containing virgin wood pulp.

Due to the paucity of published clinical data many technical tests have been devised to evaluate products in the laboratory. The only tests with published clinical validations are described by Cottenden et al. [74] who subjected six different bedpads to a variety of laboratory tests and to a multi-centre clinical evaluation in which 95 incontinent subjects tested each product in turn for a week, in random order.
Figure VI-18: Designs of pads for adults with moderate-heavy urinary incontinence. For definitions of light HEAVY and heavy HEAVY, see Section VI.4. (Grade of recommendation in brackets)
A combination of two laboratory tests (one to measure the absorption capacity and the other the absorption time of bedpads) gave a strong correlation with the percentage of subjects finding the leakage performance of a product acceptable when used as their sole protection \( r = 0.94 \) and predicted the acceptability scores of all six products accurate to within ± eight percentage points. A different absorption capacity test produced a strong correlation for the leakage performance of bedpads used as back-up to bodyworn products \( r = 0.96 \) and predicted the acceptability scores of all six products to within ± five percentage points.

**a) Summary**

No robust data are available on the effectiveness of current disposable bedpads or of their various design features or constituent materials. There is a risk of infection from bedpads made from recycled paper for immunocompromised users (Level of evidence 2). The leakage performance of bedpads (used alone or as back up to bodyworn pads) can be predicted with reasonable precision using clinically-validated laboratory tests (Level of Evidence 2).

**b) Recommendations**

- Disposable underpads should not be used for long-term management of incontinence, but have a useful role as temporary protection for chairs and beds during clinical procedures (Grade of Recommendation C).
- Immunocompromised people should not use bedpads made from recycled paper because of the risk of infection (Grade of Recommendation B).
- Where possible, clinically-validated laboratory tests should be used to rank the likely leakage performance of different products (Grade of Recommendation B).

**c) Research priorities**

Disposable underpads have a limited role incontinence management but are known to be widely used. An exploration of patient views regarding their use may help demonstrate their limitations.

9. WASHABLE UNDERPADS

Aspects of assessment that are particularly important regarding washable underpads are patient acceptability and preference, particularly with regard to willingness to be naked below the waist (if sole use intended) and availability of laundry and drying facilities.

Cottenden [83] has reviewed comparative evaluations of different washable bedpads up to about 1990. Leiby and Shanahan[84] have since published a study. Some evaluations have found significant differences between products relating, for example, to leakage performance and impact on skin health but none of the products evaluated is still available in the variant tested. In addition, compared products always differed from one another in many respects making it impossible to draw reliable generic conclusions relating to the products now available. However, the choice of topsheet material and the presence or absence of features like tuck-in flaps and integral water-proofing appear to be, primarily, matters of personal preference.

In institutional settings washable bedpads are commonly used by multiple patients and questions are often asked about the risk of cross-infection. Cottenden et al. [85] assessed the risk by determining the microbial content of 145 bedpads of five different designs after a night’s use by incontinent adults, followed by laundering using a standard foul wash procedure which included heat disinfection at 71°C for three minutes. Laundering destroyed all known pathogenic organisms, although some commensal flora were isolated in small numbers. It was concluded that foul wash laundry had left bedpads safe for multiple patient reuse with no demonstrable risk of cross-infection.

**a) Summary**

The literature contains insufficient robust data on which to base guidelines for choosing between washable bedpads. Choice of topsheet material and the presence/absence of design features like tuck-in flaps and integral/separate water-proof backing appear to be, primarily, matters of personal preference (Level of evidence 3). Provided an approved foul wash procedure is used, the risk of cross-infection between different users of a bedpads is very low (Level of Evidence 2).

**b) Recommendations**

- If considering using washable underpads for sole use (ie without a bodyworn product) the patient will need to be naked below the waist. Patient consultation and approval will therefore be needed (Grade of Recommendation C).
- Personal preferences of users with regard to topsheet material, tuck-in flaps and integral waterproof backing should be considered in making product selections (Grade of Recommendation C).
- Provided an adequate foul laundry wash cycle is used, the risk of cross-infection between successive users of washable bedpads is low and not a contra-indication for their use (Grade of Recommendation B).

**c) Research priorities**

- Comparison of washable underpads with bodyworn products when used at night.

10. ABSORBENT PADS FOR CHILDREN WITH URINARY AND/or Fecal INCONTINENCE
