It is clear that robotic assisted laparoscopic (RAL) procedures are being developed in reconstructive and paediatric urology. There is a lack of consensus about which is best for continence outcomes but review data suggest continence rates between 60 and 100 %. Data for RAL artificial sphincters in children are very early (180) but adult data for female bladder neck sphincters with just under 18 month follow-up suggest 72.7 % successful implantation rate (181). A series comparing peri-operative and continence outcomes for bladder neck reconstruction between open and RAL procedures suggest comparable safety and continence outcomes operative time, length of stay, complications within 30 days of surgery and future continence procedures (injection of bladder neck/catheterizable channel, additional bladder neck surgery, botulinum toxin A injection(182).

Conclusion: robotic bladder neck reconstruction is effective to treat urinary incontinence due to functional or anatomical deficiencies (LoE: 3)

Recommendation: robotic bladder neck reconstruction is recommended to treat urinary incontinence due to functional or anatomical deficiencies (GR:C)

6. ALTERNATIVE CONTINENCE CHANNELS

There is no doubt that the job of a reconstructive paediatric urologist is to preserve the original bladder, sphincter and urethra, where possible – there is no better alternative. The bladder can be augmented or replaced as previously described. Urethral reconstruction has been discussed, however there are occasions where it is not salvageable for either spontaneous voiding or catheterisation – in these patients continent suprapubic diversion is indicated.

6.1. The Mitrofanoff principle.

The most widely used continent catheterisable channel is eponymously known as the Mitrofanoff. The technique, tunnelling a narrow tube (originally the appendix) into the bladder or reservoir wall, was published by French paediatric surgeon Mitrofanoff, and the distal end is brought to the abdominal wall to form a catheterisable stoma (183). A number of tubes have been described as the Mitrofanoff conduit (184,185). Data show use of the appendix to have the best outcomes, however, it may not be usable in 31% of patients (185,186).

An alternative is formed by tailoring ileum using the Monti-Yang principle (186-188). The appendix has the best outcomes followed, in order, by a single Monti, double Monti and spiral Monti, although a pragmatic approach may be necessary in complex and/or revision cases (189-191). Use of the ureter is described although data are sparse – it appears that use of a ureteric channel is dependant on a pre-existing mega-ureter.

The Mitrofanoff system achieves reliable continence, which is maintained in long-term follow-up, for a high proportion of patients. Long-term data, from the original (Mitrofanoff) series, (n=23) with a mean follow-up of 20 years, showed 22 patients with no metabolic changes, 1 patient had died. The bladder neck had been closed in 21 patients, secondary bladder augmentation had to be performed in 8, while in 4 children conversion to an incontinent diversion was necessary. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion 23 continent cystostomies were performed on 15 boys and 8 girls with neuropathic bladders. Mean patient age at surgery was 8 years and 4 months (range 3 to 16(192). Recent data support this with the outcome for those having a Mitrofanoff in childhood showing a lower revision rate than in other groups (193). The technique works on the basis of a intraluminal pressure (in the channel) that is 2 to 3 times higher than that within the reservoir to achieve continence even if intra-abdominal pressure is raised. Conversely, the pressure in the lumen of Kock nipple is only slightly higher than that in the reservoir, meaning continence is less reliable (192,194). The Mitrofanoff channel may be buried either between the mucosal and muscle layers of the reservoir, or may be completely Imbrlcated with the full-thickness of a reservoir wall. A well supported tunnel of about 2- 4 cm should function well. Continence rates of 90-100% are reported, with the Mitrofanoff principle, this appears to be irrespective of diagnosis, reservoir or conduit type (195-197). Follow-up for at least ten years has shown that the system is resilient (198-200). Retrospective review of short and long-term outcomes of patients with the Mitrofanoff procedure reveal that stoma stenosis and leakage are the most frequent complications (within wide ranges of 10 – 60 % each) and, most commonly, occur early during the first two years after creation. After the initial peak of complications, there is a relatively complication-free period. Late complications are recorded, probably because of wear and tear of the channels and changes in body habitus at adolescence or in adult life (193,201-205).

RAL Augmentation cystoplasty and Mitrofanoff are developing as techniques, with comparable surgical outcomes and data to suggest improved length of stay (206). A multicentre study, focussed on RAL Mitrofanoff procedures, with 29.5 month median follow-up included 88 patients and showed an 85.2% initial continence rate which climbed to 92 % with additional procedures (207).

A modified vesicostomy is described using a gastrostomy button, which could be used as an alternative, short to medium continent urinary stoma in children with incomplete voiding (208). Although perfect continence seems attractive, it may not be in the child's best interests. A 'pop-off' valve may be in the interest of the child if catheterisation is impossible or forgotten.

6.2. The Ileo-caecal valve.

The ileo-caecal valve has been used as a convenient, alternative 'sphincter' mechanism to use if caecum and ascending colon are used to create a reservoir and terminal ileum becomes the con-

duit. Early published continence rates of 94% were not sustained because of high pressures in the tubular reservoir and failure of the valve (209,210). The Indiana system is based on the competence of the ileo-caecal valve but with a detubularised reservoir. The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rates are 96% with 2% describing catheterisation difficulties (211).

The Mainz I pouch relies on a similar principle with the addition of ,a length of terminal ileum that is intussuscepted through the ileo-caecal valve as a Kock nipple (212). It is impossible to say whether the nipple or the ileocecal valve (or both) produce the 96 % reported continence. Both systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileo-caecal valve may result in gastro-intestinal complications.

6.3. Kock pouch

The first workable continent diversion was the Kock pouch (46). The reservoir is made from 40cm ileum reconfigured to reduce the intraluminal pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which will limit the number of patients for whom this is suitable. The length of bowel needed, subsequent stone formation and stomal leakage saw it fall out of favour (213,214).

6.4. Artificial Sphincter

Authors have described the use of a low pressure AUS cuff around the channel as a last resort, to achieve continence in a reconstructed outlet (210,215). Published data are sparse and appear to show a significant device infection risk, this is reduced from 50% to 9.5 % with a staged procedure (216).

6.5. Siting a cutaneous stoma

The most commonly chosen sites are the umbilicus or the right iliac fossa (ideally below the level of underwear). It is common for a wheelchair-bound spina bifida patient to experience worsening posture with spinal collapse, and a propensity for obesity. As result, the abdomen becomes more pendulous and more difficult to for a patient to access – the umbilicus may be more suitable in this situation. The site should be determined and marked, preoperatively in a sitting position. Fundamentally, the position should be chosen allowing the patient to manage bladder emptying and irrigation for themselves.

Many other patients will chose stomal site on the basis of cosmesis. The umbilicus is discrete, the risk of stenosis is low and it is a readily identifiable landmark. The alternative is a site as low as possible on the abdominal wall ideally hidden by underwear.

The published rate of stomal stenosis is between 10 and 23% (189,193). The siting of the stoma does not appear to influence revision rates (189).

7. COMPLICATIONS OF SURGERY FOR INCONTINENCE IN CHILDREN

7.1. Storage and emptying complications

However well-functioning at first, a reservoir containing bowel, with or without a continent catheterisable channel needs life-long follow-up in a centre capable of surgical revision if needed. Published data in neuropaths showed a median time to revision surgery of ten years (217,218).

The most common issues are difficulties with catheterisation, stomal stenosis and false passages which may occur in up to 34% of patients (196). A retrospective evaluation of 500 augmentations over 25 years with a median follow-up of 13.3 years, showed the cumulative risk of further surgery at the bladder level was 0.04 operations per patient, per year of augmentation and 34% of the patients needed further surgery for complications. Bladder perforation occurred in 43 patients (8.6%) with a total of 53 events and 125 surgeries done for bladder stones in 75 cases (219). It has been suggested that urothelium should be used as preservation of the bladder epithelium may give fewer complications than enterocystoplasty (220) – although data are sparse.

Ureterocystoplasty, appears to offer good outcomes with a low complication rate, even in children with compromised renal function or transplantation (221). All intestinal reservoirs produce mucus. There is no feasible way to measure the volume of mucus, all estimates are subjective. No regime has been shown to dependably reduce mucus production (222). Anecdotally, mucus production will increase with coughs and colds, spicy food and dairy intake. For those who are troubled by mucus it is important to ensure a good oral fluid intake, perhaps a food diary and regular bladder washouts.

7.2. Reservoir rupture

The most morbid and disastrous complication following bladder augmentation is perforation; if unrecognised this will lead to peritonitis, sepsis, and even death. Reported rates of cystoplasty perforation range between 6 and 13% (52,223-225). The incidence of perforation is strongly correlated with non-compliance (relating to catheterisation) and substance abuse (226).

The diagnosis may be delayed (especially if the patient presents to a centre not familiar with their condition or surgery); the history of sudden abdominal pain and diminished or absent urine drainage are important observations. A patient will develop generalised peritonitis and deteriorate quickly (227). A ‘pouchogram’ may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography, CT cystogram and clinical suspicion. If diagnosed early, abdominal drainage, catheterisation and broad spectrum antibiotics may sometimes lead to recovery (228). If a patient does not improve markedly within 12 hours (on a non-operative regime) or if the patient is clinically sick an urgent laparotomy is needed – failure to intervene may be lethal.

Conclusion: adequate detection and treatment of reservoir rupture in patients with cystoplasty is essential to prevent clinical deterioration (LoE:2)

Recommendation: in cases of suspected reservoir rupture early detection and treatments is recommended to prevent serious, and even life threatening clinical deterioration (Gr:A)

A multicentre review from Scandinavia reported an incidence of perforation was found in 1.5% of patients with either augmentation or substitution cystoplasty. The rate was higher in neuropathic patients than any other group (227). A series of 264 children showed 23 perforations in 18 patients, resulting in one death (229). These series demonstrate the importance of a high level of clinical suspicion in any child presenting with abdominal symptoms, if they have had any form of cystoplasty (225). In a review of 500 patients with

bladder augmentation (performed in the preceding 25 years), spontaneous perforation occurred in 43 patients (8.6%), for a total of 54 events. The calculated risk was 0.0066 perforations per augmentation-year (230).

Patients and their families should be warned of this complication and advised to present to hospital immediately with abdominal symptoms, especially if there is any problem with urinary drainage. All young patients with urinary reconstructions, including enterocystoplasty, should carry suitable information to warn attending physicians, in case of emergency.

7.3. Metabolic complications

Bowel retains all its absorptive and secretory properties no matter where and for how long it is in the urinary tract, the resulting consequences may affect children more than adults simply because of the expected lifetime of the cystoplasty (231,232). In short anyone with a cystoplasty needs monitoring for metabolic complications (233). Nurse et al. found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable (234). A third of patients (but 50% of those with an ileocecal reservoir) had hyperchloraemia. All patients had abnormal blood gases, the majority having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed. In 183 patients of all ages at St Peter's Hospital who had any form of enterocystoplasty, hyperchloraemic acidosis was found in 25 (14%) and borderline hyperchloraemic acidosis in an additional 40 (22%) patients. The incidence was lower in pure ileal reservoirs when compared to those containing any colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found (235). In a series of 23 patients, Ditonno et al. found that 52% of patients with a reservoir of right colon had hyperchloraemic acidosis (236). Most studies do not distinguish between patients on the basis of renal function. All of 12 patients in one series with a pre-operative serum creatinine above 2.0mg developed hyperchloraemic acidosis within 6 months of enterocystoplasty (237). Patients need monitoring for metabolic abnormalities, including hyperchloraemic acidosis – whilst this may be subclinical if it is progressive, severe or combined with renal failure it is more likely to need treatment (238).

It is mandatory to monitor for vitamin B12 deficiency in all patients who have had ileal cystoplasty, the consequences are irreversible and failure to monitor and detect would be open to criticism. Ileal resection in children, probably leads to an incomplete defect in absorption. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which accumulates in B12 deficiency, suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years, following cystoplasty. In adults, the mean B12 level was significantly lower when the ileo-caecal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) (239,240). To avoid the serious neurological complications, regular monitoring of B12 levels is essential. In a review of 500 augmentations starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low-normal values (241). Paediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. Annual monitoring of serum B12 with replacement where necessary, beginning at 5 years following cystoplasty is recommended.

Conclusion: monitoring of metabolic changes in children who underwent a cystoplasty is essential (LoE:2)

Recommendation: monitoring of metabolic changes is recommended in children with a cystoplasty (GR:B)

The stomach is rarely used as a urinary reservoir. Its non-absorptive role in the gastro-intestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastrointestinal function. Metabolically, the acid production leading to hyperchloraemic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However, about a third of children have had serious long-term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acid urine, particularly, have limited its use (242,243).

7.4. Effects on the gastrointestinal tract

Little attention has been paid to the effects on gastro intestinal motility of removing segments of ileum or caecum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected. Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. Quality of life may be seriously impacted by changes in bowel habit(244). It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. For all the reasons above, reconstruction should be undertaken with the smallest length of bowel possible. Care should be taken in children with neurological abnormality in whom faecal continence may already be poor. Faecal incontinence may occur in a third of patients (245,246), and has been shown to have a significant impact on quality of life (247).

7.5. Renal function

Obstruction and high pressures in the bladder during storage will cause nephropathy and renal deterioration if they are not treated with (for instance) cystoplasty. Postoperatively, urinary diversion may be followed by difficult urinary tract infections and stone formation with the potential to damage renal function. It is important to monitor renal function in anyone who has undergone reconstruction or diversion. The procedures themselves do not appear to have a direct, damaging effect on renal function, unless there is a technical failure or complication. In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder (248). This suggests, at least experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

In the longer term, renal deterioration has been related to obstruction, reflux and stone formation. In one study of patients who have had a Kock pouch, these complications occurred at the same rate as found in patients with ileal conduits: 29% at 5 to 11 years (249). Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was attributed to a 'surgical' cause in all but one (250).

Although a more complicated procedure, a renal transplant can be anastomosed to an intestinal reservoir with similar long-term results as those using an ileal conduit (251,252).

7.6. Infections and stones

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer et al. reported an incidence of 52.5% during a follow-up of four years (253) with a predicted recurrence rate of up to 50%, greatest in the first two years following removal of the first stone and independent of the method of removal (254). Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.

In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs (255). Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai et al. found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch (256). This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs (257). It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies (214). There has been much speculation about the importance of mucus, as to whether it acts as the initial nidus for stone formation or additive by 'sticking' to a small stone and increasing the size. Recent data suggest that daily bladder washouts may reduce the incidence of stones and infections in reconstructed reservoirs (258). In a comparison looking at stone formers versus non-stone formers, those forming stones were found to have a lower urinary citrate and 24 hour urine volume suggesting a lower fluid intake and possible dietary factors (259). Mathoera et al. found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified (260).

Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals (261). Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies, it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones. An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self-catheterisation. Interestingly, there was no significant difference in the incidence of stones with or without an augmentation (262).

Stones are associated with inadequate drainage in the sense that in CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most 'uphill' drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones (261). Kronner et al. made the observation that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone) (257). Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as residual fragments may form the nidus for a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended (254,263,264). The high incidence of stones following enterocystoplasty suggests several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important (265). There is no evidence that prophylactic antibiotics are useful, but a clinical infection should be appropriately treated.

7.7. Growth

This short section is included to establish that there is no long-term effect on childhood growth as a result of having a cystoplasty. An initial report examining 60 children reported in 1992 found that 20% had delayed growth (266). Updated data from the same group has shown that all have caught up and achieved their final predicted height. A further study of 123 children from the same unit have shown no significant delay in linear growth (267). Animal data did show that with enterocystoplasty there was significant reduction in bone mineral density especially in the cortical compartment where there is endosteal resorption. These changes are not associated with metabolic acidosis and are lessened by continuous antibiotic administration , under experimental conditions - it is not clear how this would relate, if at all, to clinical practice (268,269). More recent follow-up data confirms no effect on growth (270-273) .

7.8. Pregnancy

Young girls and women who require urological reconstruction will commonly wish to have a family, in the same way as their peers. Consideration of this needs to be an active part of their follow-up (274). It is important that when young women reach adolescent they are informed about important risks – for instance the need for high dose folic acid for at least three months before and after conception if they have spina bifida (275). Patients also need to know that once they have bowel in the urinary tract a urine pregnancy test has a 57% false positive rate and always needs confirmation with a serum HcG test (276,277).

Surgically, paediatric urologists have described fixing pedicles out of the way to leave room for a gravid uterus in later life. Whist this sounds logical there are no data to say this makes a difference in the long term. Pregnancy (when it happens) may be complicated and requires the joint care of a high-risk obstetrician and an experienced reconstructive urologist (278). Problems can include upper tract obstruction and incontinence as the pregnancy develops. Pregnancy with a cystoplasty appears to have a good outcome, urine infection may be an issue and occasionally an indwelling urethral catheter may be necessary in the third trimester (279). With a catheterisable channel, as the pregnancy develops the channel may become distorted making catheterisation difficult, less commonly the channel may leak more – either way indwelling catheter drainage may be needed for the latter stages (280). When it

comes to delivery the important principle is to avoid an emergency caesarean section without urological support. The decision on mode of delivery is an obstetric one but may involve discussion with their urologist. Major pelvic distortion or reconstruction eg. bladder exstrophy will probably make an elective caesarean section more likely as a choice. This should be planned for around 37 weeks of gestation. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles (278). During any delivery, the bladder reservoir should be empty and an artificial sphincter deactivated.

7.9. Malignancy

The risk of malignancy in enteric augmentations has been reported to be higher than expected, and the risk increases with length of follow-up. Malignancy occurs in 0.6-2.8% of patients during median follow-up of 13-21 years. In a study including 153 patients with a median follow-up time of 28 years, malignancy was found in 4.5% (281). Animal data suggest that faecal and urinary streams must be mixed in bowel for neoplasia to occur – the risk of malignancy does seem predictably higher in patients who have had a ureterosigmoidostomy, and thus they are one of very few groups in whom regular surveillance is recommended. However, if it is chronic mixed bacterial infection, rather than the dual effluent, then all bowel urinary reservoirs are at risk. The malignancy seemed to be associated with coexisting carcinogenic stimuli, immunosuppression or with the inherent risk present with bladder exstrophy. In patients with colonic and ileocystoplasties high levels of nitrosamines have been found in the urine of most of the patients examined (282,283). Clinically significant levels probably only occur in chronically infected reservoirs (284). Biopsies of the ileal and colonic segments showed changes like those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture (285). In a review by Filmer et al., 14 cases of pouch neoplasm were identified (286). Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumours were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years of age. Cancer was found in bowel reservoirs at a mean of 18 years from formation. In a review of 260 patients with a follow-up of more than 10 years, Soergel et al. found 3 malignancies (all transitional cell carcinoma): 2 following ileocecal and 1 after caecal augmentation. Age at augmentation was 8, 20 and 24 years respectively: the tumours were found when they were 29, 37 and 44 years old. All had metastatic disease and died. The incidence of malignancy in this group was 1.2%: considering that the development of tumours usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8% (287). Hussmann et al. studied a group of 153 patients with a mean follow-up of 27 years (10-52 yrs.) after augmentation cystoplasty. In those with a neurogenic bladder (n=97) they found 2 patients with transitional cell carcinoma (both smokers), in 38 patients with bladder exstrophy 3 multifocal adenocarcinomas in the augmented segment were found and in 2 of 18 patients with urethral valves an adenocarcinoma was discovered. The overall risk of cancer was 4.5% after a median period of 32 years. Of the 7 patients, 5 died suggesting that these tumours are very aggressive and metastasised early (281). This level of carcinogenesis was supported by data from Sung (288).

Patients with a gastrocystoplasty are at increased risk of malignancy. In a review of 119 patients who underwent gastrocystoplasty across two institutions, three patients developed gastric adenocarcinoma, another had poorly differentiated transitional cell carcinoma, all occurred more than 10 years after augmentation (289-291). Unreconstructed patients with neurogenic bladder reliant solely on CIC have an increased risk of bladder cancer; this risk may increase following bladder augmentation (292). There is no universally agreed means for follow-up by either imaging or endoscopy (293). Annual endoscopy is never been proven as effective as tumours that occur have done so in screening intervals – it is important to be responsive and investigate patients who develop new symptoms including haematuria, pain or unusual urine infections (294-295).

7.10. Psychological consequences and quality of life

The main justification for performing a bladder reconstruction or continent diversion is to improve urological function and thus Quality of Life (QoL). It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults, the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments. Our prejudice is that reconstruction does, indeed, improve the lives of children although supporting evidence is very thin and based on experience in adults. The Indiana group have certainly shown that incontinence has a detrimental impact on QoL (296), thus we infer that surgery to improve continence will improve quality of life.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd et al. investigated 200 patients, half with an ileal conduit and half with a Kock pouch: there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently 'happier' were those who had had a conduit and subsequently were converted to a Kock pouch (297,298).

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QOL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives (299).

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because of a lack of validated instruments, difficulties in translating from one culture or language to another, and the difficulties in selecting control groups and variations in clinical situations. Gerharz et al. constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance. In addition, they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity (300).

Consensus statement on surgical treatment of urinary incontinence in children

Urinary incontinence in children requires careful assessment with a thorough history, physical examination and voiding diary obviating the need for further investigation in the majority. A limited group will benefit from surgery. Many patients in this group will have obvious severe congenital/anatomical abnormalities.

The rarity of conditions may dictate an individualised approach to treatment that may be tailored by the expertise and training of the treating physician. Surgical procedures develop gradually and almost never undergo systematic evaluation. The concentration of care in specialist centres removes the need to rely on one surgeon with an unlikely expertise that would allow treatment of all conditions. The combined expertise of an expert team seems to offer a model for improved clinical care.

Such centres may allow the development of improved surgical approaches for severe complex anomalies such as exstrophy, myelodysplasia and urethral valves with the goal of improved future outcomes. Centralisation may also provide the opportunity for randomised studies to determine the most specific and effective treatment.

The committee would encourage vigorous research on the molecular basis of bladder development and support the development of surgical and treatment strategies which utilise the natural ability of the bladder to develop and transform in early life.

Endeavours to promote bladder healing, protect and achieve normal bladder function should be supported. Such studies and research may lead to earlier and improved treatment of many of the complex anomalies now treated by the surgical procedures outlined in this report.

VII. PSYCHOLOGICAL ASPECTS OF URINARY INCONTINENCE, ENURESIS AND FAECAL INCONTINENCE

List of abbreviations used in this section

ADHD	Attention-Deficit/Hyperactivity Disorder
CBCL	Child Behaviour Checklist
DSM-5	Diagnostic and Statistical Manual of Mental Disorders – 5
DUI	Daytime urinary incontinence
FI	Faecal incontinence
ID	Intellectual Disability
ICD-10	International Classification of Diseases – 10
LUTS	Lower urinary tract symptoms
NE	Nocturnal enuresis
ODD	Oppositional Defiant Disorder

1. INTRODUCTION

During the past years,, an increasing body of reviews has been published on psychological factors of incontinence in children, as well as adults (1-5). A new focus of research and clinical practice is on children with special needs, who have higher rates of incontinence and behavioural problems (6). This chapter includes an update based on the recent literature and especially the ICCS standardisation document on psychological aspects in urinary and faecal incontinence (7), as well as other ICCS documents.

Children with urinary incontinence, enuresis and faecal incontinence carry a higher risk for manifest behavioural disorders, as well as for subclinical emotional and behavioural symptoms. It is important to assess and integrate psychological factors in treatment for two reasons:

1. As can be seen in Table 1, the rate of comorbid behavioural and emotional disorders is much higher than possible organic causes (7). The same care used to exclude organic causes should be applied to the assessment of behavioural aspects. Therefore, paediatricians and urologists should have a basic understanding of psychological principles to treat their young patients adequately.
2. In functional or non-organic incontinence, provision of information, cognitive therapy and behavioural modification are the most effective, first-line approaches to treatment. Medications can be helpful in many cases, but are usually not the mainstay of treatment. Surgery is rarely indicated. As most of the techniques used in “urotherapy” are based on cognitive-behavioural psychotherapy, it is essential to be acquainted with the basic psychological principles.

This chapter provides information on comorbid manifest clinical disorders, as well as symptoms which might be emotionally distressing for children and parents, but do fulfil the criteria for a disorder. Often, these will resolve upon attaining continence, while manifest disorders usually do not. In addition, children with psychological disorders are less compliant, and this explains why the failure rate of children’s incontinence treatment is much higher. It is recommended that both incontinence and any comorbid psychological disorder are treated separately to ensure effective therapy.

The relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for

Table 1: Organic causes and comorbidity of clinically relevant psychological disorders or symptom scores*

Nocturnal enuresis	
Organic causes	< 1%
Behavioural comorbidity*	20-30%
Urinary incontinence	
Organic causes	<10%

enuresis and urinary incontinence as well as of the Rome-IV classification for faecal incontinence will be used (8,9).

2. CLINICAL BEHAVIOURAL DISORDERS

Worldwide, approximately 10 to 20% of children are affected by clinically relevant mental health disorder according to ICD-10 (10) or DSM-5 (11) criteria (12). Even under most conservative estimates, 15% of children and adolescents have psychological disturbances with daily incapacitation. But are these disorders increasing? Bor et al. tackled this question in their very carefully conducted review and found that for toddlers and children, there was no major increase of psychological disorders (13). However, adolescents show an increasing risk for internalising disorders such as anxiety and depression, especially girls. The rate of comorbid behavioural disorders is increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without referring to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem,
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis,
- Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD),
- With such common disorders, no causal relationship can be present and the two may co-exist by chance.

A psychological disorder (synonyms: psychiatric, psychic, mental disorder) “is a syndrome characterised by clinically significant disturbance in an individual’s cognition, emotion regulation, or behaviour that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities” (DSM-5) (11).

Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnoses according to standardised classification schemes: ICD-10 (10) or DSM-5 (11). Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate three broad categories:

- Externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders and ADHD),
- Internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry and depressive disorders),
- Other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders and autism spectrum disorders.

Five of the most important disorders occurring in children and adolescents with NE, DUI and FI are summarised below:

Major depression has a prevalence of 2-5%. The aetiology is multifactorial with a 40-50% contribution of genetic factors. Symptoms include sadness, unhappiness, loss of enjoyment, lack of energy and interest, negative thinking, sleep and appetite problems. Treatment includes counselling, cognitive-behavioural, interpersonal and psychodynamic psychotherapy which can be combined with antidepressant medication. A population-based study of 2079 6-year-old children has shown that depressive and anxiety symptoms are more common in children with NE and DUI, and especially high in FI (14).

Anxiety disorders affect 5% of children. Again, aetiology is multifactorial, including family, temperament and to 40% genetic factors. Four subtypes predominate: separation anxiety disorder, characterised by fears associated with separation; generalised anxiety disorder with the main symptom of worrying; in social phobia avoidance of social situations is typical and in phobia a fear of objects. Treatment consists of counselling, cognitive-behavioural therapy, relaxation, exposure and skills-based techniques, psychodynamic psychotherapy and medication in severe cases (antidepressants). Studies on anxiety in children with incontinence are still rare; exceptions are the study by Equit et al. (14). A new study using DSM-5 definitions showed that 34.6% of young incontinent children had at least one anxiety disorder (15).

Attention-deficit/hyperactivity disorder (ADHD) has a prevalence of 6% and a predominantly genetic aetiology (70-80%). The main symptoms are inattention, hyperactivity and impulsivity. Treatment includes counselling, parent training and cognitive-behavioural therapy. Medication plays a major role (mainly stimulants). In one population-based study of 1391 6-year old children, children with DUI had the highest rates of ADHD (16). Many studies have been conducted on the associations of ADHD and incontinence, which have been summarised in the systematic review of von Gontard and Equit (5).

Oppositional Defiant Disorder (ODD) is characterised by persistent hostile, provocative and noncompliant behaviour and affects 2-5% of children. The aetiology is best explained by a gene-environment interaction, including a genetic disposition and dysfunctional parenting practices. Treatment consists of counselling, parent training, cognitive-behavioural therapy, school-based interventions, but usu-

ally not medication. One population-based study on 718 6-year-old children showed a high rate of ODD, especially in children with DUI (17); and another study of 1676 6-year-old children, especially those with FI were affected by ODD, ADHD or both (18).

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder, defined by persistent deficits in social communication and social interaction and restricted, repetitive patterns of behaviour, interests and activities (DSM-5) (11). These disorders are present from the early developmental period, cause clinically significant impairment and are associated with intellectual and language impairment, and other disorders. The prevalence of ASD is 0.6-1%. The aetiology is mainly genetic, with up to 90% of the variance being due to genetic factors. 15% of ASD are syndromal forms, with the Fragile-X Syndrome, Tuberous Sclerosis being the most important syndromes. The diagnosis is based on a full child psychiatric, paediatric and genetic assessment. Treatment consists of parent training and counselling, autism-specific training programmes and behavioural therapy. Medication includes neuroleptics, stimulants, antidepressants (SSRI), which are not given routinely, but only when indicated. In a recent systematic review, the associations of ASD and incontinence were summarised, as well as the many open research questions (19).

3. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH NOCTURNAL ENURESIS AND DAYTIME URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems (16.5% to 51.9%) than non-wetting children (7.8% to 10.2%), in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher, based on early population-based studies (7). Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups. To date, the largest and best population-based studies are those of Joinson et al., based on the British ALSPAC birth cohort (20, 21, 22) (see table 2).

3.1. Nocturnal enuresis

The ICCS differentiates between primary (never dry) and secondary NE (relapse after a dry period of 6 months); and monosymptomatic (no lower urinary tract symptoms - LUTS) and non-monosymptomatic NE (with LUTS). Therefore, four subgroups of nocturnal enuresis can be differentiated:

- Primary monosymptomatic nocturnal enuresis
- Primary non-monosymptomatic nocturnal enuresis
- Secondary monosymptomatic nocturnal enuresis
- Secondary non-monosymptomatic nocturnal enuresis

Epidemiological studies show clearly that, depending on definitions and instruments used, 20-30% of all nocturnal enuretic children show clinically relevant behavioural problems, 2 to 4 times higher than non-wetting children (7).

Table 2: Epidemiological, population-based studies: Percentage of children with clinically relevant behavioural problems in comparison to controls and their relative risk*

Study	Age (yrs)	N	Type of wetting	Incontinent children	Controls	Odd's ratio
Joinson 2007 (19)	7 ½ years	8242	NE	Separation anxiety: 8.0%	6.40%	1.3
				Social anxiety: 7.0%	4.60%	1.5
				Specific phobia: 14.1%	11.50%	1.2
				Generalised anxiety: 10.5%	7.70%	1.4
				Depression: 14.2%	10.90%	1.3
				ODD: 8.8%	4.70%	1.9
				Conduct disorders: 8.5%	5.70%	1.5
				ADHD: 17.6%	11.90%	1.5
Joinson 2006 (20)	7-9	8213	DUI	Separation anxiety: 11.4%	6.80%	1.8
				Attention/activity: 24.8%	13.80%	2.1
				Oppositional behaviour:10.9%	5.80%	2
				Conduct problems: 11.8%	6.20%	2
Joinson 2006 (21)	7-8	8242	FI	Separation anxiety: 4.3%	0.80%	5.4
				Specific phobia: 4.3%	1.00%	4.3
				Generalised anxiety: 3.4%	0.40%	8.5
				ADHD: 9.2%	1.90%	4.8
				ODD: 11.9%	1.90%	6.3

**DUI = Daytime urinary incontinence*
**FI = Faecal incontinence*
**NE = Nocturnal enuresis*

In the British population-based ALSPAC-study of 8242 children at the age of 7 ½ years, children with NE were affected by: separation anxiety (8.0%), social anxiety (70%), specific phobia (14.1%), generalised anxiety (10.5%), depression (14.2%), ODD (8.8%), conduct disorders (8.5%) and ADHD (17.6%) (table 2) (20).

Children with primary nocturnal enuresis were not different from controls in epidemiological studies (23). Secondary nocturnal enuresis was preceded by a higher rate of weighted life-events (24) and was significantly associated with a higher rate of psychiatric disorders, which can persist into adolescence (23). By adolescence, the attainment of dryness after the age of 10 years increased the risk for behavioural problems, independently of the primary or secondary status (25). Newer studies show that 1-2% of adolescents are still affected by nocturnal enuresis, often accompanied by psychological symptoms (26).

The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7 ½ years (27). Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-monosymptomatic forms), although the differences did not reach significance. In a new series of 1638 children, those with primary non-monosymptomatic enuresis had higer rates of psychiatric disorders than those with primary monosymptomatic enuresis (31.5% vs. 19.5%) (28).

Regarding the types of behavioural and emotional disorders, externalising disorders such as ADHD and ODD predominate (5, 16,17,18, 29).

In a retrospective study of patients with ADHD, 20.9% wet at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is a nonspecific association of ADHD and both night and daytime wetting (30). 25% of 140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls (31). The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens et al. (32), possibly due to selection bias: 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability (32). Children with ADHD continued to wet at follow-up much more often (65%) than controls (37%) (Odds-ratio 3.17). At a 4-year follow-up, 64% still had ADHD: of these, 42% continued to wet at night (compared to 37% of the controls) (33).

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of children with ADHD, but only in 22% of the controls (34). This means that children with both enuresis and ADHD require special attention – and both need to be treated separately.

3.2. Daytime urinary incontinence

Daytime wetting has been neglected in epidemiological research. The most important study is based on a cohort of 8213 children aged 7 ½ to 9 years (21). Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). Externalising disorders predominate in daytime wetting children, which, in turn, will interfere with treatment. In the same cohort, 10,000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression / anxiety were associated with daytime wetting and soiling (35). In another population-based study, 36.7% of children with urinary incontinence had ADHD symptoms, in comparison to 3.4% of dry children (16).

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria (36). With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding (34).

Daytime wetting is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated (8):

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstructive voiding
- Stress urinary incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with urgency incontinence have fewer behavioural problems than those with other types of DUI. 29% of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalising disorder. 13.5 % had a clinical total problem score in the CBCL, again mainly internalising problems (37, 38). The children are distressed by their wetting and family functioning is intact. In another study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis (39). Children with urgency incontinence have lower rates of comorbid disorders than those with voiding postponement (36% vs. 59%), but higher than controls (9%). Children with urgency incontinence predominantly have emotional, introversive disorders. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introversive symptoms predominate.

Children with voiding postponement, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8 % fulfilled the criteria for at least one ICD-10 diagnosis (37). These were mainly externalising disorders in a third of children such as Oppositional Defiant Disorder (ODD). Also, 37.3 % of children had a CBCL total score in the clinical range, again, with externalising symptoms predominating. In addition, family functioning was impaired (37,38). In another sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis (39). In summary, children with voiding postponement have highly increased psychiatric risks. Voiding postponement as one of the most important subgroups of DUI was the topic of a recent review (41).

Studies on comorbid behavioural problems in children with underactive bladder have not been performed. Systematic investigations of psychological aspects of dysfunctional voiding are rare. In some children, it represents an acquired habit, in others severe psychological disturbances are present (42). Dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports (43). DV can persist into adulthood and can be associated with anxiety and depression, especially in women (44). There have been no systematic investigations of children with giggle incontinence. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends has been observed. It is not known if the rate of behavioural disorders is increased. Regarding the other subtypes of urinary incontinence, anecdotal data have been reported for adolescents (26).

4. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH FAECAL INCONTINENCE

According to the Rome-IV classification, two subtypes of faecal incontinence can be differentiated (9):
- Functional constipation (with or without incontinence)
- Non-retentive faecal incontinence

4.1. Epidemiological Studies

In the large ALSPAC study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (see table 2) (22). In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

In clinical studies, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range (7). Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these behavioural problems are not addressed treatment will be less successful (45).

A new study demonstrated, that 27.6% of adolescents with anorexia nervosa had constipation, an over-looked comorbidity in this severe eating disorder (46).

Children with faecal incontinence and constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, (47) and 37% vs. 39%, (48). This means that the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there is no evidence that one type (i.e. with constipation) has more somatic aetiology, while the other type (i.e. without constipation) has a more psychogenic aetiology. There is no specific psychopathology typical for faecal incontinence: all types of behavioural and emotional disorders can co-exist.

4.2. Subclinical signs and symptoms

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions to-wards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

4.2.1. Impact on children

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night (40 children aged 5-15 years) (49). In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits (50): they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be “really difficult” – ranking 8th behind other stressful life-events (51).

One construct of special importance is that of self-esteem. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness (52). In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls (53) and in yet another, the self-esteem total score was higher among enuretics than norms (54). Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem (55) – but there can be no doubt that self-esteem can improve upon attaining dryness (54). Self-esteem increases even if treatment of enuresis is not successful (56), showing that care and “good doctoring” for children and parents is of great help – regardless of outcome. Recently, a focus has been on quality of life, which is reduced in children with urinary incontinence (57). Questionnaires to assess quality of life will be presented later.

Children with faecal incontinence tend to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions (58). In another study, self-esteem did not differ between children with faecal incontinence and controls (59). In a more recent study, adolescents clearly had a lower self-esteen and were highly distressed (60). In yet another study, 95% of 141 children with faecal incontinence seen in a pediatric setting had at least one psychosocial risk factor (61).

Repeatedly, quality of life was shown to be reduced in patients with faecal incontinence and constipation, as summarised in the review by Vrisman et al. (62, 63, 64).

4.2.2. Impact on parents

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little (65). In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects (66). Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms (67).

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study (68) and 2.75 years in another (69). Also, many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead (68,69).

A minority of parents show an attitude that was described as “maternal intolerance” by Butler et al (70). Convinced that their child is

wetting on purpose, the risk for punishment is increased. In some cultures, punishment is very more common: 42% of Turkish children were spanked and 13% beaten (71). Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child (72). These parental attributions and experiences must be considered in all treatment plans for enuresis, as they can decisively influence the outcome.

Parents of children with faecal incontinence are also stressed and worried about the problem (73). In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls (59). In another study of 104 families, nearly half (51%) had no unusual family problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event (74). In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

In recent studies, parents of children with constipation were stressed and had increased psychological symptoms and had more child-rearing difficulties (75, 76).

5. CHILDREN WITH SPECIAL NEEDS

Special needs is an umbrella term referring to individuals who require additional medical, psychiatric, psychological and educational assistance (6). Those with special needs comprise heterogeneous groups of physical and intellectual disability, as well as a wide variety of neurodevelopmental disorders. These disorders and disabilities continue to affect adults, i.e. they are life-long conditions. Incontinence is major, but often neglected disorder in people with special needs.

Studies have shown repeatedly that all types of incontinence are more common in children with special needs than in normally developing children, i.e. nocturnal enuresis (NE), daytime urinary incontinence (DUI) and faecal incontinence (FI). Also, incontinence has a higher likelihood of persisting into adolescence and adulthood, i.e. becoming a chronic condition. Incontinence can have an additive negative effect on the emotional state, self-esteem and quality of life of the child with special needs – and can affect his/her own daily school and family functioning.

Due to this focus on incontinence in children with special needs, the ICCS has issued an position paper specifically on neurodevelopmental disorders. These begin early in life, are mainly genetically determined and are associated with higher rates of all types of incontinence. The three most important neurodevelopmental disorders are ADHD, autism-spectrum-disorders and intellectual disability (77).

Many children with intellectual disability have special needs. Intellectual disability (ID) is defined by an IQ < 70. Mild ID (IQ 50-69) and severe ID (IQ < 50) are the two broad categories. Many different syndromes and disorders are associated with ID, most with prenatal, genetic causes. Overall, incontinence is more common in children, adolescent and young adults with ID (78). Also, there is an inverse relationship between IQ and incontinence, i.e. the lower the IQ is, the more often incontinence occurs.

Incontinence has been studied only in some of the specific syndromes of ID, such as Fragile-X, Williams, Down and Angelman syndromes (79-82). Incontinence rates of many other syndromes are summarised in von Gontard et al. (77). In addition to the IQ-level, syndrome-specific risk factors for incontinence have been identified, such as .epilepsy in Angelman syndrome and behavioural factors in other syndromes.

As many children with special needs do not receive standard assessment and adequate treatment, professionals working with children with special needs should realise that incontinence is a major and common problem in their patients and should actively offer effective treatment of incontinence, the underlying condition and associated, comorbid disorders. Daily distress will be reduced for patients, as well as parents and caregivers.

6. GENERAL PRINCIPLES: ASSESSMENT

6.1. Screening Questionnaires

Due to the high rate of comorbid behavioural disorders, the ICCS recommends screening with a broad-band, validated questionnaire (7,8). An ICCS-document provides an overview of the most important questionnaires (83). Broad-band means that a wide range of psychological symptoms are assessed. Narrow-band questionnaires are less useful as screening instruments, but are valuable in the diagnosis of specific disorders. Narrow-band questionnaires include those for depression, anxiety, ADHD, obsessive-compulsive behaviour, tics and autism spectrum disorders. If a manifest psychological disorder is suspected by history, clinical observation, exploration and broad-band questionnaires, a child psychological or psychiatric assessment is recommended. Short, medium and long screening questionnaires are available.

Conclusion: screening questionnaires are effective to diagnose comorbid behavioural disorders (LoE:2)

Recommendation: screening questionnaires are recommended to diagnose behavioural disorders (GR:B)

6.1.1. Short broad-band screening questionnaires

The ‘Parental Questionnaire – Enuresis/Urinary Incontinence (PQ-EnU)’, a parental questionnaire which has been used widely in clinical care and research, has been validated (84). It contains yes/no questions regarding nocturnal enuresis (NE) (12 items), daytime urinary incontinence (DUI) (10 items), voiding and stool habits (19 items), as well as behavioural problems (10 items). In the validation sample of 496 patients, a high correlation of .723 to .778 with diagnoses of incontinence (NE, DUI and faecal incontinence -FI) could be demonstrated. A factor analysis of the Behavioural Problem Scale (BP) revealed three factors: “attention and school deficits“ (Cronbach’s α =.665), “impulsive-aggressive behaviour“ (Cronbach’s α =.731) and “internalising problems“ (Cronbach’s α =.409). These factors showed significant correlations with Child Behaviour Checklist (CBCL – see below) total, internalising and externalising scales (.351 to .608). In summary, the PQ-EnU is a valid questionnaire to examine children with incontinence and can be used as a screening for psychological symptoms. It can be downloaded without charge (3).

The ‘Short Screening Instrument for Psychological Problems in Enuresis (SSIPPE)’ is a comparable instrument available in appendix of Van Hoecke et al. (85). It is a validated parental questionnaire, based on the Child Behaviour Checklist (CBCL) (86). It has three

scales including 7 Items for emotional problems, 3 Items for attention symptoms and 3 Items for hyperactivity/impulsivity symptoms. The authors recommend that if more than two yes answers are given for any of the 3 problem areas (emotional, attention, hyperactivity/impulsivity), this should be followed by a more detailed questionnaire such as the CBCL. If the CBCL T-scores are in clinical range (or many problem items are answered with a "2"), then a detailed child psychiatric assessment should follow.

6.1.2. Medium-length broad-band screening questionnaire

The Strengths and Difficulties Questionnaire (SDQ) is a medium-length behavioural screening questionnaire about 3-17 year olds (14). Parent and teacher versions are available, as well as self-reports for 11-17-year-old children and adolescents. It exists in several versions to meet the needs of researchers, clinicians and educationalists. In addition to the standard version, one version additionally assesses impact and incapacitation, while another version is useful for follow-up. Official translations are available in 77 languages.

All versions of the SDQ ask about 25 attributes, some positive and others negative. The items are scored on a three-point scale: not, somewhat and certainly true. The 25 items are divided between 5 scales: emotional symptoms (5 items), conduct problems (5 items), hyperactivity/inattention (5 items) and peer relationship problems (5 items) – these 4 scales form the total difficulties score. A fifth scale measures prosocial behaviour (5 items).

The Strengths and Difficulties Questionnaires, whether in English or in translation, are copyrighted documents that may not be modified in any way. Paper versions may be downloaded and subsequently photocopied without charge by individuals or non-profit organizations provided they are not making any charge to families. The questionnaires, scoring instructions, norms and related articles can be down-loaded free of charge at following website: www.sdqinfo.org

6.1.3. Long broad-band screening questionnaires

The family of Achenbach questionnaires covers the age groups from 1 1/2 years to 30 years – with self-informant-, parent- and teacher versions (86). The parental Child Behaviour Checklist (CBCL/6-18) is one of the most widely used questionnaires worldwide with translations in many different languages (over 90) and with national norms.

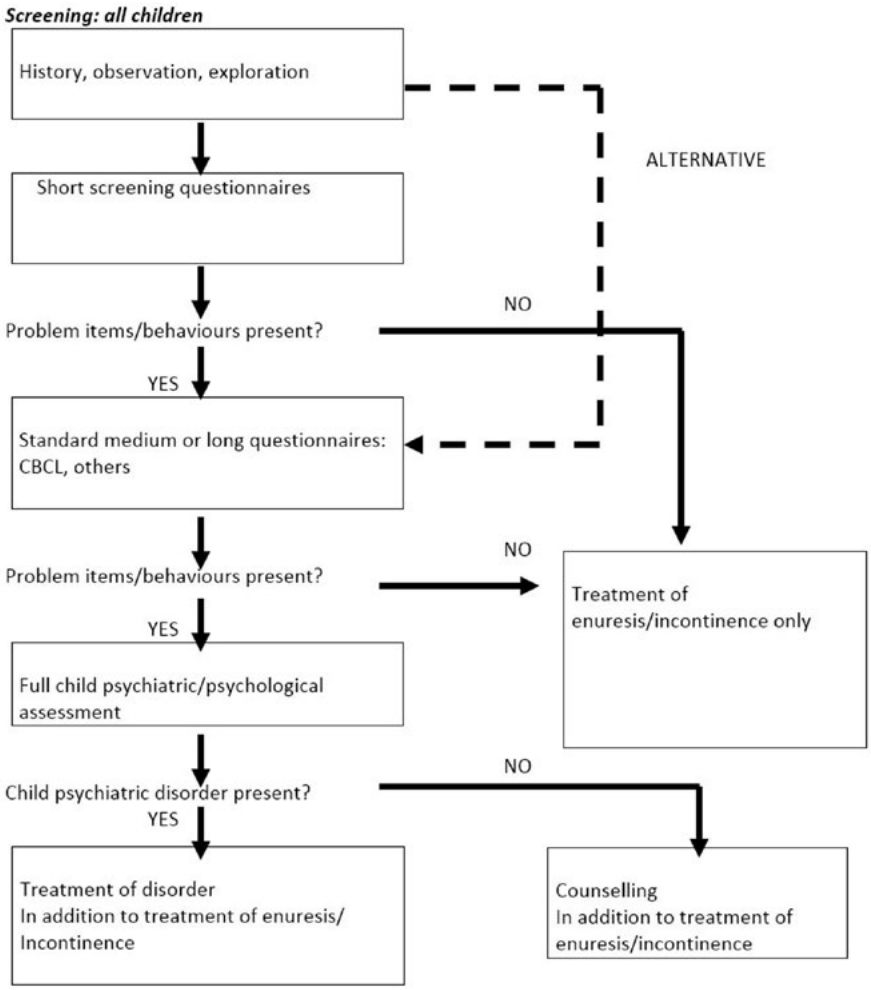

Figure 1: Flow chart for assessment of psychological symptoms (subclinical) or disorders (clinical). The specific treatment for enuresis / incontinence is the same for all children including those with symptoms requiring counselling, and those with disorders needing treatment (7)

As the name implies, the CBCL/6-18 is a parental questionnaire for the age groups of 6 to 18 years. It consists of a 113 problem items, which are scored on a three-point scale: 0= not true; 1= somewhat or sometimes true; 2= very true or often true. Three composite scales can be calculated (total score, internalizing, externalising behaviour). For these composite scales, the clinical cut-off is at the 90th percentile and the borderline cut-off at the 85th percentile. In addition, 8 other syndrome scales can offer valuable information.

The CBCL is one of many questionnaires within the Achenbach family of instruments: these aim at the pre-schoolers (1 ½ - 5 years), school age children (6-18 years), young adults (18-30 years), adults (18-59 years) and older adults (60-90 years). Self-report, parent and teacher versions exist, so that behaviour can be assessed in different contexts. All Achenbach questionnaires (such as the CBCL), manuals and related materials can be ordered under: www.aseba.org

In the ICCS documents, a general screening for emotional and behavioural problems in all settings (paediatric, urologic, child psychiatric, etc.) with a validated and standardised parental behavioural questionnaire is recommended because of the high rate of comorbid disorders in 30-50% of children (8). This can be done in two steps: using a short screening questionnaire first, followed by a long questionnaire; or in one step: using a validated, medium of long questionnaires. If many problem items are checked, a child psychological or psychiatric assessment should follow. If comorbid disorders are present, counselling or treatment, if necessary, is recommended (see figure 1).

One construct of special interest in children with incontinence is that of health-related quality of life (HQOL). In their standardisation document, the ICCS recommends to screen for changes of health-related quality of life (HrQoL) and specifically recommends using the PinQ-questionnaire, which is by far the best condition-specific HrQoL for children with incontinence (8, 88).

Generic HrQoL questionnaires can be useful in research in comparison with healthy controls and with children affected by other chronic medical conditions (89-91). Self-report versions for different age-groups, as well as proxy-report versions exist. The youngest age for self-report is 4 to 6 years, with reliable results available from 8 years onwards. The most commonly used proxy report is by parents, but caregivers, nurses and doctors can fill out these questionnaires, as well. Parental and child appraisal of HrQoL can differ. In research, comparison of child and own parental QoL can be interesting (91,92), but is usually not feasible in clinical practice.

In general, as HrQoL is a multidimensional construct, different aspects are assessed such as physical functioning, psychological well-being, social relationships, everyday life activities, satisfaction, discomfort, etc. These questionnaires can also be useful in monitoring the effects of therapy – in research, as well as in clinical practice. HrQoL-questionnaires are not useful in screening for psychological disorders, i.e. the information is not sufficient to decide if a disorder could be present or not.

6.2. Child psychiatric assessment

A child psychiatric assessment is a professional procedure with the goal of coming to a categorical decision: to see if a diagnosis, according to the standardised classification schemes (ICD-10 or DSM-I5) is present in the child or not (10,11).

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D) (94).

Questionnaires are always an essential part of a child's psychiatric assessment. They are a time-efficient way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behaviour Check List, which has been translated into many languages (CBCL/6-18) (86). In the meantime, Achenbach and co-workers have produced a whole "family" of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, including those with mental and physical handicaps (6). If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist. Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children.

After the diagnostic process has been completed, the child's disorder is diagnosed according to standardised classification schemes. The two standard classification systems are the ICD-10 (10), which is widely used in Europe and in other parts of the world and the DSM-5 (11) employed in the United States. The ICD-11 has not been issued yet, but will be in use in the coming years.

In child psychiatry, a multi-axial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intra-familial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

6.3. General principles: treatment of psychological disorder

For most children with elimination disorders, a symptom-orientated approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psycho-therapeutic interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weisz et al. (94) conclude that "psychotherapy with young people produces positive effects of respectable magnitude "(i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone (95). Of those which have been evaluated, three basic schools of psychotherapy can be differentiated:

1. Depth psychology (or psycho-analysis), which addresses and works with unconscious aspects of the psyche;
2. Family therapy, which focuses on the interaction between family members but not the individual person;
3. Cognitive-behavioural therapy, focusing on cognitions and observable behaviour, which has become the most important and effective mode of treatment for many disorders in children and adolescents.

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child's environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality should be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration should be addressed: is a short focal therapy focused on one specific problem needed, or a longer more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also by using speech, occupational, physiotherapy, music and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based "practice parameters" or "guidelines" have been developed in many countries. These interventions are usually performed on an out-patient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

6.4. General principles

6.4.1. Urotherapy

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term urotherapy is used in some countries. It is an umbrella term which has been defined as a "type of training which makes use of cortical control of the bladder, teaching children to recognise and employ conscious command over their lower urinary tract." Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to do about it and support and encouragement to go through with the training programme (96). Standard and specific urotherapy can be differentiated.

Although not a psychotherapy in a narrow sense, it employs many psycho-therapeutic techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined. Details of the general principles and practice of urotherapy can be found in a recent ICCS-document (96). Specific approaches for children with neurodevelopmental disorders are outlined in another ICCS-document (77).

6.4.2. Non-specific approaches

The first step in any diagnostic and therapeutic process is to create a good relationship with both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the provision of information is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

Conclusion: creating a good relationship , providing information, increasing the motivation and alleviation of stress and guilt feelings are effective non-specific approaches essential in the diagnostic and therapeutic process in children with nocturnal enuresis, daytime incontinence and faecal incontinence (LoE:4)

Recommendation: creating a good relationship , providing information, increasing the motivation and alleviation of stress and guilt feelings are recommended in the diagnostic and therapeutic process of children with nocturnal enuresis, daytime incontinence and faecal incontinence (GR:B)

6.4.3. Counselling

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of "demonstration", e.g. actively showing how an alarm works. In "coaching", parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include "modelling" and "role-playing". The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

6.4.4. Cognitive –behavioural therapy

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as "self-monitoring" (observation and registration), "activity scheduling" (organisation of activities) and "labelling" (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include "classical conditioning" and "operant conditioning", which basically means learning by success, which

can be achieved by different strategies using positive or negative reinforcement.

6.4.5. Baseline and observation

Baseline and observation are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration has a therapeutic effect and many symptoms diminish if they are simply observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and the dry nights symbolically for two to four weeks (3). These non-specific measures have been shown to be successful and are associated with fewer wet nights (3). In one clinical trial, for example, 18% became dry after an 8-week baseline (98).

In urgency incontinence, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart (3). For children with voiding postponement, timed voiding 7 times a day and registration in a chart is recommended (3,41).

For all children with faecal incontinence, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after meal-times in a relaxed mode for five to ten minutes (4). This is documented in a chart and can be reinforced positively. If constipation is present and a large amount of faecal mass has accumulated, disimpaction has to be performed at the beginning of treatment. Oral disimpaction is the preferred method. To avoid re-accumulation of faecal masses, maintenance therapy with oral laxatives, such as polyethylenglycol (PEG) is recommended for at least six, and up to twenty-four months (99). The preferred oral laxatives are osmotic laxatives such as PEG.

Conclusion: baseline and observation are effective techniques in the cognitive-behavioural therapy of children with nocturnal enuresis, daytime incontinence and faecal incontinence (LoE:2)

Recommendation: it is recommended to use baseline and observation techniques in the cognitive-behavioural technique of children with nocturnal enuresis, daytime incontinence and faecal incontinence (GR:C)

6.4.6. Biofeedback

Biofeedback has been shown to be effective in some elimination disorders such as dysfunctional voiding (100). It is defined as a variety of techniques, by which physiological activity is registered, enhanced and presented to the patient in real time by visual and acoustical signals). In faecal incontinence, biofeedback is no more effective than standard behavioural techniques in faecal incontinence both with (101) and without constipation (102).

Conclusion: biofeedback is effective in the treatment of dysfunctional voiding (LoE:3)

Recommendation: Biofeedback is recommended in children with dysfunctional voiding (GR:C)

6.4.7. Alarm treatment

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experiences and has been shown to be highly effective and was introduced by Mowrer and Mowrer (103).

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-analyses). Houts et al. (104) compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that “urine alarm treatments should not only be considered the treatment of choice, but the evidence from this review suggests that cure rather than management is a realistic goal for the majority of children suffering from nocturnal enuresis”. Therefore, when indicated, alarm has been endorsed as a first line curative treatment by various guidelines and by the new ICCS document on enuresis (105).

In a recent retrospective study of nearly 3000 children, who underwent alarm treatment, 76% achieved continence with a mean duration of therapy of 9 weeks. 23% of children had relapses and some children needed several courses of alarm therapy (106).

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis) (104).

These specific programmes including alarm are all essentially cognitive-behavioural techniques. Arousal training is a simply and easily performed (107,108). Children are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ½ years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively).

Finally, alarm treatment can be combined with pharmacotherapy, although the evidence for combination treatment is conflicting. The combination of desmopressin and alarm treatment has been reported in several studies (108,109). The combination with anticholinergics plays an important part in clinical practice, but has not been investigated systematically. However, when alarm treatment fails, the ICCS recommends switching to desmopressin alone (110).

Conclusion: alarm treatment is effective in nocturnal enuresis (LoE:1)

Recommendation: alarm treatment is recommended in nocturnal enuresis (GR:A)

Conclusion and summary

This review summarised the most important psychological aspects in children with enuresis, urinary incontinence and faecal incontinence.

The rate of comorbid clinical behavioural disorders is increased. Children with DUI are more affected than those with NE. Children with secondary and non-monosymptomatic NE have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD, but other disorders such as de-

pression, anxiety disorders and autism spectrum disorders can exist and must be considered.

Children with DUI have mainly externalising behavioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postponement are characterised by oppositional behaviour. Children with FI have the highest rate of associated disorders – both internalising and externalising.

These disorders will not disappear upon attaining dryness. They must be addressed, as they will interfere with the incontinence therapy due to low compliance. Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment. Children with special needs, especially those with ID, have very high rates of incontinence. Assessment and treatment of incontinence should be offered to all affected children.

Questionnaires are useful as screening instruments in the assessment process. It is recommended that questionnaires are used as a general screening procedure for emotional and behavioural problems routinely in all settings. If a psychological disorder is suspected, a full child psychiatric assessment and subsequent treatment is needed. The basic principles, including those of psychotherapy, are outlined. Psychotherapeutic techniques are used in urotherapy, especially cognitive-behavioural elements. Non-pharmacological and non-surgical techniques are most effective for most forms of incontinence. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

VIII. URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

1. INTRODUCTION

Children with special needs, i.e. intellectually and/or motor disabled, suffer lower urinary tract symptoms (LUTS) more than the normal population. Several studies have shown that nocturnal enuresis, daytime urinary incontinence and faecal incontinence are more frequent in children with special needs. Moreover, incontinence has a higher likelihood to persist during adolescence and adulthood. Although LUTS are associated with poor quality of life and health status, they are often less important to parents and physicians who are mainly focusing on physical rehabilitation. Literature on this topic is limited, but illustrates that adequate treatment improves quality of life significantly.

2. CHILDREN WITH SPECIAL NEEDS: GENERAL INFORMATION

2.1. Intellectual disability

Intellectual disability, the former mental retardation, is defined by the American Association on Mental Retardation (AAMR) as a disability characterised by significant limitations both in intellectual functioning and in adaptive behaviour as expressed in conceptual, social and practical adaptive skills. The disability originates before 18 years of age. Limitations in intellectual ability correspond to an IQ less than 70 to 75.

According to DSM -V (Diagnostic and Statistical Manual of Mental Disorders 5th edition. American Psychiatric Association (2013) Washington, DC) intellectual disability involves impairments of general mental abilities that impact adaptive functioning in three domains, or areas. These domains determine how well an individual copes with everyday tasks:

- The conceptual domain includes skills in language, reading, writing, math, reasoning, knowledge, and memory.
- The social domain refers to empathy, social judgement, interpersonal communication skills, the ability to make and retain friendships, and similar capacities.
- The practical domain centres on self-management in areas such as personal care, job responsibilities, money management, recreation, and organising school and work tasks.

In DSM-V intellectual disability is two standard deviations or more below the population mean, which equals an IQ score of 70.

Severity was defined in the DSM-IV (Diagnostic and Statistical Manual of Mental Disorders 4th edition. American Psychiatric Association (2000) Washington, DC) based on IQ ranges:

- Mild: 50-55 to 70
- Moderate: 35-40 to 50-55
- Severe: 20-25 to 35-40
- Profound: < 20-25

2.2. Motor disability:

Motor disabilities affect a person's ability to learn motor tasks such as walking, running, skipping, sitting, handwriting and others. To be considered a disability, the problem must cause a person to have motor coordination that is significantly below what would be expected for age, and the problem must interfere with activities of learning and daily living.

Although Intellectual disabilities and motor disabilities can stand on their own, in a considerable number of patients, a combination of both is diagnosed.

Intellectual disability is a common problem. Up to 10% of the school-aged children are learning impaired and as many as 3% of children in the US manifest some degree of mental retardation. The prevalence of mild mental retardation is about 1/77 (1.2%) and that of severe mental retardation is 1/300 (0.33%). For the clear majority of individuals with mental retardation (45-63%) no aetiology is identifiable. More than 800 syndromes are associated with mental retardation, of which Trisomy 21 or Down's syndrome is the best known. In addition, environmental factors, such as Foetal Alcohol Syndrome and peri- and postnatal conditions, such as CMV, rubella and hypo-ischaemic encephalopathy, may also be responsible for mental retardation.

The second most important cause of developmental disability is cerebral palsy (CP). Cerebral palsy encompasses a group of disorders of the development of movement and posture, causing activity limitation, which are attributed to non-progressive disturbances occurring in the developing foetal or infant brain [1]. Often disturbances of sensation, cognition, communication, perception and/or behaviour, and/or seizure disorders accompany the motor disorders. CP is a non-progressive injury of the brain occurring in the perinatal period and persisting through the lifespan.

The incidence of cerebral palsy is about 1.5 per 1000 births.

Twenty percent of the intellectually disabled individuals suffer cerebral palsy and 50% of the cerebral palsy patients are intellectually disabled.

3. LOWER URINARY TRACT SYMPTOMS IN CHILDREN WITH SPECIAL NEEDS: PREVALENCE

Von Wendt et al. published that 7-year-old children with mild intellectual disability differ relatively little from healthy children with respect to enuresis, (11.1% versus 9.8%), but suffered significantly more daytime urinary incontinence (16.7%) than the normal population (3.4%). The more severe the intellectual disability the higher the risk of persisting enuresis and daytime urinary incontinence [2].

Although LUTS are associated with poor quality of life and health status [3], urinary incontinence in children with CP is often considered a normal, unavoidable or minor problem. Yildiz et al. found 80 % of adult CP patients had never been referred to a physician due to urinary problems and 60 % had never been asked about urinary problems by any physician. An even higher rate of patients never had a urinary system ultrasonography, post-void residual urine measurement or urodynamic testing up until adult age.

Continence can be achieved spontaneously [4], but the continence process will be delayed and LUTS or abnormal urodynamic findings can be present at a young age [5]. In children with CP 55.5% suffer LUTS, of which urinary incontinence is the most frequent with a prevalence rate ranging between 20% and 94%. Urgency and frequency, with a respective prevalence of 38.5% and 22.5%, are also very common in CP patients. Urinary incontinence, urgency and frequency are significantly more common in children with CP compared to a healthy population.

Storage symptoms are more prevalent than voiding symptoms, with a prevalence of hesitancy in children with CP of 16.5%. Urinary tract infections (UTI), with a prevalence rate of 8.5%, are also more common in CP children than in the normal population [6].

Patients with Down's syndrome also show an impaired ability to become continent. Several studies have illustrated that children with Down's syndrome have a delay in toilet training and are more prone to incontinence afterward. One fifth of the children with Down's syndrome are not toilet trained at the age of five and nearly 50% of the toilet trained children will have incontinence, that even can persist into adulthood [7]. Niemzcyk et al. noted a significant gender difference for daytime incontinence prevalence rates, with male patients demonstrating more incontinence [8].

LUTS are also more common in children with Down's syndrome, with a prevalence around 27 %, and symptoms are also more common in male than in female patients [9]. These LUTS decrease with age, and patients with Down's syndrome older than 10 years have a five times lower chance of LUTS compared to those who are ten years or younger [10]. Kitamura et al. found LUTS to be very common in children with Down's syndrome, but remarkably neither the children nor their environment seemed to be aware of it [9].

Von Gontard reviewed the association of nocturnal enuresis, daytime urinary incontinence and faecal incontinence in children with intellectual disability in general and in patients with specific syndromes of intellectual disability including Rett's, Angelman's, Fragile-X, Prader Willi, Noonan's and Williams' syndrome. He concluded that people with profound intellectual disability have the highest rate of incontinence, whereas syndromes with mild intellectual disability have much lower rates [11-16].

Not only intellectual capacity, but also motor capacity is correlated with the development of continence. The more immobile the higher the prevalence of urinary incontinence. Motor disability, especially the degree of mobility, rather than intellectual disability seems to be the dominant factor determining urinary continence [17].

4. PATHOPHYSIOLOGY OF LUTS IN CHILDREN WITH SPECIAL NEEDS

4.1. Urodynamic findings

Samijn et al. found in their review on LUTS and Urodynamic Findings in CP patients that 84.5% had an abnormal videourodynamic study. Neurogenic detrusor overactivity (NDO) is the most common urodynamic abnormality, with an average prevalence rate of 59% [6]. The finding of NDO on urodynamics is not synonymous for the prevalence of LUTS. Several authors found pathological urodynamic findings in both symptomatic and non-symptomatic children with CP and vice versa [18-21]. Therefore, some authors stress the need for urodynamic examination in this population to discover silent bladder dysfunction or risk factors for upper urinary tract dysfunction (UUTD).

Abnormal uroflow patterns, especially staccato pattern, were found in 36.5% to 66% of CP patients [17,22,23]. Van Laecke et al. could not establish a correlation between uroflow pattern and urinary incontinence, whereas Silva et al. reported a significant correlation between abnormal uroflow patterns and the presence of LUTS [17,22].

The average prevalence rate of detrusor sphincter dyssynergia (DSD) is 11% [6].

Comparing urodynamic studies with uroflowmetry showed more pathological findings on urodynamics than on uroflow, which can be explained by the fact that uroflowmetry only measures the voiding phase.

The high prevalence of NDO can be explained by the fact that CP is caused by a cerebral insult, with lesions in the suprapontine circuitry, disturbing the inhibitory control over the pontine micturition centre [20]. Overactivity of the pelvic floor and the urethral sphincter is not expected in patients with a cerebral lesion, and may suggest a lesion of the lumbosacral cord. Severe hypoxia might be the cause of this in CP patients [24-26].

In children with CP, hesitancy is more prevalent than DSD, which may indicate that other factors than DSD contribute to overactivity of the pelvic floor. Mayo et al. suggested that hypertonia is the cause of the inability to relax the pelvic floor muscles during micturition, resulting in an increased rate of hesitancy [27]. One might conclude that children with spasticity may suffer pelvic floor overactivity as a voluntary reaction to an overactive bladder.

De Medeiros Francilaide Campos et al. found similar results in children with microcephaly and congenital zika syndrome[28]. Urodynamic evaluation demonstrated mostly immature and reflex bladder or detrusor overactivity.

Kitamura et al. found in their study that a significantly lower number of children with Down's syndrome had a normal bell-shaped uroflow pattern (18%) than age-matched control children (60%). They concluded that the non-bell-shaped uroflow patterns are due to functional and not to anatomical or organic abnormalities. [9]

4.2. Bladder capacity:
Reduced bladder storage ability is a major factor in the pathophysiology of urinary incontinence in children with special needs. Several studies illustrated that 73.5% of the CP subjects have a small bladder capacity compared to the expected bladder capacity for age (EBC). Mean bladder capacity is 58.5% of the EBC. [6] Bladder capacity can be negatively influenced by involuntary bladder contractions, characteristic for NDO, inadequate fluid intake due to swallowing problems and inadequate hydration [5, 17, 29-31]. Constipation, which can be due to restricted fluid intake, can negatively influence reduced bladder capacity [32]. Samijn et al. demonstrated maximum voided volume, a measurement for bladder capacity, significantly associated with incontinence in a population of children with CP [33].

4.3. Inadequate fluid intake
Van Laecke et al. found that only 9.9% of the children with a special need included in their study had a normal fluid intake. Although some of these children suffer swallowing problems, the major problem was found to have inadequate drinking. Increasing the fluid intake to a normal level of 1500ml/m² resulted in a significant increase in continence and maximum voided volume [17, 31].

Consistent with these results, oral fluid intake was found to be an important predictive factor for incontinence in children with CP [33]. Although children with and without incontinence did not drink enough, regression analysis demonstrated that an increase of fluid intake equal to one percent of the recommended fluid intake could have a considerable effect on the odds of incontinence.

4.4. Post-void residual
In CP patients, due to the low prevalence of DSD and hesitancy, the finding of pathologically increased post-void residual is low [18, 22, 23, 32, 33]. Similar results were found in children with microcephaly and congenital zika syndrome. [28]. In Down's syndrome patients, increased post-void residual was demonstrated in 7% [9].

4.5. Intellectual disability and motor dysfunction.
Von Gontard noted intellectual disability (i.e. IQ < 70) as a major risk factor for incontinence, with increasing rates as IQ decreased. [35]. Prevalence rates for incontinence or LUTS in general in patients with intellectual disability further depends on the syndrome and disorder.

However, LUTS are less influenced by intellectual disability than by moderate to severe motor dysfunction [17, 33, 36, 37]. With respect to children with CP, continence is less often achieved in subjects with low intellectual capacity combined with spastic quadriplegia than in subjects with high intellectual capacity combined with hemi- or diplegia [4]. The combination of both intellectual disability and spasticity has a bigger influence than both factors independently. Bross et al. concluded that urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment [18].

Involuntary spasticity of the pelvic floor, which may be part of a general spasticity, may cause LUT dysfunction [30,38]. This can also explain the potential to acquire pelvic floor hyperactivity in reaction to NDO in children with spasticity [18, 27].

In subjects with quadriplegia, LUTS and abnormal urodynamic findings are found more often than in patients with diplegia, illustrating that not only lower limb impairment, but also upper limb impairment plays a role in achieving continence [4]. The plasticity of the central nervous system enables the unaffected side to assume more control over the bladder during development. This could explain the lower prevalence of LUTS and disturbed urodynamic findings in children with hemiplegia [37].

Poor mobility is an important factor in achieving continence, as children can be faced with both organic incontinence due to their underlying disorder and functional incontinence due to the inability to reach the toilet and adequately get on the toilet [35]. Difficulties in consuming enough will influence both urinary incontinence and constipation. Moderate to severe functional impairment (GMFCS III or higher) and the spastic subtype with quadriplegic distribution will negatively influence the ability to become continent. [6].

5. COMORBIDITY

5.1. Constipation and faecal incontinence
Constipation is an important comorbidity relating to urinary incontinence in children with special needs. There is a proven correlation between constipation and urinary incontinence, detrusor overactivity, dysfunctional voiding and UTI [39]. Intellectually disabled children are more prone to constipation and faecal incontinence. Up to 70% of these children suffer constipation [40]. Up to 90% of the children with CP suffer constipation and 47% faecal incontinence, though most of them to a minor degree [41]. In children with Down's syndrome, a systematic review demonstrated bladder bowel dysfunction in 75-96% of children with LUTS. Functional constipation was most frequently seen and included 90% of the children with bladder and bowel dysfunction [42].(Level of Evidence 2a-b)

5.2. Neuropsychiatric disorders
ADHD and autism are more frequent in intellectually disabled children and there is a proven correlation between ADHD and urinary incontinence [43,44].

5.3. Sleep disorders
There is increasingly more evidence that there is a relationship between nocturnal enuresis and sleep disorders in otherwise healthy children [45-47]. Sleep is a complex neurological function. In children with brain damage, the autonomic nervous system, which is involved in pineal melatonin secretion and sleep regulation might be affected [48]. Sleep is also vulnerable to several other factors common in CP. Muscle spasms, decreased ability to change body position during sleep, epilepsy and glossoptosis, which can induce sleep disorder breathing, may be the cause of disturbed sleep in these children [49,50]. Sleep disorders like delayed insomnia, dis-

rupted sleep, early awakening or a combination of these are frequently reported in patients with CP. Newman et al. found that 44% of the patients presented at least one clinically significant sleep disorder. Nearly 50% of the children with CP have some kind of sleep problem. These problems are reported more in non-walkers (72%) than in walkers (36%) [51]. Also in patients with Down's syndrome sleep disturbances are more common [7].

6. EVALUATION OF THE SPECIAL NEED CHILD SUFFERING LUTS

Of the children with CP who are dry at adult age, most achieve continence by the age of five years old [4, 52]. Therefore, Reid and Borzyskowski suggest children with CP can merit early urological evaluation [5]. ICCS guidelines recommending urologic evaluation when LUTS are present after the age of five years old should also be used in children with special needs [53]. After the age of five years spontaneous achievement of continence drastically decreases and parents and physicians should not assume lower urinary tract dysfunction as a normal feature in these children. (Level of Evidence 1b)

In general, all the assessment principles and tools for incontinence in typically developing children apply to those with special needs. [35]. Multimodal urological, paediatric and child psychiatric skills are needed to ensure optimal treatment in many cases.

6.1. History

History taking in children with special needs is often challenging, and mainly relies on hetero-anamnestic data. It is important that not only parental information but also information from the care givers should be considered, as many of these patients spend a lot of their time in specialised institutions. The questions should include items on nocturnal enuresis, urinary incontinence, lower urinary tract symptoms and bowel function. Attention should also be paid to intellectual and motor development, family disorders, the child's psychosocial and familial situation, neurological and congenital anomalies, urinary tract infections, relevant medication and surgery. Special emphasis should be given to fluid intake and food habits.

A voiding and drinking diary, and a dry-wet calendar are essential in determining the child's voiding frequency and voided volumes, to evaluate the number of enuresis and incontinence episodes, to determine the degree of nocturnal diuresis and to evaluate the quantity and quality of fluid intake. The same should be done for stool, registering defaecation frequency, stool consistency and soiling.

6.2. Physical examination

Theoretically, physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 and anal sphincter tone and control. Practically, as this is discomforting for the child, this part of the physical examination is restricted to those where there is a suspicion of neuropathy.

Special attention should be paid to signs of neuropathy such as: spine deformity, abnormal gait, abnormal deep tendon reflexes, asymmetrical atrophy of the feet, high plantar arches, hammer toes, and signs of occult dysraphism, i.e. skin discolouration, dimples, hairy tufts, subcutaneous lipoma, asymmetrical buttock, legs or feet and oblique gluteal cleft [54]. The abdomen should be palpated to asses a full bladder, full sigmoid or descending colon and flank masses. The external genital region must be inspected for vaginitis and vulvitis, meatal web and a hymen that covers nearly the complete vaginal introitus in girls, and for penile anomalies and meatal stenosis in boys. In motor disabled children the locomotor system has to be evaluated according to muscle power, mobility, stability and spasticity. In intellectually disabled children the IQ and the functional autonomy has to be estimated.

6.3. Laboratory tests

Urine analysis to exclude pyuria, proteinuria, glycosuria, haematuria, calciuria and bacteriuria should be done at the first office visit. Urine osmolality and electrolytes should be determined in case of monosymptomatic enuresis with persistent therapy resistant polyuria.

6.4. Uroflowmetry

Uroflowmetry in children with special needs is often a problem. Intellectually disabled children are often too anxious to perform a uroflowmetry and motor disabled children are often incapable of performing a non-disturbed micturition because of their unstable position on the flow chair. ICCS guidelines recommend ensuring relaxation of the pelvic floor muscles by using foot support [55]. A standardised adequate position should be used carefully as this could have an effect on the outcome parameters. This is reinforced by the recommendation of the ICS, which stated that testing should be performed in the preferred usual position [56]. Therefore uroflowmetry, especially in moderate and severe patients, should be preferably performed in their own environment on their personally adapted toilet chair. Implementation of a correct toilet posture with maximal potential of pelvic floor relaxation during micturition is important and should therefore be trained as the natural voiding position to ensure accurate interpretation of uroflowmetry.

ICCS guidelines mention voided volumes less than 50 % of expected bladder capacity for age (EBC) are not reliable to interpret [53]. As 73.5% of the subjects with CP exhibit a reduced bladder capacity compared to EBC [6], this could further influence accurate interpretation of uroflowmetry in children with CP.

Samijn et al. tried to evaluate uroflow/EMG results in children with CP, but interpretation of pelvic floor activity was only possible in eighteen of the 79 (23%) evaluated children [33]. With six out of nine children (67%) demonstrating pelvic floor overactivity in both the continent and incontinent group, it could be suggested that pelvic floor overactivity is equally present in continent and incontinent children. However, not being able to void on uroflowmetry was defined as a significant risk factor for incontinence and could also be the result of the inability to relax the pelvic floor to start micturition.

6.5. Ultrasound

Ultrasound is used to evaluate the upper and lower urinary tract in children with LUTS especially when they are suffering from a UTI. It can also be used to measure the post-void residual.

6.6. (Video-) Urodynamic examination

These urodynamic investigations are invasive, especially in children with special needs who often lack the intellectual capacity to understand what is going to happen, or are physically unable to undergo the examination in a comfortable way. Although some authors are convinced that urodynamics should be performed in the majority of moderate and severe patients to rule out the silent bladder dysfunction or risk factors for UUTD,it is recommended that this examination should be reserved for those patients suffering therapy resistant urinary incontinence and/or recurrent UTI or when obstructive lower urinary tract problems are suspected.(GR B)

7. TREATMENT OF URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

7.1. Non-pharmacological treatment

7.1.1. Urotherapy

Urotherapy in children with special needs does not differ fundamentally from that used in normally developing children. The aim is also to achieve normalisation of the micturition pattern by a combination of patient education and cognitive, behavioural and physical therapy methods. Some previous studies have tried to implement parts of urotherapy [25, 31, 37], but none have administered urotherapy as instructed by the ICCS for typically developing children [53, 57].

Often the use of pharmacotherapy is seen as starting point of incontinence treatment. Decter et al. used a frequent voiding schedule and behavior modification with or without biofeedback in respectively eight and six children, whereas 47 children received pharmacotherapy [25]. A more recent study applied a combination of toilet posture, biofeedback and spasticity management of the pelvic floor when pelvic floor overactivity was present. When neurogenic detrusor overactivity was present, pharmacotherapy was initiated [37].

The first cornerstone of urotherapy is patience. Treating these children will certainly take more effort and time as compared to unaffected individuals, but even in severe patients it may lead to an significant improvement or cure of urinary incontinence. Discrepancy between effective and expected results could influence adherence to therapy, as primary focus of the child, parents and caregivers often lies with being dry. Communication is crucial to avoid frustration resulting from therapy not meeting expectations. Therapy should be interdisciplinary and feasible for the child and social environment.

The second is adequate fluid intake. Although often time-consuming, the results are remarkably positive as illustrated in the study of Van Laecke et al. [31]. Fluid intake does not only positively influence maximum voided volume and continence, but also contributes to an important amelioration of constipation.

The third cornerstone of urotherapy is correct toilet position. Adequate relaxation of the pelvic floor can only be achieved when sitting in a stable position. In many children with CP this can only be the case when using a personal adapted toilet chair.

The environment of the child can be adapted to decrease the influence of negative prognostic factors. An adapted toilet chair could be used to optimise pelvic floor relaxation, whereas an adapted drinking cup could influence fluid intake. The use of mobility aids could improve transfer to and on the toilet and ease of removing appropriate clothing could decrease time needed to reach the toilet.

Recommendation: Urotherapy with special emphasize to, patience, fluid intake and adequate toilet position is essential in the treatment of children with special needs suffering urinary incontinence (GR:B)

7.1.2. Treatment of Bowel Dysfunction

Constipation and faecal incontinence are common comorbidities in children with special needs. Adequate management of both constipation and faecal incontinence are recoommended for successful treatment of urinary incontinence in these patients. (GR:A)

Vande Velde et al. published a flowchart for a suggested experience based stepwise approach of constipation in children with CP [58]. First line treatment should include normal fibre intake and mobility stimulation. A fixed defaecation moment with toilet sitting is included as second line treatment and could be implemented in urotherapy interventions. In case of functional constipation, stool masses need to be evacuated with laxatives or enemas. Afterwards laxatives should be continued together with behavioural therapy and dietary interventions for months or even years [59].

7.1.3. Alarm treatment

As in normally developing children, alarm therapy can be used to treat either nocturnal enuresis or daytime urinary incontinence in children with special needs [57, 60, 61]. In the treatment of daytime incontinence, it can be used to achieve active continence, but in some therapy resistant cases it can also be used to achieve passive continence by introducing timed voiding [62]. Again, one should be aware of the fact that using an alarm in this population will be more challenging and time consuming.

Conclusion: daytime alarm is an effective treatment of daytime incontinence (LoE:3)

Recommendation: in therapy resistant patients the daytime alarm can be used (GR:C)

7.2. Pharmacological treatment

7.2.1. Antimuscarinics

If standard urotherapy fails to achieve urinary continence, antimuscarinics are the mainstay of treatment in patients with overactive bladder (OAB). Oxybutynin remains the only FDA approved antimuscarinic for OAB treatment in children. The major problem with oxybutynin is the side effects; dry mouth, constipation, blurred vision, psychologic and personality changes are common side effects, causing up to 10% of the children to stop their treatment [63]. Especially in children with special needs these side effects are more problematic as tooth decay, constipation, mood disturbances and intellectual delay, which are already relatively common in this population, can get even worse. Therefore, newer, more bladder specific antimuscarinics, only approved for adults, such as solifenacin and tolterodine are used off-label in these patients. Propiverine, which is suggested to be better tolerated than oxybutynin, has been approved in some countries for use in children [64]. When using antimuscarinics, strict follow-up with special attention to side effects and post void residual is necessary.

7.2.2. Desmopressin

In the case of monosymptomatic enuresis with proven nocturnal polyuria, as in normally developing children, desmopressin is a first line treatment [65]. This treatment should be used with care as excessive fluid intake shortly before or quickly after administration of desmopressin can cause a life-threatening water intoxication with hyponatraemia and convulsions.

7.2.3. Botulinum toxin

Botulinum toxin has been used off-label successfully for the treatment of children with neuropathic bladder and non-neurogenic bladder dysfunction [57, 66-68].(LoE 3) In accordance with treatment in normally developing children, in children with special needs it can only be considered in patients suffering OAB or urinary incontinence in whom other treatment options have failed.(GR:C)

7.3. Surgery

Children with Down's syndrome have a significantly increased risk of anterior urethral obstruction and posterior urethral valves [69]. In Down's syndrome children, where there is suspicion of obstruction of the LUT, cystoscopy under general anaesthesia with possible incision of the obstructive element should be performed. In those patients with a neuropathic bladder, refractory to conventional therapy, bladder augmentation, i.e. ileocystoplasty with or without continent catheterisable stoma (Appendico-vesicostomy, Monti, etc.) can offer the final, non-reversible, solution to achieve continence and to protect the upper urinary tract.

7.4. Clean intermittent catheterisation (CIC)

Some children do need intermittent catheterisation, especially those undergoing a bladder augmentation. Children with cerebral palsy treated with continuous baclofen can also suffer urinary retention needing intermittent catheterisation. The problem with some of these children with special needs is that they have normal genital sensation that makes catheterisation uncomfortable, or even painful. Combined with the reduced intellectual capacities of some this makes CIC nearly impossible. Therefore, an incontinence stoma is sometimes the only solution.

8. CONCLUSION

Although often thought to be a minor problem urinary incontinence remains an important issue for every special needs child. Urinary incontinence can lead to limited self-esteem and independence, and may be a considerable health care challenge. Often it is a multifactorial problem, but with adequate therapy these children are amenable to continence rehabilitation. The majority can become continent, but some will only achieve a passive form of continence.

I. INTRODUCTION

Conservative management of urinary incontinence (UI) or pelvic organ prolapse (POP) is defined as any intervention not involving surgical or pharmacological approaches (1). These comprise lifestyle modification, pelvic floor muscle training (PFMT) either alone or with the addition of biofeedback, vaginal cones, electrical stimulation (EStim), magnetic stimulation (MStim), together with tibial nerve stimulation (TNS), scheduled voiding regimens, complementary/alternative medicine and supportive rings/pessaries. In this chapter, we cover studies that provide comparative data between a conservative management approach and the absence of treatment or placebo, between two conservative management approaches or between a conservative management approach and medications or surgery.

Conservative management is considered relatively low cost and non-invasive, with minimal adverse effects. Management is typically guided by a healthcare professional and depends on user participation. Conservative interventions are part of initial management at the primary care level and are also indicated for those for whom other treatments are inappropriate, for example, those unable to undergo surgery and women who plan future pregnancies. Other indications include individuals awaiting surgery or who wish to delay surgery and those whose symptoms are not severe enough for surgical intervention.

Scientific evidence on the effectiveness of conservative interventions is growing. In this chapter, we add to the sixth edition of the International Consultation on Incontinence (ICI) chapter on conservative management, which was published in 2017 (2), integrate new evidence and update the recommendations from the previous edition. We also add a new section on conservative management of UI in patients with neurological conditions.

- The updated literature search covered the period of September 9th, 2015 to December 31st, 2020 inclusively (i.e., from the date of the last search for the sixth ICI to the seventh ICI search cut-off date of December 31st, 2020), according to the following search methods. The searches were conducted between March 1st and 9th, 2021 inclusively. We did not impose any language or other limitations on any of the searches described below.

- **Cochrane Incontinence systematic reviews**

Relevant Cochrane systematic reviews were identified for each section of this chapter, by two of the authors (CD, SW) assessing the full list of reviews (Cochrane Incontinence (3) or upon request). The leads for each section were given lists of these relevant reviews. Additional searches of the Cochrane Incontinence Specialised Register were provided to each section author to bring the review searches up to date or, if there was a gap in review coverage, a full search of the Register was conducted.

- **Additional searches for this ICI chapter**

Electronic searches

We identified relevant trials from the Cochrane Incontinence Specialised Register. For more details on the search methods used to build the Register please see the Group's webpages where details on the Register›s development can be found (4). In brief, the Register contains trials identified from the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, MEDLINE In-Process, MEDLINE Epub Ahead of Print, MEDLINE Daily, ClinicalTrials.gov, WHO ICTRP, and includes hand searching of journals and conference proceedings. The search covered:

- For sections covered by existing Cochrane reviews: from the date of the last search for the published version of the review to December 31st, 2020.
- For sections not covered by existing Cochrane reviews – complete search of all contents of the Register covering from the date of last search for the sixth ICI, September 9th, 2015 to the seventh ICI search cut-off date of December 31st, 2020.

The terms used to search the Register for each section are provided in Appendix 1.

Searching other sources

We searched the reference lists of relevant articles for other relevant trials.

In continuity with the last edition of the ICI chapter on conservative management and to ensure consistency throughout the chapter, the primary outcomes reported in this chapter include *patient-reported outcomes*: cure and cure and improvement, UI-specific or POP-specific quality of life (QoL), validated symptoms questionnaire and/or number of leakages (as per the bladder diary). Secondary outcomes considered in this chapter are *clinician-reported outcomes* (pad test, POPQ score, etc.). These were chosen in relation to each subsection's specificity and in continuity with our previous chapter.

Each subsection concludes with the level of evidence, grade of recommendations and factors affecting outcome. Separate chapters in this seventh edition address incontinence management in the frail older persons (Chapter 14), in childhood (Chapter 7), address continence products (Chapter 19) and present conservative management of faecal incontinence (Chapter 15).

Where summary statistics are presented, the raw data from which these are derived can be found in the tables within each subsection, and in trial reports and systematic reviews cited in the chapter. The chapter is intended as a stand-alone document and adds to the comprehensive reports from previous ICI editions.

II. URINARY INCONTINENCE IN WOMEN

1. LIFESTYLE MODIFICATION

A number of lifestyle factors may play a role in the development of UI and other lower urinary tract symptoms (LUTS). Lifestyle modification is the application of interventions in the management of lifestyle-related health problems (1). It is not limited to but includes weight loss, changes in physical activity level, smoking cessation, diet restriction such as caffeine reduction and other changes in life habits. These lifestyle modification interventions may be used to prevent or treat UI in women either combined or as single interventions.

Although lifestyle modification is relatively low cost and low risk, the sixth ICI (2017) cited a lack of evidence on lifestyle interventions to prevent UI. There were also no evidence-based recommendations on lifestyle modification interventions in the prevention of UI. Only a few cohort and case control studies provided low level evidence on the association between physical activity/dietary restriction and UI and suggested that moderate physical exercise and changes in diet decreased the incidence of UI. The sixth ICI noted that a weight loss of 5% of initial body weight was considered to have an impact on the reduction of UI symptoms. This formed the basis of a recommendation for overweight and obese women with UI, based on two randomised controlled trials (RCTs), cohort studies and a metanalysis of cohort studies (2).

This review section updates the evidence on the use of lifestyle modification to improve UI and related symptoms in women. Table 1 shows the number of studies included in the sixth ICI edition and the new studies included in this update (N= 5 trials: 6 comparisons). The characteristics and new data of the individual new trials can be found in Tables 2, 3, 4 and 5 for each lifestyle modification intervention.

We addressed the following questions in this update:

- Are lifestyle modification interventions (e.g., weight loss, increased/decreased physical activity, smoking cessation, dietary or fluid changes) effective in the prevention of UI?
- Are lifestyle modification interventions (e.g., weight loss, increased/decreased physical activity, smoking cessation, dietary or fluid changes) better than no treatment, placebo or control in the treatment of UI?
- Is one lifestyle modification intervention (e.g., weight loss, increased/decreased physical activity, smoking cessation, dietary or fluid changes) better than another lifestyle intervention in the treatment of UI?

Table 1. Lifestyle modification interventions studies included

Lifestyle modification interventions	ICI 2013 and 2016	ICI 2023	Total
Weight loss	5 RCTs, 6 cohort studies, 7 cross-sectional studies,1 retrospective study, 1 meta-analysis	1 meta-analysis, 1 RCT (secondary analysis)	6 RCTs, 1 (one group) non-randomised clinical trial, 8 observational studies, 2 meta-analysis
Physical activity	5 cohort studies 1 case control study	1 RCT, 1 cohort study	2 RCTs, 6 cohort studies, 1 case control study
Smoking	2 case control studies, 1 RCT (pilot, secondary analysis)	-	2 case control studies, 1 RCT (pilot, secondary analysis)
Dietary factors/fluid intake	1 case control study, 1 prospective cohort study, 1 cross-sectional cohort study, 3 observational studies	2 RCTs (1 secondary analysis, 1 pilot study)	2 RCTs (1 secondary analysis, 1 pilot study), 1 case control study, 1 prospective cohort study, 1 cross sectional cohort study, 3 observational studies

Abbreviations: RCT: randomised controlled trial

1.1. Prevention

Are lifestyle modification interventions effective in the prevention of UI?

In this update, one secondary analysis of the Women's Health Initiative (WHI) Dietary Modification Intervention (DM-I), a RCT investigating a lifestyle intervention for prevention of female UI (5) and a prospective study on the association between physical activity and LUTS in parous middle-aged women (6) were included.

1.1.1. Dietary modification intervention

The study conducted by Rogo-Gupta *et al.* (5) aimed to evaluate the effect of a low-fat and high fruit, vegetable and whole grain diet on the risk of developing de novo UI in continent postmenopausal women (Table 2). Participants were randomly assigned to receive the intervention (DM-I) including an intensive behaviour modification programme for a reduction in fat intake and an increase in fruit, vegetable, and whole grain intake. Controls received only health education materials. Despite being a secondary analysis, the strong point of this study is the large sample of 22,852 women randomised to the control arm and 19,541 to the DM-I group. Separate logistic regression models showed that one year after the intervention, continent participants in the DM-I group were less likely to develop UI (all types) compared to controls when adjusting for weight change, age, ethnicity, or hormone replacement use. Interestingly, the study found that a moderately high intake of grain (3-4.3 and 4.3-5.9 grams/day) was an effective modifier for overall UI (OR 0.86, 95% CI 0.76-0.98 and OR 0.78, 95% 0.68-0.89 respectively) and was associated with a lower risk of stress urinary incontinence (SUI) (OR 0.78, 95% CI 0.65-0.92 and OR 0.76, 95% CI 0.64-0.91 respectively). Furthermore, a diet of 1663.6-1909.48 kcal/day was associated with a lower chance of *de novo* SUI (p=0.03). However, there was no statistical difference in *de novo* urgency urinary incontinence (UUI) for the DM-I group compared to controls. Surprisingly a moderately high amount of fat decreased the chance of developing UUI, but the exact mechanism underlying this result is unclear and needs further investigation.

Regarding risk of bias (ROB), information about the main methods of the RCT was extracted from the original RCT. Randomisation was done using a permuted block algorithm. However, there was no information on allocation concealment. The nature of the intervention would not allow participants to be blinded to the intervention and outcome measures were self-reported by the participants. Intention to treat (ITT) analysis was not reported and loss to follow-up was considered to have low ROB. Despite the overall moderate ROB, the substantial number of participants included in this study provided some evidence that advising women to increase their intake of whole grains and adopting a moderate calorie diet may reduce the risk of developing UI, especially SUI.

1.1.2. Physical activity

A study prospectively analysing collected data on parous middle-aged women participating in a longitudinal study of parents and children (6) examined the associations between physical activity and a range of lower urinary tract symptoms (LUTS). At the three-year and 11.5-year follow-ups respectively, 4126 and 2770 women reported if they had symptoms of SUI, UUI or mixed UI. After three years, women in the highest category of physical activity (≥43.2 MET hours/week) were less likely to have UI (adjusted OR (aOR)=0.51; 95% CI 0.32, 0.80) compared to women in the lowest category (0 MET hours/week). After 11.5 years of follow-up, women in the highest category of physical activity were still less likely to have SUI (aOR= 0.56; 95%CI: 0.39, 0.82), UUI (aOR= 0.34; 95%CI: 0.20, 0.67) and mixed UI (aOR= 0.34; 95%CI: 0.19, 0.63) compared to women in the lowest physical activity category.

Summary

A secondary analysis of a large RCT with moderate ROB showed that a dietary intervention with high fruit, vegetable and whole grain content as well as a moderate caloric intake reduces the risk of developing *de novo* UI (all types) symptoms, especially SUI, in continent postmenopausal women. **(Level of evidence: 2)**

A large prospective longitudinal study showed that higher level of physical activity was associated with a reduced prevalence of UI, especially SUI in the medium and long term in continent parous women. **(Level of evidence: 3)**

Recommendations

A dietary intervention with high fruit, vegetable and whole grain content as well as a moderate caloric intake can be recommended to postmenopausal women to prevent UI. **(Grade of recommendation: B New)**

Higher levels of physical activity (≥43.2 MET hours/week) could be recommended to continent parous middle-aged women to prevent UI. **(Grade of recommendation: C New)**

Further high quality RCTs are required to confirm the effect of a dietary intervention with high fruit, vegetable, and whole grain content as well as a moderate caloric intake and physical activity in the prevention of incontinence in women. Finally, high quality cost-effectiveness RCTs are needed to determine the possible benefits of implementing any lifestyle intervention strategies to prevent UI, especially in higher-risk groups, such as postmenopausal, overweigh and obese women.

Table 2. Summary data on prevention

Author, Year	Comparator	N	Study population	Age	Outcomes/Results	Follow up	Notes (side effects, loss to follow-up, risk of bias)
Rogo-Gupta (2017) (5)	Dietary modification versus health education materials	N = 22852 control group and N =19541 intervention group	Postmenopausal women	No information	Participants were grouped into NUI vs. SUI if they reported UI during activity. In a separate analysis, participants were grouped into NUI and urge UUI if they reported UI with urgency. At year 1 and when adjusted, continent participants who underwent dietary modification were less likely to develop UI overall (OR 0.94, 95% CI 0.99-1, p=0.04) or SUI (OR 0.9, 95% CI 0.83-0.98, p=0.014).	12 months	RCT No side effects or loss of follow-up reported
Alhababi (2019) (6)	Highest category of physical activity (43.2 MET hours or more per week) compared to the lowest category (0 MET hours per week).	4126	Women	37.2 ± 4.6 years	Self-reported symptoms of lower urinary tract symptoms. 3-year follow up: women in the highest category of physical activity (43.2 MET hours or more per week) had lower odds of stress incontinence (aOR 0.51, 95% CI 0.32-0.80) than women in the lowest category (0 MET hours per week). After 11.5 years, women in the highest category of physical activity had lower odds of stress incontinence (aOR 0.56, 95% CI 0.39-0.82), urgency incontinence (aOR 0.34, 95% CI 0.20-0.67) and mixed incontinence (aOR 0.34, 95% CI 0.19-0.63) compared to women in the lowest physical activity category.	3 and 11.5 years	Prospective

Abbreviations: NUI: no urinary incontinence; SUI: stress urinary incontinence; UUI: urge urinary incontinence; RCT: randomised clinical trial; MET: metabolic equivalence of task

1.2. Treatment

In relation to lifestyle interventions to treat UI in women, this update includes one new meta-analysis (7) and one RCT (secondary analysis) related to weight loss and physical activity (8). It also includes one RCT (9) about physical activities and one survey about smoking (10). Finally, it includes two RCTs about dietary factors/fluid intake (11, 12).

1.2.1. Weight loss and physical activity

The characteristics of the studies are presented in Table 3. One new systematic review was conducted by the American Urogynecologic Society Systematic Review Group and assessed the impact of both surgical and behavioural weight loss interventions on UI symptoms in overweight and obese women (7). It included a total of 43 publications, mostly (76.7%) observational studies (related to surgical intervention) and 10 reports that used data from 5 RCTs (related to behavioural weight loss (BWL). Using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) the authors concluded, that there is high-certainty evidence that BWL, such as diet and exercise, decreases the prevalence of SUI by 15% to 18% and all type of UI by 12% to 17% after 1 to 2.9 years in overweight women. However, the certainty of evidence on the long-term effects (1 to 2.9 years post-intervention) of these interventions was lower and evidence about weight loss on urgency UI was graded as moderate. The RCTs included in this systematic review were all included in the previous editions of this chapter. New data published in 2018 has now been added (8). Secondary analysis of the "Programme to Reduce Incontinence by Diet and Exercise (PRIDE)" study assessed whether the BWL programme (including diet, exercise, and behaviour modification) would improve non-UI LUTS including urinary frequency, nocturia, urgency, at six months compared to a structured education programme (control group) among overweight and obese women with UI. At the six months follow-up, the overall cohort, regardless of group assignment, reported a significant improvement in multiple non-UI LUTS domains. However, LUTS outcomes did not differ between the intervention and control groups and no differences were observed based on either the amount of weight lost (≥ 5% compared to <5%) or physical activity (≥1500 kilocalorie expenditure/week compared to < 1500 kilocalories) (8).

An important limitation of this study is that not all participants in the original RCT had non-UI LUTS. This reduced power and limited the ability to detect changes in LUTS in women without UI. In addition, the multiple comparisons may have increased the risk of type 1 error and the loss to follow-up was 19% in the control group. In contrast, the original RCT found that 96% of the participants provided UI outcome data at the 6- and 18-month follow-ups (13, 14).

Summary

The addition of one systematic review to previous data continues to support BWL in the reduction of UI in women who are overweight or obese. **(Level of evidence: 1)**

BWL does not appear to be better than a structured education programme to improve non-UI LUTS, including urinary frequency, nocturia and urgency at six months among overweight and obese women with UI. **(Level of evidence: 2)**

Recommendations

BWL should be recommended to obese and overweight women with UI. **(Grade of recommendation: A)**

Table 3. Summary data on weight loss

Author, Year	Comparator	N	Study population	Age	Outcomes/Results	Follow up	Notes (side effects, loss of follow up, risk of bias)
Yazdany (2020) (7)	BWL intervention (diet modification, exercise programs, medications, and/or counselling)	-	Overweight and obese women	> 18 years	There is high-quality evidence that BWL results in modest improvements in stress and overall UI in overweight and obese women 1 to 2.9 years after the intervention	-	Systematic review No studies investigating conservative interventions reported any side effects.
Breyer (2018) (8)	BWL intervention (group sessions focused on nutrition, exercise and behaviour change)	338 intervention (N=226) or control (N=112)	Overweight or obese women with UI	Mean age: 53 years	For both groups combined, women experienced significant improvement in nocturia and urgency UI (all P < 0.001). However, lower urinary tract symptoms outcomes at 6 months did not differ between the intervention and control group. Similarly, no differences were observed based on either the amount of weight lost (>5% compared (<5%) or physical activity (> 1500 kilocalorie expenditure/week compared to < 1500 kilocalories).	6 months	Secondary analysis of RCT Losses to follow up: Intervention group: 12 (5%) Control group: 22 (19%) Adverse effects not reported

Abbreviations: BWL: behavioural weight loss; UI: urinary incontinence; RCT: randomised controlled trial

1.2.2. Physical activity

Very few data have been published on either the benefit of moderate physical activity or the adverse effect of strenuous activity on UI in women.

In this update we included one new RCT (9). Summary data are presented in Table 4.

One RCT (9) investigated the effect of a three-month physical activity programme for the reduction of abdominal fat (PRAF) in young overweight women with overactive bladder (OAB) compared to a control group (no exercise programme). The intervention comprised an aerobic training programme, in addition to abdominal muscle strengthening and general stretching exercises but excluded PFM exercises. OAB symptoms were assessed using a voiding diary and questionnaires (OAB-q and PPIUS scales). The study found significant differences in favour of the group of women who exercised [voiding per 24 h: treatment versus control group, baseline 9.1 ± 0.3 versus 8.6 ± 0.3, final 6.9 ± 0.2 versus 8.1 ± 0.2, $p < 0.0001$; mean voided volume per 24 h (ml): treatment versus control group, baseline 154.2 ± 9.1 versus 162.2 ± 9.3, final 201.3 ± 9.3 versus 164.1 ± 9.6, $p < 0.0001$]. A possible confounding factor in this study was the reduction in body mass index (BMI), which could have affected OAB symptoms, including UI. The study had an overall moderate ROB with no blinding of the participants and a high loss to follow-up in both groups, which could have further biased results.

Summary

Previous non-RCT evidence suggests that moderate exercise decreases the incidence of UI. **(Level of evidence: 3)**

One new RCT with moderate to high ROB suggests that a three-month physical activity programme for the reduction of abdominal fat is better than no exercise to reduce LUTS in overweight women with UUI. **(Level of evidence: 2)**

Recommendations

A physical activity programme for the reduction of abdominal fat could be recommended to young overweight women with UUI to reduce LUTS. Further high-quality RCTs are needed to confirm these results. (**Grade of recommendation: C New)**

Table 4. Summary data on physical activity

Author, Year	Comparator	N	Study population	Age	Outcomes/Results	Follow up	Notes (side effects, loss of follow up, risk of bias)
Hagovska (2020) (9)	Control: no exercise program TX: exercise program	70 (36- intervention, 34 – CG)	Overweight women with OAB symptoms	Average age of 26.2 years	The program for reducing abdominal fat significantly reduced the weight of the participants as well as mild symptoms of OAB after 12 weeks.	12 weeks	RCT Side effects were not addressed

Abbreviations: OAB: overactive bladder; RCT: randomised controlled trial

1.2.3. Smoking

The sixth ICI edition reports on data from a pilot RCT investigating the impact of smoking abstinence on overactive bladder (OAB) symptoms. The results showed that participants who were abstinent from smoking at the 12-week follow-up were more likely to reduce their urinary frequency (p=0.042) and ICIQ-OAB score (for more details consult the sixth ICI edition).

No new trial investigating the impact of smoking cessation on UI was found. Although cigarette smoking has been associated with UI in women, the exact mechanism underlying this association is still unknown. It is possible that smoking-induced atherosclerosis can be a pathway influencing the development of LUTS. A recent study screened a total of 10,000 women registered by a web-based internet survey company in Japan to determine the correlation between smoking habits and LUTS (10). The results showed that smoking habit was a risk factor for LUTS in women, increasing daytime frequency, nocturia, urgency and UUI, especially in the younger women (aged <40 years). Urgency and UUI prevalence decreased in correlation with the duration of smoking cessation among young female ex-smokers, but no correlation was found between smoking and the prevalence of urgency and UUI. Limitations of this survey included the study design and the use of a web-based self-administrated questionnaire. The authors reported that the study failed to obtain the satisfactory number of participants calculated by population-based numbers, especially for participants aged 70 and over. The association between cigarette smoking habits and UI suggests that cessation of smoking might decrease the prevalence of UI, especially UUI, however this is low-quality indirect evidence.

Summary

A large new survey showed that the prevalence of UUI decreased in correlation with the duration of smoking cessation among young female ex-smokers. These new data suggesting smoking cessation is related to UI and LUTS prevalence or severity adds to previous findings. (**Level of evidence: 3**)

Recommendations

Although no UI – LUTS recommendation can be made, smoking cessation may be offered to current smokers at initial encounter for the general health benefits. (**Grade of recommendation: D)**

Further high-quality RCTs are needed to confirm the impact of smoking cessation on UI.

1.2.4. Dietary modification

Factors such as diet; and caffeine intake might influence UI. In 2020, a scoping review on caffeine consumption and LUTS was published (15). This review identified 14 interventional studies, with eight RCTs and six cohort studies, all published before 2016. Therefore, no new RCTs about caffeine and fluid intake were included in this update. The scoping review's conclusion points out to a decrease in urgency episodes and in nocturnal enuresis episodes with caffeine reduction (15).

In relation to diet, a secondary analysis of one RCT (11) and one new RCT (12) were included in this update. The dietary interventions investigated were a low-fat and high fruit, vegetable and whole grain diet (11) and supplementation of vitamin D (12). Summarised data are presented in Table 5.

Part of this secondary analysis of the WHI Dietary Modification (DM), (11) is covered in the lifestyle intervention prevention section (section II.1.1.1). In a short abstract, the author studied the impact of dietary intervention (DM-I) on UI symptoms, in postmenopausal women with UI, a subgroup of the main trial. The participants were assigned to receive a dietary intervention (DM-I) including an intensive behaviour modification programme for a reduction in fat intake and an increase in consumption of fruit, vegetable and whole grains. Controls (DM-C) received only health education materials. Participants (48,835) were randomised to DM-C (29,294 (60%)) and to DM-I (19,541 (40%)). Participants who reported urinary leakage were considered to have UI and categorized as SUI if they reported UI during activity and UUI if they reported UI with urgency. The groups were homogeneous at baseline in relation to demographic characteristics. When adjusting for weight change, women in the DM-I group were less likely to report overall UI (OR 0.94, 95% CI 0.9-0.98, p=0.002) or SUI (OR 0.89, 95% CI 0.86-0.93, p< 0.001) one year after the intervention compared to controls but were more likely to report UUI (OR 1.06, 95% CI 1.01- 1.1, p=0.02).

The pilot RCT (12) investigated the efficacy of vitamin D supplementation on the reduction of UUI episodes in community dwelling postmenopausal women. The intervention consisted of 12 weeks of a weekly oral dose of 50,000 IU vitamin D3 or placebo. UUI episodes per 24-hour period decreased by 43.0% with vitamin D3 compared to 27.6% with placebo (P = .22). In obese women, UUI episodes decreased by 54.1% compared to 32.7% with placebo (P = .29). Black women obtained the largest effect of vitamin D supplementation with a 63.2% decrease in UUI episodes compared to 22.9% with placebo (P = .03). Randomisation was performed using a computer 1:1 allocation ratio, although the allocation concealment was not clearly described. Participants and the assessor were blinded to treatment or placebo. The adherence to therapy was high in both arms and the study is one of the few in this chapter to have instigated and reported adverse effects (Table 5). There was no incomplete outcome data and selective reporting, but the study lacked sufficient power to detect differences between groups.

Summary and recommendations

One secondary analysis of an RCT provides evidence that a low-fat and high-fruit, vegetable and whole grain diet have a small effect in decreasing UI symptoms independently of weight change, age, ethnicity, and hormone replacement use and therefore could be recommended. **(Level of evidence: 2; (Grade of recommendation: C)**

Vitamin D supplementation can be recommended to decrease UUI episodes in post-menopausal black women. **(Level of evidence: 2; Grade of recommendation: B)**

The levels of evidence related to other interventions such as fluid intake and reduction of daily caffeine consumption remained the same as no new RCT was added to this update. **(Level of evidence: 2)** Adequate fluid intake and reduction of caffeine consumption can be recommended for people with UI and LUTS symptoms. (**Grade of recommendation: B)**

Further large high-quality RCTs are needed to assess the impact of dietary interventions on the different types of UI in women.

Table 5. Summary data on dietary modification

Author, Year	Comparator	N	Study population	Age	Outcomes/Results	Follow up	Notes (side effects, loss of follow up, risk of bias)
Rogo-Gupta (2017) (11)	Dietary modification versus health education materials only	22.852 control and 19.541 intervention	Postmenopausal women	No information	Patients who reported urinary leakage were considered to have UI. They were categorized as having SUI if they reported UI during activity, and UUI if they reported UI with urgency. Women who received the dietary intervention were more likely to become continent in the 1-year follow-up (OR 1.08, 95% CI 1.01-1.16, p=0.03). They also had no SUI (OR 1.12, 95% CI 1.06-1.18, p<0.001) when adjusted for weight change, age, ethnicity and hormone replacement use. However, I participants receiving the dietary modification intervention were less likely to cure UUI (OR 0.93, 95% CI 0.88-0.98, p=0.01).	12 months	secondary analysis Side effects were not addressed Loss of follow up: not reported
Markland (2019) (12)	Vitamin D versus placebo	28for the intervention group and 28 for the placebo	Community-dwelling postmenopausal women	50 +	Primary efficacy estimate was the percentage change in UUI episodes. Secondary estimates included changes in other lower urinary tract symptoms. UUI episodes per 24 hours day decreased 52.4% with Vitamin D compared to 30.9% with placebo (p=0.09).	12 weeks	RCT Side effects: Palpitations (n=1), transient asymptomatic hypercalcemia (n=2) and Gastrointestinal symptoms (n= not reported) Loss of follow-up: 14%

Abbreviations: UI: urinary incontinence; SUI: stress urinary incontinence; UUI urge urinary incontinence.

1.2.5. Constipation

No new trials on constipation were found. Therefore, the evidence remains the same (small observational studies) suggesting that chronic straining may be a risk factor for the development of UI **(Level of evidence: 3).**

Recommendations

Further research is needed to confirm the role of abdominal straining in the pathogenesis of UI.

2. PELVIC FLOOR MUSCLE TRAINING

Pelvic floor muscle training (PFMT) is defined as exercise to improve pelvic floor muscle (PFM) strength, endurance, power, relaxation, or a combination of these (1). PFMT remains a key factor in the treatment of UI. Because PFM integrity appears to play an important role in the continence mechanism (see Chapter 3: Pathophysiology of urinary incontinence, faecal incontinence and pelvic organ prolapse), there is a biological rationale to support the use of PFMT in preventing and treating SUI in women (16-18). The role of PFMT in the treatment of UUI was determined afterwards (19, 20). More details about the biological rationale regarding the effect of PFMT on SUI and UUI can be found in the 2013 ICI edition of this chapter (21).

PFMT is an intervention that involves understanding PFM activation and repeating a PFM exercise programme over time. Because the effectiveness of PFMT depends on the participant's adherence during the intervention and follow-up (in the maintenance phase), a better understanding of adherence mechanisms and how they can be promoted is of major importance. The 2011 International Continence Society State of the Science Seminar on Adherence produced four papers and a Consensus Statement in 2015, reviewing present literature. They also made recommendations for increasing PFMT adherence that could be useful in both clinical and research settings (22-26).

This section presents evidence for the use of PFMT in the prevention and treatment of UI in women. The questions addressed are:
- Is PFMT effective in the prevention of UI?
- Is PFMT better than no treatment, placebo, or control treatments in the treatment of UI?
- Is one type of PFMT programme better than another in the treatment of UI?
- Is PFMT better than other treatments in the treatment of UI?
- Does the addition of PFMT to other treatments add any benefit in the treatment of UI?
- What factors might affect the outcome of PFMT in the treatment of UI?
- What is the effect of PFMT on other LUTS?

2.1. Prevention and treatment (pregnant and postpartum women only)

This subsection considers PFMT for the prevention and treatment of UI in pregnant and postpartum women (also called childbearing women). As the physiological changes of childbearing can affect PFM function, the effect of PFMT might differ in this group compared to non-childbearing women. Therefore, this group is treated separately. An updated Cochrane review was published in 2020 (27). Since our last ICI chapter (2017), eight new RCTs focusing on the prevention and/or treatment of UI were identified and reviewed for this subsection (28-35), as well as one follow-up study (36) of a previously reported trial (37) (Table 6). Trials in this section were previously grouped into three areas: 1) PFMT for the prevention of UI (performed in women without UI symptoms when randomised); 2) PFMT trials for the treatment of UI; and 3) PFMT trials for the prevention and treatment of UI (participants with and without UI symptoms enrolled). Trials were further separated into those beginning during pregnancy (prepartum) or after pregnancy (postpartum). The primary outcome of interest was self-reported UI (cure, improvement, number of leakage episodes). Other outcomes of interest included adherence measures.

2.1.1. Is PFMT effective in the prevention of UI in childbearing women?

This section addresses the question of PFMT effectiveness for primary and secondary prevention of UI in childbearing women. Clinically, it can be difficult to screen trial participants effectively to ensure that a disease is altogether absent (for primary prevention studies), present although asymptomatic (for secondary prevention). Trials investigating the prevention of UI usually enrol people purely based on the absence of symptoms. Thus, trials represent a combination of primary and secondary prevention effects.

Since the last ICI chapter, one (29) new prevention trial was found (Table 6) adding to the nine trials presented in the previous edition. The study by Sangsawang (29) included 70 continent primiparous women at 20-30 weeks' gestation. All women received antenatal education about PFM function and strengthening and how to perform PFM exercises. The supervised group PFMT programme began during pregnancy. The control group received usual antenatal care from health professionals, obstetricians, or midwives (who were not involved in the study). They received information on diet, sleep, breast feeding and antenatal exercise (which may have included advice on PFMT), from their maternity caregivers. They did not receive information about stress UI during pregnancy and performance of correct PFMT was not assessed.

Quality of data

This was a two-arm RCT. Allocation concealment and randomisation were adequate. However, the outcome assessors were not blinded. The total dropout rate was 10%: 2/35 in the intervention and 5/35 in the control group. Outcomes were measured at baseline (20-30 weeks' gestation) and the primary endpoint was 38 weeks' gestation. The trial did not report ITT analysis and adverse events.

Results

The primary outcome was self-reported UI (defined as involuntary leakage of urine during sneezing, coughing, effort or physical exertion, ≥ once per week). Significantly fewer women in the PFMT group reported SUI compared to the control group (OR 3.05, 95% CI 1.07–8.70, $P = 0.018$), and a significantly smaller amount of leakage was reported in the PFMT group (P=0.03). The authors concluded that PFMT was effective in preventing SUI in late pregnancy.

Summary

One new study was found assessing the preventive effect of PFMT. Together with previous trials, this RCT supports the effectiveness of PFMT during pregnancy to prevent SUI in late pregnancy and up to mid post-partum period. (**Level of evidence: 1)**

Recommendations

Continent, pregnant women should be offered a supervised PFMT programme (including regular health professional contact) that is intensive and aimed at strengthening PFMs to prevent antepartum and postpartum UI (up to 6 months) UI. **(Grade of recommendation: A)**

Additional trials with long-term follow-up (more than 12 months postpartum) are needed to determine long- term benefits of antenatal PFMT. Furthermore, the only study including multiparous women is a quasi-randomised trial (38). Thus, large, good-quality RCTs are needed to investigate the effects of antepartum PFMT on preventing postpartum UI in multiparous women.

2.1.2. Is PFMT effective in the treatment of UI in childbearing women?

Since the sixth ICI one new trial assessing the effects of pre- or postpartum PFMT in the treatment of UI was found (Table 6), adding to the previously reported trials.

Sigurdardottir (2020) (32) recruited 84 primiparous women with UI six to 10 weeks after delivery, who were randomised to a PFMT group (supervised by a physical therapist) and a control group (no instructions). The intervention started at ~9 weeks postpartum and consisted of 12 weekly individual sessions of PFM strength training with a physiotherapist. Adherence to the PFMT protocol was reported using exercise diaries.

Quality of data

This was a two-arm RCT. Allocation concealment and randomisation were adequate. The outcome assessors were not blinded. The total dropout rate was 16%: 8/41 in the intervention and 5/43 in the control group. Analyses were per protocol.

Results

The primary outcome was rate of UI, and the primary endpoint was six-months postpartum. A statistically significant difference in UI in favour of the intervention group was found six months after delivery (RR 0.7 (95% CI 0.51-0.96) p=0.03), but not at 12 months. However, adherence to exercise at this time point was low. No adverse effects were reported.

Summary

Data from previous trials and this new trial showed a significantly superior treatment effect of supervised PFMT on UI compared to the control group. The addition of the new trial does not change the level of evidence. **(Level of evidence: 1).**

Recommendations

PFMT should be offered as first line conservative therapy to women with persistent UI symptoms, two to three months after delivery. **(Grade of recommendation: A).**

An 'intensive' PFM strength training programme (in terms of supervision and exercise content) can be recommended as it increases the treatment effect. **(Grade of recommendation: B).**

Research recommendations

There is a need for one large, pragmatic, well-conducted and explicitly reported trial with long-term follow-up (more than five years) that investigates the effect of an 'intensive' PFM strength training programme.

2.1.3. Is PFMT effective in the mixed prevention and treatment of UI in childbearing women?

Since the last ICI, six new mixed prevention and treatment trials which assessed the effect of PFMT on symptoms of UI (28, 30, 31, 33-35) and on quality of life (QoL) (31, 34) were found, adding to the 16 previously reported trials. One follow-up study was also published (36).

Four trials included pregnant women (28, 31, 33, 35) and two included postpartum women (30, 34).

The PFMT interventions, intervention periods, outcome measures related to UI and primary endpoints varied (Table 6):

Antepartum PFMT versus usual care or no PFMT

Szumilewicz (2019) (31) compared a general group exercise programme in pregnant women that included PFMT to one without PFMT. The main outcome measure was change in neuromuscular activity in the PFMT. The original intervention, in the follow up study by Johannessen (2020) (36), compared a similar intervention to standard care and reported on UI three months after delivery.

Combined ante- and postpartum PFMT versus usual care or no PFMT

Three trials assessed the effect of instructions and home PFMT during both pregnancy and after delivery (28, 33, 35). Sut (2016) (28) and Sacomori (2019) (33) compared PFMT instructions with no instructions, while Hyakutake (2018) (35) compared PFMT instructions and pelvic floor health with usual care (most likely including information about PFMT). The primary endpoint was at the early postpartum period (28, 33, 35), while Sut (2016) (28) also reported outcomes in late pregnancy.

Postpartum PFMT versus usual care or no PFMT

Yang (2017) (30) compared three groups: two groups received a home PFMT programme with and without additional EStim and the control group had no PFMT instructions. UI was reported at three months postpartum. Lin (2020) (34) compared a control group receiving routine postpartum rehabilitation nursing (unclear if this included PFMT), and an intervention group receiving one-to-one nursing intervention with postpartum PFMT. The intervention took place over six months and the primary endpoint was after the six-months intervention (34).

Quality of data

Antepartum PFMT

Szumilewicz (2019) (31) published a RCT with adequate random sequence generation, but no information on allocation concealment and thus had unclear risk of selection bias. There was no blinding of participants or personnel (participant bias) or assessors (detection bias), and outcome data were incomplete (attrition bias). The method of collecting patient-reported UI symptom data was not blinded. Loss to follow-up was 38% in the intervention and 51% in the control group, and was related to medical issues and other reasons. The quality of the follow-up trial by Johannessen (2020) (36) has been presented in a previous edition of this chapter by Stafne (2012) (37).

Combined ante- and postpartum PFMT

Sut (2016) (28) and Hyakutake's (2018) (35) RCTs were two-armed while the Sacomori study (2019) (33) was a cluster RCT. Sut (2016) (28) randomised 64 parous pregnant women in their third trimester to a home PFMT programme during pregnancy and postpartum, while the control group received no PFMT instruction. Hyakutake (2018) (35) included 100 nulliparous women, who were randomised to two groups. The PFMT group attended a single pelvic floor health workshop. The control group received routine prepartum care with their existing maternity care provider, which most likely included advice on PFMT.

Sacomori (2019) (33) conducted a two-arm cluster RCT, including 202 primiparous women immediately after giving birth. The PFMT group received instructions in a home training programme, while the control group had no instructions.

The trials by Sut (28) and Sacamori (33) had unclear risk of selection bias. Hyakutake (35) had adequate random allocation generation and concealment, but incomplete outcome data. The method of collecting patient-reported incontinence symptoms was not blinded in any of the trials. The proportion of participants lost to follow-up was 5.4% (28), 26% (35) and 34.7% respectively (33). Losses to follow-up in intervention and control groups were quite similar in all trials, but ITT analyses were not reported.

Postpartum PFMT
Yang (2017) (30) used a random number table to randomise 240 primiparous women into three groups (control, PFMT and PFMT plus EStim) after delivery. The risk of selection bias was low, and researchers were blind to group allocation. However, outcome data were incomplete, and the proportion lost to follow up was 21.3%, but quite similar in all groups. ITT analysis was not reported. Lin (2020) (34) randomised 97 postpartum women to an intervention and a control group while in hospital. The randomisation procedure was not described and risk of selection bias unclear. Outcome data were mainly self-reported (incidence of SUI, ICIQ-SF, I-QOL). No losses to follow-up were reported.

Results

Antepartum PFMT
Szumilewicz (2019) (31) assessed UI specific QoL (IIQ-7) in late pregnancy. Only 1/55 in the control group and 9/111 in the intervention group reported symptoms initially, and accordingly, 2/27 and 9/70 reported symptoms after the six-weeks intervention RR 1.74 (95% CI 0.4, 7.52, *P*=0.46). Johannessen (2020) (36) reported a significant (RR 0.75, 95% CI 0.61-0.93, *P*=0.008) reduction in UI in the intervention group compared to control group three months after delivery. Adherence was reported in both trials.

Combined ante- and postpartum PFMT
Symptoms of UI were registered in the subscales of the questionnaires used (28, 33, 35). It is important to note that none of the PFMT interventions included regular supervision of the exercises. Adherence was reported by Hyakutake (2018) (35), Sacomori (2019) (33) but not by Sut (2016) (28).

In the trials by Sut (2016) (28), Hyakutake (2018) (35) and Sacomori (2019) (33) there was no difference in UI symptoms between groups. The primary endpoint was 6-8 weeks' postpartum. The results in the trial by Sut (28) showed that the frequency and urgency levels in both groups significantly decreased between late pregnancy and early postpartum, according to voiding diary levels. However, changes between groups were not significantly different. Hyakutake (2018) (35) and Sacamori (2019) (33) reported no significant difference between groups at six weeks postpartum, using the UDI-6 (bladder subscale).

Postpartum PFMT
Yang (2017) (30) found that significantly more women reported no UI in the PFMT group and in the PFMT plus EStim group, compared to the control group. UI was also measured by using a urine pad test, and the results showed that significantly more women in the control group leaked urine compared to the two PFMT groups (PFMT alone and with EStim). In the combined PFMT group, 66/129 reported UI compared to 56/60 in the control group, giving a RR 0.55 [0.46,0.66] (*P*<0.00001). Adherence was reported.

The results by Lin (2020) (34) showed that the incidence of SUI and ICIQ-SF scores were significantly lower in the intervention group than in the control group (*P*<0.05) and that the I-QOL scores were significantly higher (*P*<0.05).

Summary

None of the new trials specified self-reported UI prevalence, cure, or improvement as an outcome. However, symptoms of UI were registered in subscales of questionnaires used. It is also important to note that only one (34) of the interventions used to prevent or treat UI, included regular supervised PFMT sessions. It is possible that for the other trials, absence of supervision could have tempered the results. The overall quality of most of the new trials was low.

The only new antepartum mixed prevention and treatment trial on the effects of PFMT on symptoms of UI was inconclusive; however, the trial quality was low (31). In contrast, the high-quality follow-up study by Johannessen (2020) (36) showed that the antepartum PFMT programme still influenced UI symptoms three months after delivery. The three trials combining ante- and postpartum PFMT did not find significant differences between groups on postpartum symptoms of UI (28, 33, 35).

However, both postpartum treatment trials - Yang (2017) (30) and Lin (2020) (34) - found that significantly fewer women reported UI in the PFMT intervention groups compared to the control group.

It is difficult to draw conclusions on the effect of antepartum PFMT or postpartum PFMT on prevention and treatment of UI. The overall quality of many of the new trials was low, and none of the trials had UI symptoms, cure or improvement specified as an outcome measure. Moreover, the control interventions were not always compared to supervised, intensive PFM strength training, as has been previously recommended.

The characteristics of previous trials - all methodologically robust - demonstrated reduced UI prevalence in late pregnancy and six months postpartum and had high adherence to a supervised PFM strength training programme and home exercises. Similar results were demonstrated in two new mixed prevention and treatment trials assessing the effect of postpartum PFMT. **(Level of evidence: 2)**

Nevertheless, one trial using the recommended training protocol in postpartum women did not show any differences between groups (39). Even if the combined results from the published trials still are inconclusive, the benefit of ante- and postpartum PFMT to prevent and treat UI shown in most of the higher-quality studies and the lack of adverse effects of PFMT should be taken into consideration.

Recommendations

Health providers should carefully consider the costs and benefits of population-based approaches, such as professionally taught antepartum or postpartum PFMT. PFMT should be provided to all pregnant or postpartum women by a health professional regardless of their current or prior continence status.

(Grade of recommendation - antepartum PFMT: A)

(Grade of recommendation - postpartum PFMT: B)

For population-based approaches, the 'best' evidence to date suggests recommending: (a) an intervention comprising of a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting at 16-24 weeks' gestation for pregnant women, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more). **(Grade of recommendation: C)**

Table 6. PFMT on pregnant and postpartum women

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Hyakutake (2018) (35)	2-arm RCT Control group (n = 50): Routine prepartum care, likely to have received advice on PFMT. Intervention group (n=50): Instructions on PFMT + home PFMT	100	Nulliparous women with singleton gestation. Incontinence at recruitment was not reported. Single centre Canada.	A single 2-hour long pelvic floor health workshop; information pack to take home; and encouraged to contact a local PF physiotherapist. Women were instructed to perform PFMT three times daily at home starting with 5 contractions (1-sec hold) progressing to 10 contractions (10-sec hold), for the rest of their lives. No PF examination performed.	UI-specific quality of life: CG: 7.3 (12.6) IG: 5.3 (12.8) Std. 2.2. Prevention (other women)

Although there are multiple trials of PFMT for prevention of UI in peripartum women (see section II.2.1.1), there is little research on PFMT for prevention of UI in non-childbearing women. We found five new trials to add to the one trial from the previous edition. Two (40, 41) were workshops on incontinence awareness and education including PFMT and are out of the scope of this chapter. Please refer to chapter 20 on *Primary prevention, continence promotion, models of care and education* for more details on educational workshops on incontinence. Three more trials on PFMT for UI prevention were found (42-44).

PFMT details

Two trials involved post-menopausal women (42, 43) and the other one, young volleyball players (44). All three trials involved a PFMT programme supervised by a physiotherapist one to two times per week, for 12-16 weeks in addition to home PFM exercises compared to an inactive control. More details about the exercise programmes are presented in Table 7.

Quality of data

Of the three trials, one was of moderate size (43) and the two others were small (42, 44). All three presented a clear randomization method, but only one reported a clear method of concealment, blinded outcome assessors and intent-to-treat analysis (43). Loss to follow-up was moderate (20% and up) and when reported, side effects were minor. The overall ROB was considered to be low in one trial (43) and moderate in the others (42, 44), mainly due to blinding of the assessor and attrition bias.

Results

Prevalence of UI was based on quantifiable measures (pad test) (44) or on or UI-specific validated questionnaires (42, 43). In all three trials, prevalence of UI was lower in the treatment group than in the controls immediately after the intervention, supporting the effect of PFMT in the prevention of UI. No longer-term effect was reported.

Summary

PFMT could be effective in the prevention of UI in younger athletes and menopausal women, immediately after the intervention. (**Level of evidence: 2)**

Supervised PFMT can be offered to prevent UI in women **(Grade of Recommendation: B New)**.

Larger size RCTs with longer follow up are needed.

2.3. Treatment (other women)

2.3.1. Is PFMT better than no treatment, a placebo, or a control group treatment?

- This updated literature review identified 13 new trials that compared PFMT to no treatment, a sham treatment, or a control treatment (45-57). Two of the new trials were merged as they are reports from the same study (51, 56). Therefore, 13 reports of 12 new trials were included. The new identified trials were diverse and included studies from 11 countries (See Table 7). Samples involved adult women, with one trial specific to obese elderly women (57). Results from the studies added in this update are integrated with the conclusions drawn from previously reviewed studies.

PFMT details

Like in previously reviewed studies, most new trials proposed a 12-week (three-month) PFMT intervention. In some trials, the intervention was shorter, lasting from four to eight weeks (47, 48, 54, 56, 57) or longer, lasting up to 15 weeks in one trial (46). Of the 12 new trials, only six stated that a correct voluntary PFM contraction was confirmed prior to training using vaginal examination (47-50, 52, 56). Seven trials involved supervised PFMT by a physiotherapist or nurse (47-50, 54, 56, 57), and four included a regimen of home-based exercises (47-50). In four trials, supervised PFMT was delivered on an individual basis (47-49, 54), while in the other three, PFMT was conducted in group classes (50, 56, 57). Unsupervised PFMT was delivered with the aid of written and/or audio material in five trials (45, 46, 52, 53, 55). In three trials, the unsupervised programme was given in a single education session, delivered either individually (52, 53) or in groups (45). Of note, one study tested a smart phone application with no face-to-face contact with the participants (46). This application was previously tested in women with SUI (58) and this time it was applied in women with UUI or mixed urinary incontinence (MUI) (46). Furthermore, in five trials, PFMT was embedded in a multi-component programme with other behavioural or exercise components (45, 46, 49, 50, 53), but in all cases, PFM-specific exercises for the treatment of UI were considered as a main component of the intervention.

Quality of data

Of the new trials, four included more than 100 women (45, 46, 50, 56) of which two included over 400 participants (45, 50), five included 50-100 women (52-55, 57), and three involved fewer than 50 participants (47-49). Ten new trials presented a clear randomisation method (45-47, 49, 50, 52, 53, 55-57), eight reported concealment (45-47, 49, 50, 52, 56, 57), and four reported using blinded outcome assessors (45, 55-57). Four trials reported ITT analysis (45, 46, 52, 53). Loss to follow-up was low (below 10%), balanced between groups and unrelated to the study intervention in four trials (46, 50, 52, 53). When reported, side effects were minor and did not differ between groups (45, 46, 49, 50, 52, 55). The overall ROB was considered to be low in four trials (45, 46, 50, 52) and unclear in the remaining eight trials, mainly due to selection and attrition bias (47-49, 53-57). None of the newly included trials were considered to have high ROB.

Results

Similarly to the previously reviewed trials, the new added trials based their results on a variety of outcome measures, including patient-reported outcomes: cure (45, 46, 50, 55), improvement (45, 46, 52, 53, 55), UI-specific QoL or symptoms-validated questionnaires (45-49, 51-57), and number of leakages (as per the diary) (46, 48, 50, 55). Other outcomes included generic QoL or symptoms-validated questionnaires (50, 51) and clinician-reported measures, such as the 24-hour pad-test (45), PFM function (45, 47, 48, 52), and irisin (57) or myostatin (56) concentration. Cure and improvement were based on quantifiable measures such as a bladder diary (45, 46, 50, 55) or UI-specific validated questionnaires (45, 46, 52). One trial showed UI improvement based on UI-specific validated questionnaires, but only for the treatment group (53). The International Consultation on Incontinence Questionnaire - Urinary Incontinence Short Form (ICIQ-UI SF) was the most used UI-specific questionnaire (45-47, 49, 52-55), followed by the Revised Urinary Incontinence Scale (RUIS) (51, 56, 57) and the King's Health Questionnaire (KHQ) (51, 53).

When reported, cure rate favoured treatment in all trials, including the new and the previously reviewed trials. Three trials presented similar cure rates, where 32% to 55% of the participants reported

being cure (46, 50, 55). The cure rate was considerably lower in one trial compared to the other three, where only 4% of the treatment group versus 1.5% of the control group were cured (45). This difference might be related to the specificity of each intervention protocol. Particularly for the trial with lower cure rate, the intervention consisted in three months of unsupervised PFMT followed by a two-hour group class on bladder health. Additionally, no specific PFM assessment was reported to confirm whether participants performed a correct PFM contraction, which raises the possibility that not all participants were able to follow exercise instructions, and lack of supervision may have affected adherence to PFMT. Reported improvement rates varied widely, between 33% to 87% and consistently favoured treatment in new and previously reviewed trials (45, 46, 52, 53, 55, 58, 59). In the trials added to this chapter, improvement rates varied according to the definition used: Higher rates (71-87%) were reported in trials considering improvement as "a little better" to "very much better" on the Patient Global Impression of Improvement (PGI-I) questionnaire (46, 53), or as 50% reduction in UI episodes (46, 55). Lower rates (33-47%) were seen when improvement was considered as only "much better" to "very much better" on the PGI-I (53); when there was a 70% reduction in UI episodes (45); or, in one case, when improvement was based on a four-points category system using the ICIQ-UI SF total score (52).

Results favoured the treatment group in most of the trials that reported on UI-specific QoL or impact questionnaires. In this update, improvements were related to treatment in eight (45-48, 52-54, 56) out of 11 added trials that reported UI-specific QoL outcomes. Only three trials reported no difference between PFMT and control groups after the intervention (49, 55, 57). In one trial, post treatment outcomes were assessed at four weeks only in obese elderly women with UI (57), a population that may require a longer intervention time because of the increased pressure on the pelvic floor. The other two comprised a small pilot study with a high attrition rate, with 10 out of 22 participants concluding the trial (49), and an unsupervised low intensity PFMT programme (*'3-min exercise before going out'*) (55). Other outcomes that consistently favoured treatment across trials included number of leakages (46, 48, 50, 55) and pad test measured urinary loss (45). Overall better outcomes, including higher adherence and maintenance of results were observed in trials involving intense (8- to 12-week long) and supervised PFMT protocols (48, 50, 54, 60). Of note, two trials presented longer-term follow-ups (one year) that supported maintenance of results (45, 60).

Summary

PFMT is effective as a stand-alone therapy, as part of multi-component therapies embedding PFMT with concomitant behavioural strategies and lifestyle changes, and as part of general physical exercise programmes to improve physical function in women. Results expand the evidence base to include PFMT implemented by mobile technology, with a potentially broader reach, cost savings, and impact on rural health. New evidence from two high quality trials suggests the results were maintained in the longer term (one-year). Benefits are shown across age cohorts and UI type, in various cultural contexts, using several different training regimens, and assessed by multiple outcome measures. **(Level of evidence: 1)**

Recommendations

Supervised PFMT should be offered as a first line conservative therapy for women of all ages with UI. **(Grade of recommendation: A)**

Table 7. Summary of PFMT vs no treatment

Author, year	Comparator	N	Study population/ Country	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Prevention							
Alves (2016) (42)	RCT PFMT vs no treatment	42	Post-menopausal women (at least 5 years) Brazil	PFMT: 12 supervised PFMT 2x week during 30 minutes performed in group of 8-10 participants including pelvic mobility, stretching and straightening and relaxation exercises in different positions + PFMT with fast and slow contractions Control: one session of general exercises	Outcomes: primary outcome was measured using ICIQ-UI SF and ICIQ-OAB Key findings: There was a significant decrease in UI symptoms in PFMT group when compared to control for both ICIQ-UI (p=0.03) and ICIQ-OAB (p<0.001).	NR	Publication: FT Dropouts: 3/21 women in PFMT did not receive the intervention;9/21 women in the control arm did not complete the follow-up assessment AE: NR

2.3.2. Is one type of PFMT programme better than another?

Several factors can influence the outcome of a PFMT programme, such as the way it is taught and/or supervised, the parameters of the actual exercises as well as the adherence to the training regimen. But what is the most effective PFMT programme? This updated search revealed 29 new potentially eligible RCTs to address this question through 12 pre-defined comparisons. Of these, three were excluded because they did not report any incontinence outcomes (61-63). Three additional studies were not considered as they were already included as abstracts in the previous ICI, and the findings remained unchanged in the full manuscripts (64-66). Table 8 shows the studies included in the previous edition as well as the 23 eligible trials identified in this update (47, 67-88). Characteristics of each new RCT are presented in Table 9.

Table 8. Studies comparing different PFMT programs included in previous reviews and the current update (7th ICI)

	Studies included in previous ICI reviews	New studies identified in this update (7th ICI)
1. Supervision of training: amount of contact with health professionals	10	2
2. Supervision of training: individual versus group supervision	8	2
3. Exercise program: direct versus indirect exercises	8	2
4. Exercise program: generic versus individualised exercises	1	0
5. Exercise program: submaximal versus near maximal contractions	1	0
6. Exercise program: daily versus three times per week	1	0
7. Exercise program: addition of upright exercise position	1	0
8. Exercise program: addition of strength training to motor learning	1	1
9. Exercise program: addition of abdominal or hip muscle exercises	4	4
10. Exercise program: addition of an intravaginal resistance device	5	1
11. Exercise program: addition of an adherence strategy	2	2
12. Exercise program: addition of biofeedback	15	9

Quality of data

Of the 23 RCTs included, 15 provided sufficient details supporting adequate randomisation and allocation concealment methods (47, 67-70, 72-75, 77-79, 81-83). Six trials were randomised but did not provide information about treatment concealment (71, 76, 80, 84, 86, 87). Two studies did not report sufficient information on randomisation and concealment methods (85, 88). Nine RCTs stated that the outcome assessors were blinded (69, 72-75, 77, 78, 80, 86). Four studies used self-reported outcomes and participants were not blinded to treatment allocation (47, 68, 82, 83). For the remaining 10 RCTs, the assessors were not blinded, or insufficient information was presented (67, 70, 71, 76, 79, 81, 84, 85, 87, 88). Regarding the sample size, seven trials were small, including less than 20 participants per group (47, 75, 80, 83, 85, 87, 88). Nine studies included between 23 and 37 participants per comparison group (67, 68, 70, 71, 73, 76-79) and five had nearly 45 participants per group (72, 74, 81, 84, 86). Only two RCTs had a larger sample size, involving a total of 362 (69) and 600 women (82) (i.e., ≥178 per group). In four RCTs, the dropout rate ranged from 35% to 43% (70, 79, 83, 87) and hence the results of these RCTs should be interpreted with caution.

Results

- **Comparison 1. Supervision of training: amount of contact with health professionals**

Subgroup 1.1: additional group supervision

No further studies investigated the effect of adding an additional supervised group exercise session.

Subgroup 1.2: additional phone calls

No new studies investigated the effect of adding supervisory phone calls to PFMT programmes.

Subgroup 1.3: individual supervision versus no supervision

Two new RCTs were included in this comparison (67, 68). The PFMT programmes evaluated differed with regards to the amount of health-professional contact but were similar in type and quantity of PFM exercises.

For objective cure, the study by Fitz et al. (67), which was included as an abstract in the previous ICI edition, is considered in this update due to the new outcome in cure rate based on the pad test. Women in the supervised group presented a higher cure rate than women in the unsupervised group.

For improvement, the study by Mateus-Vasconcelos (68) showed that supervised PFMT resulted in a greater improvement in the ICIQ-UI scores than unsupervised training.

- **Comparison 2. Supervision of training: individual versus group**

Two new RCTs were included in this comparison. Both studies compared the same PFMT programme which differed only in the type of supervision (group versus individual) (69, 70). Dumoulin et al. (69) conducted a non-inferiority RCT comparing group to individual PFMT in women 60 years and older with SUI or MUI. In a superiority trial, Figueiredo et al. (70) investigated women with a mean age of 51 years. They were randomised to receive either individual PFMT, individual PFMT progressing into group training or group PFMT. It should be highlighted that in both studies, an individual assessment of the PFM was conducted prior to training to teach all women how to perform a proper PFM contraction. Dumoulin et al. (69) also offered women in the group arm the possibility to have an individual supervised session to verify that they were doing their contractions properly.

Dumoulin et al. (69) reported no significant differences between the two treatment arms for UI–specific symptoms and QoL outcomes (ICIQ-UI and ICIQ-LUTS QoL) at one year. Figueiredo et al. (70) found a non-significant difference between group and individual PFMT using the KHQ.

For leakage episodes, Dumoulin et al. (69) showed an average percentage reduction in UI episodes at one year of 70% in individual compared with 74% in group-based PFMT intervention. The differ-

ence between groups fell below the noninferiority margin of 10%, supporting noninferiority of group-based PFMT.

- **Comparison 3. Exercise programme: direct versus indirect exercises**

This comparison encompassed six subgroups evaluating direct versus indirect training. In "direct" PFMT, women specifically performed voluntary contractions of the PFMs, while in the "indirect" PFMT, women focused on other muscle groups to facilitate or stimulate PFM contractions. Of note, these comparisons are often affected by differences in the amount of contact time with health professionals or result from a small sample size, which makes difficult detection of clinically significant differences.

Subgroup 3.1: PFMT versus sham/imitation

No new studies were found comparing PFMT to sham or imitation PFMT treatments (e.g., crossing the ankles and pulling the legs apart).

Subgroup 3.2: PFMT versus the 'Paula method'

No further evidence was available.

Subgroup 3.3: PFMT versus the 'Sapsford' approach

One trial (71) examined the efficacy of PFMT compared to abdominal training using the Sapsford approach and found a non-significant difference between groups. However, the two treatment arms differed in the number of supervised sessions and no sample size calculation was provided. Hence caution is required when interpreting the data.

Subgroup 3.4: PFMT versus Pilates

No new RCTs were found evaluating Pilates treatments in comparison to PFMT.

Subgroup 3.5: PFMT versus hip rotator training

No further evidence was available.

Subgroup 3.6: PFMT versus hypopressive training

Our search revealed two new RCTs comparing PFMT to hypopressive training (72, 73). In the study by Jose-Vaz *et al.* (72), women with SUI received either PFMT or hypopressive training. The study by Navarro-Brazález *et al.* (73) included women with various pelvic floor disorders including SUI and MUI, and investigated three treatment arms (PFMT, PFMT plus hypopressive training and hypopresive training alone).

For improvement, Jose-Vaz *et al.* (72) showed higher changes in the PFMT group compared to the hypopressive group, while Navarro-Brazález *et al.* found non-significant differences in the Pelvic Floor Distress Inventory (PFDI) and Urogenital Distress Inventory (UDI) scores between the two groups (73). For leakage episodes, Jose-Vaz *et al.* (72) reported that women who received PFMT had significantly fewer UI episodes than women in the hypopresive training group.

- **Comparison 4. Exercise programme: generic versus individualized exercises**

No further evidence.

- **Comparison 5. Exercise programme: submaximal versus near maximal contractions**

No further evidence.

- **Comparison 6. Exercise programme: daily versus three times per week**

No further evidence.

- **Comparison 7. Exercise programme: addition of upright exercise position**

No further evidence.

- **Comparison 8. Exercise programme: addition of strength training to motor learning**

One trial compared the effects of PFMT to PFMT combined with PFM reflex activation during functional activities, such as running and jumping, in women with SUI and MUI (74). This study revealed no benefits of adding a motor learning programme to PFMT. No significant differences were found between the two groups regarding changes in ICIQ-UI scores and pad test results.

- **Comparison 9. Exercise programme: addition of abdominal or hip muscle exercises.**

This comparison encompassed two subgroups evaluating the addition of either abdominal muscle (subgroup 9.1) or hip muscle (subgroup 9.2) training to PFMT.

Subgroup 9.1: PFMT versus PFMT plus abdominal muscle exercises

Three new RCTs evaluated the efficacy of adding abdominal muscle exercises to PFMT in women with SUI (68, 75, 76). In two of the trials, the same amount of health-professional supervision was given to each group (68, 75) whereas in the other trial, limited information was available on the similarity in treatment dosage (76).

For improvement in the study by de Souza Abreu *et al.* (75), a larger reduction in the Incontinence Severity Index (ISI) scores was found in the combined group compared to the PFMT group alone, while a no significant difference was observed in the Patient Global Improvement Indices (PGI-I). The study by Kucukkaya *et al.* (76) showed a superior effect in the Urinary Distress Inventory, Short Form, (UDI-6) scores for the group combining PFMT with abdominal exercises compared to PFMT alone. In contrast, the findings of Mateus-Vasconcelos *et al.* (68) favoured PFMT alone over PFMT combined with abdominal exercises when considering differences in the ICIQ-UI scores.

For leakage episodes, the study by de Souza Abreu *et al.* (75) showed a higher reduction in UI episodes in the combined group compared to the PFMT group.

In the study by Kucukkaya *et al.* (76), fewer positive cough tests were found in the group combining PFMT with transverse abdominal exercises at four weeks of treatment. All participants in both groups were considered continent at the cough test at the three-month follow-up.

Subgroup 9.2: PFMT versus PFMT plus hip muscle exercises

The study by Marques *et al.* (77) was considered in the current update even though it was included as an abstract in the previous edition (89). The complete manuscript provided additional incontinence outcomes and included a larger sample. A non-significant group x time interaction was found between the PFMT group and the PFMT plus hip exercise group for the ICIQ-UI and KHQ scores as well as for the frequency of urinary leakage (3-day bladder diary).

- **Comparison 10. Exercise programme: addition of an intravaginal resistance device**

The study by Orhan *et al.* (78) investigated the efficacy of PFMT compared to PFMT combined with resistance training (i.e., using a tampon that was pulled out) in women with stress-predominant incontinence. No-significant differences between groups were found for self-reported improvement, Incontinence Severity Index (ISI) score, frequency of incontinence episodes and pad test results.

- **Comparison 11. Exercise programme: addition of adherence strategy**

Two trials investigated the addition of adherence strategies to PFMT training (83, 84). The two trials employed the same PFMT protocols across the study arms. In the study by Araujo *et al.* (83), a mobile application with reminders, which was not connected to any intra-vaginal probe, was used in conjunction with PFMT compared to PFMT alone in women with predominant SUI. The study by Sacomori et al. (84) employed adherence and self-efficacy strategies using discussions, videos and reminders in women with SUI, UUI or MUI.

In the two studies, significant improvements were found in all groups for ICIQ-UI scores, but no-significant differences between groups were also observed (83, 84). Higher adherence was observed in the group using the application combined with PFMT compared to PFMT alone in Araujo's study (83), whereas Sacomori *et al.* (84) reported a no significant difference between the groups.

- **Comparison 12 Teaching programme: addition of biofeedback (BF)**

Nine RCTs (five published manuscripts (47, 79-82) and four abstracts (85-88)) examined the efficacy of adding biofeedback to PFMT. Of these, three trials are not further described because no between-group statistical comparisons were presented (81, 85, 88). Comparison groups were similar with respect to the amount of supervision and intensity of training; they differed only in the addition of biofeedback (47, 80, 82, 86). Similarity treatment dosage was difficult to assess in the abstract by Ngai *et al*. (87) and treatments appeared to differ in the study by Fitz *et al.* (79). Four RCTs investigated **clinic-based** biofeedback using pressure perineometry (79, 80), ultrasound imaging (87) and electromyography (47, 80). Three trials included women with SUI or stress-predominant UI (47, 79, 80), while the abstract by Ngai *et al.* (87) did not specify the type of UI. Duration of treatment ranged from eight weeks (47, 80) to three months (79). Only one RCT evaluated **home-based** biofeedback using a Kegel-Q device (86) in women with SUI. The non-inferiority trial by Hagen *et al.* (82) investigated the addition of **both home-based and clinic-based electromyography biofeedback** compared to PFMT alone in 600 women with MUI and SUI.

No data were provided assessing self-reported cure. For improvement, three trials reported a non-significant benefit of adding clinic-based biofeedback, which was assessed using the ICIQ-UI (47) and Urogenital Distress Inventory (UDI) (87). With regard to home-based biofeedback, the abstract by Lee *et al.* (86) reported greater improvements in the biofeedback group for the Sandvik frequency and severity index. In the study by Hagen *et al.* (82) no-significant differences between the two groups were found for the ICIQ-UI and PGII.

For leakage episodes, two studies found no significant differences between the clinic-based biofeedback group and PFMT group (79, 87).

Pad and paper towel tests: Fitz *et al.* (79) reported a non-significant benefit of adding clinic-based biofeedback to PFMT based on pad-test measurements. Conversely, Özlü *et al*. (80) showed superior effects in pad test results in the two groups using biofeedback (electromyography or pressure biofeedback device) compared to PFMT alone. As for home-based biofeedback, Lee *et al.* (86) showed superior effects in pad test results when adding biofeedback, whereas a no significant difference was reported when categorising the pad test results as cured versus uncured.

Summary

Evidence synthesis

PFMT with regular (e.g., weekly) supervision is better than PFMT with little or no supervision. **(Level of evidence: 1)**

Supervised group PFMT (including verification of adequate PFM contraction) appears to provide similar benefits to individual PFMT. **(Level of evidence: 1)**

'Indirect' methods of PFMT (e.g., the 'Paula method', 'Sapsford' approach and hypopressive training) are no better than direct PFMT for treating UI. **(Level of evidence: 2)**

The combination of PFMT with other treatment modalities, such as motor learning, intra-vaginal resistance devices and adherence strategies, does not appear to provide additional benefits. **(Level of evidence: 2)**

There is conflicting evidence as to whether the combination of PFMT with abdominal or hip muscle training could increase its efficacy. **(Level of evidence: 4)**

The benefit of adding biofeedback to PFMT for improvement of UI symptoms and pad test results, in either home or clinic setting remains unclear. (**Level of evidence: 2**)

There was no statistically significant difference between groups undergoing in-clinic and home-based EMG biofeedback-assisted PFMT or non-biofeedback PFMT for SUI self-reported cure and improvement. **(Level of evidence: 1)**

Recommendations

Clinicians should offer and provide the most intensive health professional-led PFMT programme possible within service constraints. **(Grade of recommendation: A)**

Supervised individual or group PFMT with confirmation of adequate PFM contraction can be considered in postmenopausal women with SUI and MUI. **(Grade of recommendation: B New)**

Direct PFMT as opposed to indirect PFMT can be recommended **(Grade of recommendation: B New)**

There is no clear benefit for adding other modalities (i.e., motor learning, abdominal or hip muscle training, intra-vaginal resistance devices and adherence strategies) to PFMT, and therefore they cannot be routinely recommended. **(Grade of recommendation: B)**

There is no clear benefit for adding clinic- **(Grade of recommendation: B changed)** or home-based biofeedback (**Grade of recommendation: B) or both (Grade of recommendation: A New)** to a PFMT programme. However, biofeedback may be considered for sub-groups of women presenting an important PFM weakness or atrophy, or reduced proprioception.

No robust recommendation can be made about the type or specification of training (i.e., generic versus individualised exercises, submaximal versus near maximal contractions, daily versus three times per week, addition of upright exercise position).

Implications for research

Comparisons of PFMT approaches are, *de facto*, comparisons of two active treatments. It is therefore difficult to determine which approach is best unless (a) the differences in outcomes are large or (b) the RCTs are designed with sufficient sample sizes to detect small to moderate differences. Finding the best PFMT approach remains among the highest research priorities. Future studies should be sufficiently powered to detect clinically important differences or assess non-inferiority when a less costly intervention is compared to a gold standard.

Although, most new comparisons presently include few trials, they integrate new interventions such as posture rehabilitation, stabilisation exercises and general body exercises. These new comparisons will be added to our next chapter update.

Table 9. Summary of data on different PFMT programmes comparisons

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/Results	Follow-up	Notes
Araujo (2019) (83)	PFMT (16) vs. PFMT+App (17)	33	Women with predominant SUI	PFMT: Written PFM exercises. 8s hold/8s rest followed by 3 phasic PFM contractions, repeated 8x, for a total of 32 contractions. Performed twice a day (sitting, lying down or standing) for 3 months. PFMT+App: Same as PFMT (no vaginal probe) with the visual aids from the app. The app used an alarm reminder. A tool to improve adherence is presented in the manuscript.	Sign. changes in ICIQ-UI and QUID in both groups from baseline to 1,2,3 months of tx but no sign. difference btw groups. Adherence: Sign. difference in adherence btw the two groups at 2 months and 3 months in favour of the PFMT-App group.	1, 2 and 3 months of tx.	Randomisation and concealment adequate Assessor blinded Dropouts: PFMT 7/16 PFMT+App 5/17 Adverse events: not documented Dose: same PFMT programme Sample size calculation based on adherence.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/Results	Follow-up	Notes
Bertotto (2017) (47)	PFMT (16) vs. PFMT + BF (17) vs. Control (no tx) (16)	49	Postmenopausal women with SUI	PFMT: Two 20-min sessions per week for a total of 8 sessions. PFMT in various positions combined with guided imagery. Home exercises performed twice a day on non-study training days. PFMT+BF: Same PFMT protocol but with BF (in-clinic EMG-BF). Same home exercises without BF. Control: No tx	ICIQ-UI QoL: Sign. improvement from baseline to post-tx in the intervention groups (both p<.0001), but not for the control group. Sign. difference btw the control group and the two intervention groups No sign. difference btw PFMT+BF and PFMT in post-tx.	Post-tx	Randomisation and concealment adequate Assessor blinded Dropouts: PFMT 1/16 PFMT+BF 1/17 Control 2/16 Adverse events: not documented Dose: same PFMT protocol in the intervention groups No sample size calculation provided
Chiu (2018) (71)	PFMT (24) vs. Abdo (23)	47	Women ≥ age 45 y with at least one episode of SUI or MUI per month	Before the exercise sessions started, oral instructions about the human anatomy of PFMs, physiology regarding the mechanism of continence and bladder hygiene were given to both groups. Abdo: Abdominal muscle exercises for 6 training sessions over 12 weeks – diaphragmatic breathing, PFM activation, tonic activation, muscle strengthening, functional expiratory patterns (e.g., blowing nose, coughing, etc.), impact activity. **also includes PFM exercises** PFMT: 2 exercise sessions – session 1 included basic PFM exercises combined with diaphragmatic breathing. Session 2 included the advanced application of PFM contractions during daily activities. The participants were asked to perform at least 10 repetitions of PFM contractions for 5-10 s, 3-5 times per day (30-50 contractions) for 12 weeks.	The ISI, 1-hour pad test, and 3-day voiding diary improved sign. after the interventions within each group (p<.017); no sign. difference was found btw the groups (all p>.05).	Post-tx	Randomisation adequate Concealment not reported Assessor not blinded Dropouts: PFMT 4/24 Abdo 3/23 Adverse events: No participant had any adverse effects during the study. Dose: not the same - Abdo had 6 sessions, PFMT only had 2 No sample size calculation provided

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/Results	Follow-up	Notes
de Souza Abreu (2017) (75)	PFMT (20) vs. PFMT + Lumbopelvic (20)	40	Women with SUI (confirmed by cough-provocation test)	PFMT: Individual sessions of approx. 30 min each with a physiotherapist, 2x per week for 5 weeks (total of 10 sessions) + home exercises: same protocol of exercises daily, during the 5 weeks. PFMT+Lumbopelvic: Individual sessions of approx. 30 min twice a week for 5 weeks (total of 10 sessions). Same PFMT exercises as PFMT group + lumbopelvic stabilisation exercises (4 stages according to degree of complexity). Home exercises: same protocol of exercises, performed daily over the 5 weeks.	Sign. reduction in ISI from baseline to post-tx in both groups, but no sign. difference btw groups in post-tx (p=0.50). At 3-month follow up, PFMT+Lumbopelvic group presented sign. lower values compared to PFMT group (p<.006) Sign. reduction of both diurnal and nocturnal UI episodes (bladder diary) from baseline to post-tx in both groups. No sign. difference btw groups at post-tx (p>0.49). At 3-month follow up, PFMT+lumbopelvic group presented a sign. lower frequency of UI episodes compared to PFMT group (p<.001). Impression of improvement (PGI-I): nonsign. difference was found btw the two groups at post-tx (p=.18). At 3-month follow up, PFMT-lumbopelvic was superior to PFMT (p<0.001).	Post-tx and 3-month follow up	Randomisation and concealment adequate Assessor blinded Dropouts: PFMT 3/20 PFMT+Lumbopelvic 4/20 Adverse events: none reported Dose: same PFMT protocol
Dumoulin (2020) (69)	Individual PFMT (184) vs. Group PFMT (178) Non inferiority RCT	362	Women ≥60 years old with SUI or MUI ≥ 3 times/week, for ≥ 3 months	All women were taught to properly perform a PFM contraction using vaginal palpation. Individual PFMT: Weekly 1-h sessions supervised by a physiotherapist for 12 weeks, including 15 min of education (lifestyle intervention and PFM precontraction), 45 min of PFM exercises assisted by BF (strength, rapidity, endurance and coordination) and lower extremity strength and functional exercises (dance) btw PFM exercises. Home PFM exercises 5x per week. Group PFMT: Same as individual PFMT but conducted in a group of max. 8 patients. Women who reported difficulty with their exercises were offered short individual sessions with their physiotherapist to confirm correct PFM contractions. Home PFM exercises 5x per week.	Sign. reduction in leakage episode frequency (7-day bladder diary) in both groups from baseline to post-tx and 1-year follow up (p<.001). At 1 year (primary time point), the median percentage reduction UI episodes in individual PFMT was 70% vs. 74% in the group-based intervention (within the non-inferiority margin suggesting non meaningful difference btw groups). Both groups showed sign. improvement for all outcomes (micturition, nocturia, pad test 24-h, ICIQ-UI) from baseline to 1-y follow up, but no sign. differences were found btw groups.	Post-tx and 1-year follow up.	Randomisation and concealment adequate Assessor blinded Dropouts: Individual 19/184 Group 24/178 Adverse events: Individual PFMT: 6 reported vaginal spotting and 21 reported vaginal discomfort while using intravaginal BF Group PFMT: 5 reported vaginal discomfort Dose: Same PFMT protocol

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/Results	Follow-up	Notes
Figueiredo (2020) (70)	Individual PFMT (30) vs. Individual PFMT to group training (IPGT) (30) vs. Group training only (30)	90	Women with SUI	All groups had a 30-min session once per week for 12 weeks. All groups were educated about PFM and proper contractions. The same exercise protocol as they performed with the physiotherapist, was performed at home, every day, over the 12 weeks of supervised training. Individual PFMT: 12 individual sessions with a physiotherapist (with vaginal palpation for the first 4 sessions). IPGT: 4 individual sessions (with vaginal palpation for first 4 sessions) followed by 8 group sessions. Group training: 12 group sessions	The severity measured with the KHQ improved in all 3 groups (p<.001) from baseline to post-tx. No sign. difference btw groups (p=.56). The benefits of the intervention were maintained 3 and 6 months after the end of the supervised training (p<.001) (non-sign. difference btw groups). The IPGT group had a sign. Improvement. in PFM function when compared to the other groups post-tx (P < .001). Bladder diary assessed, but statistics not provided for within- or btw-group comparisons.	Post-tx, 3 and 6-month follow up	Randomisation and concealment adequate Assessor not blinded Dropouts: Individual 12/30 IPGT 6/30 Group 12/30 (all dropouts were replaced) Adverse events: none mentioned Dose: same
Fitz (2017) (79)	PFMT (37) vs. PFMT +BF (35)	72	Women with predominant SUI symptoms ≥2g leakage (pad test) and with capability to contract the PFM properly	PFMT: 24 outpatient sessions of PFM exercises without BF (40-min sessions with 10 repetitions each, 2x per week). Exercises were performed in the supine position (1st month), sitting (2nd month) and standing (3rd month) with a physiotherapist + home PFM exercises for 3 months. Home programme: 3 sets of 10 repetitions daily for 3 months. PFMT +BF: 24 outpatient/in clinic sessions of PFMT using BF (40-min sessions with 10 repetitions each, twice a week). Exercises were performed in the supine position with BF. Home exercise program: 3 sets of 10 repetitions daily for 3 months. The positions in which the exercises were performed were progressive. The protocol was personalised and based on initial evaluation of PERFECT. Each patient was evaluated for adjustment and progression on a monthly basis	Sign. changes in the number of leakage episodes (bladder diary) from baseline to post-tx and follow ups. No sign. difference btw groups. Sign. changes in severity of SUI (20-min pad test) (g) from baseline to post-tx and follow ups. No sign. difference btw groups. Cure of SUI (<2g on 20-min pad test): Sign. difference btw groups at post-tx (p=0.018), but not at 6-month follow up (p=0.358) Subjective cure: No sign. difference btw groups at post-tx or 6-month follow up.	Post-tx as well as 3- and 6-month follow up	Randomisation and concealment adequate Assessor not blinded Dropouts: PFMT+BF 10/35 PFMT 13/37 Adverse events: none documented Dose: Not exactly comparable. Same home programme and exercises in outpatient sessions, but BF group did exercises in supine position only and PFMT group progressed from supine -> sitting -> standing (during outpatient sessions). + Each patient had their own personalised programme based on the results of the PERFECT score.

Fitz (2019) (67) This article was included in the previous ICI as abstract, but the article revealed new findings	PFMTsup (34) vs. PFMT (35)	69	Women with a predominance of SUI and ≥2g of leakage in pad test who are able to properly contract their PFMs.	PFMTsup: 2 supervised sessions per week for a total of 24 sessions. 3 sets of 30 contractions followed by 3 fast-twitch contractions PFMT: Same exercise protocol, monthly appointment for exercise adjustment, including one set of PFM exercises under supervision (total of 3).	Objective cure based on the 20-min pad test (<2g of leakage): Cure was superior in the supervised group (62%, n=21/34) compared to the unsupervised group (28%, n=10/35) (p=.011) Sign. improvement in both groups for the 20-min pad test from baseline to post-tx. Higher improvements were found in the supervised group compared to the unsupervised group (p=.031). Sign. improvement in both groups in the mean number of leakages (7-day bladder diary) from baseline to post-tx. No sign. difference btw groups in post-tx (p=0.703) Compliance rate and frequency of home exercises: Sign. difference btw groups in 1st month (p=0.015), but no sign. difference btw groups in 2nd and 3rd months (p≥0.067). Satisfaction: No sign. difference btw groups.	Post-tx	Randomisation and concealment adequate Assessor not blinded Dropouts: PFMTsup 6/34 PFMT 7/35 Adverse events: Not documented Dose: same home PFMT programme

Hagen (2020) (82)	PFMT (300) vs. PFMT+BF (300)	600	Women with SUI or MUI	Both groups had 6 appointments with a continence therapist over 16 weeks PFMT: Women received supervised PFMT (60 min for the first session, then 30 min for subsequent sessions), and a home PFMT programme (3 sets of exercises daily, recorded in an exercise diary). Behaviour change techniques, bladder and bowel management information and lifestyle advice were provided as necessary. PFMT+BF: supervised PFMT as in the PFMT group and a home PFMT program. The tx incorporated EMG-BF during clinic appointments and at home.	ICIQ-UI (at 6, 12 and 24 months post-tx): No sign. difference btw groups at 6 months (mean difference 0.39, 95%CI -0.33 to 1.12), 12 months (0.57, 95%CI -0.17 to 1.31) or 24 months (-0.09, 95%CI -0.92 to 0.75). No sign. difference btw groups in cure rate (based on 2 questions of the ICIQ-UI), improvement (reduction >3 points on the ICIQ-UI) or PGII at 24-month post-tx. Exercise adherence: Proportion exercising at least once per week was 52% in the PFMT+BF group and 46.3% in the PFMT group. PFM strength: No sign. difference btw groups at 6 months.	6, 12, and 24 months post-tx	Randomisation and concealment adequate Assessor blinded (self-reported measure non-blinded) Dropouts (at 24-months post-tx): PFMT 62/300 PFMT+BF 70/300 Adverse events: Of the 48 participants who had non-serious adverse events, only 23 were possibly related to tx: PFMT 2 PFMT+BF 21 Dose: same tx regimen

Jose-Vaz (2020) (72)	PFMT (45) vs. Hypopressive (45)	90	Women with SUI	Both groups underwent 24 sessions over 12 weeks Hypopressive: Abdominal hypopressive techniques were split into 3 phases of 4 weeks each– Phase 1: 3x8 reps in different postures (ex: lying supine with legs bent, cat position etc.) Phase 2: 3x10 reps of various exercises – lying with alternating leg flexion, etc. Phase 3: 3x12 reps in different postures ex: kneeling, etc. PFMT: 3x8-12 PFM contractions per session. Also 3 phases of exercises: all phases included 3 exercises; 2 lying, one sitting - Phase 1: 3x8 reps lasting 6 sec + 3 fast contractions in a row Phase 2: 3x10 reps lasting 6 sec + 3 extra contractions Phase 3: 3x12 reps lasting 6 sec + 4 extra contractions	Both groups reduced their urinary leakage episodes (7-day bladder diary) from baseline to post-tx. PFMT group showed higher changes compared to hypopressive group (p<.001, mean diff. -1.27, IC95% −1.92 to −0.62). ICIQ-UI sign. improved in both groups from baseline to post-tx. The PFMT group showed greater changes compared to the hypopressive group (p<.001, mean diff. -4.7, IC95% −6.90 to −2.50). Manometry also presented improvement after tx for both groups with a mean difference of 11 (95% CI 6.33-15.67) in favour of PFMT.	Post-tx	Randomisation and concealment adequate Assessor blinded Dropouts: PFMT 8/45 Hypopressive 9/45 Adverse events: none mentioned Dose: same for both groups
Kucukkaya (2020) (76)	PFMT (32) vs. PFMT+transverse (32)	64	Women with SUI	PFMT: Maximal PFM contractions performed sitting or in the supine position (3 sets of 10 contractions, 3x/day) according to Sut et al. PFMT + transverse: Addition of abdominal training exercises according to Jung et al. For both groups: Exercises were performed at home individually for 8 weeks, with prior teaching at clinic, and distribution of a brochure explaining the exercises and healthy lifestyle behaviours. Diaries were completed every day (3 times a day). Weekly follow-up phone calls were made to participants to maintain motivation.	The UDI-6 score sign. improved in both groups from baseline to post-tx (p<.001). The changes in the PMFT+transverse group were sign. higher than the PFMT group from baseline to 4 weeks (p<.001) and from baseline to post-tx (p=.047) The percentage of negative cough stress tests at week 4 was sign. higher for PFMT+transverse than PFMT(p<.001). At post-tx, the stress test was negative in all participants in both groups.	During tx (on week 4 of the programme) and post-tx (after 8 weeks of tx)	Randomisation adequate Concealment not reported Blinding of assessor not reported No dropouts Adverse events: not documented Dose: Limited information to ascertain that the PFMT protocol is the same in both groups given that the references are different.

Mateus-Vasconcelos (2018) (68)	PFMTsup (34) vs. PFMT+ posterior pelvic tilt (34) vs. EStim (33) vs. PFMT w/o sup (33)	134	Women with PFM function graded at 0 or 1 using the Modified Oxford Scale (MOS)	Duration for all groups: 8 weeks. Everyone was treated by the same physical therapist. PFMTsup: Supervised PFMT with palpation. Physical therapist performed by digital vaginal palpation to provide proprioceptive stimulation and to examine the PFM contractions (3 sets of 10 contractions of 6 s each and a rest period of 6 s btw each contraction). At the end of each set, 6 quick contractions were performed. No training at home. Tx once per week. PFMT + posterior pelvic tilt: Protocol same as PFMTsup with a posterior pelvic tilt movement during the PFM contractions. No training at home. Tx once per week. EStim: Intravaginal EStim in the supine position with lower limbs extended. Current was a symmetrical biphasic, rectangular pulse. Stimulation parameters: frequency 50 Hz, pulse time 200 ms, contraction time 5 s, relaxation time 10 s and current intensity defined by the motor threshold and adjusted according to occurrence of accommodation. Total ES time: 20 min. Women were instructed not to voluntarily contract their PFM while they were receiving the ES. No training at home. Tx once per week. PFMT w/o sup: PFMT without supervision. Instructed once to do daily PFM contractions at home (3 sets of 10 contractions held for 6 s with 6 s rest btw contractions) followed by 6 quick contractions. No supervision other than instructions on day 1.	ICIQ-UI: Sign. improvement in all groups from baseline to post-tx: PFMTsup (14.55±4.94 to5.79±5.58, mean difference 8.76, 95%CI 5.80 to 11.71; p<.0001) PFMT+ posterior pelvic tilt (14.24±5.35 to 8.85±6.93, mean difference 5.39, 95%CI 2.43 to 8.35; p=.0004) ES (14.12±5.59, to 9.42±7.09, mean difference 4.70 95%CI: 1.77 to 7.65; p=.002) PFMT w/o sup (14.15±6.25 to 10.52±7.37, mean difference 3.64, 95%CI 0.68 to 6.59; p=.016) As for btw-group comparisons, sign. differences were found only btw the following groups: PFMTsup > EStim (p=0.02) PFMTsup > PFMT+ posterior pelvic tilt (p=0.04) PFMTsup > PFMTw/o sup (p=0.01)	Post-tx (after the 8 weeks of tx)	Randomisation and concealment adequate Non-blinded for self-reported outcomes Dropouts: PFMTsup 1/34 PFMT+ posterior pelvic tilt 1/34 ES 0/33 PFMT w/o sup 0/33 Adverse events: None reported

	Studies included in previous ICI reviews	New studies identified in this update (7th ICI)
PFMT vs VC (section III)	14	0
PFMT vs EStim	10	1
PFMT vs BT	4	2
PFMT vs drug therapy	9	1
PFMT vs surgery	2	1
PFMT vs continence pessary	1	0

Abbreviations: PFMT: pelvic floor muscle training; VC: vaginal cone; EStim: electrical stimulation; BT: bladder training

2.3.3. Is PFMT better than other treatments?

Trials comparing PFMT to another stand-alone intervention such as vaginal cones (VC), bladder training (BT), drug therapy, surgery, and continence pessaries are included. As shown in Table 10, previous ICI reviews included a total of 40 RCTs. Our search revealed four new studies comparing PFMT to EStim (68), BT (81, 90), drug therapy (81), and surgery (91). Characteristics of these studies are presented in Table 11 and Table 9 (some studies had more than two arms and assessed other treatment comparisons).

Quality of data

Randomisation and adequate allocation concealment were reported for three RCTs (68, 81, 90). In the study by Bergman *et al.* (91), randomisation was adequate but group allocation was not concealed. The four studies employed self-reported questionnaires and the participants were not blinded to group assignment (68, 81, 90, 91). Azuri *et al.*'s study (90), used a bladder diary and indicated that the assessor was blinded to treatment allocation. Sample sizes ranged from 70 to 164 women and involved 33 to 50 participants per study arm. Very low dropout rates were reported in three studies: Bergman *et al.* (91) had no dropouts, Mateus-Vasconcelos *et al.* (68) reported only one dropout out of 134 participants, and Rizvi *et al.* (81) had three dropouts in the BT group out of 150 participants. Azuri *et al.* (90) reported higher dropout rates, which could be explained by the four-year follow up period. The dropout rate was the highest in the group receiving Tolterodine (42%; n=18/42), but lower in the BT, PFMT and combined treatment groups (range 14%; n=6/41 – 27%; n=11/40).

Results

i. **PFMT versus VC:** *No further evidence available.*
ii. **PFMT versus EStim:** *In the study by Mateus-Vasconcelos et al. (68), women with weak PFM (grade of 0 and 1 on the modified Oxford scale) were randomised into four groups: 1) Supervised PFMT (with palpation); 2) PFMT without supervision (verbal instruction); 3) PFMT with supervision and posterior pelvic tilt movements; and 4) Intra-vaginal EStim. Significant improvements in ICIQ-IU were found in all groups from baseline to eight weeks post-treatment. However, EStim was found to be less effective than supervised PFMT.* **Note:** *women receiving EStim were instructed not to voluntarily contract their PFM.*
iii. **PFMT versus BT:** *The study by Azuri et al. (90) is the four-year follow-up of Kafri et al. (92), which examined the effects of PFMT alone and BT alone using a four-arm design. Findings from the follow-up study agree with the original study. Significant improvements were observed in all groups on all outcomes (i.e., cure rate, number of voids/24-hour, incontinence episodes per week and I-QOL score), but no significant differences between groups were found. In the three-arm study by Rizvi et al. (81), women with an overactive bladder were randomised to BT, PFMT or PFMT plus BT. Significant improvements in the UDI-6 and the Incontinence Impact Questionnaire-7 (IIQ-7) were found in all groups. However, between-group comparisons were not reported. Only the BT group showed a significant decrease in urinary frequency (collected with a bladder diary) from baseline to post-treatment, which was not observed in the other groups.*
iv. **PFMT versus drug therapy:** *Our updated search included a single RCT (90) comparing the efficacy of PFMT to tolterodine using a four-arm design in women with UUI. This study is the four-year follow-up of Kafri et al. (92), included in the previous ICI edition. Findings of the newly added study agree with the original study as significant improvements were observed in all groups on all outcomes (i.e., cure rates, number of voids/24-hour and incontinence episodes per week), but no significant differences were found between groups.*
v. **PFMT versus surgery:** *One trial investigated the effects of surgery-perineorrhaphy with distal posterior colporrhaphy compared to PFMT in women who had suffered a second degree perineal injury and various pelvic floor disorders (91)lored","hb. type":"feature"}}. Findings showed superior effects in the surgery group compared to the PFMT group for patient perceived improvement (PGI-I) as well as for the Pelvic Floor Disability Index (PFDI) and Pelvic Floor Impact Questionnaire-7 (PFIQ-7) total scores and subscales. It should however be highlighted that PFMT included only one to three visits (93).*
vi. **PFMT versus continence pessary:** *No further evidence available*

Summary

VC appear to have similar effects or are inferior to PFMT. **(Level of evidence: 1)** However, VC treatment may be inappropriate in certain cases as some women are unable to use them and because of the potential side effects as reported in four RCTs (i.e., pain, vaginitis, bleeding and a sense of unpleasantness or inconvenience)**.**

EStim had inferior effects for cure rate and improvement compared to PFMT in women with UI according to previous pooled data, as well as to the newly added trial in women with weak PFMs. **(Level of evidence: 1)**

PFMT is a superior treatment to BT for women with SUI **(Level of evidence: 2).** There is no clear evidence supporting a difference in efficacy between PFMT and BT in women with UUI and MUI. **(Level of evidence: 2)**

PFMT is more beneficial than drug therapy for UI. **(Level of evidence: 2)**

Surgery appears to yield superior effects in patient's perceived improvements, incontinence severity, and in other pelvic floor disorder symptoms. **(Level of evidence: 2)**

Data suggest some benefits of PFMT over a continence pessary alone. **(Level of evidence: 2)**

Recommendations

PFMT and VC both appear to be effective as conservative therapies for SUI, although PFMT can be favored because a subset of women is unable to use VC and there are side effects associated with their use. **(Grade of recommendation: B)**

VC with supervised training sessions by a trained health professional can be offered to women with SUI who can and are prepared to use them. **(Grade of recommendation: B)**

PFMT should be preferentially offered over EStim as first line conservative therapy for women with SUI, UUI and MUI. **(Grade of recommendation: A New)**

PFMT can be preferentially offered over BT alone, as a first line conservative therapy for women with SUI, UUI and MUI. **(Grade of Recommendation: B)**

Oxybutynin cannot be recommended over PFMT as a first line therapy in women with UUI and MUI. **(Grade of recommendation: B)**

PFMT can be offered over pharmacotherapy because drug therapy results in more adverse effects and a higher dropout rate. **(Grade of recommendation: B)**

PFMT can be offered as the first line therapy prior to surgical intervention because it is less invasive. Surgery is more effective than PFMT, but the potential benefits should be weighed against the potential adverse events and cost. **(Grade of recommendation: B)**

PFMT and continence pessaries showed significant benefits for women with UI and therefore can be recommended. **(Grade of recommendation: B)**

Table 11. Summary of data on PFMT vs other treatments

Author, year	Comparator	N	Study Population	Modalitity details or parameters	Outcomes/Results	Follow-up	Notes
Azuri (2017) (90) Included in the ICI edition as an abstract in 2013.	DT (42) vs. BT (41) vs. PFMT (40) vs. BT+PFMT+advice (41)	164	Women aged 45-75 who experienced at least 3 UUI episodes per week	DT: Tolterodine SR 4 mg BT, PFMT, BT+PFMT+advice: 4 sessions once every 3 weeks for 3 months BT: education, increasing intervals between voids and positive reinforcement PFMT: contractions in different positions (3 sets of 8–12 slow maximal contractions sustained for 6–8 s) at each session. Daily home-based programme Advice: behavioural advice (bowel education, fluid intake, posture, etc.)	All outcome measures (number of voids/24h, incontinence episodes/week and I-QOL score) sign. improved from baseline to follow up in the four groups (p<.05) No sign. differences were found btw the 4 groups in the number of voids/24h (p=.635), incontinence episodes/week (p=.206) and I-QOL score (p=.354) Cure rates were similar at follow up in the 4 groups (p=.616)	4-year follow-up	Randomisation and concealment adequate Assessor blinded Adverse events: not documented Dropouts: DT 18/42 BT 6/41 PFMT 11/40 BT+PFMT+advice 9/41 Low adherence to the tx and contamination: At follow up, only 14 patients (11.6%) had used DT (DT 7, BT 6, PFMT 0 and BT+PFMT+advice 1) 13 women (10.8%) had practiced PFMT (DT 4, BT 3, PFMT 3, and BT+PFMT+advice 4)

Author, year	Comparator	N	Study Population	Modalitity details or parameters	Outcomes/Results	Follow-up	Notes
Bergman, Westergren Söderberg (2020) (91)	Sx (35) vs. PFMT (35)	70	Primiparous or multiparous women with symptoms related to a poorly healed second-degree perineal injury	Sx: perineorrhaphy w/ distal posterior colporrhaphy PFMT: Patients received initial eval of PFM strength, then were educated about PFM function and taught how to perform proper PFM contractions – BF or EStim used when needed. They were given a PFM exercise program and scheduled for 1-3 follow-up visits.	PGI-I: Sign. more women reported being very much better or much better in the Sx group 26/35 (71%) vs. the PFMT group 4/35 (11%); p<0.01. Regarding within-group changes, all questionnaire scores (PFDI total score and subscales (POPDI-6, CRADI-8, UDI-6) as well as PFIQ total score and subscales (UIQ-7, CRAIQ-7 and POPIQ-7)) among the patients in the Sx group sign. improved (p<.003), whereas the PFMT group improved only in the POPDI-6 subscale (p=.02). As for the btw-group differences, changes from baseline to follow up were sign. higher in the Sx group than in the PFMT group for the PFDI and PIFQ-7 total scores and subscales (p<.02).	6-month follow-up	Randomisation adequate No concealment No blinding (self-reported questionnaire) No dropouts Adverse events: Sx: 5 women had local wound infections and 2 had a re-operation due to postoperative hematoma or bleeding

Abbreviations: BF: biofeedback; BID: twice a day; BT: bladder training; btw: between; CRADI-8: Colorectal-Anal Distress Inventory-8; CRAIQ-7: Colorectal-Anal Impact Questionnaire-7; DT: drug therapy; EStim: electrical stimulation; eval: evaluation; ICIQ-UI SF: International Consultation on Incontinence Questionnaire Short Form; IEF: Incontinence episode frequency; IIQ-7: Incontinence Impact Questionnaire Short Form 7; I-QOL: Incontinence Quality of Life questionnaire; OAB: overactive bladder; PFDI: Pelvic Floor Distress Inventory; PFIQ: Pelvic Floor Impact Questionnaire; PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; PFMTsup: supervised pelvic floor muscle training; PGI-I: Patient Global Impression of Improvement; POPDI-6: Pelvic Organ Prolapse Distress Inventory-6; POPIQ-7: Pelvic Organ Prolapse Impact Questionnaire-7; sign.: significant(ly); SUI: stress urinary incontinence; Sx: surgery; Tx: treatment; UDI-6: Urogenital Distress Inventory Short Form-6; UIQ-7: Urinary Impact Questionnaire-7; UUI: urge urinary incontinence

2.3.4. Does the addition of PFMT to other treatments add benefit?

In this section, the effects of PFMT combined with another therapy (i.e., VC, BT, drug therapy, surgery, and continence pessaries) are compared to the effects of the other therapy alone to address the additive benefits of PFMT. Previous ICI reviews included a total of 12 RCTs (Table 12). Our search revealed six additional studies investigating the addition of PFMT to BT (90, 94, 95), drug therapy (96) and surgery (97, 98). Details on these studies are presented in Table 13 and in Table 11 as one study also assessed other treatment comparisons.

Table 12. Studies comparing PFMT + another treatment vs this other treatment, which were included in previous ICI reviews and the current update (7th ICI)

	Studies included in previous ICI reviews	New studies identified in this update (7th ICI)
PFMT+VC vs VC	2	0
PFMT+Estim vs EStim	1	0
PFMT+BT vs BT	2	3
PFMT+drug therapy vs drug therapy	5	1
PFMT+surgery vs surgery	1	2
PFMT+continence pessary vs continence pessary	1	0

Abbreviations: PFMT: pelvic floor muscle training; VC: vaginal cone, EStim: electrical stimulation; BT: bladder training

Quality of data

Of the six studies retrieved in our updated search, three described adequate randomisation and concealment (90, 97, 98) while the remaining three reported only randomisation (94-96). In five studies, objective measures were collected by an assessor, blinded to group assignment (90, 94, 96-98). Among these trials, four also employed self-reported questionnaires and the participants were not blinded to group assignment (90, 96-98). The study by Schmidt *et al.* (95), published as a short communication, reported that the assessors were not blinded. Four studies had a large sample size ranging from 103 to 480 and involving 40 to 242 participants per study arm (90, 96-98). The two remaining trials included a total of 70 (18 per arm) (94) and 28 participants (14 per arm) (95). In the two trials investigating BT and EStim, dropout rates were low (6%) (94) or not reported (95). For the surgery trials, Sung *et al.* (97) had a small dropout rate of 3.5%, whereas McLean *et al.* (98) reported larger dropout rates of 18% at post-treatment and 65% at the two-year follow-up. In the two studies assessing drug therapy, Hagovska *et al.* (96) reported a dropout rate of 18%, while Azuri *et al.* (90) reported a dropout rate of 42% in the tolterodine group and 14% to 27% in the BT, PFMT and combined treatment groups at the four-year follow-up.

Results

i. **PFMT plus VC versus VC:** *No new evidence available.*
ii. **PFMT plus EStim versus EStim***: No new evidence available.*
iii. **PFMT plus BT versus BT:** *The study by Azuri et al. (90) is the four-year follow-up of Kafri et al. (92), examining the effects of PFMT plus BT and BT alone using a four-arm design in women with UUI. Findings in the four-year follow-up study agree with the original study. Statistically significant improvements were observed in all groups for all outcomes (i.e., cure rate, number of voids/24-hour and frequency of UI), but no-significant differences were shown between groups. Similar results were found in the study by Firinci et al. (94) in women with UUI. Improvements were observed in all groups for all outcomes (e.g. frequency of voiding, frequency of incontinence episodes and pad test) but no significant differences were found between PFMT plus biofeedback and BT groups. The study by Schmidt et al. (95) in women with SUI and MUI, showed improvements in the frequency of UI in the BT plus PFMT and biofeedback alone groups but between-group statistical differences were not reported.*
iv. **PFMT plus drug therapy versus drug therapy alone***: Hagovska et al. (96) conducted a large study comparing PFMT plus duloxetine to duloxetine alone in women with SUI. Significant differences were found between the two groups for ICIQ-IU, number of pads per day, and frequency of UI. These results were in favour of the group receiving the combined treatment.*
v. **PFMT plus surgery versus surgery:** *Two large multicentre RCTs examined the addition of perioperative PFMT to mid-urethral sling surgery in women with MUI (97) and SUI (98). Sung et al. (97) reported greater improvements in UDI scores in the PFTM plus surgery group compared to the surgery alone group at 12-month follow-up. However, the authors explained that the between-group difference did not reach MCID threshold. They also found greater improvements in the Incontinence Impact Questionnaire-6 (IIQ-6) scores, the frequency of urinary leakage, and the number of pads used in the combined treatment group. In contrast, no statistically significant between group differences were found for the PGII and Overactive Bladder Questionnaire. In the study by McLean et al. (98), mixed findings were also reported. PFMT combined with surgery yielded superior effects compared to surgery alone in terms of cure rates and Female Lower Urinary Tract Symptoms (FLUTS-UI) questionnaire total scores.*
vi. **PFMT plus continence pessary versus continence pessary:** *No further evidence.*

Summary

There is no evidence of any benefit from adding PFMT to VC in women with SUI. **(Level of evidence: 2)**

There is limited evidence of any benefit from adding PFMT to EStim in women with SUI. **(Level of evidence: 2)**

Previous pooled data suggest that it may be beneficial to add PFMT to BT. **(Level of evidence: 2)**

Previous pooled data suggest that PFMT may be more effective to reduce SUI over intravaginal oestrogen alone when treating women with vaginal atrophy. **(Level of evidence: 2)**

Based on previous pooled data and current evidence, the addition of PFMT to drug therapy (i.e., tolterodine and duloxetine) showed superior effects compared to drug therapy alone. **(Level of evidence: 2)**

Some benefits of adding PFMT to mid-urethral sling surgery were found in women with MUI and SUI. There is however uncertainty about the clinical significance of these improvements. **(Level of evidence: 2)**

Evidence suggests that there is some benefit to adding PFMT when using a continence pessary. **(Level of evidence: 2)**

Recommendations

Based on limited evidence, combining PFMT with either VC or EStim could not be recommended routinely as it does not appear to add any benefits. **(Grade of recommendation: C)**

For the treatment of SUI, UUI, or MUI in women, the addition of PFMT to BT provides additional benefits compared to BT alone and therefore could be recommended. **(Grade of recommendation: C)**

When treating women with SUI and vaginal atrophy, combining PFMT and intravaginal oestrogen over oestrogen alone could be considered. **(Grade of recommendation: C)**

For treatment of UUI (tolterodine) and SUI (duloxetine), adding PFMT to drug therapy can be considered. **(Grade of recommendation: B New)**

Adding PFMT to the insertion of a mid-urethral tape can benefit women with MUI and SUI. **(Grade of recommendation: B New)**

When treating stress-predominant incontinence, adding PFMT to a continence pessary can be considered. **(Grade of recommendation: B)**

Table 13. Summary of data on PFMT + another treatment vs this other treatment

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Follow-up	Notes
Firinci, Yildiz (2020) (94)	BT (18) vs. BT + BF (17) vs. BT+EStim (18) vs. BF+BT+EStim (17)	70	Women with idiopathic OAB	BT consisting of 4 stages (1teaching of PFM contraction for urgency suppression; 2-urgency suppression technique (PFM contraction, breathing, relaxation, distraction); 3- timed voiding programme, 4- encouragement to pursue BT. Duration of each stage not specified. BF: 20-min of intravaginal pressure BF (40 cycles of 10 s of contraction followed by 20 s of relaxation) EStim: 20 min of intravaginal EStim at 10 Hz, a 5–10 s work□ rest cycle, and 100 ms pulse width (symmetric biphasic). BF and EStim were performed 3 days per week, for a total of 24 sessions over 8 weeks	The four groups sign. improved from baseline to post-tx regarding the incontinence severity (24-h pad test), frequency of voiding and incontinence episodes (3-day voiding diary) ($p < .05$). As for btw-group differences, changes in incontinence severity (24-h pad test), frequency of voiding and incontinence episodes (3-day voiding diary) were superior in the BT+EStim and BF+BT+EStim groups compared to the other 2 groups. Cure/improvement rate (according to the 24-h pad test) was sign. higher in BT+EStim and BF+BT+EStim groups compared to the other groups.	Post-tx (after 8 weeks of tx)	Randomisation adequate Concealment not reported Assessors blinded (evaluation performed by a physician blinded to group assignation) Dropouts: BT 1/18 BT + BF 1/17 BT+EStim 1/18 BF+BT+EStim 1/17 Adverse events: None except temporary discomfort due to vaginal irritation in three women in the EStim groups Dose: same tx regimen (BT, BF and EStim) across groups. The groups differed only in the combination.

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Follow-up	Notes
Hagovska (2021) (96)	Duloxetine + PFMT (79) vs. Duloxetine (79)	158	Women with SUI	Duloxetine: 40 mg BID PFMT: exercises were performed 5x per week for 30 min per day (various positions, progression in number of repetitions, strength and endurance exercises, PFMT in conjunction with lumbo-pelvic stabilization exercises). Education was provided by a physiotherapist in cooperation with a nurse over 5 sessions.	Duloxetine+PFMT resulted in higher changes from baseline to post-tx compared to duloxetine alone: - ICIQ-UI SF (average reduction 8.3 ± 3.8 vs. 9.7 ± 4.2; p=0.04); - Number of pads/day (percentage of reduction 50.0% vs 22.5%; p < 0.001); - PGI-I: 70.8% vs. 65.6% (p=.0001); - IEF/week (voiding diary percentage of reduction 66.7% vs. 50.0%; p<.001)	After 12 weeks of tx	Randomisation adequate Concealment not reported Assessor not blinded (self-reported questionnaire). Diaries were checked by an outpatient nurse at baseline and post-tx (no more info) Dropouts: Duloxetine+PFTM 14/79 (8 related to adverse events and 6 to low adherence) Duloxetine 15/79 (related to adverse events) Adverse events: Duloxetine+PFMT 8/79 Duloxetine 15/79 Duloxetine (nausea, fatigue, insomnia, dry mouth, constipation, dizziness, headache, and diarrhea) PFMT (no adverse events reported)

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Follow-up	Notes
McLean (2021) (98)	PFMT+Sx (52) vs. Sx+usual care (51)	103	Women with predominant SUI (30-min pad test >2g and a positive cough stress test)	All participants received a handout including usual care and PFMT instructions. Sx: Mid-urethral sling PFMT: supervised PFMT, 6 sessions over 12 weeks: manual assessment, education, BF, manual therapy and home PFMT programme that was progressed. After 12 weeks, assessments (V2) were repeated and then women proceeded to sx. After sx: physiotherapy sessions at weeks 1, 3 and 5 post-Sx. Usual care: no instructions beyond handout, asked to keep log of exercise performance. After 12 weeks, assessments (V2) were repeated and then women proceeded to sx. No further instructions were given after sx.	FLUTS-UI total scores sign. improved from V1 to V3 in both groups (p<.001). PFMT+Sx group demonstrated sign. lower scores at V2 compared with V1, and at V3 compared with V2, whereas the Sx+usual care only demonstrated sign. lower scores at V3 compared with both V1 and V2. Sign. group*time effects were found (p<0.01). For both groups, the lower scores at V3 were maintained at V4 and V5. At V3, FLUTS-UI subscale scores were sign. lower for the PFMT+Sx group than for the Sx+usual care group. For both groups, the lower scores at V3 were maintained at V4 and V5. No sign. group differences in the 3-day-bladder diary and 30-min pad test at V3 (p>0.05), yet all were sign. improved at V3 relative to V1 (p<.001). Cure rate (based on FLUTS-UI subscale<4) at V3 was higher in PFMT+Sx (73%) than in Sx+usual care (47%) (p=0.012). The cure rate was also higher in the PFMT+Sx at V4 and V5 (p<.01) No sign. group difference in cure-rate at V3, V4 and V5 based on the pad test, bladder diary and FLUTS-UI total score.	Baseline (V1) Assessment prior to Sx (V2) (12 weeks after PFMT or usual care) 12-weeks post-Sx (V3) 12-months post-Sx (V4)* 24-months post-Sx (V5)* *only for FLUTS-UI	Randomisation and concealment adequate Blinding of surgeons Dropouts at V3: PFMT+Sx 10/52 Sx+usual care 9/51 Dropouts at V5: PFMT+Sx 29/52 Sx+usual care 38/51
Schmidt (2020) (95) Short communication	BT (14) Vs BT + BF (14)	28	Women with SUI or MUI with a predominance of stress symptoms	BT: Instruction sheets on behavioural measures and lifestyle changes. BF: Standardized series of mixed exercises for rapid and slow response fibers No further details presented.	Both groups showed sign. improvement in the number of daily leakages from baseline to post-tx (p<.001). Btw-group differences not reported.	Post-tx (after 12 weeks of tx)	Randomisation adequate Concealment not reported Assessor non-blinded Dropouts: none reported Adverse events: none observed

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Follow-up	Notes
Sung (2019) (97)	Sx + PT (242) vs. Sx (238)	480	Women with moderate to severe bothersome SUI and UUI symptoms ≥3 months with at least 1 SUI and 1 UUI on a 3-day bladder diary	Sx: Retropubic and transobturator midurethral sling techniques PT: Education (pelvic floor anatomy, bladder function and voiding habits) + PFMT + BT (strategies to control stress and urgency symptoms). 1 preoperative visit and 5 post operative visits over 6 months.	UDI total score: Greater improvement in the Sx+PT compared to Sx was found from baseline to 12-month follow-up (mean difference -13.4 95%CI -25.9 to -1.0; p=.04). However, the authors argued that it did not reach MCID threshold. Btw group difference non sign. at 3- and 6-month follow-up. 3-day bladder diary: Greater reduction in total number of incontinence episodes from baseline to 12-month follow-up in the Sx+PT group compared to Sx group (mean difference −1.0 95%CI −1.7 to −0.2; p=.009) Non sign. differences btw groups (baseline-12 months): Number of voids (nighttime), Overactive bladder symptom severity questionnaire (OAB-q-SS), OAB Treatment Satisfaction Questionnaire, Patient Global Impression of Improvement (PGI-I) and Patient Global Impression of Severity were not sign. different btw groups at 12 months. Sign. differences btw groups (baseline-12 months): Number of pads per day, Number of voids (daytime), void frequency (normalization), void frequency (high voiding), Incontinence Impact Questionnaire and additional treatment were sign. different btw groups at 12 months in favor of the Sx+PT group (p≤.009)	12-month follow-up* (after surgery) *Also measured at 3- and 6-month follow-up but 12-month was the primary endpoint	Randomisation and concealment adequate Assessor blinded Dropouts: Sx+PT 14/242 Sx 3/238 Adverse events (over 12 months): Worsening urgency: Sx+PT 11 vs. Sx 5 Abdominal or genital pain: Sx+PT 28 vs. Sx 36 Dyspareunia : Sx+PT 29 vs. Sx 35 Sensation of difficulty emptying bladder: Sx+PT 32 vs. Sx 31 Vaginal mesh exposure: Sx+PT 4 vs. Sx 1 Emergency department for complication: Sx+PT 5 (urinary retention 3, acute pyelonephritis 1 and lower abdominal pain 1) vs. Sx 0 Reoperation Sx+ PT 3 vs. Sx 4 (reasons for reoperation: sling release 3, mesh excision 2 and cystotomy 2)

Abbreviations: BF: biofeedback; BT: bladder training, btw: between; DT: drug therapy; EStim: electrical stimulation; FLUTS-UI: Female Lower Urinary Tract Symptoms – Urinary Incontinence questionnaire; I-QOL: Incontinence Quality of Life questionnaire; MCID: minimal clinically important difference; MUI: mixed urinary incontinence; OAB: overactive bladder; PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; PT: physiotherapy; sign.: significant(ly); SUI: stress urinary incontinence; Sx: surgery; Tx: treatment; UDI: urogenital distress inventory; UUI: urge urinary incontinence

3. WEIGHTED VAGINAL CONES

Weighted vaginal cones (VC) were developed as a method for testing PFM function as well as to provide progressive muscular overload during PFM strengthening exercises (99). In theory, when a cone is inserted into the vagina, the sensation of 'losing the cone' provides sensory feedback that prompts the PFMs to contract to prevent the cone from slipping out. Women typically start in a standing position with a weighted VC held inside the vagina for at least one minute. The amount of time for which the VC is held, and the cone weight is increased incrementally while standing. For instance, the goal could be to stand or walk around without losing the cone; the gradual increase in cone weight maintains muscle overload over the course of the exercise programme.

There are various VC weights and sizes (Figure 1) and the effects of VC may vary depending on different factors. For instance, as the orientation of the vagina is not completely vertical, some women can retain the VC without contracting the PFMs. For example, radiographic studies have shown that VC can rest in a transverse position (100). Depending on the axis of the vagina, women need to produce different force intensities to retain the VC. Thus, using VC as a measure of PFM function may be invalid. Finally, some women may find it impossible to insert the VC due to a narrowed vaginal opening or, conversely, to retain it due to an enlarged vaginal opening, prolapse, or an insufficient PFM contraction that is incapable of holding even the lightest VC.

Figure 1. Weighted vaginal cones

This section examines the evidence for VC in the prevention and treatment of UI in women. Questions addressed:

- Are VC better than no treatment, placebo, or control for the prevention of UI?
- Are VC better than no treatment, placebo, or control for the treatment of UI?
- Are VC as effective as other treatments for the treatment of UI?
- Are VC combined with PFMT better than PFMT alone for the treatment of UI?

3.1. Prevention

Consistent with previous ICI, no studies were found investigating VC for primary or secondary prevention in women.

3.2. Treatment

Three new RCTs investigating the efficacy of VC were identified. Of these, one study was not retained due to the absence of incontinence outcomes (101). Table 14 illustrates the studies included in previous consultations (N=32) as well as the two new studies. Characteristics of each new RCT are presented in Table 15.

Table 14 Studies using VCs included in previous ICI reviews and the current update (7th ICI)

	Studies included in previous ICI reviews	New studies identified in this update (7th ICI)
PFMT vs VC (section II.2.3.3i)	14	0
PFMT/VC vs VC (section II.2.3.4i)	2	0
VC vs no treatment, placebo or control treatments	5	0
VC vs other treatment	6	2
PFMT/VC vs PFMT	5	0

Abbreviations: PFMT: Pelvic floor muscle training, VC: vaginal cone

3.2.1. Are VC better than no treatment, placebo, or control treatments for UI?

The previous ICI included five RCTs comparing the effects of VC to the absence of treatment or a placebo. No new studies have been published.

Summary

VC with supervised training sessions by a trained health professional are better than control treatments for subjective reporting of *cure* or *cure/improvement* and the QOL impact of the treatment on SUI. **(Level of evidence: 1)** However, VC treatment may be inappropriate in some cases due to potential side effects (102).

Recommendations

For women with SUI, VC with supervised training sessions by a trained health professional can be offered as a first-line conservative therapy to those who can and are prepared to use them. **(Grade of recommendation: B)**

VC may be inappropriate in some cases due to an inability to insert or retain the cone, or because of side effects and discomfort and therefore assessment by a trained health professional is recommended. **(Grade of recommendation: D)**

3.2.2. Are VC as effective as other treatments for UI?

i. VC versus PFMT

As reported in Section II.2.3.3, our literature search revealed no further trials.

ii. VC versus EStim
No new studies were added to the seven RCTs included in the previous ICI editions.

iii. VC versus surgery
A single new RCT examined the efficacy of VC in comparison with trans obturator tape (103).

iv. VC versus drug therapy
Our search revealed one new study investigating the efficacy of VC compared to drug therapy (tolterodine extended) (104).

Quality of data
In the two studies (103, 104), participants were randomly assigned to treatments while the allocation concealment and blinding of assessors were not clearly reported. The study by Dur *et al.* (103) included 21 women in the VC arm and 20 women in the surgery arm respectively. Only one dropout was reported in the VC group. In the study by Yuce *et al.* (104), three women out of 19 included in the VC group dropped out of the study and one woman among the 20 included in the drug therapy group dropped out.

Results

i. **VC versus PFMT:** *No further evidence available.*
ii. **VC versus EStim:** *No further evidence available.*
iii. **VC versus surgery:** *No statistically significant differences were found in subjective self-reported cure between the VC group and the trans obturator tape group (103). However, women in the surgery group had a higher objective cure rate (cough stress test) and greater improvement in the pad test than the VC group at six-week and six-month follow-ups (103).*
iv. **VC versus drug therapy:** *No statistically significant differences between VC and tolterodine were found regarding the severity and impact of symptoms (measured with various validated questionnaires, bladder diary, and pad test) (104). Authors reported that the study may have been underpowered to detect differences between the two interventions.*

Summary

There are no significant differences between VC and EStim in terms of *self-reported cure, cure/improvement*, and improvement in pad test or the number of leakage episodes. However, both the VC and EStim groups reported adverse events. **(Level of evidence: 1)**

Trans obturator tape insertion showed superior effects compared to VC for objective cure rate and improvement in the pad test. **(Level of evidence: 2)**

There is limited evidence regarding the efficacy of VC compared to drug therapy.

Recommendations

VC and EStim can be equally recommended in the treatment of SUI and MUI**. (Grade of recommendation: B)** However, side effects and discomfort limit the utility of these modalities in clinical practice. **(Grade of recommendation: D).**

No recommendation is possible regarding VC compared to trans obturator tape insertion and drug therapy.

3.2.4. Are VC combined with PFMT better than PFMT alone?

The previous ICI included five RCTs comparing the effects of VC combined with PFMT to PFMT alone. However, our search revealed no additional studies.

Summary

Limited evidence suggests that there is no benefit from adding VC to PFMT for women with SUI. **(Level of evidence: 2)**

Recommendations

No recommendation is possible for this combined intervention. Adequately powered RCTs are needed to confirm or refute the advantages of adding VC to PFMT.

Table 15. Summary of data on VC

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/Results	Follow-up	Notes
Dur (2019) (103)	VC (21) vs. Sx (20)	41	Women with SUI (confirmed with urodynamic assessment, positive cough stress test, and standardized pad test (>3 g))	VC: VC weight 20-70 g for 15 min twice a day for 3 months (instructions provided by a gynecologist) Sx: transobturator tape	Improvement in pad test in both groups from baseline to follow ups (p<.05). Lower pad weight is observed in the Sx group compared to VC group at both 6-week and 6-month follow ups (p<.015). Subjective cure rates (self-reported) were similar in both groups at the 6-week and 6-month follow up (VC 65% vs Sx 75%; VC 75% vs Sx 80%; both p>.05). Objective cure rates (cough stress test) were sign. higher in the Sx group than in the VC group (10% vs 80%; 30% vs 75%) (p<.05).	6-week follow up 6-month follow up	Randomisation adequate Concealment not reported Blinding of assessor unknown Dropouts: VC 1/21 Sx 0/20 Adverse events: none observed
Yuce (2016) (104)	VC (19) vs. DT (20)	39	Women with OAB (urinary frequency ≥8/day / nocturia ≥2/night / urgency and OAB-V8 score ≥ 8)	VC: 4 VC (same volume and size) of different weights (20g, 34g, 50g and 68g). They had to hold the VC during various activities (e.g., stand up, walk, housework) twice a day for 10 min each time. The weight was increased if/when they were able to retain the current weight >10 min). For 8 weeks DT: tolterodine extended release 4 mg per day, for 8 weeks	3-day bladder diary: Daytime frequency, nocturia, and number of UUI episodes sign. improved from baseline to post- Tx in both groups (p<.034). No sign. differences btw groups at post- Tx were found. 24-h pad test: Sign. reduction in pad weight was found in both groups from baseline to post- Tx (p<.003). No difference btw groups at post-Tx. Similarly, the number of patients with a dry pad test was similar btw the two groups at post-Tx (VC 68.7% vs DT 84.2%; p=.613). UDI-6, IIQ-SF7, OAB-V8: Sign. reductions were found in both groups (p<.019). No sign. difference btw groups at post- Tx. Wagner questionnaire: Sign. reduction from baseline to post- Tx in the VC group (40.50±23 to 27.63±21.9; p=.002) but not in DT group (28.95±17 to 28.53±18.5; p=.591). No sign. difference btw groups at post-tx (p=.896) Urodynamic examination: Detrusor overactivity was reduced from baseline to post-tx in the VC group (10/16 to 7/16; p=.003) and DT group (5/19 to 3/19; p=.426). Btw-group differences not reported. No sign. changes were seen in either group regarding normal or strong desire to void, post-void residual, max detrusor pressure, max abdominal pressure, max cystometric capacity. Sign. differences from baseline to post-Tx were found in VC group but not in DT group for: Max vesical pressure and first sensation of bladder filing (p<.036), but no sign. difference btw groups post- Tx (p≥.068).	Post-tx (after 8 weeks of tx)	Randomisation adequate Concealment not specified Blinding of assessor: Not mentioned Dropouts: VC 3/19 DT 1/20 Adverse events: no side effects requiring discontinuation of tx occurred in either group

Abbreviations: btw: between; DT: drug therapy; IIQ-SF7: Incontinence Impact Questionnaire Short Form 7; OAB: overactive bladder; OAB-V8: Overactive Bladder-Validated 8-question Screener; sign.: significant(ly); SUI: stress urinary incontinence; Sx: surgery; Tx: treatment; UDI-6: Urogenital Distress Inventory Short Form-6; UUI: urge urinary incontinence; VC: vaginal cone

4. ELECTRICAL STIMULATION (ESTIM)

The literature concerning electrical stimulation (EStim) in the management of UI is difficult to understand due to the lack of a well-substantiated biological rationale underpinning its use. However, the theoretical basis of neuromuscular EStim is emerging with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. The mechanisms of action may vary depending on the cause(s) of UI and the structure(s) being targeted by EStim, e.g., PFM or detrusor muscle, peripheral or central nervous system. In general, the aim of EStim for women with SUI is to increase proprioception and/or improve the muscle function of an atrophied or weak PFM, while for UUI the objective is to inhibit detrusor overactivity (DO) (105).

EStim is provided by clinic-based mains powered machines or portable battery powered stimulators (Figure 2) with a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 3). Without a clear biological rationale, it is difficult to make choices about different ways of delivering EStim. Additional confusion is created by the relatively rapid market developments and a wide variety of stimulation devices and protocols that have been developed, even for the same condition. Finally, the terminology used to describe EStim remains inconsistent. EStim has not only been described based on the type of current being used (e.g., faradic, interferential), but also on the structures targeted (e.g., neuromuscular), the current intensity (e.g., Low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g., neuromodulation).

This section presents the evidence for the use of EStim in the prevention and treatment of UI in women.

Questions addressed are:
- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control, or no treatment) for the treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?

Eligible interventions were non-invasive EStim without implanted electrodes. (MStim and TNS are described in sections II.5 and II.6).

Other criteria for inclusion were: (1) randomised or quasi-randomised (alternate allocation) trial design, (2) adult women with UI or other LUTS, and (3) no participants with incontinence due to neurological or cognitive impairment (EStim for this population is presented in section VI.3), and (4) no pregnant or postpartum women (within 12 months of childbirth). Trial data reported in conference abstracts as well as full-text papers were included. EStim compared with PFMT and vaginal cones are covered in sections II.2 and II.3. This section focuses on EStim compared with no active treatment or other conservative treatments.

The primary outcomes were cure rates (the number of women with no UI episodes at the time of assessment) and improvement rates (the number of women improved, including cure). There was considerable variability in the way these outcomes were measured. Data on health related QoL and adverse effects were also extracted. Data from further follow-up were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a predominant symptom of SUI (as defined by trial investigators), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trial investigators), (3) other studies of participants with UI in which neither stress nor urgency UI represented a predominant symptom in the study population ('UI all types' hereafter), and (4) studies on overactive bladder (OAB) or DO, in which it was unclear whether all participants had UI.

In included studies, ROB was assessed for random allocation, allocation concealment (selection bias) and completeness of outcome data (attrition bias). ROB regarding blinding to the allocated intervention was high in most included studies: blinding of participants and care providers was not always feasible (other than the use of sham EStim) and blinding of outcome assessors was equally difficult for self-reported outcomes such as cure, improvement and QoL.

Overview

Fifty trials were included in the sixth ICI, of which none were on prevention. For treatment, trials from the sixth ICI were broadly similar to those from the fifth ICI. Included studies were generally at high ROB.

Figure 2. Neuromuscular electrical stimulation equipment

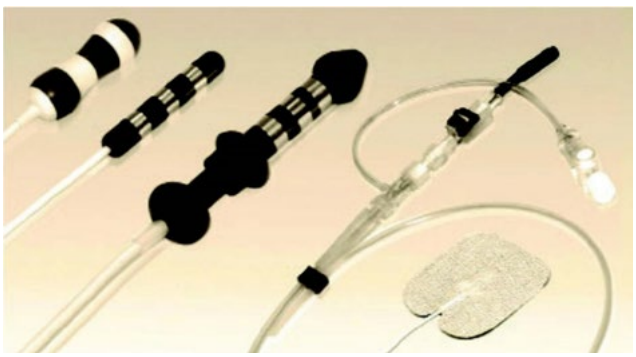

Figure 3. Neuromuscular electrical stimulation electrodes

Eleven new trials were identified for this update, making a total of 61 trials included. Three new trials targeted women with SUI or predominant SUI (106-108), and eight studies focused on predominant UUI, detrusor overactivity (DO) or OAB (incontinent or not) (94, 109-112). Further analysis of three trials can be found in section II.6. (113-115). The number of included studies by dominant type or pattern of incontinence is summarized in Table 16.

The EStim parameters and protocols in this section are summarised in Table 17. Once more, there was considerable variation in the intervention protocol. Although the biological rationale and purpose of EStim might be different depending on diagnosis, there was no consistency in the EStim protocols used for women with SUI, UUI, UI all types, or DO.

Table 16. Studies on EStim included in the previous review (6th ICI) and current update (7th ICI)

	Studies included in the previous review (6th ICI)	**New studies identified in this update (7th ICI)**	**Total**

4.1. Prevention

No trials were found.

4.2. Treatment

4.2.1. Is EStim better than no treatment, placebo, sham, or control for treatment of UI?

In the sixth ICI, 21 studies assessed the effect of EStim compared to no active treatment, including 13 in women with SUI or predominant SUI, three studies on UUI or predominant UUI, two studies on all types of UI, and three studies on DO/OAB (incontinent or not).

Two new studies were found on EStim compared to no active treatment or sham treatment. One study included 40 women with OAB and compared the effectiveness of transcutaneous electrical nerve stimulation (TENS) to a placebo TENS for reducing OAB symptoms (109). Another study included 34 women with SUI and compared surface EStim through transvaginal and sacral region stimulation with a control intervention (walking 20 min daily) (106). Characteristics of the new studies are presented in Table 18.

Results

In the study by Sharma *et al.* (109), there was a significant improvement in the Overactive Bladder Symptom Score (OABSS) in the TENS group with two patients 'completely dry' following TENS therapy. No significant improvement was found in the control group. A statistically significant difference in total OABSS was found in the TENS group compared to control group, which favoured TENS. In a study by Hwang *et al.* (106), significant differences in the UDI-6 score and pad weight were observed both between groups (EStim versus control group) and within groups (pre-EStim versus post-EStim), again favouring EStim.

Summary

EStim may be more effective than no treatment or a control treatment in improving symptoms and QoL in women with SUI. **(Level of evidence: 2)**

EStim may improve symptoms in women with UUI or OAB, but it may not cure their condition. **(Level of evidence: 2)**

Information on QoL was sparsely reported, particularly for UUI or OAB/DO, and the limited data available were inconsistent. Adverse effects appear uncommon but some women experienced discomfort with the treatment device. Scant data were available on long-term performance.

Recommendations

EStim can be recommended as being better than no treatment to improve symptoms and QoL in women with SUI. **(Grade of recommendation: B)**

EStim can be considered for treatment to improve symptoms for UUI. **(Grade of recommendation: B)**

However, this recommendation should be viewed with caution until the findings are supported or refuted in longer-term follow up.

Table 18. Summary of data on EStim vs no active treatment

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow-up	Notes (side effects, loss of follow up…)
Sharma 2016 (109)	TENS vs sham	40	OAB	OABSS Cure (dry)	TENS: 2 participants dry Significant difference between-groups favoring EStim	NR	Adverse effects: none reported
Hwang (2020) (106)	TENS vs control	34	SUI	Pad test UDS-6	TENS > control (p<0.01) TENS> control(p<0.001)	8 weeks	AEs: none Loss to follow-up: 2 patients (1 each)

Abbreviations: TENS: transcutaneous electrical nerve stimulation; OAB: overactive bladder; OABSS: overactive bladder symptom score; UDS-6: distress inventory-6

4.2.2. Is one type of EStim better than another in the treatment of UI?

Until now, a total of eight studies have assessed the effects of one approach of EStim compared with another. Of these, six studies involved women with SUI and predominant SUI, and two involved women with DO. No study focusing on UUI or predominant UUI was identified.

Six new studies including 502 women with SUI (two studies, n=222) or with OAB with/without UUI (four studies, n=280) were found. Three studies compared EStim and percutaneous TNS or transcutaneous TNS (111, 114, 115); and can also be found in Section II.6. and in Table 28. The three other studies compared Estim to other modalities. The characteristics of the new studies comparing one type of EStim to another are presented in Table 19. Different variants of EStim were assessed, either alone (108, 110, 114, 115) or as an adjunct to PFMT and biofeedback (107, 111).

Quality of data

Randomisation was reported in all six trials and was done by random draw in two studies (107, 110), online randomisation in two others (111, 114), or by using permuted block-format in one study (108) and computer sequence generated in the other (115).

Reporting of data: In two studies by the same authors, cure and improvement were reported (107, 110). QoL was assessed using I-QOL in one study (108). Adverse events were not reported in two studies (107, 110). One study reported adverse events in 19.1% of participants using an external EStim approach (device in underwear) and 13.1% of those using transvaginal EStim (108). Adverse events were mild/moderate. Urinary tract/vaginal infections occurred in 7.7% of participants using transvaginal EStim but were none reported in those who had undergone external EStim (108).

Results

For SUI or predominant SUI, one small new study found that pudendal EStim was better than biofeedback plus PFMT transvaginal EStim for cure rates and improvement rates (107). See Table 19.

One single-blind randomised controlled non-inferiority study comparing external EStim and transvaginal EStim reported that most subjects in both groups achieved more than a 50% reduction in the pad test weight respectively (56.3%, 63.0%), but non-inferiority was not established. Significant improvements in pad tests, number of incontinence episodes, pads used /day, and incontinence QoL score (I-QoL) were seen in both groups immediately after treatment with no clinically relevant between-group differences (108). See Table 19.

For UUI, one new study found that pudendal EStim was better than biofeedback-PFMT plus transvaginal EStim for cure and improvement rates (110). See Table 19.

Vecchioli-Scaldazza *et al.* (111), reported no significant differences in number of daytime voids (primary endpoint) between percutaneous TNS and transvaginal EStim + PFMT, but greater improvements were noted in number of night-time voids, UUI and voided volume as well as patient global impression of improvement (PGI-I) in favour of percutaneous TNS versus transvaginal EStim group. A significant improvement in QoL (OAB-q) was noted in the percutaneous TNS group compared with transvaginal ES+PFMT group. However, the treatment duration was different in the two groups (111). See Table 28.

Jacomo *et al.* (114), reported a reduction of UUI using transcutaneous TNS ($p<0.01$), but no change in parasacral EStim. However, no between-group differences were found. Both transcutaneous TNS and parasacral EStim showed improvement in ICIQ-OAB and ICIQ-SF (114). See Table 28.

Mallmann *et al.* reported that both transcutaneous TNS and parasacral EStim were effective, with no between-group differences in terms of KHQ domains, average KHQ and proportions of categories of ISI. However, OAB-V8 showed a significant improvement in the transcutaneous TNS group compared with the parasacral EStim group ($p = 0.019$) (115). See Table 28.

Summary

A total of 14 studies, including six new studies, assessed the effect of one approach of EStim compared to another. There were four small new trials (107, 109, 114, 115) and two relatively large-scale trials (108, 110).

Findings from updated reports on SUI only suggest that pudendal Estim could be more effective than biofeedback plus PFMT-assisted transvaginal EStim, but the data lost to follow up may have affeccted the results (107). External EStim and transvaginal EStim significantly improved predominant SUI, but non-inferiority was not established (108).

For UUI or OAB, pudendal EStim may be more effective than transvaginal EStim, but the duration of stimulation differed (110). Parasacral EStim may be as effective as transcutaneous TNS (114, 115). Included studies generally had a high ROB. **(Level of evidence: 2)** Further comparisons of EStim protocols are needed.

Recommendations

For women with SUI and UUI, pudendal EStim could be recommended as it may be more effective than transvaginal EStim in improving symptoms. **(Grade of recommendation: C)**

External EStim and transvaginal EStim could be recommended to improve SUI in short term. **(Grade of recommendation: B New)**

Transcutaneous TNS may be slightly better than parasacral EStim and therefore could be recommended. **(Grade of recommendation: C)**

There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups. More RCTs are needed.

Table 19. Summary of data on different types of EStim comparisons

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Wang (2016) (107)	Pudendal EStim vs BF-PFMT+ transvaginal EStim	42	SUI alone	Cure Improvement (determined by stress test + 24-h pad test + QoL score)	52.4% vs 14.3% (P<0.01) 85.7% vs 28.6% (P<0.1)	Post-treatment group (n=196, 52 Mo): complete resolution 47.1%	AE: NR
Wang (2017) (110)	Pudendal EStim (n=80) vs transvaginal EStim (n=40)	120	UUI alone	Cure Improvement	42.5% vs 2.5% 70.1% vs 45% Pudendal EStim > transvaginal EStim (P<0.05)	Post-treatment UUI score: Pudendal EStim > transvaginal EStim (P<0.01)	AE: NR
Dmochowski (2019) (108)	External EStim vs transvaginal EStim	180	Predominant SUI	Provocative pad test 24-h pad test I-QOL PGI-I	Non-inferiority was not established (difference -6.7%, 95% CI, -21 to 8.4%). Improved in both groups (no between-group differences) External EStim (56.3%), transvaginal EStim (63%)	NR	Missing: NMES (1.1%), transvaginal EStim (2.2%) AE: NMES (19.1%) transvaginal EStim (13.1%) UTI and vaginal infection: External EStim (0%), TES (7.7%) Device discomfort/pain : External EStim (13.5%), transvaginal EStim (2.2%)

Abbreviations: NR: not reported; EStim: electrical stimulation; EPNS: Electrical Pudendal nerve stimulation; TENS: transcutaneous electric nerve stimulation; NMES: neuromuscular external electrical stimulation device; PTNS: percutaneous tibial nerve stimulation; TTNS: transcutaneous tibial nerve stimulation; PGI-I: patient global impression of improvement; AE: adverse device effects; OAB: overactive bladder; OAB-V8: OAB-8 question awareness tool; ISI: incontinence severity index; SUI: stress urinary incontinence; UUI: urge urinary incontinence; MUI: mixed urinary incontinence; I-QOL: Incontinence Quality of Life Questionnaire; QoL: quality of life; BF: biofeedback; KHQ: King's Health Questionnaire; ICIQ-OAB: International Consultation on Incontinence Questionnaire – Overactive bladder; ICIQ-SF: International Consultation on Incontinence Questionnaire – Short-form; NS: non-significant.

4.2.3. Is EStim better than other treatments for UI?

The fifth ICI edition included six studies: one study in women with SUI, one in women with predominant UUI, and four in women with OAB/DO (wet or dry). No new studies were found for the sixth ICI. Overall, there was insufficient evidence to determine if EStim is better than vaginal oestrogens in women with SUI, propantheline bromide in women with UUI, or oxybutynin and tolterodine for DO (Level of Evidence: 2). Pharmacotherapy (drugs) appeared to be no more effective than EStim (Grade of Recommendation: B).

For this ICI, one new three-armed study was found that included EStim, oestrogen cream and the combination of both (Table 20) (112).

Quality of data

In the new study, random allocation was conducted using a computer-generated random numeric table, but with no indication of third-party involvement in the allocation procedure. Participants and evaluators were not blinded. Data were reported and analysed only for those who completed the trial. Fifteen patients were lost to follow-up. Finally, adverse effects were not reported (112).

Results

There was more improvement in the combination group than in the EStim group for all UI outcomes except for daytime voids, UI episodes and QoL. There was more improvement in the EStim group than in the oestrogen group for all parameters except for DO. No cure

rates were reported. After the six-month follow-up, deterioration was noted in all groups except for UI episodes in the combination group.

Summary

A total of seven studies, including one new moderate-quality RCT including a large number of participants assessed the effect of EStim plus another treatment versus the other treatment. One study included women with SUI, predominant UUI in two studies, and OAB/DO (UI or continent) in four studies.

The new study showed that the effects of the combination of EStim plus oestrogen was better than vaginal oestrogens alone for the treatment of UUI in women at 6 months. **(Level of evidence: 2)**

Other studies were generally assessed as having a high ROB. There is insufficient evidence to determine if EStim alone is better than vaginal oestrogens alone in women with SUI, propantheline bromide in women with UUI, or oxybutynin and tolterodine for DO. **(Level of evidence: 2)**

Recommendation

Medical treatments appear to be less effective than EStim or a combination of PFMT and EStim for SUI and therefore cannot be routinely recommended. **(Grade of recommendation: B)**

Propantheline bromide in women with UUI or oxybutynin and tolterodine for DO cannot be routinely recommended for UUI as they are less effective than EStim. **(Grade of recommendation: B)**

These findings need to be investigated further with high-quality trials, as this is a clinical question of interest to women.

Table 20. Summary of data on EStim vs another treatment

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Abdelbary (2015) (112)	Vaginal EStim (n=100) vs Vaginal estrogen (n-98) vs Combination (n=102)	315	UUI only	Cure UUI QoL	NR Improved in all groups Combination > each monotherapy (p=0.000, 0.009 ES and combination > estrogen (p=0.005, 0.004) NS Improvement decreased in all groups (Except UUI in combination groups	Post-treatment 1 week, 3 weeks and 6 months	Loss to follow-up: 15 patients (vaginal EStim n=5, vaginal estrogen cream n=7, combination n=3) Side Effects: NR

Abbreviations: EStim: electrical stimulation; UUI: urge urinary incontinence; QoL: quality of life; NR: not reported; NS: non-significant

4.2.4. Does the addition of EStim to other treatments add any benefit in the treatment of UI?

In the sixth ICI edition, 15 studies assessed the effect of EStim as an adjunct to another treatment, compared with the other treatment alone. All but two studies included women with SUI or predominant SUI. No study focusing on UUI or predominant UUI was identified.

Two new studies were available for this ICI (Table 21). Firinci *et al.* (94) was an assessor-blinded RCT, studying 70 women with UUI, and assigned them to four groups, including BT alone, BT plus biofeedback training, BT plus EStim, and BT plus biofeedback plus EStim (94). The follow-up assessment took place eight weeks after the intervention. BT included one 30-minute education session with a physician and a written brochure. Women were taught how to contract their PFMs via vaginal palpation, were encouraged to use urgency suppression strategies (PFM contraction, relaxation and distraction) and to follow a timed voiding programme based on their bladder diary. No further details were provided on the BT protocol. Biofeedback treatment included three 20-minute sessions per week. In each session, the participants completed 40 cycles of 10-second contractions followed by 20-second of relaxation performed in supine position with the aid of an intravaginal pressure probe. EStim also included three 20-minute sessions per week. The stimulation parameters were a frequency of 10 Hz, a 5–10-second work-rest cycle, and a 100ms pulse width. The symmetric biphasic pulse wave was delivered over a range of 0–100mA, according to the patient's feedback on their level of discomfort. Further analysis of this trial is found in section II.2.3.4, and II.7.2.

Giarreta *et al.* randomly assigned 106 women with OAB or MUI to a vaginal EStim plus TTNS group (n=54) and a TTNS group (n=54) (113). Further analysis of this trial is found in section II.6.2.4.

Quality of data

A power calculation and adequate random allocation were reported for Firinci *et al.* The assessor was blinded to the participant's allocation. ITT analysis was not used. Loss to follow-up was low and balanced between groups but reasons were unclear (6% giving up treatment). Side effects were minor and specific to the EStim groups (temporary discomfort due to vaginal irritation [n=3]). Overall ROB was moderate (94).

The second study by Giarreta *et al.* 2021 was published in Spanish with an English abstract only, and an assessment of the quality of the data was infeasible (113).

Results

In the study by Firinci *et al.* (94), patient-reported outcomes (number of leakages and number of pads used according to a 3-day bladder diary, UI-specific QoL or impact questionnaires) and clinician-reported outcomes (cure and improvement and UI severity, based on a 24-hour pad-test) for the four treatment groups improved compared to baseline. At post-treatment, results favoured the two combined treatment groups including EStim compared to BT alone or BT added to biofeedback. Moreover, the improvement in nocturia was significantly higher in the triple combination group (BT plus biofeedback plus EStim) compared with the other three groups.

In the study by Giarreta *et al.,* a significantly higher reduction in urinary frequency was reported (1.5 micturitions) in the EStim plus transcutaneous TNS versus transcutaneous TNS alone, but no data on cure rates or improvement rates were reported (113).

Summary

A total of 17 studies assessed the effect of EStim as an adjunct to another treatment, compared with the other treatment alone.

For comparisons of EStim with PFMT versus PFMT alone, there was no clear evidence of a difference between the groups in women with SUI or predominant SUI in terms of cure and improvement. Evidence for QoL outcomes was not consistent across studies. **(Level of Evidence: 2)**

There is no evidence to suggest that the addition of EStim to biofeedback-assisted PFMT was more effective than biofeedback-assisted PFMT in women with SUI. **(Level of evidence: 2).**

For UUI, there is no evidence from which to draw conclusions about the effect of adding EStim to PFMT or transcutaneous TNS for women with UUI. (**Level of evidence: 2, Level of evidence: 3 respectively)**

A combination of BT plus EStim or BT plus biofeedback plus EStim may be more effective than BT alone or BT plus biofeedback. **(Level of evidence: 2)**

Recommendations

For SUI, the addition of EStim to PFMT or biofeedback-assisted PFMT programmes cannot be routinely recommended **(Grade of recommendation: B)**

For OAB or MUI, the addition of EStim to BT or BT plus biofeedback can be considered as this could add benefit for the treatment. **(Grade of recommendation: B)**

Combinations of treatment approaches need to be investigated further with high-quality trials as this is a clinical/research question of interest to women.

Table 21. Summary of data on EStim + another treatment vs the other treatment

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)

5. MAGNETIC STIMULATION (MSTIM)

MStim was developed to stimulate the central and peripheral nervous systems (116). Since its introduction in 1985, the technique has been used to manage a variety of neurological and psychiatric conditions. Following the US Food and Drug Administration approval of MStim as a conservative treatment for UI in 1998, Galloway reported the use of MStim for female SUI in 1999 (117). Conventional magnetic stimulators generate repetitive pulses at frequencies of 10 to 50 Hz with a pulse width between 55 and 300 us (117-121). In general, lower frequencies (5-10 Hz) are more likely to be used to treat UUI, while higher frequencies (15-50 Hz) are suitable for treatment of SUI (122, 123)

The main advantages of MStim include patients' comfort and convenience. Compared to EStim, MStim is more comfortable because it does not require an intra-cavity probe. Moreover, patients do not need to undress or undergo skin preparation for treatment.

The exact mechanism of action of MStim has so far not been fully understood. In terms of SUI, the potential mechanism could be that the direct magnetic stimulation on PFM fibres and pudendal nerves enhances the contraction strength of PFM, and consequently increases maximum urethral closure pressure (8). For UUI, it is hypothesised that MStim could activate pudendal nerve afferents, inhibiting the spinal reflex, and/or inhibitory hypogastric sympathetic neurons, which might suppress DO (9). Moreover, MStim could improve internal urethral sphincter tone by stimulating sympathetic fibres and external sphincter tone by activating the pudendal nerve, and thereby promoting bladder relaxation (119). Additionally, MStim has been thought to significantly relieve patients' depression, which may be secondary to the improvement of UI symptoms (124, 125).

This section presents the evidence for the use of MStim in the prevention and treatment of UI in women. Questions addressed are:

- Is MStim effective in the prevention of UI?
- Is MStim better than no treatment, placebo, control, or sham for the treatment of UI?
- Is one MStim approach better than another in the treatment of UI?

- Is MStim better than other treatments in the treatment of UI?
- Does the addition of MStim to other treatments add any benefit in the treatment of UI?

Eligible interventions were non-invasive MStim. Other criteria for inclusion were: (1) randomised trial design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and, (4) no pregnant or postpartum women (within 12 months of childbirth). Trial data reported in conference abstracts as well as full-text papers published or accepted for publication in peer-reviewed journals were included.

The primary outcomes were cure rates (the number of women without UI episodes at the time of assessment) and improvement rates (the number of women with improvement in UI, including cure). There was considerable variability in the way these outcomes were measured. Women's self-reports were prioritised. However, for studies where this was not reported, the improvement/cure rates based on diaries were used as a proxy. When diary data were also not reported, the rates were based on pad tests, or any other definitions chosen by the trial investigators (93). Data on health related QoL and adverse effects were also extracted. Data at the end of the prescribed treatment phase or at the first outcome measurement (if later) were used in the analysis. Any treatment effects shown are likely to reflect maximum effects of each intervention. Data from further follow-up were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a pre-dominant symptom of SUI (as defined by trial investigators), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trial investigators), (3) other studies of participants with UI in which neither stress nor urgency UI represented a predominant symptom in the study population ('UI all types'), and (4) studies on overactive bladder (OAB) or DO in which it was unclear whether all participants had UI.

Single estimates with 95% confidence intervals (CI) were derived for each study comparison using odds ratios (OR) for dichotomous variables or mean difference (MD) for continuous variables. Summary estimates were calculated using random effects models if there was more than one study reporting the same outcome (meta-analysis).

ROB in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane UI Group. ROB regarding blinding to the allocated intervention was high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham MStim) and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and QoL.

Description of intervention

In addition to 13 studies included in the sixth ICI, four new trials were identified for this update. The number of included studies by dominant type or pattern of incontinence is summarised in Table 22 and Table 23 illustrates the intervention characteristics of the four new trials.

Table 22. Studies on MStim included in the previous review (6th ICI) and current update (7th ICI)

	Studies included in the previous review (6th ICI)	New studies identified in this update (7th ICI)	Total
MStim vs No active treatment			
SUI or predominant SUI	4	4*	8*

Table 23. Summary of data on MStim

Study	Intervention description
Lim (2017) (126)	Therapy was performed using the QRS-1010 PelviCenter chair (QRS-International, Liechtenstein) with a homogeneous magnetic field emitted via a magnetic coil embedded beneath the surface of the seat. [cD1] Patients were treated in a sitting position. The stimulation was generated at a frequency of 50Hz with an 8-second "on" and a 4-second "off" pulsing pattern. The treatment regimen involved 2 sessions per week for 2 months (16 sessions, 20 minutes each). The intensity was not described in detail.
Weber-Rajek (2018) (125)	Therapy was performed using the NeoControl chair (Neotonus Inc., Marietta, GA, USA) with a 2.0 Tesla magnetic field. Patients were treated in a sitting position. The stimulation was generated at a frequency of 50Hz with an 8-second "on" and a 4-second "off" pulsing pattern. The treatment regimen involved 3 sessions per week for 4 weeks (12 sessions, 15 minutes each). The intensity increased from 20% to 100% during consecutive treatment sessions. Also, the strength of electromagnetic stimulation matched the highest patient-tolerated level.
Yamanishi (2019) (127)	Therapy was performed using an armchair type of magnetic stimulator (Nihon Kohden, Tokyo, Japan) with a magnetic coil positioned beneath the seat of the chair. The patients were treated in a sitting position. Stimulation was generated at a frequency of 50 Hz with a 5-second "on" and a 5-second "off" pulsing pattern. The treatment regimen involved one session per week for 10 weeks (10 sessions, 20 minutes each). The intensity was set at a maximum output of ≤42% of the active stimulation during consecutive treatment sessions.
Weber-Rajek (2020) (51)	Therapy was performed using the NeoControl chair (Neotonus Inc., Marietta, GA, USA) with a 2.0 Tesla magnetic field. The patients were treated in a sitting position. The stimulation was generated at a frequency of 50Hz with an 8-seconds "on" 4-second and a 4-second "off" pulsing manner. The treatment regimen involved 3 sessions per week for 4 weeks (12 sessions, 15 minutes each). The intensity increased from 20% to 100% during consecutive treatment sessions. Also, the strength of electromagnetic stimulation corresponded to the highest patient-tolerated level.

5.1. Prevention

There remain no trials on the prevention of UI or LUTS.

5.2. Treatment

5.2.1. Is MStim better than no treatment, placebo, control, or sham for treatment of UI?

Four new studies including 298 women were identified; all participants had SUI (51, 125-127). Only two arms of one study with multiple arms were included in the comparison (51). One study included patients with SUI that were refractory to PFMT (127).

Characteristics of the four new studies comparing MStim to no active treatment are presented in Table 24. Of these, two studies used sham treatment (126, 127) and two used no intervention as the control (51, 125). As the study designs, sample populations and outcomes were heterogenous, only limited study findings could be combined.

Quality of data

Randomisation was considered appropriate in four studies (51, 125-127). Allocation concealment was considered unclear in three studies as important details were not described although two reported the use of envelopes (51, 125) and the other reported the use of a magnetic card (127) in the randomisation process. The fourth study did not describe methods used for allocation concealment (126). In terms of blinding, two studies were double-blind (125, 127) and two other studies were single-blind (51, 126). One study reported the complete data and performed data analysis based on the ITT principle (126). In three other studies, data were reported only for participants who completed the study (51, 125, 127). In the study by Yamanishi (2019), 30.8% (8/26) of participants from the MStim group and 7.7% (1/13) in the sham MStim group withdrew from the study and were not included in the analysis (127).

Results

1. SUI

When adding new studies to previously reported research, pooled data suggest that cure rates were on average significantly higher for MStim compared with no active treatment (N = 234, 23.5% versus 3.5%, OR 8.85, 95% CI 3.39 to 23.09, P<0.00001, I^2=0%) (125, 126, 128). Improvement rates were significantly higher for MStim compared to no active treatment (N = 182, 74.7% versus 25.3%, OR 8.72, 95% CI 4.46 to 17.03, P<0.00001, I^2=0%) (126, 128).

QoL was assessed in five studies, including two new studies (51, 127), but the results were inconsistent. Similar to a previous study (129), one new study found no significant differences between groups (127). In contrast, three studies, including one new study, reported that MStim was associated with significant improvement in QoL compared with no active treatment (51, 128, 130). Specifically, in the new study, four items of the KHQ were statistically significantly different and favoured MStim over control, post treatment (51). A total of three studies, including one new study, reported no adverse effects (121, 127, 129).

2. UUI

No new study was found for this update. The level of evidence and recommendations remain unchanged from the sixth ICI edition.

3. MUI

No new study was found for this update. The level of evidence and recommendations remain unchanged from the sixth ICI edition.

4. All types of UI

No new study was found for this update. The level of evidence and recommendations remain unchanged from the sixth ICI edition.

Summary

A total of 15 studies assessed the effect of MStim compared with no active treatment, including eight focusing on SUI or predominant SUI, one on UUI, one on MUI, two on all types of UI, and three on OAB/DO (where only some but not all had UI). Using

the additional data from newly identified studies, findings were broadly similar to those in the sixth ICI edition.

Evidence from a moderate- to good-quality trial of small to moderate size suggests that MStim is more effective than sham treatment for cure and improvement of symptoms in women with SUI. **(Level of evidence: 2)**

Data from five small trials on MStim examining the effect on QoL provided inconsistent results. **(Level of evidence: 2)**

For women with UUI, evidence from a small trial (120) suggests that active MStim might result in better QoL than the sham treatment, although there is some uncertainty as data were limited and no statistical test was performed. (**Level of evidence: 4)**

Active MStim was associated with higher cure rates than the sham treatment in a small trial (131) with women with MUI. **(Level of Evidence: 2)**

MStim also produced higher cure and improvement rates (118) in women with all types of UI **(Level of evidence: 2)** but this difference was not observed in women with DO (wet or dry). **(Level of evidence: 2)**

In general, adverse effects appear uncommon.

Recommendations

For women, MStim can be considered as it appears to control MUI and SUI symptoms when compared to no active treatment. **(Grade of recommendation: B New) However, this recommendation should be viewed with caution until these findings are supported or refuted in further trials with large sample sizes and clear and consistent reporting of core outcome data.**

Table 24. Summary of data on MStim vs no active treatment

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Oucomes/results	Follow up	Notes (side effects, loss of follow-up…)
Lim (2017) (126)	MStim (60) vs Sham MStim (60)	120	SUI alone	MStim: see also table 23. Sham MStim: The magnetic coil was tilted 22 degrees down.	Subjective Cure ('never' response to question 3 of ICIQ-UI SF): 19/60 vs 3/60 Objective Cure (leakage of <1g on 1-h pad test): 25/60 vs 4/60 Improvement (based on ICIQ-UI-SF): 45/60 vs 13/60 QoL: NR Adverse effects: NR	2 months	Loss of follow-up: NR Note: The study included 2 stages. Stage 1 was designed as a double-blind randomised controlled trial with a follow-up at 2 months. Stage 2 was an open-labelled study with a one-year follow-up. In stage 2, participants can choose whether or not to receive additional therapy..
Weber-Rajek (2018) (125)	MStim (30) vs No treatment (25)	55	SUI alone	MStim: see also table 23. Control: no treatment.	Cure (based on RUIS): 5/28 vs 0/24 no significant diff. between groups Improvement: NR QoL: NR Adverse effects: NR	4-week	Loss of follow-up: 2 patients in MStim group and 1 patient in control group.
Yamanishi (2019) (127)	MStim (26) vs Sham MStim (13)	39	SUI refractory to PFMT	MStim: see also table 23. Sham MStim: 1 Hz in 5-s on/5-s off cycles, with a maximum output of ≤42% of the active stimulation.	Cure: NR Improvement: NR QoL via ICIQ-QOL: N= 30 at 10-week, mean change in score, standard deviation -1.66 (3.23) vs 0.25 (1.36), P=0.377. Adverse effects: no events observed	10-week	Loss of follow-up: 8 patients in active group and 1 patient in the sham group.
Weber-Rajek (2020)* (51)	MStim (44) vs PFMT (44) vs No treatment (40)	128 (84 were involved in the comparison)	SUI alone	MStim: see also table 23. PFMT: 3 sessions per week for 4 weeks (12 sessions, 45 minutes each). Control: no treatment.	Cure: NR RUIS score (Mstim vs Control: median (IQR) at final assessments): MStim (n=37) 7 (4) P=0.001 vs Control (n=34) 9 (5) P=0.19. Improvement: NR QoL via KHQ (Mstim vs Control: median, IQR at final assessments): General health/incontinence impact, N = 71, 33.3 (33.3) vs 33.3 (50), P=0.47; Role limitations, 33.3 (50) vs 33.3 (41), P=0.52; Physical limitations, N = 71, 0 (22.2) vs 22.2 (48.6), P=0.016; Social limitations, 22.2 (22.2) vs 22.2 (31.9), P=0.027; Personal relationships, 33.3 (50) vs 44.4 (45.8), P=0.033; Emotions, 33.3 (50) vs 50 (31.2), P=0.008; Sleep/energy, 41.7 (41.7) vs 38.2 (41.7), P=0.51; Severity measures, 25 (16.6) vs 31.3 (33.3), P=0.07; Bladder-related symptoms, 6 (2) vs 7.5 (4.5), P=0.14. Adverse effects: NR	4-week	Loss of follow-up: 7 patients in MStim group and 6 patients in the control group.

** Two arms of the study were involved in the comparison.*
Abbreviations: MStim: manual stimulation; SUI: stress urinary incontinence; NR: none reported; QoL: quality of life; KHQ: King's Health Questionnaire

5.2.2. Is one approach of MStim better than another in the treatment of UI?

No new study comparing one approach of MStim with another was found for this update. The level of evidence and recommendations remains unchanged from the sixth ICI edition.

Summary and Recommendation

No new trials contributed evidence in this area. A small trial (reviewed in the previous edition) comparing the two different MStim chairs in management of UI found no significant differences between the two MStim approaches (132). There is insufficient evidence to determine if one type of MStim is better than another. **(Level of evidence: 2)**

No recommendation is possible.

5.2.3. Is Mstim better than other treatments for the treatment of UI?

There were no trials for this comparison in the sixth ICI. A single new study was identified (51). Only two arms of the new study with multiple arms were included in the comparison. In the two-arms of the study, MStim was compared to PFMT in 88 women with SUI (51). The characteristics of the new study are presented in Table 7. Further analysis of this trial is found in section II.2.3.1. Randomisation was considered appropriate (51). Allocation concealment was considered unclear as important details were not described, although the use of envelopes was reported. The study only reported data from the participants who completed the study and found no significant differences between MStim and PFMT for UI symptoms, although it should be noted that the PFMT intervention was suboptimal with only four weeks of training.

Summary and Recommendation

A new trial assessed the effect of MStim compared to PFMT. Data from two arms of the small trial suggest no significant differences between MStim and a PFMT intervention of suboptimal intensity and duration (51). There is insufficient evidence to determine if MStim is superior to another treatment. **(Level of evidence: 2)**

It is not possible to make a recommendation regarding MStim vs PFMT.

5.2.4. Does the addition of MStim to other treatments add any benefit in the treatment of UI?

No new study was found investigating the effect of adding MStim to other treatments compared with the other treatments alone. The level of evidence and recommendations remain unchanged.

Summary and Recommendation

No new trials contributed evidence in this area. A small trial found no additional benefits to adding MStim to PFMT in women with SUI (132). **(Level of evidence: 2)**

Adding MStim to PFMT could not be recommended as this does not appear to add benefits. **(Grade of recommendation: C)**

6. TIBIAL NERVE STIMULATION (TNS)

Tibial nerve stimulation (TNS) is targeted towards symptom relief of OAB and UUI (133). Indirect access to the sacral plexus is achieved by intermittent, electrical stimulation of the tibial nerve, which lies behind the medial malleolus. TNS may be minimally invasive, involving insertion of a fine needle close to the nerve (Percutaneous TNS), or non-invasive, using skin surface electrodes applied to the medial malleolar area (Transcutaneous TNS) (133).

TNS aims to stimulate the sacral nerve plexus through the afferent fibres of the tibial nerve, a mixed nerve containing L5-S3 fibres (134). The S3 nerve root contains sensory fibres from the pelvic floor and parasympathetic motor efferent fibres to the detrusor muscle as well as the pelvic sphincters and the PFMs. Afferent nerve stimulation can therefore lead to activation of inhibitory sympathetic neurons and suppression of detrusor contraction through a direct sacral route. Urodynamic studies have shown that electrical stimulation of the tibial nerve increases cystometric capacity and suppresses detrusor contraction (135-137). The full mechanism of action of treatment effect for TNS is not yet fully understood, however it is thought that the observed effects may be related to a neuroplastic reorganisation of sacral spinal reflexes and regulation of cortical excitability (138, 139).

Percutaneous TNS is performed as an outpatient procedure. It involves inserting a 34-gauge needle 3–5 cm cephalad to the medial malleolus. The needle is connected to a low-voltage stimulator device, and a grounding pad is placed on the bottom of the foot just below the smallest toe. Transcutaneous TNS may be delivered either in clinic or self-administered at home. Self-adhesive electrodes are placed behind the medial malleolus and 10cm proximal to this. The positive lead is connected to the proximal electrode and the negative to the distal electrode, and both are connected to a portable battery-powered stimulator. The intensity level of the stimulation current for percutaneous TNS and transcutaneous TNS is determined once correct positioning has been established by noting sensory and motor (hallux) reaction (Figure 4).

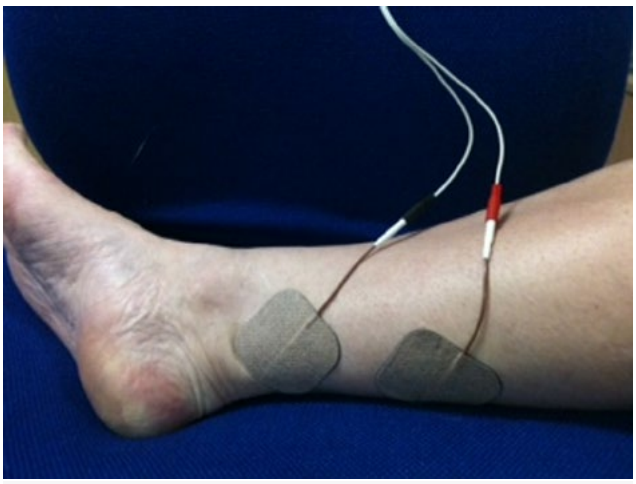

Figure 4. PTNS equipment

This section presents the updated evidence for the use of TNS in the prevention and treatment of UI in women. Date restrictions between Sep 2015 and December 2020 have been applied to the literature search and abstract-only reports have not been included.

Questions addressed are:
- Is TNS effective in the prevention of UI?
- Is TNS better than no active treatment (placebo, sham, control, or no treatment) for treatment of UI?
- Is one type of TNS better than another in the treatment of UI?
- Is TNS better than other treatments in the treatment of UI?
- Does the addition of TNS to other treatments add any benefit in the treatment of UI?
- What is the effect of TNS on other LUTS?
- What factors might affect the outcome of TNS in the treatment of UI?

Eligible interventions were TNS/neurostimulation/ neuromodulation, percutaneous or transcutaneous. Eligibility criteria for study participants and outcomes, as well as criteria used to assess 'ROB' in the included studies, were identical to those used in the previous section.

Evidence overview

A total of 17 new studies were eligible to add to the 11 studies in the 6th ICI, when TNS was first reported. Of these new studies 10 involved Transcutaneous TNS only (113-115, 140-146), 4 included Percutaneous TNS only (111, 147-149) and 3 compared Transcutaneous TNS and Percutaneous TNS. Two studies compared TNS with no active treatment (141, 146), both of which assessed transcutaneous TNS; four studies considered whether one type of TNS is better than another for UI and OAB treatment (141, 150-152); nine studies compared TNS with other treatments for UI (111, 114, 115, 142, 144, 147-150); five studies assessed the effects of adding TNS to another treatment for UI in women. No pooling of data was possible due to the heterogeneity in the interventions, comparators and outcome measures used.

The stimulation parameters for the new studies are summarised in Table 25. Treatment programmes for percutaneous TNS were similar across the studies, using the same stimulation frequency and intensity range for 30 minutes sessions, once weekly over a 12-week period. Transcutaneous TNS involved more varied treatment programmes with frequencies of 10-20Hz, stimulation intensity ranging from 10-50mA and a variety of delivery programmes ranging from 8 to 36 stimulation sessions delivered between 4- and 12-week periods.

Table 25. Summary of TNS protocols

Author, year	Type of TNS and current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration	Number stimulation sessions (total)	Target UI
Abdulseoud (2018) (140)	TTNS NR	amplitude adjusted below patient's discomfort threshold.	250 micro-seconds	10	NR	Above and behind medial malleolus and other 10 cm cephalad	30 minutes, 8 weeks	24	OAB
Ahmed (2020) (150)	PTNS TTNS NR	PTNS: 0.5 – 9mA; adjusted in accordance to patient's tolerance TTNS: 10 – 50mA; according to sensitivity and hallux mobilisation	200 micro-seconds both	PTNS 20 TTNS 10	NR	PTNS: One 34gauge needle electrode, 4-5cm cephalad to medial malleolus. One surface electrode on the medial aspect of the calcaneus TTNS: Negative surface electrode placed behind medial malleolus and positive electrode placed 10cm above it	30 minutes, 3 times weekly, 12 weeks	36	OAB
Alve (2020) (141)	TTNS NR	Group 1: current maintained at sensory threshold (tingling sensation, but without any toe flexion /hallux) Group 2: current maintained at motor threshold (visualization of hallux flexion).	200 micro-seconds both -	10	NR	An electrode was fixed and positioned 10 cm above the medial malleolus, medial to the tibia, and the other electrode was movable and positioned posterior to the medial malleolus, and could follow the path of the tibial nerve.	30 minutes, 2 times weekly, 4 weeks	8	OAB older women
Aya-la-Quispe (2020) (151)	TTNS PTNS NR	TTNS: according to sensation in foot and hallux mobilisation PTNS: 0.5 – 8mA; adjusted in accordance to patient's tolerance	200 micro-seconds both	10	NR	TTNS: calcaneus (ground electrode) and other electrode to 5 cm above medial malleolus 1.5 cm posterior to tibia. Connected to stimulus BioTENS voltage meter. PTNS: surface electrode on calcaneus (ground electrode), needle inserted percutaneous 34 gauge to 5 cm above medial malleolus 1.5 cm posterior to tibia. Needle connected to BioTENS voltage meter.	20 minutes, once weekly, 12 weeks	12	Non-neurogenic, idiopathic OAB
Giarreta (2021) (113)	TTNS Continuous	highest intensity tolerated without reaching the motor threshold	200 micro-seconds	10	NR	One electrode placed inferior edge of medial malleolus, second electrode placed along tibial nerve path, 10 cm above the first.	30 minutes Once weekly 12 weeks	12	UUI SUI
Boaretto (2019) (142)	TTNS NR	According to patient threshold, below the motor threshold: range 10 - 25mA	200 micro-seconds	10	NR	Electrode placed between the medial malleolus and the Achilles tendon. Other placed 10cm above	30 minutes 2 times weekly 6 weeks	12	OAB UUI

Author, year	Type of TNS and current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration	Number stimulation sessions (total)	Target UI
Bykoviene (2018) (143)	TTNS NR	Adjusted to highest level tolerated (10 – 50 mA) without pain/discomfort	300 micro-seconds	10	10sec work 15 sec rest ramp up 3 sec ramp down 2 sec	Both legs. Electrodes (5 x 5 cm) placed behind medial malleolus (negative) and 10 cm above the first one (positive).	30 minutes3 times weekly 6 weeks	18	UI OAB
Jacomo (2020) (114)	TTNS Biphasic	Adjusted below the motor response	200 micro-seconds	10	NR	One surface electrode placed below the left medial malleolus, second electrode placed 5 cm above the first.	30 minutes 2 times weekly 4 weeks	8	OAB
Kızılyel (2015) (147)	PTNS NR	Adjusted according to flexion of the big toe (0-10 mA).	200 micro-seconds	20	NR	34-gauge needle insert 5 cm above to either the right or left malleolus, the surface electrode was placed medial surface of the ipsilateral calcaneus.	30 minutes, Once weekly	12	OAB
Mallmann (2020) (115)	TTNS NR	Adjusted to maximum tolerable threshold	300 micro-seconds	20	NR	Neoprene anklet with embedded electrodes applied to tibial nerve path. Conducting gel used.	20 minutes 3 times weekly 6 weeks	18	OAB UUI MUI
Manríquez (2016) (144)	TTNS NR	Adjusted by patients each time they achieved motor response (plantar flexion of the big toe and/or toe fanning)	NR	20	NR	NR	30 minutes 2 times weekly 12 weeks	24	OAB
Martin-Garcia (2019) (152)	PTNS TTNS Continuous	TTNS: Adjusted avoiding flexion of the big toe or fanning or other toes PTNS: Adjusted according to flexion of the big toe or fanning of all toes, or tingling sensation in the sole of the foot, maximum tolerable level (0.1 – 20 mA)	200 micro-seconds	20	NR	TTNS: Bilaterally. Surface round electrodes, one placed 3 finger-breaths above the medial malleolus and the other medial surface of the ipsilateral calcaneus. PTNS: Bilaterally, 34-gauge needle insert 3 finger-breaths above the medial malleolus and posterior to the medial border of the tibia, the surface self-adhesive electrode was placed medial surface of the ipsilateral calcaneus.	TTNS 30 minutes, 3 times weekly 6 months. PTNS 30 minutes 4 weekly 6 months	TTNS > 78 PTNS: 6	OAB
Schreiner (2021) (145)	TTNS Continuous	According to the sensitivity and mobilization of the patient's hallux (10-50 mA)	200 micro-seconds	10	NR	Unilateral. Negative electrode was placed on the medial malleolus of the right ankle, and the positive electrode 10 cm proximal to the other	30 minutes Once weekly 12 weeks	12	UI
Ugurlucan (2013) (148)	PTNS NR	According to flexion of the great toe or fanning of the toes and a tingling sensation and adjusted to pain threshold	200 micro-seconds	20	NR	34-gauge needle insert 3-4 cm above the medial malleolus between the posterior margin of the tibia and soleus muscle.	30 minutes, Once weekly 12 weeks	12	OAB

Author, year	Type of TNS and current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration	Number stimulation sessions (total)	Target UI
Vecchiolo-Scaldazza (2017) (111)	PTNS NR	NR	NR	NR	NR	NR	30 minutes, 2 times weekly 6 weeks	12	OAB
Vecchi-olo-Scaldaz-za (2018) (149)	PTNS NR	According to patient's sensory and motor response 0.5 – 9 mA	NR	20	NR	34-gauge needle insert 6-8 cm above to the medial malleolus and slightly posterior to the tibia	30 minutes once weekly 8-12 weeks	12	OAB
Welk (2020) (146)	TTNS NR	Patient was instructed to titrate the amplitude of the current to their maximum non-painful tolerance or toe twitch	200 micro-seconds	10	NR	Skin surface electrodes posterior and 5-10 cm above the medial malleolus of the same leg behind the medial tibial edge	30 minutes, 3 times weekly 12 weeks	36	OAB

Abbreviations: NR: not reported; TTNS: Transcutaneous tibial nerve stimulation; PTNS: Percutaneous tibial nerve stimulation; OAB: Overactive bladder; UUI: urge urinary incontinence; SUI: stress urinary incontinence; UI: urinary incontinence; MUI: mixed urinary incontinence

6.1. Prevention

No studies that investigated either primary or secondary prevention of UI or LUTS were identified.

6.2. Treatment

6.2.1. Is TNS better than no active treatment (placebo, sham, control, or no treatment) for treatment of UI?

Two new studies compared transcutaneous TNS with no active treatment (Table 26) (141, 146). Both studies included women with OAB where some but not all participants had UI. In one study (141) the participants were older women aged 60 years and over.

In one study, outcomes from participants in a sensory-threshold group and those in a motor-threshold group were compared with no stimulation (141). A sham procedure was employed as a comparator in the other study (146). The sham procedure was described as having electrodes placed on the lateral side of the lower leg and using a frequency of 10Hz and a pulse width of 200microseconds, increased in intensity until they could feel a tingling sensation.

Quality of data

Both studies described using computer generated randomisation and allocation concealment but neither study reported the method of allocation concealment. Blinding of assessors was confirmed in both studies. Results were reported for everyone who entered the trial in one study (146), and the other study (141) reported attrition of 6/39 from the sensory-threshold group, 3/33 from the motor-threshold group and 4/29 from the no intervention control group. The reasons for drop out from each group were unrelated to the treatment. Sample size calculations were provided in both studies. Analysis was by ITT in one (146) and per protocol in the other (141). Adverse events were 'almost nil' in one study (141) and no adverse effects were reported in the other (146). Overall, ROB was assessed as high for both studies.

Results

(a) UUI. Neither included study reported information on cure rates. In one study (141) UUI episodes and ICIQ-OAB improved statistically significantly in both the sensory-threshold and the motor-threshold groups compared with no active treatment. No difference in 24-hour pad weights was found between the transcutaneous TNS group and sham group in the other study (146). Reported degree of discomfort associated with UUI was statistically significantly reduced in both groups in one study (141). No serious adverse effects were reported in either group.

(b) DO/OAB. There was no information on cure rates. In one study (141) urinary frequency, urgency, nocturia were statistically significantly improved in both the sensory-threshold and the motor-threshold groups compared with no active treatment. No difference in Patient Perception of Bladder Condition or frequency was found between the transcutaneous TNS

group and sham group in the other study (146). Reported degree of discomfort associated with UUI was statistically significantly reduced in both groups in one study (141).

Summary

A total of five studies assessed the effects of TNS compared with no active treatment. One study investigated percutaneous TNS, and four studies investigated transcutaneous TNS. Four studies were small (20-43 participants), and one had 101 participants. Four were generally assessed as having a high ROB and one had a low ROB but was small and underpowered. Data pooling was not possible.

Data available from three studies on women with UUI or OAB suggests TNS may be more effective than no active treatment in improving symptoms and quality of life, although no data were available on cure. **(Level of evidence: 2)**

The included studies reported no serious adverse effects associated with either active or sham treatment. **(Level of evidence: 2)**

No evidence was available for women with SUI or predominant SUI.

Recommendations

For women with UUI or OAB, TNS could be considered as its use may be more effective than no active treatment in symptom control. **(Grade of recommendation: C)**

More studies with larger sample sizes and consistent and clear reporting of core outcomes would be beneficial in reaching a conclusion on the effectiveness of TNS over no active treatment.

6.2.2. Is one type of TNS better than another in the treatment of UI?

Four studies compared types of TNS. Transcutaneous TNS and percutaneous TNS were compared in three studies (150-152) and one study compared transcutaneous TNS delivered at two different stimulation intensities – sensory threshold and motor threshold (141) (Table 27). Two studies investigated TNS as a primary intervention for UUI (141, 151) and one investigated effectiveness of transcutaneous TNS compared to percutaneous TNS for maintenance of symptom improvement in responders to percutaneous TNS (152)lectronic-resource-num></record></Cite></EndNote>A. A further study compared transcutaneous TNS and percutaneous TNS added to drug therapy for reducing severity of overactive bladder symptoms in post-menopausal women (150).

Quality of data

Computerised randomisation was used in two studies (141, 151) and sealed envelopes in two (141, 152). Adequate allocation concealment was reported in one study (152) and was unclear in the other three (141, 150, 151). Two studies (150, 151) did not report blinding of assessors however assessor blinding was reported by two (141, 152). One study reported ITT analysis (152), one a per protocol analysis (141); the type of analysis was not reported in two (150, 151). There was no attrition in two trials (150, 152) and no apparent inequality in loss to follow-up across the groups in one study (141), where attrition of 15% in the transcutaneous TNS sensory-threshold group, 9% in the motor-threshold group and 14% in the control group were reported, but reasons were not given. Ayala-Quispe (2020) (151) did not report on follow-up. Adverse events were 'almost nil' in both sensory and motor thresholds in one study of transcutaneous TNS (141). No adverse effects associated with transcutaneous TNS were reported for three studies (150-152) but two studies reported minor discomfort with percutaneous TNS (151, 152) and bleeding at the needle site was reported by one (152). Power calculations were reported for two studies (141, 152). Overall ROB was low in two trials (141, 152) and high in two studies (150, 151).

Results

a) UUI: No included studies reported information on cure rates. Two studies (141, 151) reported statistically significant reductions in UUI episodes. One with transcutaneous TNS at both sensory-threshold and motor-threshold compared to no treatment (p=0.0001) (141) and one with transcutaneous TNS and percutaneous TNS compared to baseline (p=0.0001) (151). Two studies found no statistically significant difference between effectiveness of transcutaneous TNS and percutaneous TNS for treating UUI at 12 weeks (p=0.968) (151) or for maintaining outcomes over a 6-month period (p=0.755) (152). One study found no statistical difference between two stimulation intensities of transcutaneous TNS at 5 weeks (p= 0.139) (141).

b) OAB: No included studies reported information on cure rates. Two studies (150, 151) reported statistically significant reductions in OAB symptoms with both transcutaneous TNS and percutaneous TNS compared to baseline (p<0.0001, (150); p=0,0001, (151)). One study reported statistically significant reductions in OAB symptoms with transcutaneous TNS delivered at both sensory and motor thresholds compared to no treatment (p=0.0001) (141). Two studies found no statistically significant difference between effectiveness of transcutaneous TNS and percutaneous TNS for treating OAB symptoms at 12 weeks (p=0.947, (150); p=0.968; p=0.436, (151)) or for maintaining outcomes over a 6-month period (p=0.160) (152). One study found no difference between effectiveness of sensory and motor thresholds of transcutaneous TNS for treating OAB symptoms at 5 weeks (frequency p=0.186, urgency p=0.375, nocturia p=0.415, (141)). No difference in quality of life improvement was found between the two types of TNS in two studies (p=0.577, (150); p=0.088, (151)).

Summary

Four small studies (24-72 participants) assessed different types of TNS and three had a high ROB. Three assessed the effects of transcutaneous TNS compared to percutaneous TNS and reported no difference between percutaneous TNS and transcutaneous TNS in effectiveness for treatment of urgency UI or OAB symptoms. **(Level of evidence: 2)**

Two studies reported no differences in QoL improvements between transcutaneous TNS and percutaneous TNS.

Overall data available from three studies on women with UUI or OAB suggests transcutaneous TNS and percutaneous TNS are equally effective in improving symptoms and quality of life, although no data were available on cure. **(Level of evidence: 2)**

One study compared two different intensities of transcutaneous TNS and found both were effective in treating urgency UI and OAB symptoms in women.

Two studies reported minor adverse effects associated with percutaneous TNS. No adverse effects associated with transcutaneous TNS were reported by three studies. (**Level of evidence: 2)**

Recommendation

For women with urgency UI or OAB, transcutaneous and percutaneous TNS could be recommended as each is equally effective treatments. Transcutaneous TNS is associated with fewer adverse effects. **(Grade of recommendation: C)**

More studies with larger sample sizes and consistent and clear reporting of core outcomes would be beneficial in reaching a conclusion on the effectiveness of transcutaneous TNS compared with percutaneous TNS.

6.2.3. Is TNS better than other treatments for treatment of UI?

Nine new studies compared TNS with another treatment (111, 114, 115, 142, 144, 147-150) (Table 28). Four studies assessed transcutaneous TNS (114, 115, 142, 144), four assessed percutaneous TNS (111, 147-149) and one compared both transcutaneous TNS and percutaneous TNS with another treatment (150). In five studies the other treatment was an antimuscarinic drug: oxybutynin (142, 144, 150), solifenacin (149), tolterodine (147). In three studies TNS was compared with another type of EStim: transvaginal Estim (148); parasacral transcutaneous electrical stimulation (114, 115) and in one study percutaneous TNS was compared with transvaginal EStim and PFMT (111). The target population had OAB (with UI in some but not all of the participants) except for one study (142) where the participants all had UUI. One study was focused on OAB symptoms (150). No study on SUI or predominant SUI was found. Six studies were two arm randomised trial designs and three were three-arm trials comparing percutaneous TNS vs tolterodine vs percutaneous TNS and tolterodine (147); percutaneous TNS vs solifenacin vs percutaneous TNS and solifenacin (149); or transcutaneous TNS vs oxybutynin vs PFMT (142). The findings for TNS versus a single other treatment are reported here.

Quality of data

Computerised randomisation was used in five studies (111, 114, 115, 148, 149), sealed envelopes in one (150) and method of randomisation was not reported in three studies (142, 144, 147). Adequate allocation concealment was reported in four studies (111, 114, 149, 150) and was unclear in the other five (115, 142, 144, 147, 148). Blinding of participants and/or intervention providers was not reported by any study as this is not possible for the type of physical interventions under investigation. However, assessor blinding was only reported in three studies, by two investigators (111, 114, 149). One study reported a per protocol analysis (114) and in all others type of analysis undertaken was not reported. Attrition rates were provided in five studies (114, 115, 144, 148, 149). Attrition in three studies comparing TNS with another form of EStim (114, 115, 148) showed similar losses of 14% in one

(114) due to participant travel difficulties; greater loss to follow up in the parasacral transcutaneous electrical stimulation group of 16% compared with no loss in the TNS group (115) and twice the attrition in the TNS group compared to the transvaginal EStim group in one study (148) but no reasons were provided for loss in either study. No loss to follow-up was reported in three studies (111, 147, 150) and no information was provided on attrition by one study (142). Two studies comparing TNS with antimuscarinic drug treatment provided information on attrition, both showing higher attrition in the groups receiving the drugs. Attrition of 23% was found in the group taking solifenacin compared to 3% in those receiving percutaneous TNS in one study (149) due to side effects of dry mouth and constipation. Similar side effects were the reasons provided for attrition in another study where 12% of the drug group were lost to follow up compared to 6% of the transcutaneous TNS group (144). No other adverse effects were noted in the seven studies that reported them (111, 114, 115, 142, 144, 147, 149). Power calculations were reported for three studies (114, 115, 144). Overall, ROB was high in eight trials (111, 115, 142, 144, 147-150) and low in one study (114).

Results

(a) UUI. One study reported information on cure rates. Significantly more women receiving transvaginal EStim reported they were cured compared to those receiving percutaneous TNS (148) (p=0.08) however the study was underpowered with a high ROB and disproportionate attrition of 23% in those receiving percutaneous TNS compared to 8% in the transvaginal EStim group, with no reasons provided. The interventions differed in terms of number of stimulation sessions: 18-24 transvaginal EStim group compared with 12 in the percutaneous TNS group.

Improvements in UUI episodes were reported in seven trials (111, 114, 115, 142, 144, 147-149). Four studies compared TNS with a drug treatment (136, 142, 144, 149) and reported outcomes for UUI. In three studies outcomes were based on bladder diaries (142, 144, 147) and in one the OABSS (149). In all four studies (144, 147, 149) UUI episodes were statistically significantly decreased in the TNS group and three studies also reported statistically significant reductions in the antimuscarinic drug groups (144, 147, 149). One study reported statistically significantly better reduction in UUI episodes using percutaneous TNS compared to tolterodine (147) and one 3-arm study (142) reported statistically significantly better reductions in UUI episodes with transcutaneous TNS compared to oxybutynin and also with transcutaneous TNS compared to PFMT. For the four studies comparing TNS and other forms of EStim (111, 114, 115, 148) three reported UUI based on bladder diaries (111, 114, 148). Two reported statistically significant reductions in UUI episodes with both types of EStim (114, 148) and no between group differences in effectiveness. One study (111) showed statistically significant reductions in the number of UUI episodes following a course of percutaneous TNS but not with transvaginal EStim combined with PFMT. In one study (115) there was no difference between transcutaneous TNS and parasacral transcutaneous electrical stimulation in improvements in the proportions of categories in the Incontinence Severity Index (p=0.307).

Quality of life outcomes were reported by five trials (115, 142, 147-149) and in all, QoL was statistically significantly improved with TNS. Three studies reported no statistically significant difference between the groups, based on KHQ in two studies (115, 148) and the PGI-I at 3 months (post-treatment) in one study (149). However, in one study (147) a statistically significant difference in the IIQ-7 at three months was reported between the groups in favour of percutaneous TNS and in another (149) at 10 months' follow-up, where the PGI-I was statistically significantly better in the percutaneous TNS group than the solifenacin group. One study (142) reported statistically significantly improved quality of life in the TNS, PFMT and oxybutynin groups based on the Overactive Bladder-V8 (OAB-V8) but did not compare them.

(b) OAB: In one study (142) 32% participants reported their urgency to be cured following 12 sessions of transcutaneous TNS. An equal number reported cure with a 12 sessions programme of PFMT. Improvements in OAB symptoms after TNS interventions were reported by five studies based on bladder diary information: five studies reported statistically significant improvements in urinary frequency (111, 142, 144, 147, 149); four studies reported statistically significant improvements in urgency (111, 114, 144, 149), five studies reported statistically significant improvements in nocturia (111, 114, 142, 147, 149).

Quality of life outcomes were reported in four studies based on the Overactive Bladder Questionnaire (OABq). Statistically significant improvements with both percutaneous and transcutaneous TNS added to oxybutynin compared to oxybutynin alone were reported (150); and with percutaneous TNS compared with transvaginal EStim and PFMT (111) and transcutaneous TNS compared with extended release oxybutynin (144). No difference between the groups was found in two studies (149, 150). Statistically significantly improved scores on the OAB-V8 with transcutaneous TNS compared to parasacral stimulation were found in one study (115).

Summary

Nine new studies were included bringing the total to fourteen comparing TNS with another treatment. These were small (20-70 participants) and generally assessed as having a high ROB. There were limited and widely heterogeneous data reporting mainly short-term outcomes with minimal long-term follow up. Data pooling was not possible.

Comparing TNS with drug treatment, three studies reported TNS to be as effective as drug treatment and one study reported transcutaneous TNS to be better than drug treatment for treating urgency UI in the short-term. **(Level of evidence: 2)**

Two studies reported that quality of life improved at three months with both TNS and drug treatment, with no significant difference between them, but in one of the studies only the percutaneous TNS group maintained improved quality of life at 10 months follow up. One study reported that quality of life improved more in the percutaneous TNS group. **(Level of evidence: 2)**

When comparing TNS with other non-drug treatments for urgency UI, two studies reported TNS to be statistically significantly better than the other treatment (parasacral EStim; transvaginal EStim plus PFMT) and two studies reported TNS to be as effective as other forms of ES. **(Level of evidence: 2)**

For reducing severity of OAB symptoms TNS was statistically significantly better than drug treatment in two studies and it was as effective as drug treatment for reducing symptoms of frequency (three studies), urgency (two studies) and nocturia (one study)**. (Level of evidence: 2)**

TNS was better at reducing overall OAB symptom severity compared with other-non-drug treatment (parasacral EStim; transvaginal EStim plus PFMT) in two studies. Urgency, nocturia and frequency improved significantly with TNS in two studies compared to another non-drug treatment. **(Level of evidence: 2)**

.

6.2.4. Does the addition of TNS to other treatments add any benefit in the treatment of UI?

Six new studies assessed the effect of TNS as an adjunct to another treatment, compared with the other treatment alone or with percutaneous TNS alone (113, 140, 143, 145, 147, 149) (Table 29). Four studies involved transcutaneous TNS (113, 140, 143, 145) and two percutaneous TNS (147, 149). For the transcutaneous TNS studies one compared the effects in women with OAB (where some but not all participants had UI) of combining transcutaneous TNS with transvaginal EStim versus transcutaneous TNS alone (113); one compared transcutaneous TNS combined with daily trospium versus transcutaneous TNS alone in women with OAB (140); one compared transcutaneous TNS combined with lifestyle changes and PFMT versus lifestyle changes and PFMT alone in women with OAB (143) and one compared transcutaneous TNS combined with BT and PFMT versus BT and PFMT alone in older women with UUI (145). Both percutaneous TNS studies were three-arm trials comparing percutaneous TNS combined with an antimuscarinic drug (tolterodine, solifenacin) versus percutaneous TNS or drug alone in women with OAB (147, 149). The results for percutaneous TNS plus drug versus percutaneous TNS alone or drug alone are reported here. No study focusing on SUI or predominant SUI was found.

Quality of data

Computerised randomisation was used in four studies (113, 143, 145, 149) and sealed envelopes in one (140). Adequate allocation concealment was reported in three studies (113, 140, 149) and was unclear in the other three (143, 145, 147). Two studies (143, 147) did not report blinding of assessors however assessor blinding was reported by four (113, 140, 145, 149). Two studies reported ITT analysis (113, 145), one reported a per protocol analysis (143); the type of analysis was not reported in three (140, 147, 149). There was no attrition reported in three trials (140, 145, 147). Attrition of 23% due to adverse effects of the antimuscarinic drug solifenacin was reported in one trial (149) compared to 6% in the combined solifenacin and percutaneous TNS group. In one trial (113) 9% of transcutaneous TNS group participants were lost to follow-up for 'personal reasons' compared to 26% of the transvaginal EStim plus transcutaneous TNS group participants, where reasons for drop out given were: 4 women did not agree with the use of the vaginal electrode, 7 women found the transvaginal EStim uncomfortable and 4 left for personal reasons. In one study (143) attrition of 17% in the PFMT group and 10% in the PFMT plus transcutaneous TNS group occurred due to time needed to attend appointments (2 in each group) and exacerbation of comorbidities (2 in PFMT group). No adverse effects associated with transcutaneous TNS were reported for five studies (113, 140, 143, 147, 149) but one study (145) reported minor discomfort at electrode placement site in three participants. Power calculations were reported for four studies (113, 140, 143, 145). Overall ROB was assessed as low in one study (113) and high in five studies (140, 143, 145, 147, 149).

Results

a) UUI. No information was available on cure rates.

Significant improvements in UUI episodes were reported in four trials (113, 145, 147, 149) by bladder diary (113, 145, 147) or patient reported symptom score (OABSS) (149). Both of the studies comparing percutaneous TNS combined with an antimuscarinic drug (147, 149) found statistically significant improvements in UUI over percutaneous TNS alone (147, 149) or the drug alone (149). One study (113) reported statistically significant reductions in UUI episodes with transcutaneous TNS alone and when combined with vaginal EStim no additional benefits were conferred. One study (145) reported that improvement rates were statistically significantly higher for the group combining transcutaneous TNS with PFMT and BT, compared with PFMT and BT alone at 16 weeks. ICIQ-SF scores improved for both groups of older women, but the combination treatment group had a statistically significantly greater improvement and their satisfaction with transcutaneous TNS treatment was maintained for 12 months in 80.5%.

Quality of life outcomes were reported by four trials (113, 145, 147, 149) using the KHQ (113, 145, 147) and PGII (149). In all studies quality of life was statistically significantly improved by treatments assessed. In two studies (113, 147) there was no difference reported in quality of life with the addition of vaginal EStim (113) or tolterodine (147) but in one study (145) the combination treatment group of transcutaneous TNS added to PFMT and BT showed a statistically significantly greater improvement. In one study (149) the Global Impression of Improvement was statistically significantly greater in the combined drug and percutaneous TNS group at three months and sustained over the 10 month follow up period.

b) OAB. No information was available on cure.

Statistically significant improvements in urinary frequency with both TNS alone and TNS added to other treatments were reported by all six studies (113, 140, 143, 145, 147, 149). Differences between the groups were reported in four studies (113, 140, 147, 149) in favour of TNS alone (113, 147) or when combined with another treatment: PFMT and BT (145) or antimuscarinic drug (149). Improvements in urgency were reported by three studies (113, 143, 149) with two studies reporting no difference between the treatments (113, 143) and one study (149) reporting statistically significant differences in favour of the combined treatment for both the drug versus the percutaneous TNS and drug combined and also percutaneous TNS versus percutaneous TNS and drug combined. Four studies reported statistically significant improvement in nocturia. Three studies (113, 147, 149) reported no difference between the groups and one study (145) reported statistically significantly reduced nocturia frequency in the transcutaneous TNS added to PFMT and BT group.

Quality of life was reported by two studies using the IIQ (140) and the Overactive Bladder Questionnaire-Short Form (149). Both reported statistically significant improvements in quality of life with TNS treatment alone and TNS combined with drug treatment (trospium – (140), or solifenacin – (149)) but the improvements were statistically significantly better with the combination treatment.

Summary

Six small studies were included (20-106 participants) bringing the total to nine assessing the addition of TNS to another treatment. All except one study was assessed as having a high ROB. There were limited and widely heterogeneous data reporting mainly short-term outcomes with minimal long-term follow up. Data pooling was not possible.

Three studies reported that TNS successfully improved OAB symptoms/urgency UI and quality of life in women with OAB, but outcomes were better if TNS was added to an antimuscarinic drug treatment. This effect was sustained for a longer term (10 months) for the treatment with TNS than the treatment without TNS. **(Level of evidence: 2)**

Data from one study suggested that the addition of transcutaneous TNS to PFMT and BT was more effective in improving OAB symptoms/urgency UI and quality of life than PFMT and BT alone, in older women with UUI. The improvements were

sustained for 12 months in those older women who responded to the initial combined treatment. **(Level of evidence: 2)**

One study showed the success of transcutaneous TNS as a single therapy and no additional benefit from adding transvaginal ES for OAB symptoms/urgency UI and quality of life. **(Level of evidence: 2)**

Adverse events from TNS are uncommon.

Recommendations

Transcutaneous TNS or percutaneous TNS can be considered for symptom control in combination with other effective treatments by women with urgency UI or OAB. **(Grade of recommendation: B New)**

This recommendation should be viewed with caution until the findings are supported or refuted in further trials with large sample sizes and clear and consistent reporting of core outcome data.

Other LUTS
No trials were identified that analysed the effect of TNS in women with other LUTS alone, e.g., frequency of voiding, urgency and/or nocturia.

Factors Affecting Outcome
The included studies did not address factors that could potentially affect the response to treatment with TNS. A greater discussion of these factors is provided in the section on UI in men and women (see section V.1.4).

7. SCHEDULED VOIDING REGIMENS

This section examines the evidence on use of scheduled voiding regimens in cognitively intact, non-institutionalised women with UUI, SUI and MUI, and provides recommendations for their use in clinical practice. The chapters on frail older adults (Chapter 14) provides a detailed review of regimens that are used in people living with frailty or cognitive impairment. Trials involving women with OAB-wet or dry are included when UI-specific outcomes are reported. Outcomes that are not specific to UI (i.e., frequency, or OAB-specific symptoms or QoL validated questionnaires) are reported separately (section II.7.3. Other LUTS).

Scheduled voiding regimes have been categorized as: bladder training (BT), timed voiding, habit training, and prompted voiding (1). Habit training and prompted voiding are usually implemented by caregivers in institutional settings with cognitively and/or physically impaired adults, therefore this section focus on the use of BT and timed voiding, though most of the evidence available for the target population pertains to the effects of BT.

BT is also referred to as bladder drill, bladder discipline, bladder re-education, and bladder re-training. The intervention targets people with OAB or UUI, who do not suffer from significant cognitive or physical impairment. Its goal is to support lifestyle and behavioural changes to regain bladder control through education, progressively increasing voiding intervals using urgency suppression techniques and positive reinforcement (153). Specific goals of BT are to: 1) correct faulty habit patterns of frequent urination (if present), 3) improve control over bladder urgency, and 2) restore patient confidence in controlling bladder function. The underlying mechanism of how BT achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from improved individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the “reserve capacity” of the lower urinary tract system (154-156).

Timed voiding is a passive toileting assistance programme, initiated and maintained by caregivers for patients who cannot participate in independent toileting (1). It is a fixed voiding schedule that remains unchanged over the course of treatment (157). The goal is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity.

Questions addressed in this section include:
- Can scheduled voiding regimens prevent UI?
- What is the most appropriate BT protocol for treating UI?
- Is BT better than no treatment, placebo, or control treatments for UI?
- Is BT better than other treatments for UI?
- Does the addition of another treatment to BT add any benefit for treating UI?
- Does the addition of BT to other treatments add any benefit for treating UI?
- Is timed voiding effective for treating UI?
- What is the effect of BT on other LUTS?
- What factors might affect the outcome of BT?

7.1. Prevention
No trials which examined scheduled voiding regimens as a sole intervention in the prevention of UI were found.

7.2. Treatment
Previous recommendations related to BT as a treatment for UI were based on reviews of individual published trials (92, 158-161) and three systematic reviews that provided descriptive syntheses with evidence grading (162-164). In this ICI, two new trials (94, 165) and one long-term follow-up of an existing trial (90) were identified and are described below. See Table 30.

7.2.1. What is the most appropriate bladder training (BT) protocol?
Previously, no trials that compared two or more methods of BT were identified. In this update, one trial comparing individual to group BT (165) was found.

Quality of data
In a non-blinded trial by Hulbæk *et al.* (165), 91 women were randomised to group or individual BT and followed-up for two months. A power calculation and adequate random allocation/concealment were reported. This was an open label trial, therefore both outcome assessor and participants were aware of treatment allocation. ITT analysis was used. Loss to follow-up was low and balanced between groups, with reasons unrelated to treatment. Side effects were minor and temporary (more frequent voiding treated by the general practitioner with antibiotics, n= 1). Overall, this trial was at low to moderate ROB.

Group treatment (three to four patients per group) followed the same protocol as individual treatment. In both settings, BT was performed daily for a two-month period supported by a diary, in addition to three training sessions at the hospital coached by a continence nurse.

Results

The number of UUI episodes was reduced after two months of individual or group BT, but there was no significant between group difference (mean difference, final-baseline: 1.8 [−5.2; 8.8], p=0.6 for group and −0.6 [−1.7; 0.6], p=0.3 for individual treatment). Furthermore, groups did not differ at the follow-up. Other outcomes were related to OAB symptoms and are reported bellow (section II.7.3. Other LUTS); they were also no different within or between groups.

Considering the lack of trials comparing two or more BT approaches, a content analysis was performed looking at the protocols used in all trials investigating effects of BT (not only those comparing different BT protocols). Twenty-four trials on BT involving a total of 3,355 women were identified, including two trials involving 161 women added since the last update (94, 165). Several of the trials previously reviewed (159, 160, 166-171) provided minimal or no details regarding the specific BT protocol used. Both newly included trials are more specific regarding the intervention description (94, 165). In this review of BT protocols, information from the two new studies is added to and integrated with previous information.

All protocols involved some type of patient education, namely:

- Brief verbal (167, 168) or written instructions (172, 173)
- Verbal, written and audio-visual instruction (94, 154, 156, 165, 174)
- Introduction to an individual who successfully completed BT (169)

If specified, education was provided by nurses (154, 156, 165, 166, 171, 175, 176), general practitioners (177), or physiotherapists (92, 158, 161).

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant's voiding pattern or 30 minutes beyond the participant's average (172, 178) or longest (158) voiding interval.
- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens (169), after 48 hours of dryness (179), every four to five days (178) or weekly if schedule was well-tolerated (154, 156, 158, 165).
- Goals for optimal voiding intervals varied from three to four hours.
- Voiding was 'mandatory' with restriction of voiding in between assigned toileting times even if UI occurred (169), a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable (154, 156, 176), or self-scheduling of voiding with a target goal to reach (172).
- Voids were not scheduled (allowed) during sleeping hours (169); none of the other protocols identified how voids during sleeping hours were handled.

In some protocols, the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation (94, 154, 156, 158, 161, 165, 172, 176) and PFM contraction (94, 154, 158, 165, 166, 173). In other studies, there was encouragement to suppress urgency, but it was not clear what strategies were used (168, 177, 180). Feedback techniques included self-monitoring (94, 154, 156, 165, 167, 170, 176), goal setting with feedback of progress (175), and positive reinforcement (94, 154, 156, 165, 178).

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments (165, 174, 176, 180)
- Fluids allowed up to a certain level (1,500 ml) (179)
- No fluid modifications (154, 156, 158, 172, 177)
- Advice on constipation prevention (165, 176)
- Lifestyle modification (unspecified) (165)

Both inpatient and outpatient BT programmes have been used. Outpatient programmes are more commonly described, and the amount of health professional contact ranged from 20 weekly visits (161), to eight weekly visits (171), six weekly visits (154, 156), three visits every two weeks over six weeks (158, 178), and three visits over two months (165). A "simplified" BT treatment with minimal to no health professional contact (instructions given to patients on a one-page instruction sheet) has also been tested (94, 172, 173).

Considering the overall lack of consistency in BT reports across studies, key recommendations were synthesised to guide healthcare professionals on promoting consistent, cohesive, and achievable BT programmes. These were based on the evidence gathered to date, as well as the new International Continence Society Consensus statement on BT (153), and include:

- Supervision from a healthcare practitioner
- Duration of at least six weeks, varying according to the person's progress and goals
- Regular review and reinforcement (coaching) by the healthcare practitioners
- Follow-up support, in accordance with the person's goals and preferences
- Verbal and written information and education provided by the healthcare practitioner
- Voiding intervals agreed and implemented based on bladder diary and individual goals (usually during waking hours only) that can be standardised or individualised:

  a) If standardised, a fixed (or pre-determined) voiding schedule of half-hourly or hourly voids is implemented for an agreed time period. Once achieved, this schedule is increased by a pre-determined duration of 5, 10, 15 or 30 minutes at each progression point
  b) If tailored, individualised voiding intervals are implemented based on the person's average voiding interval calculated from their voiding diary. Progression time to prolong voiding intervals is negotiated on an individual basis, for example increased by 5, 10, 15, 30 minutes per week

- Urge & urgency suppression or deferment, including relaxation, PFM contraction, distraction techniques, self-motivation using self-affirming statements and application of perineal pressure. When urgency is controlled, the person is encouraged to walk to the toilet at a normal pace

- Active encouragement and support for:
  a) Self-monitoring
  b) Self-determining of progression
  c) Self-affirming strategies

Summary

Key recommendations on BT implementation and reporting were synthetised from the evidence available to date and the new Consensus statement on BT (153). **(Level of evidence: 2)**

Recommendations

Clinicians should provide the most intensive BT supervision possible within service constraints. **(Grade of recommendation: D)**

Clinicians and researchers are advised to follow the evidence based recommendations and the latest consensus statement on BT (153).

The ICS consensus statement and review papers on adherence and PFMT could be useful to clinicians and researchers (22-25).

Several areas could be investigated in future trials, including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

7.2.3. Is BT better than no treatment, placebo, or control treatments?

As a sole therapy, BT has been used in the treatment of OAB, urodynamic SUI, MUI, UUI and UUI in the absence of DO.

No new trials were identified that addressed this question. Previously, five RCTs involving 515 women were identified that compared the effect of BT to no treatment or control (156, 170, 171, 176, 177). Out of four trials with relevant analysable data (156, 170, 171, 177), three reported improvements in the BT group compared to the control group (156, 170, 177). The trial quality and detailed results were presented in previous editions of this chapter.

Summary

The few available trials (reviewed previously) were small and of variable quality. No new trials were identified in this update.

There is limited **Level 1** evidence that BT may be an effective treatment for women with UUI, SUI and MUI. **(Level of evidence: 1)**

Recommendations

BT should be recommended as first line conservative therapy for UI in women. **(Grade of recommendation: A)**

Additional high-quality RCTs are needed that examine the effect of BT versus no treatment in treatment of women with UUI, SUI and MUI.

7.2.4. Is BT better than other treatments?

This section considered trials that compared BT alone versus another active therapy.

For the comparison of BT versus PFMT see section II.2.3.3.

The only other comparison for which trials were found was BT versus drug therapy (DT). In total, three small trials were identified that randomised 214 women with UUI to BT or DT (92, 169, 178). This update includes a new study, Azuri *et al.* (90), which presents a four-year follow-up of an RCT that was first published in 2013 (92) comparing BT, PFMT, DT (tolterodine, 4 mg) or combined behavioural therapy (BT and PFMT). Results from the BT and DT group comparison are included here, while results of the BT versus PFMT comparison are included in Section II.2.3.

Quality of data

Kafri *et al.* was a single-blind trial in which 83 women were randomised to DT or BT. Follow-ups took place- over 12 months (92) in the initial study and four years later in Azuri *et al.* (90). A power calculation and adequate random allocation/concealment were reported. The assessor was blinded to the participant's allocation. ITT analysis was used. Drop-out rates were unbalanced and likely related to treatment allocation (DT=36% 15/42 [13 unsatisfied with allocation; one acute back pain and one dizziness]; BT= 5% 2/41 [one medical complication and one no response to treatment]). Side effects were not tracked. After the four-year follow-up, dropout rates were still higher in the DT group (43% versus 15%), but reasons for dropping out or side effects were not reported (90). Overall, ROB was unclear.

Results

In Kafri *et al.* and Azuri *et al.* (90, 92), the number of self-reported UUI episodes per week significantly decreased at three months, 12 months and four years and were equal in the BT and DT groups. Differential dropout suggested DT was associated with more adverse effects, but this was not clearly reported. Similar results were reported in a previously reviewed trial (178), in which no differences in effect between DT and BT were observed in the short term (6 weeks), but DT was associated with higher drop-out rates. Conversely, in the same trial, DT results were not maintained in the long term (6 months) and the authors concluded that DT was not well tolerated and provided only short-term beneficial results while BT was well accepted and provided more persistent results (3 months).

Summary

Despite the additional follow-up of an existing low- to moderate-quality trial, it remains unclear whether BT or DT is more effective in women with OAB or UUI. This result is consistent with the findings of the 2004 Cochrane review (163), which concluded that there was insufficient evidence to determine whether first line therapy should be BT or anticholinergic drugs. Of interest, DT has been consistently associated with higher drop-out rates and adverse events in the long term. **(Level of evidence: 1)**

Recommendations

Either BT or anticholinergic drugs can be recommended to women with OAB or UUI. **(Grade of recommendation: B)**

BT may be the recommendation of choice and preferred by women and clinicians because of the absence of drug related adverse effects. **(Grade of recommendation: D)**

7.2.5. Can any other treatment be added to BT to add benefit?

Trials included here investigated the effects of BT versus BT plus therapy A to address the additive benefit of therapy. One new trial was identified, which tested the additional benefit of biofeedback, EStim or both when added to BT (94).

Quality of data

Firinci *et al.* (94) was an assessor-blinded randomised controlled trial, in which 70 women with OAB symptoms were randomised to either: (1) BT alone, (2) BT added to biofeedback, (3) BT added

to EStim, and (4) BT added to both biofeedback and EStim. The follow-up assessment took place at eight weeks. BT included one 30-minute education session with a physician and a written brochure. Women were taught how to contract their PFMs via vaginal palpation, were encouraged to use urgency suppression strategies (PFM contraction, relaxation and distraction) and follow a timed voiding programme based on their bladder diary. No further details were provided on the BT protocol. Biofeedback treatment included three 20-minute sessions per week. In each session, the participants completed 40 cycles of 10-second contractions followed by 20 seconds of relaxation performed in supine position with the aid of an intravaginal pressure probe. EStim also included three 20-minute sessions per week. The stimulation parameters were frequency at 10 Hz, a 5-10-second work-rest cycle, and a 100 ms pulse width. The symmetric biphasic pulse wave was delivered over a range of 0–100mA, according to the patient's feedback on their level of discomfort.

A power calculation and adequate random allocation were reported. The assessor was blinded to the participant's allocation. ITT analysis was not used. Loss to follow-up was low and balanced between groups, but reasons were unclear (6%, giving up treatment). Side effects were minor and specific to the EStim groups (temporary discomfort due to vaginal irritation [n=3]). Overall, ROB was moderate.

Results

Although inclusion criteria mentioned OAB symptoms only, different UI-specific outcomes were reported, including patient-reported outcomes (UI-specific QoL or impact questionnaires; number of leakages and number of pads used according to a 3-day bladder diary) and clinician reported outcomes (cure and improvement and UI severity, based on a 24-hour pad-test). For all outcomes, the four groups improved compared to baseline. At post-treatment, results favoured the two combined treatment groups including EStim compared to BT alone or BT added to biofeedback.

Summary

One new small moderate-quality trial contributed evidence in this area, suggesting that the effect of BT may be enhanced by EStim or EStim with biofeedback, but not biofeedback alone. **(Level of evidence: 2)**

Previous data from two small trials, comparing BT (or BT plus placebo) versus BT plus DT in participants with OAB, suggested that the effect of BT may be enhanced by the active drug. **(Level of evidence: 2)**

However, both trials were small, conducted in -mixed sex samples and outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with DT.

Recommendations

EStim or EStim plus biofeedback can be recommended as an adjunct treatment to BT, although further studies are needed. (**Grade of recommendation: B New**)

Direct comparisons are needed of BT versus BT plus DT for the treatment of UI to address the question of whether the effect of BT can be augmented by DT.

7.2.6. Does the addition of BT to another treatment add benefit?

Trials included needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. A search of relevant trials that investigated the effects of PFMT alone versus PFMT plus BT, and DT alone versus DT plus BT was performed. No new trials focusing on this question were identified.

Summary

Previous evidence suggests that there is no evidence of additional benefits of combining brief written BT instructions with tolterodine (2mg twice daily) or solifenacin (5/10mg daily) compared to DT alone for UUI, although these trials were likely underpowered to study UI outcomes. **(Level of evidence: 2)**.

Recommendation

The addition of written information on BT to an antimuscarinic DT cannot be routinely recommended as it does not appear to further improve UI in women with OAB. **(Grade of recommendation: B)**

More research is needed using an appropriately supervised BT programme combined with DT versus DT alone.

7.2.7. Is timed voiding effective for treating UI?

No new trials were identified that tested timed voiding for UI in women without cognitive or physical disability.

Summary

There were no new RCT, or high-quality observational studies identified that provided evidence on the effects of timed voiding for UI in cognitively intact, community-dwelling women. Based upon the data from one previously reported small uncontrolled study, it appears that a two-hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function. **(Level of evidence: 3)**

Recommendations

Timed voiding with a two-hour voiding interval could be considered as a sole intervention for women with mild UI or infrequent voiding patterns. **(Grade of recommendation: C)**

Timed voiding could also be considered as an adjunct to another treatment.

7.3. Other LUTS

Three new trials (94, 165, 181) and one long-term follow-up study of an existing trial (90) were identified, which reported on other LUTS. Outcomes included OAB-specific improvement, OAB-specific QoL or impact questionnaires, number of urgency episodes, frequency and nocturia. Firinci *et al.* (94) compared the added benefit of biofeedback and EStim when added to BT and reported on frequency and nocturia (other UI-specific outcomes presented in sections II.7.2.4 above and section II.4.2.4). Hulbæk *et al.* (165) compared two methods of BT (individual versus group treatment) and reported on OAB symptoms, number of urgency episodes and frequency using an OAB-specific questionnaire (other UI-specific outcomes

are presented in section II.7.2.1 above). Lee *et al.* (181) compared moxibustion (hot acupuncture) to BT and reported on OAB-specific QoL or impact questionnaires, frequency and nocturia. No UI-specific outcomes were reported in this trial. Finally, Azuri *et al.* (90) presented a four-year follow-up of a trial comparing DT to BT (92), and reported on the number of voids per 24 hours, in addition to UI-specific outcomes presented above (section II.7.2.3).

Quality of data

The quality of the data in Firinci *et al.* (94), Hulbæk *et al.* (165) and Azuri *et al.* (90) are presented earlier. Lee *et al.* (181) was a small assessor-blinded trial with a crossover design, in which 28 women were randomised to either behaviour treatment alone (including BT) or moxibustion. After four weeks, the treatment offered to the two groups was reversed. The follow-up took place at four weeks (before the crossover) and at eight weeks (after the crossover). Only results reported before the cross-over (at four weeks) were considered here. Behavioural training included instructions related to scheduled voiding (gradually increasing the time between bathroom visits) and lifestyle modifications (participants were asked to avoid coffee, tea, alcohol, soda, artificial sweeteners, chocolate and spicy foods). No further details were provided on the BT protocol.

This was a feasibility study and there was therefore no power calculation and a small sample size (28 participants, 14 per group). Adequate random allocation/concealment were reported, and the assessor was blinded to the participant's allocation. ITT analysis was used. The drop-out rate was unbalanced and high considering the sample size (all from the BT group: 29% [4/14]). Reasons for loss to follow-up were not clearly stated. Side effects were also unbalanced and exclusive to the moxibustion therapy, including superficial second-degree burns (n=2). Overall, ROB was moderate to high.

Results

Results from studies added to this update are integrated with information from previously reviewed studies below.

i. Urgency:

One new trial reported on urgency outcomes. No statistically significant differences were found within or between groups following individual and group BT treatment (165). In previously reviewed trials, urgency results were conflicting. An older trial suggested BT was superior to DT (169), but another reported greater improvement in urgency after DT or DT plus BT treatment compared to BT alone (166). Two larger trials found no additional improvement in urgency when a simplified BT treatment was added to DT in participants with OAB (172, 173).

ii. Daytime (diurnal frequency) and voids per 24 hours:

Two newly identified trials reported on frequency: one trial found no statistically significant differences within or between groups following individual and group BT treatment (165). In the other trial, improvements were reported across all groups, including BT alone or combined with biofeedback and/or EStim (94). Overall, frequency improved to a greater extent in BT groups that included EStim, compared to BT alone or BT combined with biofeedback. One other newly identified trial (181), and one long-term follow up of an existing trial (90), reported on voids per 24 hours. In the first study, no differences were found within or between groups following BT alone or added to moxibustion (181). In the second, both BT and DT were statistically significantly and equally effective to reduce voids in the short (three months) and long term (four years) (90, 92). On average, subjects reported two to four fewer voids per 24 hours immediately after treatment.

In previously reviewed trials, frequency improved to a greater extent in BT groups compared to no treatment (156, 170, 171). In trials testing BT compared to DT, frequency improved in both groups similarly (166, 178), or to a greater extent in the BT group (169). In one trial testing the additive effect of DT to BT, a greater reduction in frequency was reported in the BT plus DT group compared to BT plus placebo group (167). Lastly, two trials found that "simplified" BT significantly augmented the effect of DT alone. The BT plus tolterodine group showed more improvement in voiding frequency compared to DT alone (33% versus 25% improvement, respectively; $p<0.001$). Furthermore, BT plus solifenacin reduced the number of voids in 24 hours to a greater extent compared to DT alone (2.8 versus 2.1 fewer voids in 24 hours; $p<0.001$) (172, 173).

iii. Nocturia:

Three new trials were identified that reported on nocturia (94, 165, 181). Firinci *et al.* reported improvements in nocturia across all treated groups, including BT alone or combined with biofeedback and/or EStim (94). As for other outcomes of this trial, greater improvements were seen in BT groups that included EStim, compared to BT alone or BT plus biofeedback. Lee *et al.* reported on nocturnal volume and frequency, both favouring BT combined with moxibustion over BT alone (181). Hulbæk *et al.* (165) reported on nocturia bother, using a visual analogue scale, which slightly favoured individual over group BT treatment.

Three previously reviewed trials reported data comparing BT with no treatment and found reductions in nocturia after BT but not in the control group (156, 170, 171). Four previously reviewed trials compared BT with DT. Two smaller trials found that BT was superior to DT for treating nocturia (169, 178). Another trial compared BT plus placebo versus BT plus DT (167) and found no difference in nocturnal micturition frequency. Song (2006) reported that nocturia improved similarly in women with OAB treated with BT (56.1%), tolterodine (65.4%), and the combined treatment (66.3%) (166).

Summary

No trials which tested the effectiveness of BT compared to no treatment or a control for urgency were identified.

It remains unclear whether BT is more effective when provided individually or in groups, or if BT or DT is more effective in treating urgency. **(Level of Evidence: 2)**

Two large, high-quality trials show that the addition of "simplified" BT to DT improved frequency but did not provide additional benefits for treating urgency. **(Level of evidence: 1)**

Several trials, including one newer long-term follow-up study, suggest that BT is effective for improving frequency **(Level of evidence: 1)**, but it is unclear whether BT or DT is more effective. **(Level of Evidence: 2)**

In one new small moderate-quality trial, frequency improved more in BT groups that included EStim, compared to BT alone or BT combined with biofeedback. **(Level of evidence: 2)**

A few small, randomised trials of variable quality suggest that BT is effective at treating nocturia. **(Level of evidence: 2)**

One small new trial of moderate quality found that BT added to EStim is more effective to treat nocturia than BT alone or added to biofeedback. **(Level of evidence: 2)**

One small pilot study suggested that BT combined with moxibustion is more effective than BT alone to treat nocturia. **(Level of evidence: 3)**

The results were inconclusive for one large high-quality trial comparing individual and group BT to treat nocturia. **(Level of evidence: 2)**

Finally, small trials did not find that BT (or BT plus DT) is more effective than DT for the treatment of nocturia, but evidence is limited. **(Level of evidence: 2)**

Recommendations

The routine addition of a "simplified" BT to DT should be considered in the treatment of voiding frequency in women with UI and OAB. **(Grade of recommendation: A New)**

BT can be recommended to treat frequency in women with UUI. **(Grade of recommendation: B)**

Either BT and/or an anticholinergic drug can be recommended as they are effective to treat frequency in women. **(Grade of recommendation: B)** However, medication side effects always need to be considered.

Adding EStim, but not biofeedback, to BT may provide additional benefits for treating frequency and therefore can be recommended. **(Grade of recommendation: B New)**

BT can be offered as treatment for nocturia. **(Grade of recommendation: B)**

Combining EStim to BT can be recommended over BT alone, for treating nocturia. **(Grade of recommendation: B New)**

Moxibustion could be considered in addition to BT for treating nocturia. **(Grade of recommendation: C New)**

Either BT alone or BT plus anticholinergic drugs can be recommended for treating nocturia (with OAB) as they appear equally effective. **(Grade of recommendation: B)**

7.4. Factors affecting outcome

Few trials on BT have examined predictors of treatment response. New trials in this update did not contribute additional information related to predictors of timed voiding or BT treatment response.

Table 30. Summary of scheduled voiding regimens

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Firinci (2020) (94) Turkey	(1) BT added to biofeedback (BT+BF) (2) BT added to electrical stimulation (BT+ES) (3) BT added to biofeedback and electrical stimulation (BT+BF+ES)	N=70 BT: 18 BT+BF: 17 BT+ES: 18 BT+BF+ES:17	Women with OAB (>18 years, mean 56 years)	30 min education + written brochure, including: (1) PFM contraction assessment and education via digital palpation; (2) urgency suppression strategies (PFM contraction, relaxation and distraction); (2) relaxation; (3) timed voiding program based on BD; and (4) motivation.	UI-specific outcomes: UI-specific QoL or impact (IIQ-7); number of leakages (3-day BD); number of pads used (3-day BD); cure and improvement (24h pad-test); severity of incontinence (24h pad-test) Other patient-reported outcomes: frequency (3-day BD), nocturia (3-day BD), satisfaction (Likert scale) For all outcomes: all groups improved significantly compared to baseline. Overall results significantly favoured combined treatments including ES (BT+ES and BT+BF+ES) over BT alone or BT + BF	Post-treatment (8 weeks)	Side effects: temporary discomfort due to vaginal irritation (BT+ES=2, BT+BF+ES=1), no ITT analysis Loss to follow-up: 4 (one from each group)

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Hulbæk (2016) (165) Denmark	BT in groups (3-4 participants per group)	N=91 BT individual (BTi): 43 BT group (BTg): 48	Women with OAB (>18 years, mean 57 years)	Same for both arms: 2-month program including three training sessions supervised by a continence nurse. The BT programme included: (1) patient education; (2) scheduled voiding; and (3) motivation. The scheduled voiding was planned at each session based on the BD.	UI-specific outcomes: number of leakages (ICI-OAB-Q) Other patient-reported outcomes: improvement (PGI-I); number of urgency episodes (ICI-OAB-Q); frequency; OAB symptom-specific VAS (ICI-OAB-Q) For all outcomes: no significant difference between baseline and post-treatment or between groups post treatment.	Post Tx (2 months)	Side effects: more frequent voiding, treated with antibiotics (n=1). Treatment group unspecified Loss to follow-up: 12 (5 BTi, 7 BTg) did not fulfil the inclusion criteria, ITT analysis
Kafri (2013) (92) Azuri (2017) (90) Israel	(1) Drug therapy, tolterodine SR 4 mg (DT) (2) Pelvic floor muscle training (PFMT) (3) Combined Tx: BT, PFMT and behavioural advice (CPFR)	N=164 BT: 41 DT:42 PFMT:40 CPFR: 41	Women with ≥ 3 episodes of UUI per week (45-75 years; mean 57 years)	3-month BT program including 4 sessions with a physical therapist The BT program included: (1) patient education, (2) scheduled voiding using a prefixed or flexible timetable; and (3) psychological support and encouragement.	UI-specific outcomes: number of leakages (BD); UI-specific QoL or impact (I-QOL, VAS, ISI); pads/week Other patient-reported outcomes: frequency (BD); generic QoL questionnaire (LLFDI) Both BT and DT were significantly and equally effective for all outcomes at 1 and 4 years, except for number of leakages at 4 years, which favoured DT. 31% (11/35) and 25% (6/24) of the BT and DT were dry at 4 years, p=0.62	Post Tx (3 months), 1 year and 4 years	Side effects: dizziness (1 women in the DT group) Loss to follow-up: 27 post treatment (2 BT, 15 DT, 6 PFMT, 4 CPFR); 29 at 12 months (2 BT, 15 DT, 8 PFMT, 4 CPFR); 44 at 4 years (6 BT, 18 DT, 11 PFMT, 9 CPFR), ITT analysis Note: Adherence to DT was significantly lower than to BT, PFMT or CPFR (64% vs. 85-95%, p=0.01). Main reason for drop-out: unhappy with allocation (13/15).
Lee (2018) (181) Korea	Moxibustion (M) and bladder training (M+BT)	N=28 BT: 14 M+BT: 14	Women with OAB for over 3 months (between 20-75 years, mean 53 years)	4 weeks of BT including 8-12 sessions. The BT programme included: (1) gradually increasing the time between bathroom visits; (2) fluid intake advice (avoid potential bladder irritants).	UI-specific outcomes: none Other patient-reported outcomes: OAB-specific QoL or impact (OAB-V8, OABSS); LUTS (VAS); frequency; nocturia and volume (3-day BD). Only OABSS was different between groups at 4 weeks, favouring combined treatment (M+BT).	Post Tx (4 weeks), cross-over (8 weeks)	Side effects: superficial second-degree burns (n=2) Loss to follow-up: 4 (4 BT, 0 M+BT), ITT analysis Note: Pilot study, cross-over design, (only results reported before cross-over were considered here) No outcomes on UI, results reported in section 7.3. Other LUTS

8. COMPLEMENTARY AND ALTERNATIVES MEDICINES

Complementary and alternative medicine (CAM) refers to a series of medical and health care practices and products, which are not part of conventional medicine (182). According to the National Centre for Complementary and Alternative Medicine's (NCCAM) recommendation, CAM can be grouped into five domains: i) biologically-based therapies that use the substances found in nature, such as herbal therapy; ii) manipulative and body-based approaches that are based on the movement or realignment of parts of the body, such as massage and chiropractic; iii) mind-body interventions that focus on the influence of brain and mind on health, such as meditation, yoga, and Tai Chi; iv) energy therapies that involve use of energy field, such as Qi Gong; v) whole medical systems that cut cross more than one of the other groups, such as acupuncture, Ayurveda, and homeopathy (183).

This section reviews the current evidence for the effects of CAMs on UI. Eligible interventions were typical CAM interventions, including acupuncture, herbal therapy, massage, yoga, Tai Chi, Qi Gong, meditation, Ayurveda and homeopathy. In terms of types of acupuncture, scalp acupuncture, body acupuncture, electroacupuncture, warm acupuncture, elongated needle, auricular acupuncture and fire needle were included. In contrast, cupping, acupressure, laser acupuncture and dry needle acupuncture were excluded, because laser acupuncture and dry needle acupuncture are not routine or traditional acupuncture approaches, and cupping and acupressure are identified as different therapies to acupuncture. Eligibility criteria for study participants and outcomes, as well as criteria used to assess ROB in the included studies, were identical to those described in the previous section on MStim. (Section V).

In addition to the eight studies included in the sixth ICI, a new Cochrane review and 14 new trials were identified for this update (184). Of those, eight studies focused on the efficacy of acupuncture. The Cochrane review and three studies centred on the effectiveness of yoga. Additionally, three studies assessed the effect of herbal therapy. Included studies are summarised in Table 31 by pattern of incontinence or dominant UI type.

8.1. Prevention

No new trials were identified.

8.2. Treatment

8.2.1. Acupuncture versus no treatment, sham acupuncture or any other treatment

8.2.1.1. SUI

Five new studies were identified, including 930 women (185-189). The characteristics of the five new studies are presented in Table 32. Of those, two used sham treatment (186, 187) and two others used PFMT as the control (185, 189). Another study used midodrine as the control (188). As most of the new studies had different comparators and outcomes than the previous studies, only limited findings could be combined.

Quality of data

Randomisation was appropriate in three studies (186-188). By contrast, two studies did not provide sufficient information on the method of randomisation (185, 189). Allocation concealment was adequate in two studies (186, 189). Three other studies did not describe methods used for allocation concealment (185, 187, 188). In terms of blinding, two studies used a double-blind design (participants and outcome assessors) (186, 187), while three others were non-blinded (185, 188, 189). In addition, four studies reported the complete data (185, 186, 188, 189), whereas one only reported the data on participants who completed the study (187).

Results

Two previous low-quality RCTs reported that acupuncture may be associated with more improvement in women with SUI compared with no treatment or midrodrine (190, 191). Another previous trial reported that acupressure may enhance PFM strength and improve QoL compared to a sham treatment or usual care (192). Pooled data from the two new studies suggest that cure rates were on average statistically significantly higher for acupuncture compared to PFMT (N = 156, 32.1% versus 9%, OR 4.79, 95% CI 1.93 to 11.87, P<0.0007, I^2=19%), and improvement rate was on average significantly higher for acupuncture compared to PFMT (N = 156, 87.2% versus 73.1%, OR 2.88, 95% CI 0.16 to 50.74, P=0.003, I^2=88%)

Table 31. Studies of CAMs included in the previous review (6th ICI) and current update (7th ICI)

	Studies included in the previous review (6th ICI)	New studies identified in this update (7th ICI)	Total
Acupuncture vs other intervention SUI OAB/UUI MUI	3 3 2 (1 for UUI or MUI)	5 1 2	8 4 4
Yoga vs other intervention OAB/UUI UI all types	No study found	1 Cochrane Meta-analysis 1 2	1 Cochrane Meta-analysis 1 2
Herbal therapy vs other intervention OAB/UUI UI all types	No study found	1 2 (1 for SUI or MUI)	1 2

Abbreviations: SUI: stress urinary incontinence; OAB: overactive bladder; UUI: urge urinary incontinence; UI: urinary incontinence

(185, 189). However, these new trials had a high ROB and treatment intensity was unequal between intervention groups. In a new study comparing acupuncture to sham acupuncture, more women reported improvement in the acupuncture group at six weeks (N = 492, MD -15.0 95% CI -23.2 to -6.9, P<0.001), 18 weeks (N = 482, MD -25.6, 95% CI -34.3 to 16.9, P<0.001), and at the 30-week follow-up (N = 482, MD -25.6, 95% CI -34.2 to 16.9, P<0.001), respectively, compared to sham acupuncture (186). There was no difference in reported adverse events between the acupuncture and sham acupuncture groups (N = 496, 1.6% versus 2.0%, OR 0.8, 95% CI 0.21 to 3.03) (186). Another new study reported a significant improvement in QoL in the acupuncture group but not in the sham acupuncture group (187). Pooled data from one new study and previous research suggest that improvement rates were significantly higher for acupuncture compared to midodrine (N = 240, 86.7% versus 61.7%, OR 4.76, 95% CI 1.5 to 15.11, P<0.008, I^2=60%); however, there were no differences for cure rates (N = 240, 28.3% versus 18.3%, OR 1.8, 95% CI 0.97 to 3.34, P=0.06, I^2=0%) (188, 190).

Summary

A total of eight new trials assessed the effect of acupuncture on SUI compared with no active treatment and another treatment. Data from two small trials suggest that acupuncture may be more effective than PFMT for curing and improving SUI symptoms **(Level of evidence: 3)**, but results from these low-quality trials should be taken with caution. More research is needed before recommendation can be made.

Evidence from two trials one small (n=90) and one large (n= 492) good-quality trial suggests that acupuncture may have benefits for the improvement (186) of SUI symptoms and QoL (187) compared to a sham treatment. **(Level of evidence: 2)**

Additional findings from a newly identified study of moderate size (n=240) suggest that acupuncture may be associated with greater improvement of symptoms compared to midrodrine. **(Level of evidence: 2)**

Recommendations

Acupuncture could be recommended as an optional treatment for women with SUI. **(Grade of recommendation: C)**

Further high-quality RCTs are needed.

Table 32. Summary of data on acupuncture vs no active treatment or other treatment

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss to follow-up…)
Chen (2015) (185)	Electroacupuncture (45) vs PFMT (45)	90	SUI	Electroacupuncture: 30-min electroacupuncture at bilateral BL35 and BL33 plus scalp acupuncture with a continuous wave of 80-100 Hz, daily for 8 weeks. PFMT: 15-30 min PFM contractions, 3s hold/3s rest, 2-3 sets a day for 8 weeks.	Self-reported cure: 10/45 vs 4/45 Self-reported improvement: 37/45 vs 39/45 QoL: NR Adverse effects: NR	8-weeks	Loss of follow-up: None
Zheng (2015) (189)	Electrovacua-puncture (33) vs PFMT (33)	66	SUI	Electroacupuncture: 20-min electroacupuncture at CV3, CV4, and bilateral KI12, BL23, and BL33, twice a week for 4 weeks. PFMT: 10 PFM contractions, 3s hold/3s rest, 5 sets a day for 4 weeks.	Cure (based on 1-h pad test): 15/33 vs 3/33 Improvement (based on 1-h pad test): 31/33 vs 18/33 QoL: NR Adverse effects: NR	4-weeks	Loss of follow-up: None

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss to follow-up…)
Liu (2017) (186)	Electroacupuncture (252) vs Sham electroacupuncture (252)	504	SUI	Electroacupuncture: 30-min electroacupuncture at bilateral BL35 and BL33 with a continuous wave of 50 Hz and a current intensity of 1 to 5mA, 3x per week for 6 weeks. Sham electroacupuncture: 30-min sham electroacupuncture without electricity output, at bilateral sham BL35 (1 cun≈20 mm horizontal to BL35) and BL33 (1 cun≈20 mm lateral to BL 33), 3x per week for 6 weeks.	Cure: NR Self-reported improvement: N=492 at 6-weeks (end of treatment), 210/246 vs 75/246; N=482 at 18-week, 185/243 vs 66/239; N=482 at 30-week, 183/243 vs 68/239. QoL: NR Adverse effects: N=496, adverse effects include subcutaneous hematoma, fatigue, pain, and palpitation. 4/247 vs 5/249	30-weeks	Loss of follow-up: 9 patients in electroacupuncture group and 13 patients in sham electroacupuncture group.
Wang (2020) (187)	Acupuncture (45) vs Sham acupuncture (45)	90	SUI	Acupuncture: 30-min acupuncture session at bilateral BL 54 through ST 28, once a day for 10 days. Sham acupuncture: 30-min non-permeable sham acupuncture at bilateral BL 54, once a day for 10 days.	Cure: NR Improvement: NR QoL via I-QOL: N = 88 at 10-days (end of treatment), mean difference 41.05;95% CI 36.44 to 45.66 N = 88 at 4-week, mean difference 41.93; 95% CI 37.1 to 46.76. Adverse effects: NR	4-weeks	Loss of follow up: 1 patient in acupuncture group and 1 patient in sham acupuncture group.
Wang (2016) (188)	Electroacupuncture (90) vs Drug treatment (midrodine) (90)	180	SUI	Electroacupuncture: 30-min electroacupuncture at bilateral BL23, BL32 and BL35 with a disperse-dense wave of 50-70 Hz 6x per week for 4 weeks. Drug treatment: midrodine 2.5mg, 3x per day for 4 weeks.	Cure (based on ICIQ-SF and 1-h pad test): 30/90 vs 20/90 Improvement (based on ICIQ-SF and 1-h pad test): 78/90 vs 62/90 QoL: NR Adverse effects: NR	4-weeks	Loss of follow up: None

8.2.1.2. OAB, UUI, MUI

In this update, four new studies including 684 women were identified (49, 193-195). One trial was excluded because it did not report data for women and men separately (193). The characteristics of the other three new studies (N= 584) are presented in Table 33. One trial compared electroacupuncture to sham electroacupuncture in 50 women with OAB that were refractory to anticholinergics (195). In a pilot study, 34 women with MUI were randomised to three groups including acupuncture, PFMT and waitlist control (49). See section on PFMT (II.2.3.1) for more details. Finally, a non-inferiority trial tested electroacupuncture versus PFMT plus solifenacin in 500 women with MUI (194). In the three new trials and five previous trials, it was inappropriate to combine study findings as there was heterogeneity in the control intervention or sample populations.

Quality of data

Randomisation was considered appropriate in the three new studies (194, 195). Allocation concealment was considered adequate in only two of the three studies (49, 194). In terms of blinding, one study proposed a single-blind design (195), while the two others were non-blinded (49, 194). One study reported the complete data (194), while two other trials only reported the data for participants who completed the study (49, 195). In particular, the dropout rates in the study by Solberg (2016) were 25%, 40% and 50% in acupuncture, PFMT, and the waiting list group respectively (49), which could have biased the results.

Results

No included studies reported information on cure or improvement rates. In the two previous trials, no statistically significant differences were detected for improvement of UI frequency when comparing acupuncture with sham or placebo treatment (196, 197). A new trial showed that electroacupuncture was associated with improved OABSS, KHQ and urodynamic parameters compared to a sham acupuncture treatment (P<0.01) in women with refractory OAB to anticholinergics (195). For women with MUI, a pilot trial found no statistically significant difference in ICIQ-UI SF scores between acupuncture and PFMT or between acupuncture and no treatment after the intervention. However, this trial was small and possibly underpowered (49). Results from two previous trials showed few differences between acupuncture and antimuscarinic treatment (oxybutynin or tolterodine) for frequency, urgency and UUI improvement (198, 199). Findings from a non-inferiority trial showed that electroacupuncture was not inferior to PFMT combined with solifenacin, with a between-group difference (-1.34%, 95% CI, -9.78% to 7.10%, P<0.001) for the reduction of UI episodes in women with MUI (194).

Summary

Three trials on the effect of acupuncture on OAB, UUI and MUI compared with no active treatment and another treatment were assessed. When pooling these data with previous trials, four trials (small to medium size) of varying quality found limited to no benefit of acupuncture compared to various sham treatments for MUI and OAB\UUI in women. (**Level of evidence: 2**)

Several factors limit these results, including a small sample size, moderate to high ROB and heterogeneity of active and sham treatments.

Two trials comparing acupuncture to DT in women with OAB, UUI and MUI found no difference between treatments. **(Level of evidence: 2)**

One moderate-quality trial suggested electroacupuncture was not inferior to PFMT plus DT for the treatment of MUI. **(Level of evidence: 2)**

Recommendations

Either electroacupuncture or anticholinergic drugs can be recommended for the treatment of OAB, UUI and MUI in women. **(Grade of recommendation: B)**

Table 33. Summary of data on acupuncture vs no active treatment or other treatment

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Zhang (2015) (195)	Electroacupuncture (25) vs Sham electroacupuncture (25)	50	OAB refractory to anticholinergic	Electroacupuncture: 30-min electroacupuncture at bilateral BL32, BL33 and BL34 with a disperse-dense waves of 4/20 Hz, 5x per week for 6 weeks. Sham electroacupuncture: 30-min sham electroacupuncture without electricity output, at non-points located 15 mm lateral to each point, 5x per week for 6 weeks.	Cure: NR Improvement: NR QoL via KHQ: N= 45 at 6-weeks (end of treatment), mean difference -260; 95% CI -314.6 to - 205.4. Adverse effects: N= 45, adverse events include minor pain at the needling sites 3/23 vs 2/22	6-weeks	Loss of follow-up: 2 patients in electroacupunc-ture group and 3 patients in sham electro-acupuncture group.

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Solberg (2016) (49)	Acupuncture (12) vs PFMT (10) vs Waiting list (12)	34	MUI	Acupuncture: 30-min acupuncture alternately at 2 groups of points. Group 1 included CV3, CV4, CV6, and bilateral SP6, KI3, KI7, (PC6, LR3 and SP3 with related symptoms), Group 2 included GV4, GV20, and bilateral BL 23, BL 28, BL31, BL32, BL33, BL34, SP6, (BL 14, BL18 and BL20 with symptoms), 1-2x per week for 12 sessions over 12 weeks. PFMT: 25 min of PFMT, following a 20-min general exercise program (no details were provided). Waiting list: no treatment	Cure: NR Improvement: NR QoL: NR Adverse effects: N=34, adverse events included tiredness, symptoms worsening. 1/12 vs 1/10 vs 0/12	12-weeks	Loss of follow-up: 3 patients in acupuncture group, 4 patients in PFMT group, and 6 patients in waiting list group
Liu (2019) (194)	Electroacupuncture (250) vs PFMT plus solifenacin (250)	500	MUI	Electroacupuncture: 30-min electroacupuncture at bilateral BL33 and BL35 with a sparedense wave, 10/50 Hz, 0.1 to 5.0 mA, three times a week for 12 weeks. PFMT +solfenacin: PFMT (intensive exercises at the hospital and home exercises) + Solifenacin, 5 mg daily. Intensive exercises include PFM contractions, 8s hold/8s rest + 4 rapid 1-2s contractions a minimum of 12x for each posture (supine, sitting, and standing). Home exercises include additional 12 contractions 3x per day at home.	Cure: NR Self-reported improvement: N=478 at 12-weeks, 236/244 vs 223/234; N=480 at 36-weeks, 235/245 vs 225/235. QoL via ICIQ-SF: N = 497 at 12-weeks, mean difference -0.23; 95% CI -0.74 to 0.27; N = 497 at 24-weeks, mean difference -0.47, 95% CI -1.13 to 0.19; N = 497 at 36-week, mean difference -0.26, 95% CI -0.9 to 0.39. Adverse effects: N = 497, adverse events included subcutaneous hematoma, dry mouth, constipation, stomach ache, diarrhoea, dyspepsia, heartburn, upper respiratory tract infection, cough, dizziness, hypogeusia, blurred vision, headache, herpes zoster, lower back pain, pruritus, urinary tract infection, dysuria, dry eye, facial oedema 43/249 vs 91/248	36-weeks	Loss of follow-up: 4 patients in electroacupunc-ture group and 8 patients in PFMT plus solifenacin group.

Abbreviations: OAB: overactive bladder; NR: not reported; QoL: quality of life; KHQ: King's Health Questionnaire; PFMT: pelvic floor muscle training; MUI: mixed urinary incontinence; ICIQ-SF: International Consultation on Incontinence Questionnaire-Urinary Incontinence Short Form

8.2.2. What is the most effective acupuncture protocol?

No studies were found addressing this question.

8.2.3. Yoga

Yoga is a mixture of physical and mental exercises that originated in ancient India. In this update of the 6th ICI, a Cochrane systematic review (200), which included two trials (201, 202), and an additional trial (203) were identified, and 105 participants were involved. The characteristics of the three studies are presented in Table 34. One trial compared yoga to mindfulness-based stress reduction in 30 women with predominant UUI (201). Huang *et al.* performed two studies comparing yoga to no active treatment. This included a pilot study involving 19 women with UI that explored the efficacy of yoga for six weeks compared with no treatment (202). The other trial assessed the effectiveness of yoga in 56 women with UI over three months compared to a non-specific muscle stretching and strengthening programme as the control (203).

Quality of data
Randomisation was considered appropriate in the three studies (201-203). Allocation concealment was considered adequate in two out of three studies (201, 203). One study did not describe the methods used for allocation concealment (202). In one trial, the investigators and all staff involved in abstracting data were blinded, although participants were not blinded (203). Two other studies were not blinded (201, 202). Only one trial reported the complete data (201), while the two other trials only reported data on participants who completed the study (202, 203).

Results
In the 2019 Cochrane systematic review, data from two trials were not combined into a meta-analysis due to the difference in comparators. Uncertainty about the effectiveness of yoga was also addressed (200). Both studies included in the Cochrane review and the additional trial did not report information on cure or improvement rates. Pooled data from two studies in which yoga was compared with no active treatment suggested that yoga resulted in a statistically significant decrease in UI episode frequency compared to no active treatment (N=68, MD-1.21, 95% CI -2.07 to -0.35, P=0.006, I^2=0%) (202, 203). One study reported that yoga resulted in a statistically significant improvement QoL as evaluated by the UDI-6 (P<0.01) (202), while another study found no statistically significant difference between yoga and no active treatment (203). One study found that yoga was associated with fewer symptoms and improvement in QoL than mindfulness-based stress reduction for managing predominant UUI in women (201).

Summary

The three included studies had a small sample size (19-56 participants) and a moderate to high ROB. Pooled data from two studies on women with UI suggest that yoga may be more effective than no active treatment in improving symptoms, although the effect on QoL was inconsistent. **(Level of evidence: 2)**

For women with predominant UUI, evidence from one small trial suggests that yoga might be associated with reduced improvement of symptoms and QoL compared to mindfulness-based stress reduction. **(Level of evidence: 3)**

Recommendations

On the present evidence, no recommendation on the use of yoga on UI is possible. **(Grade of recommendation: D New)**

More randomised controlled trials with large sample sizes and clear and consistent reporting of core outcome data would be beneficial in reaching a firm conclusion on the effectiveness of yoga over other treatments.

Table 34. Summary of data on yoga vs no active treatment or other treatment

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Baker (2014) (201)	Yoga therapy (15) vs MBSR (15)	30	Predominant UUI	Yoga therapy: participants were taught by a certified yoga instructor in a weekly yoga class for 8 weeks. The class focused on the "Asanas" or physical practice and how to prevent injury and promote relaxation of the muscles. MBSR: The 8-week MBSR program is a structured program that teaches participants a variety of meditation practices, mindfulness-yoga, walking meditation, and discussions on the relationship between stress, illness, and health.	Cure: NR Improvement: NR QoL via OAB-HRQL: N= 24 at 8-weeks (end of treatment), median change from baseline 8.7% vs 29.27%; N= 20 at 6-month, 8% vs 43.9%; N= 21 at 1-year, 13.04% vs 36.09%. Adverse effects: NR	1 year	Loss of follow-up: NR

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Huang (2014) (202)	Yoga therapy (10) vs Waitlist control (9)	19	All types of UI	Yoga therapy: participants were scheduled to attend two 90-minute group yoga classes per week for 6 weeks, led by a certified instructor. The program focused on a core set of 8 postures. Waitlist control: no treatment	Cure: NR Improvement: NR QoL via BDI-6: N = 18 at 6-weeks (end of treatment), mean difference -0.9, 95% CI -1.4 to -0.3. Adverse effects: N=18, no details were described. 2/9 vs 2/9	6 weeks	Loss of follow-up: 1 patient in yoga group dropped out.
Huang (2019) (203)	Yoga therapy (28) vs Nonspecific muscle stretching and strengthening program (28)	56	All types of UI	Yoga therapy: participants were scheduled to attend two 90-minute group yoga classes per week for 6 weeks, led by a certified instructor. The program focused on a core set of 15 postures. In addition to attending group classes, participants were asked to practice yoga at home at least 1 additional hour per week. Nonspecific muscle stretching and strengthening program: participants were scheduled to attend two 90-minute group classes per week for 6 weeks, led by an instructor. The program focused on nonspecific muscle stretching and strengthening and avoided engaging the pelvic floor or promoting mind relaxation. In addition to attending group classes, participants were asked to practice exercises at home at least 1 additional hour per week.	Cure: NR Improvement: NR QoL via BDI-6: N = 50 at 3-month (end of treatment), percentage change from baseline 53% vs 37%. Adverse effects: N=56; included gastrointestinal, genitourinary, musculoskeletal, neurological or psychological, ophthalmologic, and respiratory adverse events. (no specific adverse events were listed) 23/28 vs 25/28	3 months	Loss of follow-up: 1 patient in yoga group and 5 in control group dropped out.

Abbreviations: MBSR: Mindfulness-based stress reduction; UUI: urge urinary incontinence; UI: urinary incontinence; NR: not reported; QoL: quality of life; OAB-HRQL: overactive bladder symptom and health-related quality of life questionnaire; BDI-6: Beck Depression Inventory

8.2.4. Herbal Therapy

Available evidence on herbal therapy was limited. In the sixth ICI, no trials were identified. In this update, three trials including 278 women were identified (204-206). The characteristics of the three studies are presented in Table 35. All three studies used placebo as the control (204-206). As the three new trials had little duplication in the outcomes or sample populations it was inappropriate to combine study findings.

Quality of data

Randomisation was considered to be appropriate in the two studies (204, 206), whereas the third study did not provide sufficient information on the method of randomisation (205). Allocation concealment was considered to be adequate in two studies (204, 206), while another one did not describe methods used for allocation concealment (205). All three studies were double-blinded (204, 206). Additionally, all three studies only reported data on participants who completed the study (204-206).

Results

No trials reported information on cure or improvement rates. For women with OAB, a study showed that cranberry may result in a statistically significant reduction of daily micturition (-1.91, 95% CI -3.74 to -0.88, p<0.05) and urgency episodes (-2.81, 95% CI -4.82 to -0.80, p<0.01) at 24 weeks of follow-up compared with placebo (204). For women with UI, findings from two other trials showed that herbal therapy was associated with a significant reduction in the ICIQ-UI SF score compared to placebo (205, 206). Additionally, a study reported that herbal therapy resulted in a statistically significant improvement in QoL in UI patients as evaluated by ICIQ-UI SF's question 5 (205), while another study found no significant difference in QoL between herbal therapy and placebo, evaluated by the OABQ-SF HRQL sub-score and SQOL-F (204).

Summary

Three trials assessed the effect of herbal therapy on OAB and UI compared with no active treatment and another treatment. Data from the three small- to moderate-sized studies of moderate quality suggest that herbal therapy could be more effective than no active treatment in improving UI and LUTS, although the effect on QoL was inconsistent. **(Level of evidence: 3)**

Recommendations

Herbal therapy could be recommended over no therapy for improving UI and LUTs symptoms in women with OAB and UI but not for improvements in QoL. **(Grade of recommendation: C New)**

More randomised controlled trials with large sample sizes and clear and consistent reporting of core outcome data would be beneficial in reaching a firm conclusion on the effectiveness of herbal therapy.

Table 35. Summary of data on herbal therapy vs no active treatment or other treatment

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Cho (2020) (204)	Herbal therapy (46) vs Placebo (52)	98	OAB	Herbal therapy: 1 pill of dried cranberry powder (500 mg of proprietary full spectrum dried cranberry fruit), orally 1x per day for 24 weeks Placebo: 1 placebo pill (500 mg proprietary mixture of maltodextrin and food grade colours), orally 1x per day for 24 weeks	Cure: NR Improvement: NR QoL via OABQ-SF HRQL subscore: N = 60 at 24-weeks (end of treatment), mean difference -3.11; 95% CI -8.14 to 1.92. QoL via SQOL-F: N = 60 at 24-week (end of treatment), mean difference -2.16, 95% CI -8.15 to 3.82. Adverse effects: NR	24-weeks	Loss of follow-up: 11 patients in herbal therapy group and 6 in control group.
Niktabe (2018) (205)	Herbal therapy (44) vs Placebo (45)	99	SUI or MUI	Herbal therapy: 2.3 mL of qost oil (Hydro alcoholic extract from dried roots of Saussurea costus) was used by local application to the area between the navel and pubic region without massage 2x per day for 6 weeks. Placebo: 2.3 mL of cold pressed sesame oil was used by local application to the area between the navel and pubic region without massage 2x per day for 6 weeks.	Cure: NR Improvement: NR QoL via ICIQ-SF Question 5: N = 82 at 6-weeks (end of treatment), mean difference -2.81;95% CI -3.93 to -1.69; at 10-week (follow-up), mean difference -2.83;95% CI -4.07 to -1.59. Adverse effects: NR	10-weeks	Loss of follow-up: 1 patient in yoga group

Author, year	Comparator	N (randomised)	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Palacios (2020) (206)	Herbal therapy (41) vs Placebo (40)	81	All type of UI	Herbal therapy: 1 pill of Femaxeen (cytoplasmic extracts of pollen 160 mg, pumpkin seed extract 300 mg and vitamin E 10 mg), 1x per day for 90 days, taken orally. Placebo: 1 placebo pill per day for 90 days, taken orally.	Cure: NR Improvement: NR QoL: NR Adverse effects: N=76, adverse events include elevated transaminases, increased cholesterol levels, and headache. 2/38 vs 1/38	90-days	Loss of follow-up: 3 patients in herbal therapy group and 2 in control group

Abbreviations: MUI: mixed urinary incontinence; UUI: urge urinary incontinence; SUI: stress urinary incontinence; UI: urinary incontinence; NR: not reported; QoL: quality of life; OABQ-SF: overactive bladder questionnaire short form; OAB-HRQL: overactive bladder symptom and health-related quality of life questionnaire; BDI-6: Beck Depression Inventory

9. SUMMARY CONSERVATIVE MANAGEMENT OF UI IN WOMEN

9.1. Lifestyle interventions

Prevention

Based on the secondary analysis of a large RCT, a dietary intervention with high fruit, vegetable, and whole grain content as well as a moderate caloric intake can be recommended to postmenopausal women to prevent UI. **(Grade of recommendation: B New)**

Based on one longitudinal study, higher levels of physical activity (≥43.2 MET hours/week) coud be recommended to continent parous middle-aged women. **(Grade of recommendation: C New)**

Treatment:

Behavioral weight loss should be recommended to obese and overweight women with UI. **(Grade of recommendation: A)**

A physical activity programme for the reduction of abdominal fat could be recommended to young overweight women with UUI to reduce LUTS (**Grade of recommendation: C New)**

A low-fat and high-fruit, vegetable and whole grain diet could be recommended as it has a small effect in decreasing UI symptoms independently of weight change, age, ethnicity, and hormone replacement use. **(Grade of recommendation: C New)**

Vitamin D supplementation can be recommended to decrease UUI episodes in post-menopausal women in women of certain ethnicity. **(Grade of recommendation: B)**

An adequate fluid intake and the reduction of caffeine consumption can be recommended for people with UI and related LUTS symptoms. (**Grade of recommendation: B)**

9.2. PFMT

Childbearing women

Prevention

Continent, pregnant women should be offered a supervised PFMT programme (including regular health professional contact) that is intensive and aimed at strengthening PFMs to prevent antepartum and postpartum UI (up to 6 months) UI. **(Grade of recommendation: A)**

Treatment

PFMT should be offered as first line conservative therapy to women with persistent UI symptoms, two to three months after delivery. **(Grade of recommendation: A)**

An 'intensive' PFM strength training programme (in terms of supervision and exercise content) can be recommended as it is related the treatment effectiveness. **(Grade of recommendation: B)**

Prevention and treatment

Health providers should carefully consider the costs and benefits of population-based approaches, such as professionally taught antepartum or postpartum PFMT. PFMT should be provided to all pregnant or postpartum women by a health professional regardless of their current or prior continence status.

(Grade of recommendation - antepartum PFMT: A)

(Grade of recommendation - postpartum PFMT: B)

Women Others

Prevention

Evidence suggest that PFMT is effective in the prevention of UI in younger athletes and menopausal women, immediately after the intervention. (**Level of evidence 2)** Supervised PFMT can be offered to prevent UI in women. **(Grade of Recommendation: B New)**

Treatment

Supervised PFMT should be offered as a first line conservative therapy for women of all ages with UI. **(Grade of recommendation: A)**

Clinicians should offer and provide the most intensive health professional-led PFMT programme possible within service constraints. **(Grade of recommendation: A)**

Supervised individual or group PFMT with confirmation of adequate PFM contraction can be considered in postmenopausal women with SUI and MUI. **(Grade of recommendation: B New)**

Direct PFMT as opposed to indirect PFMT can be recommended **(Grade of recommendation: B New)**

There is no clear benefit for adding other modalities (i.e., motor learning, abdominal or hip muscle training, intra-vaginal resistance devices and adherence strategies) to PFMT and therefore they cannot be recommended. **(Grade of recommendation: B)**

There is no clear benefit for adding clinic- **(Grade of recommendation: B changed)** or home-based biofeedback (**Grade of recommendation: B) or both (Grade of recommendation: A New)** to a PFMT programme. However, biofeedback may be considered for sub-groups of women presenting an important PFM weakness, atrophy, or reduced proprioception.

PFMT and VC are both effective as conservative therapies for SUI, although PFMT can be favoured because a subset of women is unable to use VC and there are side effects associated with their use. **(Grade of recommendation: B)**.

VC with supervised training sessions by a trained health professional can be offered to women with SUI who can and are prepared to use them. **(Grade of recommendation: B)**

PFMT should be preferentially offered over EStim as first line conservative therapy for women with SUI, UUI and MUI. **(Grade of recommendation: A New)**

PFMT can be preferentially offered over BT as a first line conservative therapy for women with SUI, UUI and MUI. **(Grade of Recommendation: B)**

Oxybutynin cannot be recommended over PFMT as a first line therapy in women with UUI and MUI. **(Grade of recommendation: B)**

PFMT and drug therapy (i.e., alpha-adrenergic agonist, tolterodine) interventions showed significant benefits for UI outcomes, although drug therapy results in more adverse effects and a higher dropout rate. PFMT can be offered as the first line therapy **(Grade of recommendation: B)**

Surgery is more effective than PFMT for SUI, but the potential benefits should be weighed against the potential adverse events and cost. PFMT can be offered as the first line therapy because it is less invasive. **(Grade of recommendation: B)**

Both PFMT and continence pessaries can be considered for the treatment of UI as both showed significant benefits for women. **(Grade of recommendation: B)**

Based on limited evidence, combining PFMT with either VC or EStim may not add any benefits and could not be routinely recommended. **(Grade of recommendation: C)**

For the treatment of SUI, UUI, or MUI in women, one could consider the addition of PFMT to BT, which provides additional benefits compared to BT alone. **(Grade of recommendation: C)**

When treating women with SUI and vaginal atrophy, combining PFMT and intravaginal oestrogen over oestrogen alone could be considered. **(Grade of recommendation: C)**

For treatment of UUI (tolterodine) and SUI (duloxetine), adding PFMT to drug therapy can be considered. **(Grade of recommendation: B New)**

Adding PFMT to mid-urethral tape can have potential benefits and could be considered in women with MUI and SUI. **(Grade of recommendation: B New)**

When treating stress-predominant incontinence, adding PFMT to a continence pessary can be considered. (**Grade of recommendation: B)**

9.3. Cones

Treatment

For women with SUI, VC with supervised training sessions by a trained health professional can be offered as a first-line conservative therapy to those who can and are prepared to use them. **(Grade of recommendation: B)** Assessment by a trained health professional is recommended. **(Grade of recommendation: D)**

VC and EStim can be equally recommended in the treatment of SUI and MUI**. (Grade of re-commendation: B)** However, side effects and discomfort appear to limit their utility in clinical practice. **Grade of recommendation: D).**

9.4. EStim

Treatment

EStim can be considered over no treatment to improve symptoms and QoL in women with SUI. **(Grade of recommendation: B)**

EStim can be considered for treatment to improve symptoms for UUI. **(Grade of recommendation: B)** However, this recommendation should be viewed with caution until the findings are supported or refuted in longer-term follow up.

For women with SUI and UUI, pudendal EStim could be recommended as it may be more effective than transvaginal EStim in improving symptoms. **(Grade of recommendation: C)**

External EStim and transvaginal EStim can be recommended to improve SUI in short term. **(Grade of recommendation: B New)**

Transcutaneous TNS may be slightly better than parasacral EStim and therefore could be recommended. **(Grade of recommendation: C)**

There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups. More RCTs are needed.

Medical treatments appear to be less effective than EStim or a combination of PFMT and EStim for SUI and therefore cannot be routinely recommended. **(Grade of recommendation: B)**

Propantheline bromide in women with UUI or oxybutynin and tolterodine for DO cannot be routinely recommended for UUI as they are less effective than EStim. **(Grade of recommendation: B)**

For SUI, the addition of EStim to PFMT or biofeedback-assisted PFMT programmes cannot be routinely recommended as there appears to be no additional benefit. **(Grade of recommendation: B)**

For OAB or MUI, the addition of EStim to BT or BT plus biofeedback can be considered as this adds benefit to the treatment **(Grade of recommendation: B)**

9.5. MStim

Treatment

For women with SUI, MStim can be recommended over no active treatment. **(Grade of recommendation: B New)** However, this recommendation should be viewed with caution until the findings are supported or refuted in further trials with large sample sizes and clear and consistent reporting of core outcome data.

Adding MStim to PFMT does not appear to be beneficial and therefore could not be recommended **(Grade of recommendation: C)**

9.6. TNS

Treatment

For women with UUI or OAB, TNS could be considered over no active treatment in symptom control. **(Grade of recommendation: C)**

For women with urgency UI or OAB, transcutaneous and percutaneous TNS could be recommended as each appears to be equally effective treatments. Transcutaneous TNS is associated with fewer adverse effects. **(Grade of recommendation: C)**

Transcutaneous TNS or percutaneous TNS can be considered for symptom control in combination with other effective treatments by women with urgency UI or OAB. **(Grade of recommendation: B New)**

9.7. Scheduled voiding regimens

Treatment

BT should be recommended as first line conservative therapy for UI in women. **(Grade of recommendation: A)**

Clinicians should provide the most intensive BT supervision that is possible within service constraints. **(Grade of recommendation: D)**

Either BT or anticholinergic drugs can be recommended for women with OAB or UUI **(Grade of recommendation: B)**.

BT may be preferred by women and clinicians because of the absence of drug related adverse effects. **(Grade of recommendation: D)**

EStim or EStim plus biofeedback can be recommended as an adjunct treatment to BT, although further studies are needed. (**Grade of recommendation: B New**)

The addition of written information on BT to an antimuscarinic drug cannot be routinely recommended as it does not appear to further improve UI in women with OAB. **(Grade of recommendation: B)**

Timed voiding with a two-hour voiding interval could be considered as a sole intervention for women with mild UI or infrequent voiding patterns. **(Grade of recommendation: C)**

The routine addition of a “simplified” BT to DT should be considered in the treatment of voiding frequency in women with UI and OAB. **(Grade of recommendation: A New)**

BT can be offered to treat urinary frequency. **(Grade of recommendation: B)**

Either BT and/or an anticholinergic drug can be recommended as both are effective intreating frequency in women. **(Grade of recommendation: B)**

Combining EStim, to BT but not biofeedback can be recommended and may provide additional benefits for treating frequency. **(Grade of recommendation: B New)**

BT can be offered as treatment for nocturia. **(Grade of recommendation: B)**

Combining EStim and BT cannot be recommended over BT alone for treating nocturia. **(Grade of recommendation: B New)**

Moxibustion could be considered in addition to BT for treating nocturia. **(Grade of recommendation: C New)**

BT alone or with anticholinergic drugs can be considered for treating nocturia (with OBA), as they appear equally effective. **(Grade of recommendation: B)**

9.8. Complementary and alternative medicine

Treatment

Acupuncture could be recommended as an optional treatment over no treatment for women with SUI. **(Grade of recommendation: C)**

Either electroacupuncture or anticholinergic drugs can be recommended for the treatment of OAB, UUI and MUI in women. **(Grade of recommendation: B)**

Herbal therapy could be recommended over no active treatment for improving UI and LUTs in women with OAB and UI, but not for QoL.(**Grade of recommendation: C New)**

III. PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (POP) refers to the descent of one or more of the anterior vaginal wall, posterior vaginal wall, uterus, cervix or vaginal vault (cuff scar after hysterectomy). The presence of any such sign should be correlated with relevant prolapse symptoms (207). Women with prolapse commonly have a variety of pelvic floor symptoms. The more common symptoms are: the feeling of (or seeing) a vaginal bulge, a feeling of something coming down, pelvic pressure, low backache, urinary tract symptoms (e.g. frequency, incomplete emptying), anorectal symptoms (e.g. incomplete emptying, having to digitate to empty) and sexual symptoms (e.g. dyspareunia, vaginal laxity) (207). The prevalence of symptomatic POP in the general population is 11.4% (4–12.2%) (208), but this increases to 41% in women over the age of 50 (209). The aetiology of prolapse is multi-factorial. Risk factors include pregnancy, childbirth, congenital or acquired connective tissue abnormalities, denervation or weakness of the PFM, ageing, menopause and factors associated with chronically raised intra-abdominal pressure (e.g., heavy lifting) (210-213). Treatment depends on the severity of the prolapse and its symptoms, and the woman's general health (214). Conservative treatment is generally considered for those with a lesser degree of prolapse, those who wish to have more children, those with frailty or those unwilling or unable to undergo surgery. The aims of conservative treatment in the management of prolapse are threefold and include:

- Preventing the prolapse worsening;
- Decreasing the frequency or severity of symptoms caused by prolapse (i.e., pelvic pressure, vaginal bulging, backache, urinary, bowel and sexual dysfunction);
- Avoiding or delaying of the need for surgery.

Study selection criteria for inclusion in the update

The evidence presented in this section is drawn from recent Cochrane systematic reviews (215), and literature identified from this chapter search strategy (Appendix 1). As the number of studies employing higher quality study designs has continued to increase in the field, we have *included only* RCTs. Because the focus of this chapter is treatment and prevention of prolapse, the main focus of the outcome measures selected are on prolapse signs and symptoms. Therefore, only RCTs that report at least one prolapse outcome were included.

Quality of data

The methodological quality for included trials was assessed using the Cochrane ROB tool (216). Trials were independently assessed by 2 of the authors of this chapter, and judged as either at 'low risk', 'unclear' or 'high risk' across six domains (selection, performance, detection attrition, reporting and other potential sources of bias). The ROB is summarised graphically for each trial in Appendix 2.

Summary of new studies included in the update

We have identified 42 new RCTs as suitable for inclusion. Four of these studies were published outside our search dates (217-220), but were not previously included in earlier versions of this chapter, so we have included this evidence here for completeness. Most of the studies employed a parallel group RCT design (36/43) and were carried out in the USA (9/43) and China (8/43). Multi-arm RCT data are presented as randomised paired comparisons indicated as i, ii or iii. For example, data from Berzuk *et al.* (2015) are presented as three trials of (i) Enhanced education vs standard education; (ii) Standard education vs control (no treatment) and (iii) Enhanced education vs control (no treatment).

We have presented **updated** evidence for the use of conservative management of prolapse in three sections:

- **Section 1. Educational and lifestyle interventions**: seven studies (35, 40, 218, 221-224) of which five studies (seven randomised comparisons) (35, 40, 218, 223, 224), were aimed at prevention of prolapse and two studies focused on treatment of prolapse (221, 225) (see Table 37: Characteristics of included studies for Educational / lifestyle interventions),
- **Section 2. Physical interventions**: 22 studies (30, 73, 91, 217, 219, 220, 226-241). Of these 11 studies aimed at prevention of prolapse (30, 91, 217, 219, 220, 226-231) (see Table 38; Characteristics of included studies of physical interventions for prevention of prolapse) and 11 studies focused on prolapse treatment (73, 232-241) (see Table 39; Characteristics of included studies of physical interventions for treatment of prolapse),
- **Section 3. Pessaries**: 13 studies (242-254), of which one study aimed at prevention (242), and the remaining 12 studies focused on treatment (243-254) (Table 40. Characteristics of included studies for pessaries).

Groupings were broadened to allow data to accumulate within comparisons, to provide stronger and more clinically useful evidence. Consequently, within each of these sections we have divided the evidence into studies aimed at prevention of prolapse and treatment trials. For ease of use, we have summarised the volume of evidence identified earlier editions alongside the new evidence identified in this update in Table 36.

Table 36. Summary of the volume of evidence identified in this update and earlier version of this chapter

	Intervention	Comparator	Number of prevention studies included in previous ICI reviews	New prevention studies identified in this update (References)	Number of treatment studies included in previous ICI reviews	New Treatment studies (References)
Section 1. Educational and lifestyle interventions	Educational / lifestyle intervention (alone or in combination)	No treatment/ usual care/ no active treatment	45 observational studies. No RCTs.	3 studies [35, 40, 223]	1 secondary analysis of an RCT	No studies identified
	Educational / lifestyle intervention (alone or in combination)	An active treatment (or combination)		3 studies [40, 218, 224]		2 studies [221, 225]
Section 2. Physical interventions	Physical intervention (alone or in combination)	No treatment/ usual care/ no active treatment	2 RCTs	6 studies [30, 217, 219, 220, 227, 256]	13 RCTs	1 study [239]
	Physical intervention (alone or in combination)	An active treatment (or combination)		7 studies [30, 91, 226, 228, 229, 230, 256]		5 studies [73, 232, 234, 236, 240]
	A physical intervention combined with a non-conservative adjunct	An active treatment (or combination)	No RCTs	No studies identified	6 RCTs	5 studies [233, 237, 238, 241, 263, 264]
Section 3. Pessaries	Pessary (alone or in combination)	Control / waiting list or no active treatment	No RCTs	1 study [242]	No RCTs	No studies identified
	Pessary (alone or in combination)	An active treatment (or combination)		No studies identified	Preliminary data from 2 RCTs and data from a small trial with recruitment issues	2 studies [244, 248]
	Pessary (alone or in combination)	Surgery		No studies identified	No studies	1 study [254, 268]
	Pessary (alone or in combination)	Another pessary		No studies identified	No studies identified	3 studies [247, 252, 253]
	Studies aimed at optimising pessary management or reducing pessary-related complications			No studies identified	No studies identified	6 studies [243, 245, 246, 249, 250, 251]

Abbreviations: RCT: randomised controlled trial

1. EDUCATIONAL AND LIFESTYLE INTERVENTIONS

Lifestyle and educational interventions seek to avoid the onset and exacerbation of prolapse by decreasing intra-abdominal pressure. For example, heavy (or incorrect) lifting, being overweight and being constipated can cause chronically increased intra-abdominal pressure, which in turn may lead to the development or worsening of prolapse. Education and lifestyle interventions for prolapse might include the following:

- education/advice relating to the effects of body weight/weight reduction,
- education/advice relating to the effects of exacerbating activities (e.g., lifting, coughing),
- education/advice relating to the effects of straining to defecate,
- education/advice relating to the effects of diet and fluid,
- education about the pelvic floor anatomy and conditions.

1.1. Prevention

1.1.1. An educational/lifestyle intervention (alone or in combination) versus no treatment/ usual care/ no active treatment

In this update, three new trials (four randomised comparisons) of lifestyle and educational interventions (either on their own or in combination with other treatments) were identified (35, 40, 223). Salient features of each trial are summarised in Table 37 and the ROB for each trial is presented in Appendix 2.

Quality of data

Berzuk and Shay (2015) (40) (ii) (iii) conducted a 3-arm RCT to assess whether a pelvic floor health education presentation could improve female office workers' knowledge about their pelvic floor and raise their awareness of pelvic floor dysfunction (PFD), including prolapse. Women were randomly allocated to one of three groups: enhanced educational intervention; standard educational intervention or no intervention. The enhanced educational intervention comprised a 60-minute educational presentation on female pelvic health and PFM function including verbal instruction in a home PFM strengthening programme. The session included definitions and risk factors for PFD, the impact of neglect or injury on the PFMs, and available treatments. Healthy behavioural strategies such as proper toileting postures and habits, and bladder and bowel-friendly diet information were presented. Approximately two months following the education intervention, the enhanced educational intervention group were asked to attend a second presentation. The purpose of this second 60-minute presentation was to review the information previously presented to determine the effect of a 'reminder' or 're-education' variable. Women in the standard educational intervention did not get a repeat presentation two months later. Women in the control group received no intervention. Online surveys using validated tools including the Prolapse and Incontinence Knowledge Quiz, PFDI-20, PFIQ-7 and PFM exercise items were completed by all groups on three occasions (at baseline, after the first educational presentation and two months later).

In the PREPARED trial, Hyakutake and colleagues (35) conducted a RCT to assess whether attending a pregnancy workshop would improve pregnant primiparous women's postpartum pelvic floor health knowledge and symptoms. Women with a first singleton gestation were randomised to receive either an education intervention (i.e., 2-hour pelvic floor health workshop delivered while the women were still pregnant) or routine prenatal care. The workshop covered a variety of topics including anatomy, definitions, risk factors, the effect of various modes of delivery, PFMT, preventive strategies, and treatments for PFD. Women were given a workbook with diagrams, tables, and resources. The main outcomes were assessed using questionnaires to measure the difference between groups in knowledge scores; PFMT-specific knowledge and practice; prolapse (POPDI-6) and pelvic floor symptoms (PFDI-20) and condition-specific quality of life (PFIQ-7); and mode of and satisfaction with delivery. Questionnaires were completed by women when they were recruited and again at 6-weeks postpartum.

Takacs and colleagues (2020) (223, 255) conducted a RCT to investigate the effects of an oral dietary supplement aimed at improving postpartum recovery of pelvic floor injuries (and other related symptoms). Postpartum women who had no complications during their pregnancy and who had a first-time normal vaginal delivery were enrolled within 48 hours of delivery. Women were randomised to receive either a specially formulated postpartum supplement plus routine prenatal vitamin (intervention) or a routine prenatal vitamin (control). Women in the treatment group were asked to take a daily oral dose of the supplement (4g leucine, 30 mg zinc, 900mg omega-3 fatty acids) for six weeks. Secondary outcomes included POPDI-6 and UDI-6 symptom questionnaires and POP-Q. Questionnaire data were collected at baseline (immediately following delivery) and 6 weeks post-delivery. POP-Q data were collected at 6 weeks postpartum.

Results

One hundred and sixty-one female volunteers were randomised in the Berzuk (2015) trial (40); 54 received enhanced education, 55 received the standard education intervention, and 52 were allocated to the no treatment group. Of these, 145 completed the trial; 6 women dropped out of the enhanced education group. Seven women dropped out of the standard education group. Three women dropped out of the control arm. Women who received both education interventions (iii), and those receiving only the first education intervention (ii) had significantly better knowledge of pelvic floor anatomy and awareness compared with the control group. The groups receiving education also had significantly fewer pelvic floor symptoms (on PFDI-20) accompanied with significantly better quality of life (on PFIQ-7).

One hundred women were randomised in the PREPARED trial (35): 50 were allocated to each group. Postpartum data were available for 37 women per group. Thirteen women dropped out of the pelvic floor health workshop group. In the control group, 13 women did not return their questionnaires. Women in the intervention arm scored significantly higher on a pelvic floor knowledge questionnaire, reported performing daily PFMT more frequently than women in the control group and were more confident in performing PFMT. Women in the intervention group also reported significantly fewer bowel symptoms than women in the control group. However, there were no differences in urinary or prolapse symptoms, mode of delivery, complications, or satisfaction with delivery between the two groups.

Takacs and colleagues (2020) (223, 255) randomised 66 women: 32 received the intervention, and 34 received the control. Five women in the intervention group did not complete the trial. Eight women dropped out from the control group. There was no significant difference in any of the individual POP-Q measurements between groups at 6 weeks postpartum. However, when the POP-Q data were dichotomised, the authors reported a statistically significant difference in anterior vaginal wall prolapse at or beyond the hymenal ring in the control group compared to the treatment group. No statistically significant difference was found between the groups on POPDI-6, UDI-6, or zinc serum levels at six-weeks. However, the authors note that statistically significantly more women reported bothersome bulge symptoms (based on Q3 from the POPDI-6) in the control group compared with women receiving the intervention.

Summary of the evidence from the previous edition

In this update we have only included evidence from RCTs.

Summary of the evidence identified in this update

Three new studies were included in this comparison.

- A small-medium size study with a moderate-high ROB delivering an educational workshop led to better knowledge of pelvic floor anatomy compared to no intervention, and fewer pelvic floor symptoms (40). **(Level of evidence: 2)**
- A small study with a moderate-high ROB showed women who took part in a pelvic health workshop during pregnancy had better knowledge and better PFMT adherence postpartum compared to controls but there were no differences in delivery outcomes or symptoms. **(Level of evidence: 2)**
- A small study with a moderate ROB evaluating a postnatal oral dietary supplement did not show any difference in women's prolapse symptom scores compared to controls although women receiving the supplement were significantly less like-

ly to have anterior prolapse beyond the hymen or to report a bothersome bulge. **(Level of evidence: 2)**

Recommendations

Improving pelvic floor knowledge in healthy women could be recommended to reduce pelvic floor symptoms **(Grade of recommendation: C New)**

1.1.2. An educational/lifestyle intervention (alone or in combination) versus another active treatment (or combination)

In this update, three trials of lifestyle and educational interventions (either on their own or in combination with other treatments) compared with another active treatment (or combination) were identified (40, 218, 224). Salient features of each trial are summarised in Table 37 and the ROB for each study is presented in Appendix 2.

Quality of data

Our review identified one randomised paired comparison (Berzuk 2015) (i) that compared the effectiveness of an enhanced educational intervention with a standard educational intervention, discussed above (40).

Gozukara and team (2014) (218), conducted a RCT comparing the effects of weight loss on pelvic floor symptoms, prolpase and UI. Overweight and obese women with UI were randomly allocated to a six month behavioural weight loss programme, or a structured education programme (218). Women in both groups were asked to agree not to initiate new treatments for incontinence or weight reduction during the trial. All women were provided four 1-hour group education sessions in the preceding month *prior* to randomisation. Each session included about 20 women, and they consisted of information about the beneficial effects of weight loss, physical activity, and healthy eating on urinary complaints provided by an internist, dietitian, and urogynecologists. In addition, women allocated to the weight loss programme received information about a calorie and fat restricted diet of 1,200–1,800 kcal daily, depending on initial weight, with less than 30% of calories from fat, designed to produce an average loss of 7–9 % of initial body weight within 6 months. The women also met monthly for 6 months in groups of 15–20 for 1-hour sessions that were led by an internist in nutrition, exercise, and behaviour change. Women were provided with sample meal plans suited for their calorie restrictions. They were also encouraged to gradually increase their physical activity. Monthly consultations with women employed behaviour modification techniques (e.g., self-monitoring of diet and exercise) throughout the programme. Women were assessed using the PFDI, including POPDI-6 subscale, and POP-Q at baseline and again at 6 months.

Tuuli and colleagues (2020) (224) conducted a RCT to determine the impact of pushing timing (immediate vs delayed) during the second stage of labour on women's pelvic floor. Primiparous women at term were randomly allocated (at complete cervical dilation with neuraxial analgesia) to either immediate pushing or asked to delay pushing for an hour. Outcome measures included rate and extent of prolapse using POP-Q, PFDI-20 and PFIQ-7, in their subscales including POPDI-6 and POPIQ-7. Data were collected at baseline (questionnaires only) and at six weeks and six months postpartum.

Results

Berzuk and Shay (2015) (40) compared an enhanced educational intervention compared with standard educational intervention. Descriptions of the intervention and details of the dropouts are summarised in 1.1.1. The enhanced educational intervention group had statistically significantly greater pelvic floor knowledge compared with the standard educational group.

In the Gozukara *et al.* (2014) (218) study 378 women were randomised, with 189 women allocated to each group. Of these 321 women completed the trial; 26 women dropped out of the intervention group (lost to follow-up or declined to continue) and 31 women dropped out of the control group (lost to follow-up or declined to continue). Women in the intervention group lost significantly more weight than women in the control group. Women in the weight loss intervention group also had significantly lower totalPFDI-20 score and POPDI-6 subscore at six months. The genital hiatus, perineal body, and Ap measurements on POP-Q were significantly lower in the weight loss group compared with the control group after 6 months.

Tuuli and colleagues (2020) (224) randomised 2414 women; of which 941 completed the questionnaires at baseline (452 women in the immediate pushing group, and 489 women in the delayed pushing group). At the six-week follow-up, 38 women immediate group and 40 women from the delayed pushing group had dropped out; at six months a further 27 women had dropped out of the immediate group and 37 women from the delayed pushing group. There was no significant difference between groups on the POP-Q at six weeks or six months postpartum. No significant difference was seen between groups on the PFDI-20 or PFIQ-7 questionnaires.

Summary of the evidence identified in this update

Three new trials were included in this comparison.

- A small-medium sized study with a moderate-high ROB found an enhanced educational presentation led to better knowledge of pelvic floor anatomy compared to standard educational presentation (40). **(Level of evidence: 2)**
- A large study with generally low ROB showed that a weight loss programme resulted in improved POP symptoms and POPQ measurements in women with UI (218). **(Level of evidence: 2)**
- A large study with an unclear ROB comparing the impact of immediate versus delayed pushing timing during labour on women's pelvic floor outcomes showed no difference on prolapse severity or symptoms, nor on other pelvic floor symptoms. **(Level of evidence: 2)**

Recommendations

An enhanced educational intervention may be recommended to improve healthy women's knowledge of their pelvic floor. **(Grade of recommendation: D New)**

A weight loss programme in overweight women with UI could be considered for improved prolapse symptoms and severity. **(Grade of recommendation: C New)**

1.2. Treatment

1.2.1. Educational / lifestyle interventions (alone or in combination) with no treatment, usual care or no active treatment were identified

In this update, no new trials were identified.

Summary of the evidence from the previous edition

No trials identified

Summary of the evidence identified in this update

No trials were identified highlighting a gap in evidence.

Recommendations

None

1.2.2. Educational / lifestyle intervention (alone or in combination) with another active treatment (or combination)

Two trials of lifestyle and educational interventions (either on their own or in combination) were identified (221, 225). Salient features of each trial are described in Table 37. ROB is summarised in Appendix 2.

Quality of data

The RECOUP trial conducted by Mueller *et al.* (2017) (225) compared the effects of two different prescribed postoperative activity recommendations after reconstructive prolapse surgery. Women undergoing reconstructive pelvic surgery for prolapse (stage II or greater) were randomised to receive recommendations that were either 'liberal' (i.e., no restrictions on lifting or high-impact activities) or restricted (i.e., instructions recommending limited activity). Recommendations for each group were given verbally, detailing their assigned postoperative activity recommendations. Women in the liberal activity group were told to resume activity postoperatively "at their own pace with no restrictions on lifting or high-impact activity (including running, aerobics, sit-ups, and other high-impact activities). Those assigned to restricted activity recommendations were told to abstain from heavy lifting or high-impact activities for 3 months". Women in both groups were given the same recommendations for other activities like walking and stairs and sexual intercourse. Each group also received identical written postoperative instructions except for the activity recommendation section before surgery by a clinic nurse or advance practice nurse. The primary outcome was patient satisfaction. Secondary outcomes included POP-Q measurements, PFDI-20 and PFIQ-7 questionnaires for pelvic floor symptoms, including their prolapse subscale, and QOL. Data were collected pre-operatively, and at two weeks, six weeks and three months after surgery.

In a similar study, Arunachalam (2020) (221) conducted an RCT comparing the impact of postoperative activity instructions on disease specific symptom bother and impact on quality of life. Women were randomised to receive either liberal or restricted instructions following pelvic reconstructive surgery. Details of the instructions were not described. Women were asked to complete PFDI-20 and PFIQ-7 questionnaires, including the prolapse subscales. Questionnaire data were collected at six weeks post-surgery.

Results

The RECOUP study (225) randomised and allocated 108 women to the trial interventions, of which 95 (n=45 liberal, n=50 restricted) completed the primary outcome. Eight women dropped out of the liberal intervention: six did not receive the allocated intervention and two were lost to follow-up. Five women dropped out of the restricted group. Satisfaction with the result of the surgery was equally high in both groups three months after surgery. Women in the liberal postoperative instruction group had statistically significantly fewer prolapse symptoms using the prolapse subscale score of the PFDI-20 compared with women in the restricted group. There was no significant difference between the groups on the PFIQ-7 or its prolapse subscale, or the POP-Q except for point Bp measurements which was statistically significantly better in the liberal group.

Arunachalam (2020) (221) recruited 157 women, of which 146 women completed the study: 72 women in the liberal group and 74 in the restricted group. There was a significant difference between the two groups in prolapse symptom score in favour of the liberal group as measured by the POPDI-6, but no significant difference in quality of life as measured by the PFIQ-7.

Summary of the evidence identified in this update

Two new trials were included in this comparison. Both studies compared the effectiveness of post discharge instructions (restricted activities compared to liberal activities) in women, after prolapse surgery. The findings from the two studies agree that liberal post-operative activity recommendations lead to fewer prolapse symptoms. **(Level of evidence:2)**

Recommendations

Liberal post-operative instructions could be recommended rather than restricted activities for reducing post-operative prolapse symptoms. **(Grade of recommendation: C New)**

Table 37. Characteristics of included studies for educational / lifestyle intervention

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes and key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Arunachalam (2020) (221)	RCT Liberal post-operative activity recommendations vs restricted post-operative recommendations	146	Women scheduled for prolapse surgery USA	Liberal or restricted instructions following pelvic reconstructive surgery. No other details about the intervention are provided.	Outcomes: Activities Assessment Scale, accelerometer readings, PFDI-20 and PFDI-7 Key findings: no significant difference between the liberal or restricted groups on physical activity between the groups, but women in the liberal instruction group reported significantly less symptom distress on POPDI-6 compared with women in the restricted group at 6 weeks follow-up.	PA measures were collected at baseline, 2 weeks and 6 weeks FU surgery. Questionnaires data collected 6 weeks post-surgery	Publication: FT Dropouts: NR AE: not described
Berzuk (2015) (i) (40)	3-arm RCT Three randomised paired comparisons	109	Women working in a large corporation who volunteered (no incentive) for a women's health research study Canada	Enhanced education: 60-minute educational presentation on PFH and PFM function including instruction in home PFM strengthening program + 60-minute presentation 2 months later to review previous information Standard education: 60-minute educational presentation on PFH and PFM function including instruction in home PFM strengthening program CG: no treatment	Outcomes: primary outcome was Pelvic Floor Knowledge measured using Prolapse and Incontinence Knowledge Quiz, 24 true or false statements, score 0 to 24 converted to %, higher score indicates better knowledge. Secondary outcomes: Pelvic floor symptoms and QoL measured using the PFDI-20 and PFIQ-7 Key findings: participants in the two groups receiving education showed significantly better knowledge ($p<0.001$), PFD symptoms ($p<0.001$), and QoL ($p<0.05$), compared with those in the control group.	T1 (baseline), time 2 (24 hours after the first presentation), T3 (following the second presentation to group A – 2 months after the first presentation	Publication: FT Dropouts: accounted for. 10/161 withdrew post-randomisation; data from a further 6 women was excluded because they didn't attend a presentation or fully complete a survey. AE: none (personal communication)
Gozukara (2014) (218)	RCT Behaviour weight loss program + Structured education program vs Structured education program	378	Overweight/ obese women (i.e., BMI> 25 kg/m2) who also had >5 or more episodes of any UI in a-3-day voiding diary Turkey	Behaviour weight loss program – calorie and fat restricted diet plus behavioural modification techniques delivered over 6 months. All women were provided 4x 1-hour group education sessions in the preceding month prior to randomisation. Each session included about 20 women, and they consisted of information about the beneficial effects of weight loss, physical activity, and healthy eating on urinary complaints provided by an internist, dietitian, and urogynecologists.	Outcomes: POP-Q, PFDI-20 (Turkish version), number of UI episodes Key findings: women in the weight loss group had a significantly higher weight loss compared to the control group ($p<0.001$), and a reduction in SUI. POPDI-6 and total PFDI scores were significantly reduced in the weight loss group compared with the control group. There was little difference between groups on POP-Q measurements with women in the weight loss group only showing significantly lower measurements on the genital hiatus, perineal body and Ap measurements.	Data were collected at baseline and at 6 months (i.e., immediately post-intervention)	Publication: FT Dropouts: 26/189 women in the weight loss group and 31/189 in the structured education group declined to continue or were lost to follow-up. No reasons were given for why women declined AE: none described in the paper

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes and key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Hyakutake (2018) (35)	RCT PREPARED trial Pelvic floor health workshop delivered during pregnancy vs usual care	100	Primiparous women aged 20 years +, with a singleton pregnancy, with maternity providers including obstetricians, mid- wives, and family physicians Canada	IG: Two-hour workshop on pelvic floor health, and given a workbook with diagrams, tables, and resources. CG: received routine prenatal care	Outcomes: primary outcome was pelvic floor health knowledge questionnaire at 6 weeks PP. Secondary outcomes included PFME specific knowledge and practice of PFMEs, PFDI-20, POPDI-6, CRADI-8, UDI-6, PFIQ-7, CRAIQ-7, UIQ-7 mode of delivery and satisfaction with the delivery 6 weeks PP. Key findings: women in the pelvic floor health workshop group had significantly more pelvic floor knowledge (p=0.02), performed daily PFMT more frequently (p=0.002) and were significantly more confident in performing PFMT (p=0.004) and had fewer bowel symptoms (p=0.046) than women in the control group. No significant differences in prolapse symptoms between groups.	Questionnaires were completed at recruitment and 6 weeks PP	Publication: FT Dropouts: 40/50 received the intervention; 5 were lost to follow-up, 3 developed pregnancy related complication and 2 women withdrew for personal reasons; only 37 women returned their questionnaires Drop-out details not reported for the control group; only 37 women in this group returned their questionnaires. AE: none described in the paper
Mueller (2017) (225)	RCT Liberal post-operative activity recommendations vs restricted post-operative recommendations	108	Women undergoing reconstructive pelvic surgery for stage II or greater prolapse USA	Women in the liberal group were told to resume postoperative activity at their own pace with no restrictions on lifting or high-impact activity (including running, aerobics, sit-ups, and other high-impact activities). Women in the restricted group were told to abstain from heavy lifting or high-impact activities for 3 months. Each group received identical written postoperative instructions with the exception of the activity recommendation section before surgery. Women then underwent planned surgery. On discharge from the hospital, women were provided with a duplicate of the appropriate postoperative instructions, again detailing their assigned postoperative activity recommendations.	Outcomes: primary outcomes included patient satisfaction after surgery based on women's responses How satisfied are you with the result of your prolapse surgery? Secondary outcomes: POP-Q, PFDI, PFIQ, health-related quality of life as assessed by the Patient-Reported Outcomes Measurement Information System profile, Activity Assessment Scale, women to quantify their high-impact activity by asking the following question: During the past month, on average, on how many days in each week did you do strenuous or very hard exercise; that is, exercise that caused you to work up a sweat and made your heartbeat fast. For example, high- impact activities such as aerobics, dancing, jogging, or tennis. Women also provided an answer of minutes per day spent performing these activities. Key findings: At 3 months, satisfaction with surgery was equally high in both groups. Women in the liberal postdischarge instruction group had significantly fewer prolapse symptoms using the prolapse subscale score (PFDI-20) compared with women in the restricted group (p=0.13). There was no significant difference between the groups on POP-Q stage except for point Bp measurements which was significantly improved in the liberal group.	Routine clinical postoperative appointments were conducted at 2 weeks, 6 weeks, and 3 months after surgery.	Publication: FT Dropouts: Restricted intervention: 5 women did not receive the intervention (dropped-out); none lost to FU. Liberal group: 5 not eligible, 1 dropped out; 2 lost to FU. AE: not described

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes and key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Takacs (2020) (223, 255)	RCT Oral dietary supplement + routine prenatal vitamin vs routine prenatal vitamin	66	PP women who had no complications during the course of their pregnancy with a normal first-time birth with vaginal delivery Hungary	IG: Supplement was a multi-vitamin composition aimed to promote healing of muscular injuries following delivery (prenatal vitamin, 4g leucine, 30 mg zinc, 900mg omega-3 fatty acids) once a day for six weeks CG: prenatal vitamin	Outcomes: primary outcomes included vaginal squeeze pressure and levator muscle injury. Secondary outcomes included POPDI-6, UDI-6, zinc serum samples and POP-Q. Key findings: significantly fewer women reported bothersome bulge in the supplement group at 6 weeks pp (p=0.02), but there were no differences between groups on POP-Q measurements.	Questionnaire data were collected at baseline (immediately following delivery) and 6 weeks post-delivery. Serum samples and POP-Q were collected at 6 weeks PP	Publication: AB, FT Dropouts: 5/32 women in the IG did not complete the trial; 2 were lost to FU and 3 withdrew because of minor AE. 8/34 dropped out from the CG; four were lost to FU, two withdrew consent before starting, one developed a minor AE, and one woman refused the clinical examination at the six-week FU. AE: minor AE reported in both groups including a rash (one case from each group), inability to swallow the tablets in one woman (IG) and one woman thought her infant's vomiting was related to the supplement in the IG
Tuuli (2020) (224)	RCT Immediate pushing vs delayed pushing during second stage of labour	941	Nulliparous women at term USA	At complete cervical dilation with neuraxial analgesia) women were asked to either immediate pushing or asked to delay pushing for an hour	Outcomes: rate and extent of prolapse using POP-Q, and PFDI-20, PFIQ-7 and Fecal Incontinence Severity Index questionnaires Key findings: no significant differences between groups on PFDI-20 total scores at 6 weeks (p=0.18) or 6 months (0.09) or PFIQ-7 total scores at 6 weeks (p = 0.27) or at 6 months (p=0.30)	Data were collected at baseline (questionnaires only) and at six weeks and six months PP	Publication: AB Dropouts: 6-week FU, 38/452 women from the immediate group; and 40/489 women from the delayed pushing group had dropped out; at six months a further 27 women had dropped out of the immediate group and 37 women from the delayed pushing group. Reasons for dropouts are NR AE: not described

2. PHYSICAL INTERVENTIONS

The PFMs play a critical role in giving structural support to the pelvic organs and pelvic openings. It is hypothesised that improving PFM function may improve this structural support. Physical interventions predominantly include PFMT. A programme of supervised PFMT includes assessment of the woman's PFMs and her ability to contract these muscles; education about the PFMs and how they support the pelvic organs; instruction in how to correctly perform PFM exercises and "the Knack". An individualised exercise programme is prescribed for the woman to follow. Adjuncts to PFMT (such as biofeedback) or other physical therapies (such as neuromuscular EStim) may be used. Other interventions, which are hypothesised to work indirectly on the PFM, also fit under the heading of physical interventions. Examples of these interventions are transversus abdominis muscle contraction and hypopressive exercises.

2.1. Prevention

2.1.1. Physical intervention (alone or in combination) vs no treatment/ usual care/ no active treatment

In this update, six studies (10 randomised comparisons) of physical interventions were identified (30, 217, 219, 220, 227, 256). Key features of each trial are described in Table 38. ROB is summarised in Appendix 2.

Quality of data

Fritel and colleagues (227) conducted a RCT to examine the postnatal effect of prenatal supervised PFMT with written instructions in nulliparous pregnant women. Women between 20 and 28 weeks of gestation were randomised into two groups. The prenatal PFMT group received individual supervised exercises conducted during the 6th and 8th month of pregnancy. Women were seen individually by a specialist physiotherapist once a week for 8 weeks. Each 20 to 30-minute session consisted of standing contractions (5 minutes), lying contractions (10 minutes) and learning how to start a pelvic floor contraction just before exerting intra-abdominal pressure (the 'knack'). Women also had their PFM contractions assessed through a vaginal examination in each session. Women were encouraged to perform the PFMT daily but were given no specific instructions about the number or intensity of each. The control group received written information about the anatomy of the pelvic floor and pelvic floor contraction exercises. Both groups received written instructions about how to perform exercises at home. Women were assessed at baseline, end of pregnancy, and 2 and 12 months postpartum. The primary outcome measured was the severity of UI assessed using the ICIQUI-short form questionnaire (validated in French). Other outcomes included the Female Pelvic Floor Questionnaire (with bladder, prolapse, bowel and sex subscales), a clinical examination with the POP-Q and a 24-hour pad test which were performed at baseline and at the 2-month postpartum visit.

Glazener (2014) (217) reported prolapse outcomes from the PROLONG study which aimed to improve postnatal urinary and faecal incontinence. Women (primiparous and multiparous) were randomly allocated to receive either a nurse-led intervention (after delivery) comprised of PFMT and BT or standard care in this large multicentre trial. PFMT was delivered by specially trained nurses and involved three individual, face-to-face instruction (with BT if indicated) at 5, 7 and 9 months after the birth. Data were collected at trial entry, and at 1 and 6 years (257, 258). In 2014, Glazener and colleagues presented the data from the 12-year follow-up, which included data about women's prolapse symptoms (using the POP-SS) for the first time.

Kou and colleagues (2013) (220) conducted a RCT evaluating the effectiveness of postpartum pelvic floor rehabilitation in women 6 weeks after giving birth. The study was published in Chinese and a translation was available. Women aged between 25-35 years were randomly divided into two groups: the intervention group received PFMT and EStim, and women in the control group received standard postnatal care. The intervention involved PFMT consisting of 150-200 contractions of 3-s, performed 2-3 times per day. Each session lasted 20-30 minutes and used the Phenix EStim device, twice a week. The authors measured POP-Q at 6 weeks and 12 months postpartum.

Liu and colleagues (219) conducted a single centre RCT that compared PFMT during pregnancy with standard care in low risk primigravida women. The study was published in Chinese and a translation was available. Women were recruited during their first pregnancy visit (16-30 weeks' gestation) and were randomly allocated to receive either PFMT or usual care (standard educational information). Pelvic floor physiotherapists supervised the PFMT. Women were asked to repeat a contraction of 5 to 10 seconds, follow by 5 to 10 seconds rest, then fast contractions 10-15 times. They were encouraged to perform this sequence for 15-20 minutes, 2-3 times daily and continued for 8 weeks. POP-Q was measured at 6 weeks after delivery.

In the Yang 2017 (30) 3-arm single-centre RCT, primiparous women aged between 20-35 years and with an episiotomy or second-degree tear were randomly assigned to one of three groups:

- a *'training group'* that received PFMT and other pelvic exercises from two days postpartum until three months postpartum. Two specialists provided the 20-minute training session, which consisted of teaching a programme of five second contractions followed by five seconds of relaxation. The vaginal palpation method was employed to ensure that women performed the exercises correctly. Women were also instructed to complete other pelvic movement exercises (swinging bent legs from left to right; pulling a bent knee towards the chest followed by gentle swaying). When the women were judged to have correctly mastered the exercises, they were then allowed to complete them at home and encouraged to complete them 2-3 times per day.
- a *'combination group'* who received the same rehabilitation exercises as the training group, plus 15 sessions of transvaginal EStim at low voltage, low frequency, beginning at week 6 postpartum. EStim sessions were delivered 3 times a week and lasted 30 minutes. Two specialist trained staff members delivered the stimulation using the PHENIX Neuromuscular Stimulation Therapy System. Current frequency was 60–80 Hz. The ratio of the EStim duration (contraction) and interval time (relaxation) was individualised and adjusted depending on the woman's response.
- A '*control group'* who were given routine postpartum guidance (two hours postpartum) delivered by two specially trained staff members. Guidance included information on appropriate physical and sport activity to promote postpartum recovery, dietary advice (e.g., eating more vegetables and fruits) to avoid constipation, general advice to avoid forceful coughing and lifting heavy objects, and advice on breastfeeding.

Data were collected during the third month after delivery. Outcomes that were measured included prolapse severity using POP-Q.

Zhang and colleagues (256) conducted a 4-arm RCT that randomised primiparous women 6 weeks after a vaginal delivery into one of the following:

- Control group (standard care)
- PFM exercise group
- Weighted vaginal cones ('vaginal dumbbell group')
- Biofeedback combined with electrostimulation (subdivided into two groups: individual vs traditional)

Details about each of the interventions were limited as no full text paper is currently available. Data were collected at baseline (6 weeks postpartum), 3 months postpartum and 9 months postpartum (i.e., 6 months' post-intervention). Outcomes measured at these timepoints included severity of prolapse using the POP-Q and PISQ-12.

Results

Of the 282 women recruited in the multicentre RCT conducted by Fritel and colleagues (227), 140 nulliparous pregnant women were randomised to the physiotherapy group and 142 to the control group. By the end of the pregnancy, 224 women had completed the study; at 2 months post-partum 212 women were still enrolled in the study and by 12 months post-partum 190 women completed the study. The authors reported no difference in prolapse or pelvic floor symptoms at baseline, end of pregnancy, and at 2 and 12 months postpartum between the groups.

Glazener and colleagues (2014) originally randomised 747 women, of which 371 were allocated to the PFMT group and 376 to the standard care arm. At the 12-year follow-up, 230 women in the PFMT arm responded and 241 women in the standard care group responded. One hundred and forty-one women dropped out of the PFMT group and 145 women dropped out of the standard care group. The prevalence or severity of prolapse symptoms or number of women having surgery for prolapse did not differ between groups at the 12-year follow-up. The researchers objectively measured POP-Q in a subsample of women (35%) at 12 years (76 women in PFMT group and 89 women in standard care) and found no evidence of a difference in prolapse severity between the groups.

One hundred and fifty women were randomised in the Kou (2013) study (220); of these, 80 women received the intervention and 70 were enrolled in the control arm. No dropouts were reported. The incidence of stage I POP was significantly lower in the intervention group at 12 months postpartum compared with women in the control group.

Liu 2013 (219) randomised 360 pregnant women (180 women in each group) but data were only reported for 329 women as 31 women (14 PFMT group; 17 control) were lost to follow-up six weeks after delivery: the reasons were not provided. Significantly more women in the treatment group exhibited stage 0 prolapse and significantly fewer had stage II prolapse at 6 weeks post-partum compared with women in the control group; however, there were no differences between groups in the percentage who had stage I prolapse.

In this section we also consider the findings from two randomised paired comparisons comparing the effectiveness of a physical intervention with standard care:

- Yang 2017 (i) training group vs control group,
- Yang 2017 (iii) combination group vs control group.

The findings from the third randomised comparison (i.e., combination group vs training group) is considered later in section III.2.1.2.

Of the 240 women randomised across the three study arms, a total of 189 women were seen for follow-up measurements at 3 months after delivery. Seventeen women from the training group; 14 women from combination group and 20 women from the control group withdrew from trial or were lost to follow-up. Women in the training and combination group were significantly more likely to have had an improvement in the stage of prolapse, compared to women who received standard postpartum care (30).

Our review also identified three relevant randomised paired comparisons (Zhang (i, iv and vi) (256) that compared the effectiveness of:

- Zhang 2016 (i) PFM exercises vs control group
- Zhang 2016 (iv) weighted vaginal cones vs control group
- Zhang 2016 (vi) biofeedback plus EStim (subdivided into two groups: individual vs traditional) vs control group.

The results from three other randomised comparisons from this study (256) are presented later in section III.2.1.2. In this trial 2700 women were enrolled; 675 women were randomly allocated to each of the four study arms and 2403 women were evaluated after 6 weeks treatment. Reasons for dropouts were not fully reported but recorded as "lost to follow-up" (69 in control group, 74 in PFM exercise group, 81 in vaginal cones group and 73 in the biofeedback plus EStim group). Data reported in the abstract are limited and authors concluded that "biofeedback combined with EStim has advantages over the PFM exercises", but no statistical data were available to compare data across groups, and we anticipate that the results from this large-scale multicentre trial will be available in the next update.

Summary of the evidence from the previous edition

PFMT is shown to prevent symptoms of prolapse which develop in the longer term after childbirth, but not immediately after childbirth. **(Level of evidence: 1)**

Summary of the evidence identified in this update

Conflicting evidence from two large trials of ante-natal PFMT with high ROB reported less severe prolapse stage at 6 weeks' postpartum (219) and no difference in prolapse stage or symptoms in the postpartum period up to 12 months compared to control (227).

Evidence from two large uncertain to high ROB trials of postpartum PFMT +/- EStim (30, 220) reported a difference in prolapse stage between groups in favour of the intervention. **(Level of evidence: 2)**

Recommendations

Antenatal PFMT cannot be routinely offered for prevention of postnatal prolapse**. (Grade of Recommendation: B)**

Postnatal EStim in addition to PFMT could be recommended as beneficial in preventing prolapse in women in the post-partum period. (**Grade of recommendation: C New)**

2.1.2. Physical intervention (alone or in combination) vs an active treatment (or combination)

In this update, seven studies (9 randomised paired comparisons) of physical interventions were identified (30, 91, 226, 228-230, 256). Key features of each trial are described in Table 38. ROB is summarised in Appendix 2.

Quality of data

Artymuk and colleagues (226) conducted a RCT comparing PFMT using two different devices. Women who had delivered a baby in the preceding 12 months were randomly allocated to either PFMT using the EmbaGYN pelvic floor training device or to perform assisted PFMT using Magic Kegel Master pelvic floor training device. Women in both groups were asked to use the "postpartum" exercise setting. Women were asked to perform PFMT for 20 minutes per day over 4 weeks. The researchers contacted the women in both groups to offer support and encouragement. Questionnaires (PFDI-20 and FSFI) were administered at baseline and immediately post-intervention.

Bergman and colleagues (2020) (91) conducted a RCT that compared PFMT with perineorrhaphy in women with a poorly healed (more than 6 months postpartum) second-degree perineal tear. Women were randomly allocated to receive either PFMT or surgical treatment. Women in the PFMT group were initially referred to a physiotherapist for an assessment of their PFM strength. Women were educated about their PFMs and taught how to perform a PFM contraction. Biofeedback or EStim was used, if needed, to help women correctly perform PFM exercises. They were given a home-based exercise programme which involved women gradually building up 10 maximal contractions, (5 seconds long), three times per day and one maximal contraction of 30–60 seconds. Women were then scheduled for 1–3 follow-up visits. Women in the surgical group were scheduled for perineorrhaphy with distal posterior colporrhaphy which was standardised prior to the commencement of the trial. Surgeries were performed in the outpatient surgical ward by one of five urogynecologists. Primary outcome was treatment success, defined by PGI-I. Secondary outcomes included the PFDI-20 and PFIQ-7 (and their prolapse subscales), the Pelvic Organ Prolapse/UI Sexual Questionnaire, POP-Q and HADS. Data were collected at baseline and at 6 months.

Huan (2020) (228) recently conducted a RCT comparing PFMT plus EStim, biofeedback compared with PFMT. Postpartum women (4-6 weeks postpartum) with no pregnancy complications were randomly assigned to receive either individualised, tailored PFMT plus EStim, biofeedback or PFMT alone. Women in the PFMT alone intervention received group education about the symptoms and causes of pelvic floor disorders and PFMT training methods. Women were then taught to do PFM exercises at home. Exercises were performed in the horizontal position and involved contracting PFMs for 5-seconds and relaxing for 5-seconds with three rapid contractions at the end of the session. Each session lasted approximately 15 minutes. Women were asked to perform the exercises twice a day, and gradually increase the frequency and intensity over 6 months. After discharge, women were phoned every two weeks for the first three months, and then every four weeks in the last three months of the intervention. Women in the PFMT plus EStim biofeedback group received tailored PFMT training combined with EStim biofeedback therapy. A total of 10 biofeedback therapy sessions were delivered: three times per week with each session lasting 20 mins. Four weeks later the individualised PFMT training was delivered as described for the PFMT alone group. Women were phoned every two weeks for the first three months, and then every four weeks in the last three months of the intervention. Outcomes included PFDI-20 and PFIQ-7 (prolapse subscales not reported), PISQ-12 and POP-Q. Data were collected at baseline and at six months.

Juninger (2018) (229) conducted an RCT comparing a bladder neck effective PFM rehabilitation programme with PFMT with EMG-biofeedback in women with SUI. The authors argued that PFMT programmes can vary in approach and that comparison was necessary to determine the effectiveness of one approach against another. Women with SUI who were able to perform a PFM contraction were randomised to either the bladder neck effective PFM rehabilitation programme or EMG-biofeedback augmented PFMT. Women in the bladder neck effective PFM rehabilitation programme were given perineal ultrasound for visual biofeedback for teaching and practicing bladder neck support and elevation as well as PFM precontraction daily for three months. Women in the EMG-biofeedback augmented PFMT group were given an EMG-biofeedback device with a vaginal probe for performing daily home exercises for three months. A specialist physiotherapist checked the performance of women in both groups three times. Women were then offered to switch groups after three months according to their preference. The primary outcome measure was subjective improvement-cure rate after 3 months. Secondary outcomes included changes in a validated German pelvic floor questionnaire (Bladder, Bowel, Prolapse and Sex subscales). Data were collected at baseline and immediately post-intervention.

Sun and colleagues (2015) (230) conducted a RCT to examine whether PFMT could prevent or improve women's pelvic floor function postpartum. Although the trial was published in Chinese, a translation was available. Women who had given birth to a single child at term were randomised to receive EStim plus PFMT with biofeedback (intervention) or PFMT at home (control). Women in the intervention group started the intervention at 6 weeks postpartum. EStim was tailored but commenced at a frequency of 8 -33 Hz (pulse width 320-740 microns) in the first two weeks and increased in weeks 3 – 4 to 20-80 Hz (pulse width 20-320 microns). Women were seen twice a week for four weeks, and each session lasted approximately 20 minutes. Outcome measures included prolapse severity using POP-Q, PFIQ-7 and PISQ-12. Data were collected at 6 weeks, 6 months and 12 months postpartum.

Our review identified also one randomised paired comparison Yang 2017 (ii) (30) (Table 38) that compared the effectiveness of combination training with training alone in primiparous women. Details of this trial, dropouts and methodological quality are described earlier in section III.2.1.1 (see Yang (i/iii) (30), Table 38).

Our review also identified three relevant randomised paired comparisons (Zhang (ii, iii and v) (256) that compared the effectiveness of:

- Zhang 2016 (ii) PFM exercises vs weighted vaginal cones
- Zhang 2016 (iii) PFM exercises vs biofeedback plus EStim (subdivided into two groups: individual vs traditional)
- Zhang 2016 (v) weighted vaginal cones vs biofeedback plus EStim (subdivided into two groups: individual vs traditional).

Details of this trial, dropouts and methodological quality are described earlier in section III. 2.1.1.

Results
Eighty women in the postpartum period were randomised in the Artymuk trial (226) (40 in each group). Of these, 34 women completed the study in the EmbaGYN group, and 36 women completed the study in Magic Kegel Master group. The reasons for drop-out were not clearly reported but the authors reported that these women were excluded from the analysis because of poor adherence. Immediately post-intervention, there were no significant differences between the groups for any of the outcomes.

Seventy women were randomised in the Bergman (2020) study (91); 35 women were allocated to each group. In the PFMT arm, 33 women received the intervention, one woman did not receive the allocated intervention and crossed over to the surgical arm and one woman was reported as not meeting the inclusion criteria as she had a history of grade 4 perineal tear. In the surgical arm, 30 women received the intervention; 4 did not receive the allocated intervention (three did not undergo surgery and one crossed over to the PFMT arm) and one woman did not adhere to the protocol as she had a concomitant mid-urethral sling. No woman was lost to follow-up in either arm. Surgical treatment had a significantly higher treatment success rate – defined as "much better" and "very much better" on the PGI-I questionnaire, and significantly greater improvement in all secondary endpoints at 6 months of follow-up.

Huan (2020) (228) randomised 124 women of which 62 were allocated to the PFMT +biofeedback and EStim and 62 received routine PFMT. No dropouts were reported. The POP-Q stage of women in the PFMT + biofeedback and EStim group was significantly better than women who received PFMT alone. There was no significant difference in PFDI-20, PFIQ-7 and PISQ-12 scores between the two groups.

Juninger (2018) (229) randomly allocated 83 women: 47 to the bladder neck effective PFM rehabilitation programme and 36 women to the PFMT with EMG-biofeedback arm. Nineteen women did not start treatment because of time constraints and illness, leaving 32 women allocated to each group. No further dropouts were reported. Data were difficult to interpret based on the results reported in the abstract and the prolapse symptom score was significantly different between groups at baseline. The prolapse score was presented as divided into two groups (so losing the randomisation) and we were unable to draw any conclusions.

Three hundred and twenty four women were randomised in the Sun and colleagues (2015) trial (230) (200 women in intervention group and 124 in control group). The POP-Q staging point Aa showed a statistically significantly greater improvement in the treatment group compared with the control group; no other difference was seen for any of the other POP-Q points. There was no statistically significant difference between groups on the QoL questionnaire or sexual life questionnaire.

Yang 2017 (ii) (30) (Table 38) compared the effectiveness of combination training with training alone in primiparous women. Details of this trial, dropouts and methodological quality are described earlier in section III.2.1.1. (see Yang (i/iii) (30), Table 38). Women in the combination group had significantly better stage of prolapse, compared to women who received rehabilitation exercises alone. However, based on the limited statistical data, this does not appear to be statistically significantly different between the groups.

Data reported in the Zhang 2016 (ii, iii and v) abstract (256) are limited with no statistical data available to compare data across groups, and we anticipate that the results from this large-scale multicentre trial will be available in the next update.

Summary of the evidence from the previous edition

No trials identified.

Summary of the evidence identified in this update

Seven trials (9 comparisons) were included in this update, however for three trials (5 comparisons) no conclusions could be drawn (30, 229, 256). The remaining four trials (91, 226, 228, 230) were conducted in postnatal women. One of these was a small, high ROB study which showed no difference between two different types of PFMT device (226). Another small, moderate ROB showed that surgery was better than PFMT at six months follow-up for treatment of post-natal tears (91)idence. One moderate size study with an uncertain ROB found no difference in symptoms between PFMT + EStim and PFMT alone but POP-Q was better with combined (PFMT + stimulation) treatment (228). One large study with a moderate ROB showed that POP-Q was better at 12 months post-partum in the EStim and PFMT + biofeedback group compared to PFMT alone (230). **(Level of evidence: 2)**

Recommendations

A combination of EStim plus PFMT, or EStim plus PFMT and biofeedback given preventatively postpartum could be recommended as this combination is shown to improve the stage of prolapse compared with PFMT alone. (**Grade of recommendation: C New)**

2.1.3. A physical intervention combined with a non-conservative adjunct vs no treatment/ usual care/ no active treatment

In this update, no new trials were identified.

Summary of the evidence from the previous edition

No trials identified.

Summary of the evidence identified in this update

No trials were identified highlighting a gap in evidence.

Recommendations

None.

2.1.4. A physical intervention combined with a non-conservative adjunct vs an active treatment (or combination)

In this update, no new trials were identified.

Summary of the evidence from the previous edition

No trials identified.

Summary of the evidence identified in this update

No trials were identified highlighting a gap in evidence.

Recommendations

None.

Table 38. Summary of key characteristics of prevention studies of women with POP and physical interventions

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Artymuk (2020) (226)	RCT Device assisted PFMT trainer vs device assisted PFMT trainer	70	Women in post-partum period Russia	Women in both groups asked to perform assisted PFMT exercises for 20 mins/day over 4 weeks. Group 1 used the EmbaGYN and Group 2 used the Magic Kegel Master device.	Outcomes: PFDI-20, FSFI, PFM strength measured Key findings: No significant differences between groups for on any outcomes.	Baseline and at 4 weeks (immediately post-intervention)	Publication: FT Dropouts: 10 women were excluded from the analysis due to non-adherence to the exercise program (p2) AE: Not described in the paper.
Bergman (2020) (91)	RCT PFMT vs surgical treatment (perineorrhaphy)	70	Women with a poorly healed (more than 6 months postpartum) second-degree perineal tear Sweden	PFMT assessment provided with education about PFM and biofeedback and/or electrstimulation if needed. Home-based exercise program involved gradual build-up to 10 maximal contractions, (5 seconds long), three times per day and one maximal contraction of 30–60 seconds. Women in surgical treatment group received perineorrhaphy with distal posterior colporrhaphy.	Outcomes: primary outcome treatment success, defined by PGI-I. Secondary outcomes included the PFDI-20, PFIQ-7, the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire with three additional unvalidated questions for vaginal symptoms, POP-Q and HADS Key findings: Surgical treatment had a significantly higher treatment success rate – defined as much better and very much better on the PGI-I questionnaire, and significantly greater improvement in all secondary endpoints at 6 months of follow-up	Baseline and at 6 months	Publication: FT Dropouts: 2/35 women in PFMT did not receive the intervention; 5/35 women in the surgical arm did not receive the intervention and one woman did not adhere to the protocol AE: Not described

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Fritel (2015) (227)	RCT Prepartum PFMT vs written PFMT instructions	282	Nulliparous pregnant women randomised in 2nd trimester France	Women in the physiotherapy group were given 8 sessions of individually supervised exercises delivered by a trained physiotherapist or midwife Both groups of women were given written PFMT instructions	Outcomes: primary outcome was ICI-UI short form questionnaire (validated in French). Secondary outcomes included clinical examination with the POP-Q, clinical assessment of PFM strength and a 24-hour pad test were performed at baseline and at the 2-month postpartum visit. Key findings: no difference in UI severity, prevalence, or pelvic floor symptoms at baseline, end of pregnancy, and at 2 and 12 months postpartum between the groups.	Baseline, end of pregnancy, and 2 and 12 months postpartum.	Publication: FT Dropouts: 93/140 women in the physiotherapy group and 97/142 had a primary outcome available at 12 months. AE: None related to the treatment were reported in the PFMT group.
Glazener (2014) (217)	RCT (PROLONG study) PFMT and bladder training vs standard care	471 (original RCT randomised 747)	Women in post-partum period	Specially trained nurses. Individual PFMT instruction (with bladder training if indicated) at 5, 7 and 9 months after the birth Standard care	Outcomes: primary outcome was the incidence of UI, secondary outcomes FI and POP-SS Key findings: prevalence or severity of prolapse symptoms or number of women having surgery for prolapse did not differ between groups at 12-year follow-up	Baseline, year 1, year 6 and 12 years (collected POP-SS data for first time)	Publication: FT Dropouts: 141 dropped out of the PFMT group (1 died, 31 moved and 109 did not respond) and 145 women dropped out of the standard care group (1 died, 42 moved and 92 did not respond). AE: none related to PFMT reported

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Huan (2020) (228)	RCT PFMT plus electrical stimulation biofeedback vs PFMT	124	Women in post-partum period PRC	PFMT alone: group education about PFD and PFMT, taught PFM exercises at home (individual) comprised of contracting PFM for 5-seconds and relaxing for 5-seconds with three rapid contractions at the end of the session, 2 sessions / day (each session lasted approx. 15 mins) gradually increasing in frequency and intensity. Intervention delivered over 6 months. PFMT plus electrical stimulation biofeedback: received tailored PFMT training (as described above) combined with electrical stimulation biofeedback therapy (10 biofeedback therapy sessions were delivered: three times per week with each session lasting 20 mins). Four weeks later the individualised PFMT training was delivered as described for the PFMT alone group.	Outcomes: PFM strength, A3 reflex, POP-Q, PFDI20, PFIQ-7 and PISQ-12. Key findings: POP-Q score of women in the PFMT and electrostimulation group significantly better than women who received PFMT alone. No significant difference in PFDI-20, PFIQ-7 and PISQ-12 scores between groups	Baseline and at six months	Publication: FT Dropouts: none AE: not described in the paper
Jung-inger (2018) (229)	RCT Bladder neck effective PFM rehabilitation program vs PFMT with EMG-biofeedback (BFB)	83	Women with SUI Germany	Bladder neck effective PFM rehabilitation program: perineal ultrasound for visual biofeedback for teaching and practicing BN-support and elevation as well as PFM precontraction daily for 3 months PFMT with EMG-biofeedback (BFB): given an EMG-BFB device with a vaginal probe for performing daily home exercises for three months. Specialist physiotherapist checked the performance of women in both groups three times	Outcomes: primary outcome measure was subjective improvement-cure rate after 3 months. Secondary outcomes included changes in a validated German pelvic floor questionnaire (Bladder, Bowel, Prolapse and Sex subscales) Key findings: Data is difficult to interpret based on the abstract and the prolapse symptom score was significantly different between groups at baseline. The prolapse score was presented as divided into two groups (so losing the randomisation) and we are unable to draw any conclusions	Baseline and immediately post-intervention	Publication: AB Dropouts: 19 women did not start treatment (time constraints and illness). No further dropouts reported. AE: Not described in the paper.

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Kou (2013) (220)	RCT PP pelvic floor rehabilitation device combined with PFMT vs standard PP rehabilitation education only	150	Women recruited at 6 weeks PP with POP stage I-III PRC	PFMT plus use of the Phenix device for electrostimation. PFMT regimen was 2-3 times / day for 20-30 mins for each session or 150-200 contractions (3 seconds for each contraction then relax). Women also received electrostimulation twice/ week. Control group: standard PP education only	Outcomes: Vaginal resting and vaginal squeezing pressure, Incontinence rate and POP-Q measured at 6 weeks PP and 12 months PP Key findings: PFM strength measures were significantly different between the two groups at 6 months. This difference between groups was sustained at 12 months. The incidence of stage I POP was also significantly lower in the intervention group at 12 months postpartum (21/80) compared with women in the control group (30/70). The number of women with stress UI was also significantly lower in the intervention arm at 6 months postpartum (2.5% vs 12.86%), and at 12 months postpartum (3.75% vs 14.29%).	Baseline (6 weeks PP), 6 months PP and 12 months PP	Publication: AB available in English. Original paper in Chinese; translation provided. Dropouts: no dropouts reported. AE: Not described in the paper.

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Liu (2013) (219)	RCT PFMT vs standard care	360	Women recruited 16-30 gestation week, first pregnancy PRC	IG: PFMT supervised by pelvic floor physiotherapists. PFMT regimen included repeat contraction of 5 to 10 seconds, follow by 5 to 10 seconds rest, then fast contractions for 10-15 times, perform the above sequence for 15-20 minutes, 2-3 times daily for 8 weeks. CG: standard care	Outcomes: measured pelvic muscle tension with Phenix equipment, on vaginal squeezing pressure, vaginal resting pressure and POP-Q for detecting pelvic prolapse conditions Key findings: PFM strength was significantly higher in the PFMT group compared with women in the control group at the end of the intervention. In addition, significantly more women in the treatment group reported either no prolapse or stage II prolapse compared with women in the control group; however, there were no differences between groups for those with stage I prolapse.	Baseline (first pregnancy visit), At labour (first, second and total stages of labour), PFM tension measures were measured at 8 weeks and POP-Q was measured at 6 weeks after the delivery	Publication: AB available in English. Original paper in Chinese; translation provided. Dropouts: 31 dropouts reported (IG:14, CG: 17; reasons for drop-out not provided) AE: Not described in the paper.
Sun (2015) (230)	RCT Electrostimulation plus biofeedback treatment vs PFMT exercises at home	324	Women who gave birth to a single child at term, first reviewed at day 42 PP PRC	IG: received electrical stimulation plus biofeedback. Stated at 6 weeks PP, two sessions (20 mins each) / week CG: performed PFMT exercises at home but no details were given	Outcomes: primary outcome tool was PFIQ-7. Secondary outcomes included PISQ-12, pelvic floor muscle strength (type I and II fibres), vaginal dynamic pressure, POP-Q Key findings: Significant improvement in muscle fibre strength in treatment group compared with the control group at 6 weeks PP which was sustained at 6 and 12 months postpartum. POP-Q staging point Aa showed a significant improvement in the treatment group compared with the control group; no other difference was seen for any of the other points. No significant difference between groups on the quality-of-life questionnaire or sexual life questionnaire.	Baseline: 6 weeks PP, 6months PP and 12 months PP	Publication: AB is available in English. Original paper in Chinese; translation provided. Dropouts: at 6 weeks (Total:6, I: 0, C: 6), 6 months (Total:17, I: 10, C: 7), 12 months (Total: 207, I: 128, C: 79) Reasons: 6 weeks (incomplete baseline information), 6 months (4 gravidity, 7 loss to follow up), 12 months most unclear (5 gravidity, 11 loss to follow up) AE: Not described in the paper.

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Yang (2017) (30)	3-arm RCT Individuals were randomised across three groups resulting in 3 randomised paired comparisons	240	Primiparous women aged between 20-35 years and with an episiotomy or second-degree episiotomy tear PRC	Training group: received PFM exercises and other pelvic exercises from two days PP until three months PP. Each session was 20-minutes which consisted of five second contractions followed by five seconds of relaxation, asked to perform 2-3 times per day. Combination group: received the same rehabilitation exercises as the training group, plus 15 sessions of direct vaginal low voltage, low frequency electrostimulation beginning at week 6 PP. Control group: routine PP guidance (two hours PP) delivered by two specially trained staff members.	Outcomes: POP-Q, degree of incontinence score, pad test, pubic symphysis clearance, and PFM electrophysiological measures Key findings: Limited statistical data available (see text)	Data were collected during the third month after delivery ne	Publication: FT Dropouts: 189/240 women were seen for follow-up measurements at 3 months after delivery. 17 women from the training group; 14 women from combination group and 20 women from the control group withdrew from trial or were lost to follow-up AE: none described
Zhang (2016) (231, 256)	4-arm RCT Individuals were randomised across four groups resulting in 6 randomised paired comparisons	2700	Primiparous women 6 weeks after a vaginal delivery PRC	PFM exercise group Weighted vaginal cones ('vaginal dumbbell group') Biofeedback combined with electrostimulation Control group (standard care)	Outcomes: POP-Q, PISQ-12 and measures of PFM strength. Key findings: Limited data available	Baseline (6 weeks PP), 3 months PP and 9 months PP (i.e., 6 months' post-intervention)	Publication: AB Dropouts: unclear Adverse events: not reported

2.2. Treatment

2.2.1. A physical intervention vs no treatment, placebo control or sham

One trial comparing a physical intervention with standard care met the selection criteria for inclusion in this comparison (239). Key features of this study are shown in Table 39. ROB is summarised in Appendix 2.

Quality of data

Orhan and team (239) conducted a RCT comparing PFMT plus biofeedback with standard care. Women with prolapse were randomly allocated to receive either PFMT combined with biofeedback or standard care (details not reported). Women in both groups were given lifestyle advice. The intervention was delivered for 12 weeks. The primary outcome measure was self-reported perception of improvement. Secondary outcomes included severity of prolapse symptoms measured using the POP-SS and PFDI-20 questionnaires. Data were collected at baseline and immediately post-intervention at 12 weeks.

Results
In the Orhan (2017) trial (239), 22 women were randomised. Drop-outs were not reported in the abstract. At the study conclusion, there was a statistically significant difference between the groups for self-reported symptom questionnaires (PFDI-20 and POP-SS) favouring the intervention.

Summary of the evidence from the previous edition

Previous editions have reported evidence from 13 RCTs. These trials compared PFMT with a "minimal intervention control" arm (e.g., lifestyle advice, self-instruction manual or other type of exercise / general fitness). These studies provided evidence of the benefit of PFMT in reducing prolapse and pelvic floor symptoms in women. **(Level of evidence: 1)** There was some evidence that PFMT had an effect on prolapse stage and some that there was not.

Summary of the evidence identified in this update

One new study was included in this comparison.

A small size study (239) with an unclear ROB compared PFMT plus biofeedback with standard care and found significant improvement in prolapse symptoms and pelvic floor symptoms more broadly. **(Level of evidence: 2)**

No new studies were found for this comparison on the effect of PFMT on prolapse stage, therefore the evidence remains contradictory **(Level of evidence 2)**

Recommendations

PFMT can be offered to women with symptomatic prolapse as it is associated with a reduction in prolapse symptoms and pelvic floor symptoms. (**Grade of recommendation: A)** It is uncertain whether PFMT reduces prolapse stage (**Grade of recommendation: B)**

PFMT plus biofeedback may be recommended as this combination is shown to improve prolapse symptoms and pelvic floor symptoms compared with standard care**. (Grade of recommendation: C New)**

2.2.2. A physical intervention (alone or in combination) vs an active treatment (or combination)

In this update, five studies (seven randomised comparisons) were identified (73, 232, 234, 236, 240). Salient features of each trial are described in Table 39. ROB is summarised in Appendix 2. Two other studies are also judged as relevant to this comparison (see Cheung 2016 (244) and Panman 2016 (248). The quality of data and results from these studies are summarised in the section on pessaries (see III.3.2.2).

Quality of data
Ahadi 2017 (232) conducted a pilot RCT to evaluate the impact of biofeedback on quality of life in women diagnosed with stage I-II prolapse. The authors argued that while biofeedback was frequently used alongside PFMT, little was known about the effectiveness of biofeedback-assisted PFMT compared with PFMT alone. Women were randomised to a home-based PFMT programme, lifestyle advice leaflet and biofeedback (intervention group) or PFMT and lifestyle advice leaflet (control group). Women were initially seen by a physician who performed a physical examination and taught the women how to perform the exercises. Women in both groups received the same home exercise protocol comprised of 10 repetitions of a 5 second squeeze followed by a 5 second release. Women were asked to perform five sets per day for 12 weeks. A lifestyle advice leaflet was also given to all women. Women in the intervention group also received two 30-minute sessions of pressure biofeedback each week delivered over 4 weeks (total of 8 sessions). The primary outcome measure was the validated Persian (Farsi) version of P-QoL questionnaire (including a prolapse severity subscale). Secondary outcome measures included stage of prolapse using POP-Q system. Data were collected at baseline and 4-5 weeks and 12 weeks follow-up.

Caagbay 2020 (234) recently published an RCT evaluating the impact of lifestyle advice and PFMT instruction on quality of life in Nepali women. They argued that while there is growing evidence for the use of PFMT in a wide range of populations, the evidence of effectiveness for women living in rural communities in low-and-middle income countries is still lacking. Caagbay (2020) (234) recruited women who were attending a reproductive health screening camp in Kathmandu Valley, who were diagnosed with stage I-III prolapse. Women were then randomised to receive lifestyle advice and PFMT instruction (intervention) or usual care (control). Women in both groups had an initial physical examination conducted by an experienced gynaecologist. During this examination, women were asked to perform a PFM contraction by "squeezing their muscles around the gynaecologist's finger as though they were trying to avoid passing gas". They were also given additional verbal instruction and biofeedback using digital pressure to ensure they were performing the contraction correctly. Women in the intervention group received individual, face-to-face education using an informational flipchart. This included information about how to correctly perform PFM contractions and how to perform the 'knack'. Women were advised to perform PFMT daily and to work up gradually to complete a set of ten PFM squeezes and a 10-second hold. Lifestyle advice included information about conservative management of prolapse. Women were also taught about pelvic anatomy, prolapse (definition, causes, symptoms) and treatment options and where to get help. The flipchart took 20 minutes to complete, and women were encouraged to ask questions. Women in the control group received usual care, which comprised of brief verbal instruction about PFMT like that provided to women in the intervention group. The primary outcome measure was the change from baseline in the P-QoL domains measured at 6 weeks, 12 weeks and 6 months' post-intervention. Secondary outcomes included POP-Q, which was assessed clinically at baseline and 6 months. Women were also asked to keep an exercise diary to document PFMT exercise adherence.

Gorji and colleagues (2020) (236) conducted an RCT to explore the addition of hip muscle exercises to a PFMT exercise regime. This built on previous work which hypothesised that prolapse causes lumbo-pelvic-hip musculoskeletal weakness in addition to the functional failure to support pelvic organs (259). Women with stage II or III prolapse were randomised to receive either PFMT and postural or positional inversion exercises (intervention group) or PFMT alone (control). Women in both groups had a total of 12 sessions delivered over 4 weeks (3 sessions per week). The PFMT included exercises as described by Hagen *et al.* (2014) (260). Women in the intervention group were also

asked to perform 10 repetitions of four postural or positional inversion exercises using an inversion wedge. These additional exercises are described in more detail in Table 39. Outcome measures included POP-Q stage, ICIQ-FLUTS, P-QoL (including prolapse severity) (Persian version). Data were collected at baseline and immediately post-intervention.

Navarro and colleagues recently published their findings from a 3-arm RCT which aimed to compare the effectiveness of hypopressive exercises with PFMT and to a combination intervention (Hypopressive exercises plus PFMT) (73). Women with self-reported signs or symptoms of stress or MUI, anal incontinence, and/or a gynaecologist diagnosis of stage I-II prolapse were randomly divided into three groups:

- *PFMT:* women received individualised PFMT instruction based on components of the PERFECT scheme (261). Within each session, women were encouraged to perform 10 repetitions of 10 maximal effort, rapid contractions lasting one second each to maintain an isometric contraction up to 10 seconds. Training was tailored for each woman based on progression at each session, and EStim, biofeedback, resistance training and dynamometric devices were used if the physiotherapist felt it was appropriate. PFMT instruction was delivered twice a week for 8 weeks. Each session was approximately 45 minutes' duration. Following each session, women were instructed to perform the daily exercises at home aiming for one to three sets of 5-10 repetitions between one and three times per day.

- *Hypopressive exercises:* women were instructed to perform hypopressive exercises using methods reported by Caufriez (262). Women were initially taught to do the "hypopressive manoeuvre" which involved maximal exhaling, then breath-holding, expanding rib cage drawing their abdomen inward and upward without breathing in, sustaining this for 10 seconds before resuming normal breathing. The hypopressive manoeuvre was performed in different positions: standing, kneeling, sitting and lying and women were taught a total of 33 exercises. Training was delivered twice a week for 8 weeks with each session lasting approximately 45 minutes. During the final week of training, the physiotherapist and each woman selected three exercises for home-based exercise. Women were asked to repeat each exercise three times per set and to perform 1 to 3 sets per day. Women in this group were also given feedback on PFM contractions (during their vaginal palpation assessment) and were taught the knack but were asked not to perform any specific PFMT exercise.

- *Combination training:* women in this group received a combination of PFMT and hypopressive exercises as described above. Women in the combination group split their session equally between PFMT and hypopressive exercise but PFM contractions were never combined with hypopressive exercises. Women were asked to exercise at home alternating between PFMT and hypopressive exercises.

Women in all groups were also taught about the anatomy and physiology of the pelvic floor using printed materials and 3-D models. They were also given lifestyle advice and given instruction about toileting habits and taught to use the knack manoeuvre when doing any task that could increase intra-abdominal pressure. Interventions were delivered individually and face-to-face by the same (unblinded) specialist physiotherapist. The primary outcomes measures included: PFIQ-7 and PFDI-20. Data were collected at baseline, immediately post-intervention and at 3-, 6- and 12-months post-intervention.

Resende and colleagues (2019) (240) also examined the effectiveness of hypopressive exercises compared with PFMT. In their study, they randomised women with stage II untreated and symptomatic prolapse to receive either PFMT or hypopressive exercises. Women in the PFMT group were given three training sessions. In session one, they were taught about the anatomy and physiology of the pelvic floor. They were then asked to contract their PFM using a mirror while lying in a supine position. The physiotherapist observed the movement to make sure it was correct. Later in the session, they were then given lifestyle advice. In the second session, a weighted vaginal cone was used to improve the woman's awareness of the PFM with the physiotherapist removing the cone while the woman attempted to keep it inside the vagina using PFM contractions. Later in the same session each woman received vaginal palpation. In the final session PFMT was performed using the home exercise protocol in three positions (lying, sitting, standing). Women were asked to perform three sets of 8 – 12 maximum voluntary contractions, hold for six seconds each and 12 seconds rest between contractions followed by three fast contractions. Women in the hypopressive exercise group also participated in three sessions. In addition to learning about pelvic floor anatomy and physiology they were also taught about the transverse abdominal muscles and how to activate these muscles. In the second session, women were instructed how to do the hypopressive manoeuvre (262) as reported earlier in this section (see Navarro (2020)). Women were discouraged from performing voluntary PFM contractions. In the final session, women were trained in the home hypopressive exercise protocol in lying and standing positions. Women were asked to complete two sets of 8-10 repetitions per day (one in each position) holding each contraction for 5- 8 seconds, with each session lasting approximately 40 minutes. Women in both groups were then asked to perform their daily exercises at home for 12 weeks. They received a call from the physiotherapist once a week and were seen individually for a face-to-face appointment twice a month. All women received standardised lifestyle advice. The physiotherapist delivering the intervention was given training before the beginning of the trial. The primary outcome measured was prolapse symptoms using P-QoL; secondary outcomes recorded were prolapse severity using POP-Q. Data were collected at baseline and immediately post intervention.

Results

In the Ahadi (2017) (232) study, forty women were randomised (20 to each group) of which 38 completed the trial. One woman in the intervention group did not receive the intervention as she was pregnant and one woman in the control group was lost to follow-up due to a hysterectomy. Women in the intervention group had statistically significantly more improvement in seven of the nine P-QoL domains (prolapse impact, role limitation, physical limitation, personal relation, emotion, sleep/energy and severity measures) compared to control. These findings were observed at the 4-5 weeks follow-up and sustained at 12 weeks follow-up. There were no significant differences at either follow-up time-point between the two groups for either PFM strength or stage of the prolapse.

Of the 140 women initially randomised in the Caagbay (2020) study, 136 were allocated (n=69 intervention; n=67 control). Four women were excluded because they had a stage IV prolapse. At the 6-month telephone follow-up, 102 women were reviewed; trialists were unable to contact 15 women in the intervention group and 17

women in the control group. Data were reported as missing from two additional women in the control group. At six months, there were statistically significant differences between groups in six out of nine P-QoL domains (general health, prolapse impact, physical limitations, emotions, sleep and severity measures) and for prolapse, bladder and bowel symptoms, favouring the intervention group. Only 27/136 women attended for the 6-month examination, with women citing insufficient time to visit the clinic, consequently secondary outcomes could not be analysed.

Forty women were randomised in the Gorji (2020) study; 20 women in each arm (236). No dropouts were reported. Women receiving PFMT and postural or positional inversion exercises had statistically significantly better scores in three domains of the P-QoL questionnaire (general health, physical limitation and social limitation).

In the Navarro (2020) (73) study, 99 women were randomised equally across the three arms (33 in each group). One woman from the PFMT group and one woman in the hypopressive exercise group did not complete the intervention because they became pregnant. Three women (one in the hypopressive group and two in the combined group) were lost to follow-up. There was no statistically significant difference between groups immediately post-intervention or at 3-, 6- and 12-months post-intervention in any prolapse or pelvic floor symptom measures or related quality of life. However, the authors presented data to show that these measures did improve *within* groups.

Resende 2019 (240) randomly assigned 70 women (35 in each group). Nine women were lost to follow-up (5 from PFMT group; 4 from hypopressive exercise group) because of motivational problems or other health problems. Women in the PFMT group showed statistically significantly more improvement in five symptoms (vaginal bulge/lump, heaviness or dragging on the lower abdomen, straining to empty bladder, stress incontinence, vaginal bulge interfering with emptying bowel) and in four out of nine P-QoL domains (prolapse impact, role limitations, social limitations and personal limitations) compared to women in the hypopressive exercise group. Women in the PFMT group also exhibited more improvement in prolapse severity compared with women who received the hypopressive exercise training.

Summary of the evidence from the previous edition

Earlier editions of this chapter synthesised the evidence for all PFMT interventions and are described at the beginning of section III (Table 36).

Summary of the evidence identified in this update

Five new studies were included in this comparison:

- Two medium size trials with low ROB compared PFMT with hypopressive exercises, and with a combination of the two. One found PFMT to be more effective in treating prolapse symptoms and severity than hypopressive exercises, while the other found no significant difference between the two, nor between either intervention, or a combination of PFMT plus hypopressive exercises. The benefit of hypopressive exercises as an alternative, or an addition to, PFMT is uncertain for treatment of prolapse. **(Level of evidence: 2)**
- One small, moderate ROB trial found no significant difference in prolapse stage or PFM strength for women treated with PFMT plus biofeedback compared to PFMT alone. **(Level of evidence: 2)**
- One large, moderate ROB trial found a significant prolapse symptom and quality of life benefit for Nepali women receiving an educational session including lifestyle advice and PFMT instruction, compared to verbal instruction in PFMT. **(Level of evidence: 2)**
- One small, moderate ROB trial found a significant quality of life and PFM strength benefité, but no prolapse symptom benefit, for women receiving postural exercises plus PFMT compared to PFMT alone. **(Level of evidence: 2)**

Recommendations

PFMT plus biofeedback does not offer benefit compared to PFMT alone for treatment of prolapse and may not be routinely recommended**. (Grade of recommendation: D New)**

An educational session including lifestyle and PFMT instruction may be considered as it does offer benefits over verbal PFMT instruction alone when treating prolapse. **(Grade of recommendation: D New)**

Postural exercises in addition to PFMT may be considered as they offer benefit over PFMT alone in treating prolapse. **(Grade of recommendation: D New)**

2.2.3. A physical intervention combined with a non-conservative intervention vs an active (non-conservative) treatment (or combination)

For this update, five studies (seven randomised comparisons) were identified (218, 233, 237, 241, 263, 264). Salient features of each trial are described in Table 39. ROB is summarised in Appendix 2.

Quality of data

Brandt (2019) (233, 264) conducted a three-arm RCT that compared the impact of PFMT or core training or usual care on prolapse in women scheduled for prolapse surgery. Women who were waiting for pelvic reconstructive surgery to manage their prolapse were randomly allocated to three groups: PFMT programme, core stability programme or control. Further descriptions of the interventions were not available in the abstracts. Each intervention was delivered for six months (from pre-to-postoperative). Outcome measures included P-QOL and POP-Q. It is unclear from the abstract when data were collected.

In a conference abstract, Dawson and colleagues (2017) (263) presented their findings from an RCT which aimed to evaluate whether PFMT offered post-operatively would improve women's quality of life following prolapse surgery. Women having pelvic reconstructive surgery to manage their prolapse were randomly assigned to PFMT immediately post-surgery (intervention) or standard post-operative care (control). A trained pelvic floor physiotherapist delivered a six-week standardised protocol of PFMT. Women in the control group received routine postoperative care. Outcome measures included PFIQ-7 and PFDI-20 (total scores only), and POP-Q. Data were collected at

baseline, immediately post-intervention and 6 weeks' post-intervention.

Duarte and colleagues (241) conducted a RCT comparing the effectiveness of incorporating perioperative PFMT training on prolapse symptoms after surgery. Women who were candidates for prolapse surgery (stage II-IV) were randomly allocated to receive either perioperative PFMT (intervention) or surgery only (control). The intervention group received a 9-week PFMT protocol with four intensive, supervised sessions before the surgery (twice a week for 2 weeks), and received seven supervised sessions, 40 days after the surgery. The PFMT was delivered by a physiotherapist with more than 10 years' experience. Each session comprised four sets of maximum contractions (7 second hold, 7 second rest) performed in a variety of positions. Women were encouraged to perform the contractions at home at least three days per week. The control group received surgery and usual post-operative care. The primary outcome was the PFDI-20 questionnaire. Secondary outcomes included PGI-I. Data were collected at baseline (15 days before surgery) and at day 40 and day 90 after surgery.

Jelovsek and colleagues (2018) (237) published the five year outcomes from the OPTIMAL trial which was reported in the 6th ICI. This extended OPTIMAL (E-OPTIMAL) trial aimed to follow-up women who took part in the original trial 5 years after their index surgery from April 2011 through June 2016. Women in the OPTIMAL trial were allocated to perioperative behavioural therapy with PFMT or usual care. The primary outcomes for the PFMT intervention were time to surgical failure defined as (a) apical descent greater than one-third of total vaginal length or anterior or posterior vaginal wall beyond the hymen or retreatment for prolapse (anatomic failure), or (b) bothersome bulge symptoms (based on change from baseline preoperative POPDI scores). The primary behavioural outcomes were time to anatomical failure and POPDI.

Nyhus and colleagues (2020) (218) conducted a RCT to evaluate the effectiveness of preoperative PFMT in women waiting for prolapse surgery. Women were randomised to receive either daily PFMT following enrolment into the trial until their surgery, or to receive no intervention while waiting. Women in the PFMT arm were asked to perform daily PFMT consisting of 8-12 contractions (duration of 6-8 seconds in 3 sets). Women were seen by a specialist physiotherapist (in weeks two and six) for a vaginal examination to ensure that the exercises were being done correctly. Women were also offered weekly group exercise sessions. They were also given lifestyle advice information and asked to perform contractions in situations that could increase intra-abdominal pressure. Women in the control were scheduled for surgery but received no other intervention. Outcomes included sensation of vaginal bulge. Data were collected at baseline (day of inclusion), day of surgery and at six months.

Results

Eighty-one women were randomised to receive either PFMT (24 women), core stability programme (28 women) or control (18 women) in the Brandt (2019) study (233, 264). Dropouts are not reported in the abstract. There were no significant differences across groups for any of the measures reported, except for a significant difference in P-QoL total score, with better scores for women in the core stability group.

In the Dawson study (263) 46 women were enrolled, however only 34 women completed the study (16 in PFMT; 18 in control). Reasons for the dropouts were not reported. There were no significant differences between the two groups for severity of prolapse or prolapse symptoms.

Duarte and colleagues (241) randomised 96 women with prolapse: allocating 48 to the perioperative PFMT group and 48 to the control group (no PFMT). In the perioperative PFMT group, two women were lost to follow-up (unable to be contacted) by day 40. There were no dropouts from the control group. Both groups reported a marked improvement in prolapse symptoms after surgery but there was no between group difference in pelvic floor symptoms at day 40 or at day 90 on the PFDI-20 total score, or on any of the subscales including prolapse symptoms (POPDI-6, CRADI-8, UDI-6). There was no significant difference between groups on PFIQ-7 or any of the subscales of PISQ-12. Women who received the additional perioperative PFMT protocol perceived marginally greater global improvement compared with women in the control group by day 90 on PGI-I but this was also not statistically significant.

In the E-OPTIMAL trial reported by Jelovsek *et al.* (237) 309 women were eligible for follow-up in the extended trial, of these 285 enrolled and 244 completed the extended trial. There were no differences between groups on either primary outcome. Almost two-thirds of women met *a priori* trial definitions of failure 5 years after surgery with no significant difference between perioperative behavioural muscle training and usual care on rates of anatomic failure and prolapse symptom scores.

Nyhus (238) randomised 159 women of which 81 were allocated to the intervention arm and 78 were allocated to the control group. Six women dropped out of the intervention group before the day of surgery; three did not want any further examinations and three women cancelled surgery. Two women dropped out of the control group and cancelled their surgery as their symptoms improved. At the post-operative follow-up there was no statistically significant between group difference in any outcome including vaginal bulge.

Summary of the evidence from the previous edition

Six trials have previously been published evaluating PFMT and surgery; none of the trials showed evidence of an effect of PFMT. **(Level of evidence: 1)**

Summary of the evidence identified in this update

Five new studies (six comparisons) were included:

No significant differences were evident in four comparisons of peri-op physical intervention (PFMT or core stability exercises) with surgery versus surgery alone (233, 237, 241, 264). The ROB was low or uncertain and the sample size small to large. **(Level of evidence: 1)**

One comparison of pre-op PFMT with surgery vs surgery alone, with low ROB and a large sample size (238) showed no significant difference between groups post-op. **(Level of evidence: 2)**

One comparison of post-op PFMT with surgery vs surgery alone (263), with uncertain ROB and a small sample size, showed no significant difference. **(Level of evidence: 2)**

Recommendations

Adding a physical intervention to prolapse surgery, pre-, peri- or post-operatively did not improve symptoms or severity and cannot be recommended routinely. **(Grade of recommendation: B New)**

Table 39. Summary of key characteristics of treatment studies of women with prolapse and physical interventions

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Ahadi (2017) (232)	RCT Home-based PFMT exercise program plus lifestyle advice plus biofeedback vs Exercise group (PFMT+lifestyle advice)	40	Women aged 18-75 years with stage I-II prolapse Iran	Home based PFMT protocol consisted of five sets and each set included 10 repetitions of a 5-s squeeze followed by a 5-s release. Participants also given a lifestyle advice sheet. Biofeedback program included eight 30 min-sessions of pressure biofeedback which were accomplished by Enraf- NONIUS (Mymed632x) device. PFMT consisted of 5 sets per day over 12 weeks; biofeedback: twice a week for 4 weeks (8 x 30 min sessions)	Outcomes: primary outcome was Persian (Farsi) version of P-QOL questionnaire. Secondary outcomes included PFM strength and POP-Q Key findings: Women in the intervention group had a significant improvement in 7/9 P-QoL domains at the 4-5 weeks follow-up and sustained at 12 weeks follow-up. No significant differences at either follow up time-point between the two groups for either PFM strength or stage of the prolapse	Baseline, 4-5 weeks and 12 weeks follow-up	Publication: FT Dropouts: 1 woman did not receive the allocated intervention in the experimental group (home-based PFMT + LA +biofeedback) due to pregnancy; 1 dropout in the control group (PFMT+lifestyle) due to hysterectomy AE: authors reported no adverse effects
Brandt (2019) (233, 264)	3-arm RCT Individuals were randomised across three groups resulting in the following randomised paired comparisons: Brandt (2019) (i) PFMT or usual care Brandt (2019) (ii) Core training vs usual care Brandt (2019) (iii) PFMT vs core training	81	Women scheduled for prolapse surgery South Africa	PFMT program, core stability program or control. Further descriptions of the interventions were not available in the abstracts. Each intervention was delivered for six months (from pre-to-postoperative).	Outcomes: P-QoL, SF-36, 2-D ultrasound, POP-Q, the PERFECT scale, EMG, Sahrmann scale and PBU. Medical and exercise history, exercise compliance and the Visual Faces Scale for pain assessment were also recorded. Key findings: no significant differences across groups for any of the measures reported, except for a significant improvement in PQoL scores for women in the core stability group.	Unclear – insufficient information	Publication: AB Dropouts: not reported in the abstracts AE: not described in the publication

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes (side effects, loss of follow up…)
Caagbay (2020) (234)	RCT PFMT plus lifestyle advice vs standard care	136	Women attending a reproductive health screening camp in Kathmandu Valley, diagnosed with stage I-III prolapse Nepal	Individual, face-to-face education using an informational flipchart (20 mins) about how to perform PFMT and how to perform the knack) trained in PFMT (given a physical exam plus biofeedback using digital pressure) plus lifestyle advice which included information about conservative management. Asked to perform PFMT daily and to work up gradually to complete a set of ten PFM squeezes and a 10-second hold. Usual care comprised brief verbal instruction about PFMT similar to that provided to women in the intervention group	Outcomes: primary outcome was the PQoL. Secondary outcomes included POP-Q, modified Oxford scale and exercise diary Key findings: Women in the intervention had significant improvement in 6/9 P-QoL domains and for prolapse, bladder and bowel symptoms at six months. Only 27/136 women attended for the 6-month examination, with women citing insufficient time to visit the clinic, consequently secondary outcomes could not be analysed. No women completed the exercise diary.	P-QoL was measured at baseline, 6 weeks, 12 weeks and 6 months post-intervention. Secondary outcomes were collected at baseline and 6 months	Publication: FTvand PhD thesis Dropouts: 136/140 were allocated (4 women had stage IV prolapse and were excluded); At the 6-month telephone follow-up, 102 women were reviewed; trialists were unable to make contact with 15 women in the intervention group and 17 women in the control group. Missing data from 2 women in the control group. Only 27/136 women attended for the 6-month examination, with women citing insufficient time to visit the clinic AE: not described in the publication
Cheung (2016) (244)	See Table 40 for details	-	-	-	-	-	-
Dawson (2017) (235)	RCT Postoperative PFMT vs standard postoperative care	46	Women who presented with prolapse and desired vaginal reconstructive surgery for resolution of their condition USA	PFPT consisted of a 6-week standardised protocol with a trained pelvic floor physical therapist, no other details available. Standard postoperative care: not described	Outcomes: PFIQ-7, PFDI-20, VAS for daily pain and sexual pain, FSFI, and the WHOQOL-BREF questionnaires prior to surgery; 6-week postoperative visit, patients were given the VAS and WHO-QOL-BREF; 12-week visit patients were given PFIQ-7, PFDI-20, FSFI, WHOQOL-BREF and VAS Key findings: no significant differences between the two groups for WHO QOL-BREF or severity of prolapse.	Baseline, 6-week follow-up (immediately post-intervention) and 12-week follow-up (6 weeks post intervention)	Publication: abstract Dropouts: 46 women were enrolled in the study however only 34 women completed the study; 18 in the standard post-operative arm and 16 in the postoperative PFMT arm. Reasons for dropouts were not reported. AE: not described in the publication

Duarte (2020) (241)	RCT Prolapse surgery with perioperative PFMT or a control group (prolapse surgery only)	96	Women aged between 35 and 80 years with prolapse symptoms (bulging); surgical indication to undergo anterior, apical and/or posterior repair; and prolapse stage II- IV Brazil	Perioperative PFMT: Four sessions of intensive supervised PFMT twice a week for 2 weeks preoperatively and returned 40 days postoperatively for an additional seven sessions, giving a total of 11 supervised individual PFMT sessions Sessions included four sets of 10 repetitions of maximum voluntary contractions with a 7-second hold and a 7-second rest period between each contraction Prolapse surgery: standard follow up	Outcomes: primary outcome: PFDI-20 including its subscales POPDI-6, CRADI-8 and UDI-6. Secondary outcomes: PFM strength was measured using a Peritron manometer (peak, endurance and mean strength); PFIQ-7, including its subscales UIQ-7, CRAIQ-7 and POPIQ-7; PSIQ-12; PGI-I Key findings: no between group difference in prolapse symptoms at day 40 or at day 90 on the PFDI-20 total score or on any of the subscales (POPDI-6, CRADI-8, UDI-6). No significant difference between groups on any of the secondary outcomes (PFM strength, PFIQ-7 or any of the subscales of PISQ-12)	Baseline: 15 days before surgery; 40 days after surgery; and 90 days after surgery	Publication: FT Dropouts: 96 women were randomised, 48 to each group. At day 40 postoperative 2 were lost to follow-up (not contactable) in the intervention group. No dropouts in the control group. No dropouts reported at day 90 AE: not described in the publication
Gorji (2020) (236)	RCT PFMT plus postural or positional inversion exercises (intervention group) vs PFMT alone	40	Women with stage II or III prolapse Iran	PFMT included exercises as described by Hagen et al (2014) (267). Women in the intervention group were also asked to perform 10 repetitions of four postural or positional inversion exercises using an inversion wedge. Both groups had a total of 12 sessions delivered over 4 weeks (3 sessions per week).	Outcomes: POP-Q stage, ICIQ-FLUTS, PQoL (Persian version) and PFM strength (cm H2O) Key findings: Women receiving PFMT and postural or positional inversion exercises showed significant improvement in three domains on the PQoL questionnaire. (general health, physical limitation and social limitation). PFM strength was significantly greater in the intervention group compared with the control group	Baseline and immediately post-intervention (at 4 weeks)	Publication: FT Dropouts: none AE: not described in the publication

Jelovsek (2018) (237)	Five-year outcomes from the Extended-OPTIMAL (E-OPTIMAL) Perioperative BPMT group vs usual care	285	Followed up women in the original trial 5 years from surgery to compare surgical failure, changes in quality of life, and complication rates of the 2 surgical and 2 behavioral treatment groups USA	Women randomided to perioperative BPMT visited centrally trained pelvic floor therapists 2 - 4 weeks before and 2, 4, 6, 8, and 12 weeks after surgery. Women practiced PFMT exercises and received individualised education on behavioural strategies to reduce urinary and colorectal symptoms during each visit. Maximum of 45 contractions per day, duration ranging from 1 to 3 seconds / contraction. Postoperatively the interventionist adjusted the patient's exercise regimen by gradually increasing the number (maximum ranging from 45 to 60 per day) and duration (maximum = 10 seconds) of each contraction. At the final postoperative session, the interventionist provided patients with a maintenance exercise program consisting of 15 contractions per day at the maximum contraction duration achieved during the intervention period	Outcomes: primary behavioural outcomes were time to anatomic failure (defined as POP-Q points Aa, Ba, Ap, or Bp beyond the hymen, point C descending >one-third of total vaginal length, or retreatment) and change from baseline (preoperative) and POPDI scores Key findings: no significant difference between perioperative behavioural muscle training and usual care on rates of anatomic failure and symptom scores. No meaningful difference in secondary outcomes including UDI, CRADI, PGI-I or adverse events.	Annual evaluation during postoperative years 3-5. Each visit and interview occurred within 3 months of the anniversary of the index surgery	Publication: FT Dropouts: The OPTIMAL trial (Barber et al. 2014 (273) previously reported in 5th Edition ICI chapter. At year 5: 309/374 women from the original study were eligible for this extended trial. 285 women enrolled in E-OPTIMAL and 244 (86%) completed the trial. Dropouts are accounted for in Figure 2.

Navarro (2020) (73)	3-arm RCT Individuals were randomised across three randomised paired comparisons	99	Women with PFD – other details not available Spain	PFMT alone: Pelvic floor muscles exercises guided throw vaginal palpation and intravaginal biofeedback. Women were encouraged to perform 10 repetitions of 10 maximal effort, rapid contractions lasting one second each to maintain an isometric contraction up to 10 seconds. PFMT instruction was delivered twice a week for 8 weeks; session lasted 45 mins Hypopressive exercises: Thirty-three hypopressive exercises described by Caufriez 1997 (269). Women were taught the hypopressive manoeuvre which was performed in different positions: standing, kneeling, sitting and lying and women were taught a total of 33 exercises. Training was delivered twice a week for 8 weeks; sessions lasted 45 mins. During the final week of training, the physiotherapist and each woman selected three exercises for home-based exercise. Women were asked to repeat each exercise three times per set and to perform 1 to 3 sets per day. Combination training: PFMT guided throw palpation and biofeedback + hypopressive exercises. All women received the same educational strategy and were instructed in the knack manoeuvre. All interventions were carried out by the same physiotherapist for 8 weeks. A qualitative study was nested in the RCT; 31 women were interviewed. Interviews were recorded, transcribed manually, and thematic analysis was conducted.	Outcomes: PFDI-20, PFIQ-7 and PFM strength Key findings: no statistically significant difference between groups immediately post-intervention or at 3-, 6- and 12-months post-intervention.	Baseline, 3, 6- and 12-months post-intervention	Publication: FT Dropouts: One woman from the PFMT group and one woman in the hypopressive exercise group did not complete the intervention because they became pregnant. Three women (one in the hypopressive group and two in the combined group) were lost to follow-up AE: reported in the three intervention groups with one woman reporting exacerbated back pain in the combined intervention group and five women in the hypopressive exercise group who needed to modify the exercise because the intervention caused pain, or they were unable to perform them correctly

Nyhus (2020) (238)	RCT Daily PFMT following enrolment into the trial until their surgery vs no intervention while waiting for surgery	151	Women scheduled for prolapse surgery Norway	PFMT: daily PFMT consisting of 8-12 contractions (duration of 6-8 seconds in 3 sets). Women were seen by a specialist physiotherapist (in weeks two and six) for a vaginal examination to ensure that the exercises were being done correctly. Women were also offered weekly group exercise sessions; given lifestyle advice and asked to perform contractions in situations that could increase intraabdominal pressure Control group: scheduled for surgery but received no other intervention	Outcomes: PFM strength using the modified Oxford scale, vaginal manometry, ultrasound and sensation of vaginal bulge. Adherence was recorded in a training diary Key findings: no statistically significant difference between groups at postoperative follow-up on any outcome.	Baseline (day of inclusion), day of surgery and at six months	Publication: FT Dropouts: Surgery group - 6 women dropped out before surgery; 3 did not want any further examinations and 3 women cancelled surgery. Control group: 2 women cancelled their surgery as their symptoms improved. AE: two major complications after surgery; an intestinovaginal fistula after laparoscopic sacrocolpopexy and one haemorrhage which required a second operation. 3 women reported postoperative infections and one woman had complications with persisting residual urine
Orhan (2020) (239)	RCT PFMT plus biofeedback vs usual care	22	Women with prolapse Turkey	PFMT combined with biofeedback using the Myomed 632 biofeedback device to instruct women about how to perform the exercise for 12 weeks Control group: usual care Women in both groups were given lifestyle advice	Outcomes: primary outcome was self-reported perception of improvement. Secondary outcomes measures included POPP-SS and PFDI-20 questionnaires, and PFM strength and endurance. Key findings: statistically significant difference in the change of PFM strength, PFDI-20 and POP-SS scores between PFMT plus biofeedback and control groups ($p<0.05$)	Baseline and immediately post-intervention (at 12 weeks)	Publication: abstract Dropouts: not described AE: not described in the publication

Resende (2019) (240)	RCT PFMT vs Hypopressive exercises	70	Symptomatic women with untreated stage II prolapse Brazil	PFMT group: 3 training sessions including provision of information about the pelvic floor, instructed about how to make the correct PFM contraction, life-style advice, use of a weighted vaginal cone to improve awareness of the PFM, vaginal palpation and PFMT performed using the home exercise protocol in three positions (lying, sitting, standing). Women were asked to perform three sets of 8 – 12 maximum voluntary contractions, hold for six seconds each and 12 seconds rest between contractions followed by three fast contractions. Hypopressive home exercise programme: bimonthly sessions with a physiotherapist. The protocol included 3 sessions to learn how to perform the exercises correctly followed by 3 months of exercise with monthly progression. Women in both groups were then asked to perform their daily exercises at home for 12 weeks	Outcomes: primary outcomes included PQoL, and specific questions (yes/no response) to investigate POP symptoms (bulge/ lump, pelvic heaviness, backache) and other potentially related POP symptoms (e.g bladder and bowel symptoms). Secondary outcomes were POP-Q, PFM function and electrical activity (Oxford, Endurance and MVC SEMG). Key findings: Women in the PFMT group showed significantly more improvement in five symptoms (vaginal bulge/lump, heaviness or dragging on the lower abdomen, straining to empty bladder, stress incontinence, vaginal bulge interfering with emptying bowel) and in 4/9 P-QoL domains compared to women in the hypopressive exercise group. Women in the PFMT group also exhibited more improvement in prolapse severity and PFM function compared with women who received the hypopressive exercise training.	Baseline and after 3 months of treatment	Publication: FT Dropouts: 5 women dropped out in the PFMT group (3 with motivational problems and 2 due to other health conditions); 4 women dropped out in the Hypopressive exercise group (2 with motivational problems and 2 due to other health conditions) AE: not described in the publication

3. PESSARY INTERVENTIONS

A vaginal pessary[1] is a device that provides structural support for the vaginal walls and pelvic organs that lie behind them (215). Pessaries are frequently used as a first-line option for women who do not wish to have surgery, or in women who have a higher risk of surgical complications or women with recurrent prolapse. There is currently no evidence to support the use of a specific type of pessary, and choice is largely based on clinical experience and trial and error. However, it is generally accepted that the ring pessary should be tried first because of ease of insertion and removal, and if this fails, other pessaries can be investigated (265). A Cochrane review by Bugge *et al,* published in 2013 (266) identified one RCT that compared two different types of pessaries (ring versus Gellhorn), and the authors concluded that there is no consensus on the use of different types of device, the indications nor the pattern of replacement and follow-up care. Consequently much of the evidence for the effectiveness of pessaries presented in previous editions has relied heavily on observational studies (265). Here, we present the current evidence-base drawing on the recently updated Cochrane review published in 2020, which identified four new RCTs for inclusion (215). We have also included nine additional RCTs, which were not included in the Cochrane review, as they fell outside the scope of the review of effectiveness. This additional body of evidence is focused on optimising pessary management or reducing some of the well-known barriers to successful pessary usage (e.g., common side effects). Key features of each study are described in Table 40. The ROB for each of the studies is presented in Appendix 2.

3.1. Prevention

3.1.1. Pessary (alone or in combination) versus control, waiting list or no active treatment

In this update, one trial evaluating a pessary intervention compared with no treatment focussed on prevention of prolapse was identified (242). Key features of this trial are described in Table 40 The ROB is summarised in Appendix 2.

Quality of data

Baessler and colleagues (242) piloted an RCT to determine whether women receiving a pessary early (i.e. 1 to 3 days after their first vaginal birth with stage II prolapse) would report an improvement in their prolapse symptoms. The authors argued that a study to explore early intervention was necessary because 39% of women had a stage II prolapse at 6 weeks postpartum; with almost a third of women still describing prolapse symptoms 12 months postpartum. In this study, women diagnosed with stage II prolapse following their first vaginal delivery were randomised to receive either a vaginal ring pessary for 6 weeks postpartum or standard care (i.e., no intervention). Preference groups were established for women who declined randomisation. The authors measured POP-Q, Australian Pelvic Floor Questionnaire (German version) at 6 weeks and 12 months postpartum. Complications such as reduced lochia or infection were also recorded.

Results

Forty-four women were initially enrolled in the Baessler trial (242); three preferred the pessary and seven preferred standard care. Thirteen women were randomised to the vaginal ring pessary and 21 women received standard care. Pessary placement was not possible in two women. At 12 months, three women were lost to follow-up in the pessary group and 10 women in the standard care group. The authors stopped the trial early because of 'slow' recruitment and pessary problems, which the authors reported as resolving once the pessary was removed. In the abstract, data for the preference and randomised groups are presented together, but Bugge (2020) (215) presents the separated data (personal communication) at 12 months. There was no significant difference in perceived improvement in prolapse symptoms in women in the pessary group compared to women in the standard care group at 12 months on the Australian Pelvic Floor Questionnaire. There was no significant difference between groups on the severity of prolapse as measured by POP-Q at 12 months.

Summary of the evidence from the previous edition

No RCTs were identified for the prevention of prolapse.

Summary of the evidence identified in this update

One new study was included in this comparison. A small size study with a moderate ROB (242) that compared a postpartum vaginal ring pessary with standard care showed no difference in the severity of prolapse for women with stage II prolapse postnatally or women's perceived improvement in prolapse symptoms. **(Level of Evidence: 2)**

Recommendations

Vaginal ring pessary cannot be recommended routinely in women early after delivery to prevent or improve prolapse. **(Grade of recommendation: B)**

3.1.2. Pessary (alone or in combination) versus an active treatment (or combination)

In this update, no new trials were identified.

Summary of the evidence from the previous edition

No RCTs were identified.

Summary of the evidence identified in this update

No trials were identified in this comparison highlighting a gap in evidence.

Recommendations

None.

3.2. Treatment

3.2.1. Pessary (alone or in combination) versus control, waiting list or no active treatment

In this update, no new trials were identified.

Summary of the evidence from the previous edition

The previous update was based on prospective case-controlled cohort studies, which suggested that pessaries are a viable op-

[1] In this chapter, we do not include pessaries used to support pregnancy.

tion for women who complain of a symptomatic prolapse and can be recommended. **(Level of evidence: 3, Grade of recommendation: B)**

Summary of the evidence identified in this update

No trials were identified in this comparison highlighting a gap in evidence.

Recommendations

None.

3.2.2. Pessary (alone or in combination) vs another active treatment (or combination)

In the previous edition, preliminary data for two relevant studies (244, 267) were reported. Since then both trials have been fully reported and are now included in the recent Cochrane review update (215). Consequently, a more comprehensive description is presented below. Salient features of each trial are described in Table 40 and the ROB is profiled in Appendix 2.

Quality of data

Panman and colleagues 2017 (248, 267) conducted a large multicentre RCT comparing the long-term effectiveness and cost-effectiveness of pessary treatment compared with PFMT in menopausal women diagnosed with symptomatic POP. Women in the PFMT arm received PFMT, supervised by an experienced registered physiotherapist. They were initially educated on pelvic floor function, and then taught how to contract their PFMs. Women received feedback about their contractions using digital palpation or myofeedback using EStim if required. All women were initially asked to do the same exercise protocol. This 'basic exercise' programme included a series of graded exercises initially starting with three blocks of 8–12 fast contractions (1-sec each) followed by 1 second of relaxation; 30–60 seconds of rest between each block; building up to a (nearly) maximal contraction (hold 6–10 seconds); 3–5 fast contractions (1 second on top of the maximal contraction). They were asked to repeat this three times with 1-2 minutes' rest between exercises. The basic exercise programme was later tailored for each woman based on specific needs identified during their pelvic floor examination, and additional exercises were included. Women were given advice about going to the toilet (e.g., keeping their feet flat on the floor, not to strain, etc.). Women were also provided with lifestyle advice (e.g., use the 'knack' exercise, avoid heavy lifting, avoiding constipation, etc.), and a lifestyle leaflet at their 3-month follow-up. The PFMT lifestyle and exercise programme are documented in a supplementary online file (see Table 40). Women were then asked to perform the exercises at home 2-3 times per day, 3 – 5 times per week.

Women enrolled in the pessary arm tried a pessary for two weeks (ring pessary). A refit was offered using different types of pessaries as required: a ring with support followed by a Gellhorn or Shaatz pessary. Women were offered a maximum of three refits. The pessary intervention was provided by one of four research physicians who had been trained by an experienced urogynecologist. Women were seen every three months by their GP or by the research physician to clean and replace the pessary and record any side effects. The primary outcome was distress experienced due to pelvic floor symptoms measured using the PFDI-20 questionnaire, and its subscales including POPDi-6, at 24 months. Secondary outcomes included pelvic floor related quality of life; costs; prolapse stage; and participants' perceived symptom improvement. Women were followed up at 3, 12 and 24 months after starting PFMT or having a successful pessary fitting.

Cheung and colleagues carried out a RCT in women with symptomatic POP (stage I-III) who had never received previous treatment (244). Women were randomised to receive either a ring pessary plus PFMT, or PFMT alone (244). Women in the pessary plus PFMT group were assessed by a specialist gynaecologist and then fitted with a vaginal ring pessary, using the largest pessary that was comfortable for the woman. Reinsertion of the same pessary (or the next size) was performed up to a maximum of three times. Women were contacted by phone two weeks later to see how successful the pessary fitting was. If women reported that the pessary had slipped out, they were offered a reassessment and replacement. Women in both groups were taught PFMT by specialist nurses (who were also trained as continence advisors). The standardised PFMT course included a teaching session (within two weeks after the first consultation) and three individual training sessions delivered at 4, 8, and 16 weeks. Women were encouraged to perform two sets of 8–12 exercises per day (with 8–10 exercises per session *at least* twice per week). The specialist nurses continued to encourage women to perform the PFMT at each follow-up session. The trial had two primary outcomes: change in prolapse symptoms measured using the PFDI-20 (Chinese version) and change in PFIQ-7 (Chinese version) at 6 and 12 months. Secondary outcomes included the discomfort of prolapse symptoms using a visual analogue score, severity of prolapse using POP-Q. Desired treatment for the prolapse in the first consultation before any intervention and at the 12-month follow-up and complications were also documented.

Results

Of the 162 enrolled in the Panman study (267), 80 women were randomised to PFMT and 82 to a pessary. Four out of the 80 women in the PFMT group did not attend any PFMT appointments and another 10 discontinued (Table 40). Pessary fitting was successful in 47/82 women; 35 women did not receive pessary treatment mostly due to an unsuccessful fitting (Table 40). There was aa statistically significant between group difference in the adjusted POPDI-6 scores at 24 months but the authors concluded that this was not clinically meaningful. The meta-analyses presented in Bugge (215), based on unadjusted data showed no difference between groups in perceived improvement in the PFDI-20 or POPDI-6 prolapse subscores at 12 or 24 months. The number of women reporting an improvement in symptoms was not statistically significantly different between groups at 12 or 24 months. There was also no difference in prolapse-specific quality of life measures between the groups at 12 or 24-month follow-up. The number of women with complications and adverse events (vaginal bleeding, voiding difficulty) were presented as a *per protocol* analysis. No adverse effects were reported in the PFMT group, but of the 35 women who were still using a pessary at 24 months, 21 reported one or more side effects including vaginal discharge (n=14), increased UI (n=5), and irritation / erosion of the vaginal wall (n=10). Based on their meta-analysis, the authors concluded that pessaries may substantially increase the risk of adverse events compared with PFMT. Pessary treatment was reported as less expensive than PFMT ($309/woman in pessary group vs $437/women in the PFMT arm) over the two-year period (248).

Of the initial 311 women recruited to the Cheung trial (244), 276 were randomised, 137 to PFMT treatment and 139 to vaginal pessary plus PFMT. Seven women dropped out of the pessary plus PFMT group (3 were lost to follow-up, 1 with cervical cancer and 3 with missing data). Nine women dropped out of the PFMT alone group (7 were lost to follow-up and 2 with missing data). Women in the pessary plus PFMT group reported statistically significantly fewer prolapse symptoms compared with women who received PFMT alone at both 6 and 12 months on POPDI-6. Women in the pessary plus PFMT had a statistically significantly improved prolapse-specific quality of life compared with women in the PFMT alone group at 12 months based on their POPIQ scores. Fifty-six women out of 132 (42%) in the pessary plus PFMT group failed to retain a pessary but their data appear to have been included in the final analysis. Nine women (9/132) had abnormal vaginal bleeding and 6/132 had unusual or bothersome vaginal discharge. Complications reported in the PFMT alone group included: 4/128 women with abnormal vaginal bleeding and 2/128 unusual or bothersome vaginal discharge (244). While there was no statistically significant difference between the groups for abnormal vaginal bleeding, Bugge (215) concluded that *"Pessary plus PFMT may slightly increase the risk of abnormal vaginal bleeding compared with PFMT alone (RR 2.18, 95% CI 0.69 to 6.91; 1 study; 260 women; low-certainty evidence".*

Summary of the evidence from the previous edition

Preliminary data from two relevant studies (244, 267) were reported. Since then both trials have been fully reported and are now included in the recent Cochrane review update (215).

Summary of the evidence identified in this update

Two new studies were included in this comparison.

A moderate-large size study with a low ROB that comparing PFMT with pessary showed no difference between groups in clinical outcomes including prolapse symptoms, but PFMT was more expensive and pessary had more adverse events (267). **(Level of evidence: 2)**

A moderate-large study with very low ROB comparing PFMT with PFMT plus pessary showed better prolapse symptom and quality of life outcomes in the combined group with no significant difference in complications (244). **(Level of evidence: 1)**

Recommendations

Pessary and PFMT could both be recommended as treatment for prolapse, but cost and adverse events need to be taken into consideration. **(Grade of recommendation: C New)**

The combined use of a vaginal pessary plus PFMT, rather than PFMT alone, can be recommended for treatment of prolapse. **(Grade of recommendation: B New)**

3.2.3. Pessary and Surgery

In the previous chapter, there were no trials comparing the effectiveness of pessary use with surgery. This update includes one study (254, 268), which is also described in Bugge (2020) (215).

Quality of data

Coolen *et al*. (2018) (254, 268) conducted a trial to compare women with symptomatic prolapse (stage II or greater) according to their preference for either a pessary (Portex ring) or prolapse surgery (254). They aimed to conduct an RCT, however of the 113 women recruited to the trial, only six women were randomised; the remainder were treated according to patient preference and the study was subsequently reported as a prospective cohort study. Data from the women randomised were unavailable in the published studies, but Bugge (2020) stated that contact had been made with the trialists and these data would be presented in the next review update (215).

Summary of the evidence from the previous edition

No RCTs were identified.

Summary of the evidence identified in this update

Only 6 women were randomised in the trial identified. No conclusions can be drawn.

Recommendations

None

3.2.4. Pessary (alone or in combination) vs another pessary (alone or in combination)

In this section, we have identified three new RCTs (247, 252, 269); two of these were excluded by Bugge (2020) (215) because the data were presented from a mixed population and it was not possible to extract separate data for women with prolapse only (247), and one study had an adjunct component which meant that *"it would not be evidence of the effectiveness of the pessary itself"* (Bugge, 2020, p15) (215). We have chosen to include these here as they provide important evidence of the effectiveness of pessary usage. Salient features of each trial are described in Table 40. ROB is summarised in Appendix 2.

Quality of data

The cross-over RCT conducted by Ziv *et al.* (2019) was reported over multiple conference abstracts (253, 269, 270). Ziv and colleagues described a new disposable device for the management of POP which was evaluated clinically for its impact on vaginal microflora and *Staphylococcus aureus* (SA) levels compared to a commercially available ring pessary. The authors described the new disposable device as *"housed in small dimensions within an applicator and is self-inserted vaginally. Within the vagina the device opens to become a ring of up to 91 mm. Once inserted, the applicator can be discarded. The device can remain within the vagina for up to 7 days"*. To remove the device, women were instructed to pull the string, which causes the device to collapse. However, following publication of this trial, the clinical trial registry entry has been redacted as the clinical device has "not been approved or cleared by the US FDA".

Meriwether and colleagues (2015) (247) conducted a multi-centre RCT comparing the effect of hydroxyquinoline-based gel (TrimoSan – a mildly acidic vaginal lubricant) in first time pessary users (TrimoSan group) with new pessary users not using the gel (no treatment) to examine whether the gel could reduce the prevalence of bacterial vaginosis or other bothersome vaginal symptoms (vaginal

discharge, itching, pain, sores). The trialists also published a series of linked secondary analyses from this study exploring: sexual function and pessary management in women (271); changes in vaginal microenvironment (272, 273); and the continued use of pessaries in women from different ethnic backgrounds (274, 275). Prior to the pessary fitting, women were asked to complete questionnaires about vaginal symptoms, hormone therapy and had a bacterial vaginosis (BLUE) test and a vaginal secretion swab. Following pessary fitting women were then randomised to standard pessary care with the gel (twice weekly) or standard pessary care. Women were followed up at 2 weeks and 3 months, and the questionnaires, BLUE test and slide collection repeated.

A randomised trial carried out by Tontivuthikul (2016) (252) examined the effect of locally applied oestrogen cream on vaginal health. Post-menopausal women with prolapse who had successfully used a pessary for six weeks and who were using vaginal conjugated equine oestrogen cream (0.5g daily for the first two weeks following fitting, and then twice per week for the next four weeks) were enrolled in the study. During the first six weeks, women were also advised to remove their pessary every evening and reinsert in the morning. Women were then randomised to either continuing to use the oestrogen cream (0.5 g) once a week (treatment group) or asked to discontinue (control group) for 24 weeks. The primary outcome was a vaginal health assessment, which included a vaginal symptom score (dryness, soreness, itching/irritation and discharge), vaginal pH, and vaginal maturation. Secondary outcomes comprised difficulty in using the pessary and endometrial thickness. Data were collected at baseline, 12 and 24 weeks.

Results

The results reported by Ziv *et al.* 2019 (253, 269, 270) from a trial comparing a new device with a commercially available ring pessary are limited, and the dropouts are not fully reported. Women using the new devices showed an improvement in their prolapse in 95.3% of cases (see Table 40). The levels of vaginal microflora and *Staphylococcus aureus* levels were described as low in both groups.

A total of 184 women were randomised in the Meriwether (2015) study (247); 92 to the TrimoSan group and 92 to the standard care group. At the two-week follow-up, 111 women responded (64 in the TrimoSan group; 47 in the standard care group); at month three, 147 women attended for follow-up (73 TrimoSan group, 74 standard care group). Reasons for loss to follow-up are detailed in Table 40. The prevalence of bacterial vaginosis based on the swab test or on the questionnaire (based on the prevalence of at least one vaginal symptom) was not significantly different between the groups at 2 weeks or at 3 months. Women were also equally satisfied with their pessaries in both groups.

Of the 40 women who were randomised into the Tontivuthikul (2016) study (252), 20 were allocated to the vaginal conjugated equine oestrogen cream and 20 to the control group. There were no dropouts from either arm. The trialists reported no statistical difference between groups for the vaginal health assessment (vaginal symptom score, vaginal pH, and vaginal maturation) at any time point (baseline, 12 or 24 weeks). They also reported no significant difference between the groups for secondary outcomes, although data for endometrial thickness were only presented for 31 women.

Summary of the evidence from the previous edition

No RCTs were identified.

Summary of the evidence identified in this update

Three new studies were included in this comparison.

- A small size study with moderate-high ROB compared the use of a new disposable vaginal device with a commercially available ring pessary. Data from this trial are limited and not yet fully reported (253, 269, 270).
- A moderate size study with moderate ROB compared the use of hydroxyquinoline-based gel – a mildly acidic vaginal lubricant on the prevalence of bacterial vaginosis in first time pessary users with no treatment and found no statistically significant difference on any outcome (247) **(Level of evidence: 2).**
- A small size study with moderate ROB compared the extended use of oestrogen cream in post-menopausal women with women who were asked to discontinue the cream. No differences on vaginal health were found between the two groups (252). **(Level of evidence: 2)**

Recommendations

Use of hydroxyquinoline-based gel in first time pessary users may be considered according to expert's opinion but there is no evidence of benefit or harm. **(No recommendation possible)**

Extended use of oestrogen cream use in postmenopausal pessary users may be considered according to expert's opinion. There is evidence for neither harm nor benefit. **(No recommendation possible)**

3.3. Studies aimed at optimising treatment protocols in women with POP

In this update, six studies focussed on optimising pessary management or reducing pessary-related complications were identified (243, 245, 246, 249-251). Salient features of each trial are described in Table 40. ROB is summarised in Appendix 2.

Quality of data

Escobar 2017 (246) conducted a mixed methods study including a survey and a pilot RCT to assess whether simulation training delivered to medical professionals (residents) could improve pessary placement skills. Residents were randomised to either an enhanced education intervention or to a control group (standard education). Both groups received a didactic lecture on pessary sizing and placement, but residents in the enhanced education group received an additional hands-on tutorial regarding pessary sizing and placement on a small-scale pelvic model prior to the post-test written and practical examination. Outcomes included written and practical examination six months after initial testing.

In a conference abstract, Chinthakanan and colleagues (2019) (245) compared women's satisfaction with ultra-low dose estriol plus *Lactobacillus acidophilus* vaginal tablets (Estriol group) with a vaginal moisturiser (moisturisers group) in women who were able to -manage their own pessary over a two month follow-up period. The estriol group received a vaginal tablet daily for the first 6 days, then 2 tablets per week for 8 weeks. Women in the moisturisers group received one application every 3 days for 8 weeks. Outcomes were measured at 4- and 8-weeks

follow-up and included women's satisfaction using the Thai-version Patient Global Impression of Improvement - Incontinence (Thai PGI-I), subjective complaints (i.e., foul smell, vaginal discharge, vaginal irritation and abnormal vaginal bleeding), and objective outcomes of vaginal health (i.e., vaginal abrasion, pH) and number of adverse events.

Taege and colleagues (2017) (250) conducted a double-blind randomised placebo controlled trial that studied the effect of applying a topical anaesthetic cream at the time of routine pessary change. Women were randomised to receive either four grams of 5% EMLA cream (eutectic mixture of lidocaine 2.5% and prilocaine 2.5%) or an equal volume of placebo cream (emollient cream containing purified water, white petrolatum, cetyl alcohol, stearyl alcohol, propylene glycol, glycerin, sodium lauryl sulfate, diazolidinyl urea, Iodopropynyl butylcarbamate). Women attended their routine urogynaecology outpatient appointment for pessary change, and the cream was applied. After five minutes the pessary was removed, a speculum exam was conducted, and the pessary insertion was performed. Outcomes included a satisfaction score for pessary use and a visual analogue scale pain score (0 = no pain to 10 = severe pain). The pain score was completed prior to placement of the study cream, immediately after pessary removal and immediately after pessary insertion. Physicians were also asked to mark their perception of women's pain using the same VAS score.

Propst (2018) conducted a randomised non-inferiority trial comparing the timing of routine pessary care appointments to determine the optimal interval for women to be seen by their healthcare providers to prevent pessary-related complications (249). Women who were existing pessary users (ring, Gellhorn or incontinence dish pessary to treat prolapse, incontinence or both) were invited to attend their routine outpatient appointment at 12 weeks (usual care group) or attend a routine appointment at an extended interval at 24 weeks (extended interval group). Pessary care included pessary removal and cleaning. Women were followed for 48 weeks. The primary outcome was the incidence of vaginal epithelial abnormalities (types 3 and 4) (i.e., an epithelial break or erosion). Secondary outcomes included rate of all types of vaginal epithelial abnormalities (i.e., epithelial erythema, granulation tissue, epithelial break, or erosion) at 24 and 48 weeks, patient satisfaction, degree of bother due to vaginal discharge, and number of unscheduled visits.

Tam and colleagues (2019) also undertook an RCT to examine the effect of time intervals on the replacement of pessaries (251). Existing users with a vaginal ring pessary for prolapse (stage I-IV) were randomised to either have their pessary replaced at 3 months (3 monthly treatment group) or at 6 months (6 monthly control group). Women in both groups received a pelvic examination and a new pessary was fitted at the baseline appointment. At the second visit, women received a speculum examination, and the pessary was replaced in the 3 monthly treatment group, or the same pessary was re-inserted after cleaning (6 monthly control group). Women in both groups were followed up at 3 and 6 months. The primary outcome was the complication rate – defined as complications arising from the use of vaginal pessary. Women were also asked to score their satisfaction with the use of a vaginal pessary using a visual analogue scale. Secondary outcomes included POP-Q, prolapse symptoms (aware of prolapse, vaginal soreness, dragging sensation, low back pain), urinary symptoms, bowel symptoms and sexual symptoms. The symptom questionnaires used were not reported.

Anglim and team (2020) (243) conducted an RCT to explore women's satisfaction with different models of pessary care, specifically comparing a 3-month follow-up with a 6-month follow-up. New users with a primary diagnosis of prolapse were randomised to receive either a follow-up appointment at three months or to a follow-up appointment at six months. Before taking part in the trial, all women received vaginal oestrogen (tablet or cream) for at least two weeks prior to being fitted with their pessary. The fittings followed standard procedures and a variety of pessaries were used (e.g., ring pessary, Gelhorn, Shaatz and Marland devices). Women were reassessed after two weeks and if the pessary was successful then they were randomised into one of the two trial arms. Follow-up outcomes were the same at both appointments and comprised discussion of pessary expulsion, bladder and bowel complications. The physician removed the pessary and performed a routine examination. The pessary was reinserted if there were no complications and notes made in the management plan. The primary outcome was the score on the Pessary Satisfaction Form at 12 months.

Results

Twenty-four medical residents completed the follow-up assessment at 6 months in the Escobar study (246). The authors reported a small but non-significant improvement within the intervention group, signalling improved retention of clinical skills on the practical assessment. The control group showed no improvement in their practical exam. No data comparing the two groups were reported, but 80% of residents reported that the simulation was a valuable learning experience.

In the Chinthakanan study (245), 60 women were randomised into two groups (30 women in each group). Attrition rate was low for the trial with one woman dropping out of the estriol group, but no reason was provided. No statistically significant difference for any outcomes (POP-Q, duration of pessary use or genitourinary symptoms (foul smell, vaginal discharge, vaginal irritation, abnormal vaginal bleeding), patient satisfaction) was evident between the groups at 4- or 8-weeks follow-up.

Fifty-four post-menopausal women were randomised to receive the topical anaesthetic (EMLA) cream (n=28) or placebo (n=26) in the Taege trial (250). One woman withdrew from the EMLA cream because of vaginal erosion preventing the reinsertion of her pessary. There was no statistically significant difference between the two groups on their baseline or reinsertion pain scores, but women receiving the EMLA cream reported significantly lower pain scores at pessary removal regardless of the experience level of the provider.

Of the 130 women enrolled in the Propst trial (249), 66 were randomised to receive extended interval pessary care (every 24 weeks) and 64 received usual care (every 12 weeks). Nine women discontinued the intervention in the extended arm, and 10 women withdrew from the usual care arm. The rate of type 3 and 4 vaginal epithelial abnormalities met the criterion for noninferiority of extended-interval pessary care. There was no difference in the incidence of vaginal epithelial abnormalities (of any type) between the two groups at any point in the study, with most women in the extended arm reporting that they preferred fewer appointments. Unscheduled visits were reported in both groups (14 women in the usual care group and 12 in the extended group), and usually occurred as a result of need to treat the vaginal epithelial abnormalities.

In the Tam study (251), sixty women were randomly allocated to each arm (30 women in each group). One woman was lost to follow-up in the 3-monthly treatment group. The complication rate, defined as adverse event necessitating discontinuation of the pes-

sary, was not statistically significantly different between groups. No statistically significant differences were evident between groups for patient satisfaction, change in self-reported symptoms or stage of prolapse.

In the EPIC trial, Anglim and team (243) assessed 203 women for eligibility and randomised 20 women; 9 women were allocated to the 3-month follow-up schedule and 11 women to the 6-month follow-up schedule. Three women from the 3-month schedule discontinued the study and 4 women from the 6-month schedule discontinued the study. The trial was stopped early after two years as the trialists did not reach their target sample size (n=70). Women in the 6-month group reported higher dissatisfaction with having to wait too long between visits, although the level of bother was low in both groups. Discomfort occurred more in the 3-month group and UI was common in both groups.

Summary of the evidence from the previous edition

No RCTs were identified.

Summary

Six new studies were included in this comparison:

- Three addressed the length of time between pessary appointments (only one small trial had low ROB, and one was stopped due to very low recruitment) providing some evidence that outcomes for longer follow up intervals are similar to those for shorter intervals. **(Level of evidence: 2)**
- One small unclear ROB trial evaluated pessary fitting training but reported no between group comparisons. **(Level of evidence: 4)**
- One small unclear ROB trial compared vaginal oestrogen plus lactobacillus acidophilus with a vaginal moisturiser found no difference between groups in POP-Q, symptoms, or satisfaction. **(Level of evidence: 2)**
- One small low ROB trial compared an anaesthetic cream with a placebo for pessary changes and found lower pain scores with the anaesthetic cream at pessary removal. **(Level of evidence: 1)**

Recommendations

A longer follow up interval for pessary users (e.g., 24 weeks, or 6 months) compared to a shorter interval (e.g., 12 weeks, or 3 months) could be recommended. **(Grade of recommendation: C New).**

The use of an oestrogen plus lactobacillus acidophilus vaginal tablet could not be recommended as there is no evidence of benefit. **(Grade of recommendation: C New)**

Use of an anaesthetic cream over placebo could be considered to reduce pain on pessary removal. **(Grade of recommendation: C New)**

Table 40. Summary of Pessaries and prolapse studies (Notes: * Key findings as extracted from Bugge et al. (2020) (215))

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Anglim (2020) (243)	RCT Pessary maintenance visit at 6 months FU vs pessary maintenance at 3 months FU	20	Women (age >18 yrs) with prolapse who opted for pessary management Canada	Variety of vaginal pessaries – common silicone pessaries incl. covered ring, Gelhorn, Shaatz and Marland. Women with successful pessary fitting were reassessed 1-2 weeks later and then randomised to either a 3- or 6-month FU	Outcomes: At each follow-up, women were asked about the following issues: recurrent pessary expulsion, discomfort, UI, vaginal bleeding, difficulty with defecation, and foul/ heavy discharge. Pessary difficulties (reinsertion, changes in management or discontinuation/withdrawal) was also documented. Pessary satisfaction form Key findings: only able to recruit 20 women, 35% dropped out, high satisfaction and similar between groups, UI was common in both groups 57-67%.	Baseline, 6 months, and 12-month follow-up	Publication: FT Dropouts: After 2 years, recruited 20 women of which 7 dropped out; 3/9 women dropped out of the 3-month FU schedule and 4/11 women dropped out of the 6-month FU group. Of these 2/7 shortened their FU interval and the remaining discontinued pessary usage. AE: bleeding, discharge and abrasion occurred in low numbers for both groups. Unable to reach sample size as most participants did not meet inclusion criteria (recruitment rate of 9.9% and target was 70 women
Baessler (2019) (242)	RCT Vaginal pessary ring vs standard PP care	44	Women 1-3 days after first vaginal birth with stage II prolapse Germany	Vaginal pessary ring (no other details available) Standard care: no interventions for 6 weeks	Outcomes: POP-Q, PUS, Australian Pelvic Floor Questionnaire (German version with validated PP module) Key findings*: Bugge reported no evidence of benefit or harm for any of the following outcomes at 12 months PP: site specific grading of prolapse using POP-Q (anatomical or posterior measurement of prolapse), Bladder problems compared with usual care; cure or improvement of of sexual problems	Baseline, 6 weeks PP and 12 months PP	Publication: AB but additional data presented in updated Cochrane review (218) Dropouts: 3 lost for follow-up in the pessary group and 10 lost for follow up in standard care. Pessary placement not possible in 2 women. Study was stopped early because of slow recruitment and occasional pessary problems AE: Two women reported reduced lochia and 1 reported vaginal pain

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Cheung (2016) (244)	RCT PFMT and insertion of a vaginal pessary (pessary group) vs Pelvic floor exercise training (control group)	276	Women with symptomatic stage I to stage III prolapse PRC	Vaginal ring pessary was inserted by a gynaecologist. The largest pessary that was comfortable for the women was used. If the vaginal pessary slipped out, reinsertion of same or next size of vaginal pessary was performed up to three times. A telephone hotline was given for both groups for early consultation if needed. Women in this group also received PFMT (detailed below) PFMT group: standardised PFMT training which included a teaching session within 2 weeks after the first consultation and three individual training sessions at 4, 8, and 16 weeks. Women were advised to practise daily with at least two sets of 8–12 preset exercise repetitions per day, with 8–10 exercises per session at least two times per week.	Outcomes: Primary outcomes: PFDI, PFIQ (Chinese validated versions). Secondary outcomes included distress caused by prolapse symptoms, desired treatment, and any complications Key findings*: Women in the pessary plus PFMT group reported a significant improvement in their prolapse symptoms compared with women who received PFMT alone at both 6 and 12 months on POPDI-6. Women in the pessary plus PFMT had a significantly improved prolapse-specific quality of life compared with women in the PFMT alone group at 12 months based on their POPIQ scores.	Baseline, 6 months, 12 months	Publication: FT and also reported in the updated Cochrane review (218) Dropouts: accounted for. In the pessary group 3 women were lost to follow-up and 1 had cervical cancer at 6 months: Missing data for 3 women at 12 months. In the PFMT alone group, 3 women were lost to follow-up at 6 months, 4 lost to follow up at 12 months and missing data for 2 women at month 12. AE: 56 women in the pessary plus PFMT group failed to retain a pessary, 9/132 had abnormal vaginal bleeding and 6/132 had unusual or bothersome vaginal discharge. Complications reported in the PFMT alone group included: 4/128 women with abnormal vaginal bleeding and 2/128 unusual or bothersome vaginal discharge
Chinthakanan (2019) (245)	RCT Vaginal moisturisers + pessary vs ultra-low dose estriol & Lactobacillus acidophilus vaginal tablets	60	Women able to take care, insert, and remove pessary by herself and did not use local oestrogen or vaginal moisturisers for 3 months Thailand	Estriol group received 1 vaginal tablet (ultra-low dose estriol & Lactobacillus vaginal tablets) daily for 6 days then 2 tablets per week for 8 weeks Moisturisers group received one application every 3 days for 8 weeks.	Outcomes: Primary outcome was patient's satisfaction using Thai-version Patient Global Impression of Improvement (Thai PGI-I). Secondary outcomes were subjective and objective outcomes of vaginal health Key findings: No significant difference between groups at 4 and 8 weeks for any of the following outcomes: age, BMI, POP-Q, duration of pessary used, and genitourinary symptoms. Patient satisfaction on the Thai PGI-I was equally high in both groups at 4 and 8 weeks (93.1% vs. 96.7%, P=0.487 at 4 weeks and 89.7% vs. 93.3%, P=0.484 at 8 weeks)	Baseline, 4 weeks and 8 weeks	Publication: AB Dropouts: one dropout; no reasons given AE: no serious events

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Coolen (2018) (254, 268)	RCT Pessary use vs prolapse surgery	6	Women with symptomatic prolapse (stage II or higher) The Netherlands	Pessary treatment (ring or a Falk pessary). Prolapse surgery: vaginal native tissue repair of compartments that affected according to the POP-Q score and required surgery.	Outcomes: Primary endpoint was disease specific quality of life at 12 months follow-up, according to the prolapse domain of the UDI. Key findings: Due to strong patient preference randomisation was not possible and only 6 women were randomised therefore no conclusions can be drawn.	Baseline and 12 months follow FU	Publication: FT, AB but only 6 women were randomized (2 to the pessary group and 4 to the surgery group) and a remaining 107 women took part in the prospective cohort study (72 choose pessary treatment and 35 choose surgery).
Escobar (2017) (246)	Survey and pilot RCT Hands-on teaching model + lecture vs lecture only	25	Resident physicians USA	IG: Hands-on training model using a small-scale size pelvic model to demonstrate proper pessary fitting (sizing and placement) plus lecture CG: received lecture only	Outcomes: Written exam, satisfaction survey Key findings: there was no significant difference between groups on the practical exam (immediately post-intervention) (p=0.66) or after 6 months (p=0.85)	Baseline, immediately post-intervention and 6 months FU	Publication: AB Dropouts: one resident physician dropped out; reasons not reported AE: not described
Meriwether (2016) (247, 271)	RCT Standard pessary care with the use of TrimoSan placed vaginally twice weekly or to standard pessary care without TrimoSan gel	184	Woment who were first time pessary users USA	IG: Hydroxyquinoline-based gel (TrimoSan – a mildly acidic vaginal lubricant) in first time pessary users (TrimoSan group); twice weekly CG: new pessary users not using the gel (standard care)	Outcomes: questionnaires about vaginal symptoms, hormone therapy, bacterial vaginosis (BLUE) test and a vaginal secretion swab Key findings: No significant difference in bacterial vaginosis on Nugent's criteria or on the BLUE testing at 2 weeks or 3 months. The prevalence of at least one vaginal symptom did not differ between groups at two weeks or at three months The TrimoSan group was equally likely to want to continue their pessary use compared with the standard care group at 2 weeks (90% vs 86%, p= 0.64) and 3 months (63% vs 60%, p= 0.76).	Baseline, 2 weeks and 3 months	Publication: FT Dropouts: At the two-week follow-up, 111 women responded (64 in the IG; 47 in the CG); at month 3, 147 women attended for follow-up (73 IG, 74 CG). Reasons for loss to follow-up across the trial included: no FU, partial FU (i.e. attended one visit but not another visit), no Gram stain results (only questionnaires, inadequate Gram stain and two women with unverified data AE: none reported but women were excluded from taking part in the trial if they had a known allergic or suspected adverse reaction to the gel.

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Panman (2016) (248, 267)	RCT PFMT vs pessary	162	Menopausal women diagnosed with symptomatic prolapse The Netherlands	PFMT: PFMT supervised by an experienced registered physiotherapist. Training and education; taught how to contract their pelvic floor exercises. Women received feedback about their contractions using digital palpation or myofeedback using electrostimulation if required. All women were taught the knack and there is supplemental material etc which is available online at: http://links.lww.com/MENO/A179 Pessary: trialled a pessary for two weeks (ring pessary). A refit was offered using different types of pessaries as required: a ring with support followed by a Gellhorn or Shaatz pessary. Women were offered a maximum of three refits. The pessary intervention was provided by one of four trained research physicians who had been trained by an experienced urogynaecologist.	Outcomes: primary outcome measure was PFDI-20 at 24 months. Secondary outcomes included prolapse, urinary, and anorectal symptoms; quality of life; costs; sexual functioning; prolapse stage; PFM function; and participants' perceived symptom improvement Key findings*: Bugge reported no significant difference between groups on the PFDI-20 or POPDI-6 scores at 12 or 24 months. The number of women self-reporting an improvement in symptoms was also not significantly different between groups at 12 or 24 months. There was also no significant difference on PQoL measures between the groups at 12 or 24-month follow-up.	Baseline, 3, 12 and 24 months after starting PFMT or having a successful pessary fitting	Publication: FT and also reported in the updated Cochrane review (218) Dropouts: 4/80 women in the PFMT group did not attend any PFMT appointments and another 10 discontinued; pessary fitting was successful in 47/82 women; 34 women did not receive pessary treatment mostly due to an unsuccessful fitting. AE: none in the PFMT group; 21/35 women in the pessary group reported one or more side effects at 24 months. These were: increased vaginal discharge in 14 women, increased UI in 10 women, and irritation/ erosions of the vaginal wall in 10 women.
Propst (2018) (249)	RCT Extended pessary care vs routine pessary care	130	Women who were existing pessary users who used the pessary to treat prolapse, UI or both USA	Routine pessary care (appointment scheduled at 12 weeks) Extended pessary care (appointment extended to 24 weeks) Pessary care in both groups included pessary removal and cleaning	Outcomes: primary outcome was incidence of vaginal epithelial abnormalities. Secondary outcomes included rates of vaginal epithelial abnormalities, patient satisfaction, degree of bother due to vaginal discharge, number of unscheduled visits Key findings: rate of epithelial was not significantly different between the two groups: 1.7% in the extended arm and 7.4% in the routine pessary group, which met the criteria for noninferiority. There was no difference in the rates of vaginal epithelial abnormalities between the groups at any time.	Baseline, and follow-up to 48 weeks	Publication: FT Dropouts: 9/66 women discontinued the intervention in the extended arm; 10/64 withdrew from the routine pessary arm. AE: none reported other than the epithelial abnormalities that were described.

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Taege (2017) (250)	RCT Application of anaesthetic cream at time of pessary change vs placebo cream at time of pessary change	54	Postmenopausal women who were existing pessary users USA	IG: 4g topical EMLA cream applied at the time of pessary change on patient discomfort. CG: placebo cream of equal volume applied	Outcomes: satisfaction score for pessary use and a VAS pain score. Physicians were also asked to mark their perception of women's pain using the same VAS score. Key findings: women in the EMLA cream group had significantly lower pain at pessary removal when compared with those assigned to placebo (p=0.015)	Baseline (immediately before pessary change) and immediately post-intervention	Publication: FT Dropouts: one woman dropped out from the EMLA group as she had issues with vaginal erosion which prevented reinsertion of the pessary AE: none reported and no issues with irritation
Tam (2019) (251)	RCT Pessary replacement at 3 months vs pessary replacement at 6 months	60	Women with stage I-IV prolapse using vaginal ring pessary Hong Kong, PRC	Vaginal ring pessary was replaced at either 3 or 6 months.	Outcomes: Primary outcome was complication rates as a result of using the pessary. Other outcomes included satisfaction with the pessary, change in self-reported symptoms, change in prolapse stage. Key findings: higher complication rate in the 6-monthly group than the 3-monthly group at month 9 but not statistically significant (p = 0.061). No statistically significant differences between groups in patient satisfaction scores, other prolapse-related symptoms or staging of prolapse.	Baseline and FU at 3 and 6 months	Publication: FT Dropouts: accounted for. One woman lost to FU in the 3-month FU group. AE or unintended events: no harms or unintended effects in each group
Tontivuthikul (2016) (252)	RCT Local oestrogen cream vs discontinued oestrogen cream	40	Postmenopausal women with prolapse who had successfully used a pessary for 6 weeks and who were using vaginal conjugated equine oestrogen cream Thailand	During the first six weeks, women were advised to remove their pessary every evening and reinsert in the morning. Women were then randomised: IG: continuing to use the oestrogen cream (0.5 g) once a week CG: asked to discontinue (control group) for 24 weeks.	Outcomes: primary outcome was a vaginal health assessment which included a vaginal symptom score, vaginal pH, and vaginal maturation. Secondary outcomes comprised difficulty in using the pessary and endometrial thickness Key findings: no statistically significant differences between groups for all vaginal health assessment at 12- and 24-weeks post-intervention. There was also no significant difference between groups about the difficulty to insert and remove the pessary or the endometrial thickness.	Baseline, 12 and 24 weeks	Publication: FT Dropouts: none AE: one woman in the CG with vaginal ulcer which resolved with treatment

Author, year	Study design/ Comparator	N	Study population / Country	Modality details or parameters	Outcomes / Key findings	Data collection and follow up time-points	Notes
Ziv (2019) (253, 269, 270)	Cross-over RCT Effect of a new disposable vaginal device for prolapse vs CARP	58	Limited detail. Pre-treatment POP-Q stages included 49 cases (32.2%) of stage I prolapse, 101 cases (66.4%) with stage II, and 2 cases (1.3%) with stage II prolapse. Israel / USA	IG: ND inserted for up to 7 days. Allowed to use as many devices as they wish (1-7 days) CG: CARP remained in situ for whole usage phase. First usage phase of 30±2 days began after a 14-16-day washout period. Followed by another 14-16-day washout period and then a second usage cross-over phase, where each group used the alternate device also for 30±2 days.	Outcomes: Vaginal swabs and cultures for microfora analysis. Women completed a daily diary, documenting length of use, functionality and AE. Key findings: While using the ND, 139 cases (95.3%) had complete reduction of their prolapse (stage 0), 5 cases (3.4%) had stage I prolapse, and 2 cases (1.3%) had stage II prolapse. In 98.7% of the cases prolapse during device usage was of either stage 0 or II. Low prevalence for SA. Following usage, 7 ND users (12%) and 5 CARP users (8.6%) had various SA counts detected in the vagina. Rate of fluctuation in SA counts (increase/decrease) while using either device was 13.8% (8/58).	Baseline, after first FU phase and after second FU phase	Publication: AB Dropouts: Unclear; 58 women completed the study per-protocol, using both vaginal devices AE: No vaginal infections, bothersome vaginal symptoms, or urinary infections in the ND group. In the CARP group there was one case of overt vaginal infection, two cases of UTI, and 2 cases of bothersome vaginal complaints.

Abbreviations: AB: abstract; AE: adverse events; CARP: commercially available ring pessary; CG: control group; CRADI-8: Colorectal-Anal Distress Inventory; CRAIQ-7: Colorectal-Anal Impact Questionnaire; EMLA: eutectic mixture of lidocaine 2.5% and prilocaine 2.5 %; FI: faecal incontinence; FT: full-text; FU: follow-up; IG: intervention group; IIQ-7: Incontinence Impact Questionnaire; ND: new vaginal device; NR: not reported; PA: physical activity; PFD: pelvic floor disease; PFDI-20: Pelvic Floor Distress Inventory; PFH: pelvic floor health; PFIQ-7: Pelvic Floor Impact Questionnaire; PFM: pelvic floor muscle; PFMT: pelvic floor muscle therapy; PGI-I: Patient Global Impression of Improvement-Incontinence; PISQ-12: Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire; POP: pelvic organ prolapse; POPDI-6: Pelvic Organ Prolapse Distress Inventory; POPIQ-7: Pelvic Organ Prolapse Impact Questionnaire; PP: postpartum; PRC: Peoples Republic of China; PUS: perineal ultrasound; QoL: quality of life; RCT: Randomised controlled trial; SA: Staphylococcus aureus; UDI-6: Urinary Distress Inventory; UI: urinary incontinence; UTI: urinary infection; VAS: visual analogue scale.

4. SUMMARY CONSERVATIVE MANAGEMENT FOR POP

4.1. Educational and lifestyle intervention

Prevention

- Improving pelvic floor knowledge in healthy women could be recommended as it may reduce PFD symptoms **(Grade of recommendation: C New)**
- An enhanced educational intervention may be recommended to improve healthy women's knowledge of their pelvic floor. **(Grade of recommendation: D New)**
- A weight loss programme in overweight women with UI could be considered for improved prolapse symptoms and severity. **(Grade of recommendation: C New)**

Treatment

Liberal post-operative instructions could be recommended rather that restricted activities for reducing post-operative prolapse symptoms. **(Grade of recommendation: C New)**

4.2. Physical Interventions

Prevention

Antenatal PFMT cannot be routinely offered for prevention of postnatal prolapse**. (Grade of Recommendation: B)**

Postnatal PFMT +/- EStim could be recommended as beneficial in preventing prolapse in women in the post-partum period. (**Grade of recommendation: C New)**

Treatment

PFMT can be offered to women with symptomatic prolapse as this is associated with a reduction in prolapse symptoms and pelvic floor symptoms. (**Grade of recommendation: B)**

PFMT plus biofeedback may be recommended as this combination improves prolapse symptoms and pelvic floor symptoms compared with standard care**. (Grade of recommendation: C New)**

PFMT plus biofeedback does not offer benefit compared to PFMT alone for treatment of prolapse and may not be routinely recommended**. (Grade of recommendation: D New)**

An educational session including lifestyle and PFMT instruction may be considered as it appears to offer benefits over verbal PFMT instruction alone when treating prolapse. **(Grade of recommendation: D New)**

Postural exercises in addition to PFMT may be considered as they offer benefit over PFMT alone in treating prolapse. **(Grade of recommendation: D New)**

Adding a physical intervention to prolapse surgery, pre-, peri- or post-operatively did not improve prolapse symptoms or severity and cannot be recommended routinely. **(Grade of recommendation: B New)**

4.3. Pessary interventions

Prevention

Vaginal ring pessary cannot be recommended in women early after delivery to prevent or improve prolapse. (**Grade of recommendation: B)**

Treatment

Pessary and PFMT could both be recommended as treatment for prolapse, but cost and adverse events need to be taken into consideration. **(Grade of recommendation: C New)**

The combined use of a vaginal pessary plus PFMT, rather than PFMT alone, can be recommended for treatment of prolapse. **(Grade of recommendation: B New)**

A longer follow up interval for pessary users (e.g., 24 weeks, or 6 months) compared to a shorter interval (e.g., 12 weeks, or 3 months) could be recommended. **(Grade of recommendation: C New).**

The use of an oestrogen plus lactobacillus acidophilus vaginal tablet could not be recommended routinely as there is no evidence of benefit. **(Grade of recommendation: C New)**

Use of an anaesthetic cream over placebo could be considered to reduce pain on pessary removal. **(Grade of recommendation: C New)**

IV. URINARY INCONTINENCE IN MEN

UI in men remains under-reported and under-studied in comparison to studies in women. Pooled prevalence of UI in community-based men ranges from 4.81-32.17% (276). UI and other LUTS in men increase with age, with variations in prevalence rates reflecting different study populations, definitions of incontinence and methods (277). Despite the prevalence of UI and LUTS in older men, the aspect which continues to receive the most consideration with respect to conservative management is post-prostatectomy UI after radical prostatectomy (RP).

1. LIFESTYLE MODIFICATION INTERVENTIONS

Lifestyle recommendations are part of the primary care approach to prevention of chronic disease. Smoking cessation, healthy eating and weight loss, and caffeine and alcohol reduction are intended to be preventative in the onset of diabetes, obesity and cardiovascular disease. Little attention is placed on prevention of UI in men and few new trials were found to add to this edition.

1.1. Weight loss by obese or overweight Men

No new trials were found on weight loss.

1.2. Smoking

No new trials were found on smoking cessation in men.

1.3. Dietary modification in men

There were no RCT assessing impact of diet for preventing the development or worsening of LUTS in men. Four longitudinal cohort studies were identified that provided some evidence of the impact of diet on LUTS and UI scores (278-281). For more details, see Table 41.

Bauer *et al.* (278) followed 2,960 men diagnosed with non-metastatic prostate cancer for a median of 8.3 years with validated dietary questionnaires and the Expanded Prostate Cancer Index Composite SF domain (EPIC-SF), every four years to evaluate the impact diet has on urinary scores. They found that the Mediterranean Diet Score and other individual score components or dietary fat subtypes were not associated with UI scores. However, higher vegetable intake was associated with modestly higher UI scores (indicative of better urinary function) (P-trend=0.003). Conversely, men who consumed more monosaturated and polysaturated fats had worse urinary function with lower UI scores (P-trend=0.04) especially on the irritation/obstruction sub scores.

In a study examining the association between vitamin C intake and LUTS, 1,100 men aged 30-79 were randomly selected to take part in a larger study including 3,201 women (279). The authors found that men with a higher vitamin C intake at follow-up had lower scores on the American Urological Association (AUA) Symptom Index, with voiding and storage sub scores ranging from 0.6 to 2.0 points lower, compared to men with inadequate vitamin C intake (P<0.05).

Holton *et al.* (280) evaluated a subgroup of 1,670 men from an initial cohort of 5,994 men aged 67-100. This subgroup included men without severe LUTS at baseline and no prostate cancer diagnosis, who did not receive treatment for LUTS during the study. The study compared the dietary antioxidant intake of these men, some of whom developed LUTS while others did not. The authors found no significant association between antioxidant intake and LUTS progression or remission over seven years.

Fruit and vegetable intake was correlated with LUTS in a four-year study of 1,564 men by Liu (2016) (281). Using the international prostate scoring system (IPSS), they found that men over age 65 who had a higher intake of fruit and vegetables, had significantly reduced LUTS when compared to those who did not. The difference was stronger in those who ate more dark, green leafy vegetables (p= 0.006). Development of benign prostatic hyperplasia (BPH) and progression of LUTS was also lower in this group.

Summary

There is some evidence that dietary factors such as dark green leafy vegetables and vitamin C may reduce LUTS and incontinence prevalence. **(Level of evidence: 3)**

Recommendations

Weight loss: Weight loss through lifestyle changes can be recommended to obese and overweight men with UI, particularly those with type 2 diabetes. **(Grade of recommendation: B)**

Smoking abstinence could be recommended for men with UI. **(Grade of recommendation: C)**

A reduction in caffeine intake could be recommended for men with incontinence symptoms; evidence suggests that the equivalent of two cups of coffee per day (250mg) is associated with UI in men. **(Level of evidence 3: Grade of recommendation: C)**

High vegetable, fruit and vitamin C intake could be recommended to men in the primary and secondary prevention of LUTS, UI and BPH. **(Grade of recommendation: C New)**

Larger RCTs are needed to assess effect of lifestyle modification interventions on the prevention of incontinence and LUTS in men.

Table 41. Table of included studies of lifestyle interventions for UI in men

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Bauer (2018) (278)	Cohort	2960	Men diagnosed with non-metastatic prostate cancer	Participants after diagnosis of prostate cancer were assessed by the usual consumption of food items and supplements. Based on intake of specific food items the participants were categorized by the Mediterranean Diet Score, as follow: 0-3: low n=1039 4-5: moderate n=1015 6-9: high n=906	Mediterranean Diet Score and other individual score components or dietary fat subtypes were not associated with UI scores. However, higher vegetable intake was associated with lower rates of self-reported UI.	26 years	Adverse events: NR
Curto (2015) (279)	Cohort	1100	Participants from Boston area between 30-79 years old and balanced in number of Hispanic, black and non-Hispanic white race/ethnicity* *Data stratified for men and women	Using a food frequency questionnaire, dietary and supplemental vitamin C intake was assessed.	AUA Symptom Index (AUASI) to evaluate LUTS showed significant associations were found between dietary and supplemental vitamin C and progression of total LUTS or voiding symptoms.	5 years	Adverse events: NR
Holton (2016) (280)	Cohort	1670	Community-dwelling men aged 65-100 enrolled from US sites with no history of prostate cancer and treatment for LUTS	Participants were assessed using 69-item block food frequency questionnaire for dietary antioxidants intake (vitamin C, vitamin E, β-carotene, α-carotene, β-cryptoxanthin, lycopene, lutein/zeaxanthin) and analysis were stratified by LUTS symptoms at baseline as follow: Mild: n=1193 Moderate: n=477	AUA Symptom Index (AUASI) to evaluate LUTS showed that none of the dietary antioxidants was associated with a lower probability of LUTS progression or remission.	6.9 ±0.4 years	Adverse events: NR

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Liu (2016) (281)	Cohort	1564	Men aged 65 years and older who were able to walk independently were recruited on voluntary basis from local community of Hong Kong	Using a 289-item validated semi-quantitative food frequency questionnaire the dietary intake was assessed. The participants were categorized according to the fruits or vegetable intake, as follow: low moderate high	LUTS symptoms were assessed using IPSS. Compared to moderate group, high levels of fruits and vegetables intake significantly reduced LUTS symptoms, especially high intake of fruits, vegetables, dark and leafy vegetables. Associations of fruits and vegetables intake and progression of LUTS showed that compared to moderate group, high intake of dark and leafy vegetables reduced the risk of LUTS progression. Total FV consumption was not significantly associated with the overall LUTS progression.	4 years	Adverse events: NR

Abbreviations: UI: urinary incontinence; NR: not reported; AUA: American Urological Association; LUTS: lower urinary tract symptoms.

2. PELVIC FLOOR MUSCLE TRAINING

Post Prostatectomy Incontinence (PPI) is still the main focus of studies on PFMT for the management of UI in men. Different PFMT protocols are being assessed, and PFMT has been compared to other modalities including Pilates and EStim. Heterogeneity and varying outcome measures affected the ability to compare trial findings. More detail needs to be included on the specifics of PFMT exercise prescription and protocol (282) (283). Due to the changes in the types of trials being undertaken, the format of this section has changed slightly from previous editions. Studies have been separated into eight groups of interventions:

2.1. Pre- and peri-operative PFMT for management of PPI

2.2. Pre and post radical prostatectomy PFMT for management of PPI

2.3. PFMT for management of PPI compared to other modalities

2.4. PFMT compared to or plus alternative interventions for management of PPI

2.5. TURP (transurethral resection of the prostate)

2.6. PFMT for management of UI after radiation therapy

2.7. PFMT effect on erectile dysfunction and climacturia

2.8. PFMT for Other LUTS

A total of 28 new RCTs were found that assessed PFMT as a standalone treatment or combined with other conservative treatments to manage PPI. These were added to the 58 studies from the previous ICI reports (2). Twenty-two of the trials involved men pre or post RP (N=2,065 randomised), one trial involved men post TURP (N=72 randomised), two trials assessed PFMT after radiation therapy (N=227 randomised) and one used PFMT to manage climacturia and erectile dysfunction (ED) (N=33). Studies were of varying quality and blinding of participants to group allocation was not possible. Recommendations are found at the end of each section.

2.1. Pre- and peri-operative PFMT for management of PPI

Only two new trials were found assessing the effect of pre-operative PFMT (284, 285), and one trial examined the effect of starting PFMT while the catheter was still in place (286). These trials were added to the five previously included trials. The two pre-operative trials looked at the type of PFM training done. Sayner (2019) (abstract only) compared functional PFMT (n=15) twice daily to standard PFMT (n=15) three times daily. There was no description of the difference between a PFMT programme and a functional PFMT programme, other than that the latter had functional integration of the PFM (285). The main outcome measure was the ICIQ-SF measures at four, 12 and 26 weeks post-operatively. Santa Mina compared a prehabilitation programme (n=44) to usual care (n=42). Prehabilitation consisted of whole-body exercise plus PFMT, while the usual care group were given a written manual with PFMT to be completed before surgery. Whole body exercise was described as home-based moderate-intensity exercise prior to surgery (60 minutes, 3-4 days week plus daily PFMT preoperatively). The primary outcomes were the FACG and IPSS measured pre-operatively, at four,12 and 26 weeks (284). Filocamo (286) (abstract only) compared starting PFMT on day three post-operatively while the catheter was still in place (n=20) to a group who started after the catheter was removed on day 10 (n=19). Outcome measures were a bladder diary, QoL and ICIQ-male scores, and a 24-hour pad test at one, three, six, nine and 12 months. The primary outcome was no pad use and negative 24-hour pad test.

There was no indication of what PFMT consisted other than tightening around the catheter with the PFMs (286). In this chapter, we report on UI cure, improvement, symptoms and QoL, and if these outcomes were not available, the pad test.

Quality of the data
Sayner (285) described an un-blinded prospective, single-centre, pilot randomised controlled trial. Allocation concealment and ITT analysis was not reported. There were six participants lost to follow-up (three in each group). The study by Santa Mina (284) did not mention concealment of allocation nor of any blinding. The author acknowledged that this trial was not powered to reliability to detect between group differences. Filocamo and colleagues (286) used a randomised approach but no information was provided on sample size analysis or *post-hoc* power analyses. There were four dropouts (two in each group) due to post-operative complications.

Results
Sayner and colleagues (285) reported no adverse events and the ICIQ-SF showed a statistically significant difference in favour of the functional PFMT group at 26 weeks (mean difference: 3.67, p=0.02). Santa Mina (284) described good participation in this trial and general outcomes were improved in the prehabilitation group, but there was no statistically significant difference in outcome between groups. Twenty-nine percent of participants were lost to follow-up and there were five non-serious adverse events related to the general exercise programme: self-resolving haematuria (n=1), self-resolving atrial fibrillation while jogging during home-based exercise (n=1), leg pain (n=1), aggravation of lower arm muscle strain/lateral epicondylitis (n=1). In Filocamo's study (286), 4/18 (22%) participants in the PFMT group with the catheter *in situ* were completely continent at one month, 11/18 (61%) were continent at 3 months, 15/18 (83%) at six and nine months, and 16/18 (89%) at 12 months. In the group starting PFMT after the catheter was removed, 2/17 (11%) participants were completely continent at one month, 4/17 (23%) at three months, 7/17 (41%) at six months, 8/17 (47%) at nine months and 14/17 (82%) at 12 months. The difference was statistically significant at three, six and nine months but not at one and 12 months. Continence was attained earlier if PFMT was started earlier, but the effect wore off at 12 months.

Summary

When participants start PFMT before surgery, they become continent more quickly than when they start after surgery. Men attain continence up to three months earlier, but at 12 months, this difference is no longer apparent. **(Level of Evidence: 2)**

The new studies have the same issues as previously stated. They are small, vary in design and quality and have different outcome measures. Research is needed to clarify if early attainment of continence is economically viable and psychologically necessary.

Recommendation

Pre-operative instruction in PFMT can be recommended to facilitate earlier recovery of continence in men undergoing RP. **(Grade of recommendation: B)**

2.2. Pre and post radical prostatectomy PFMT for management of PPI

Five new trials were added to the existing nine which examined PFMT starting preoperatively and continuing post operatively for the management of post prostatectomy incontinence. Bassi (287) (abstract only) looked at pre and post PFMT (n=22) versus usual care (n=14), without giving any detail on training protocol. They used a 24-hour pad test, the ICIQ-UI SF, SF 36; IPSS and International Index of Erectile Function (IIEF-5), which were measured at baseline (pre-op) and at four, 12 and 26 weeks postoperatively. De Lira *et al*. (288) evaluated a protocol in an RCT after open RP. Looking at a usual care control group (n=15) versus treatment group (n=16) consisting of PFMT given over two physiotherapist-guided pre-operative sessions, which continued after surgery. PFMT took place three times per day with increasing intensity. The outcome measures were IIEF-5 and ICIQ-SF at baseline and three months post-surgery. Jalalina and colleagues (289) aimed to determine the effect of three months of PFM strengthening exercises on UI and QoL in participants after a suprapubic prostatectomy. Participants were asked to perform up to 100 PFM contractions per day. There were few details about the PFMT programme other than it was done in various positions and was prescriptive rather than individualised. The paper does not describe what the control group did. Outcome measures were ICIQ-UI SF and I-QOL obtained on admission, on day two post-operatively, and at seven days, and at two and three months. Participants kept a record of the frequency of exercises, and researchers phoned daily to increase motivation.

Millios (290) compared usual care (n=47) consisting of PFMT versus a high-intensity training routine. A very detailed protocol was described in this study. Usual care instructions were delivered by a physiotherapist pre-operatively in two 30-minute sessions, which encouraged three sets of daily PFMT consisting of 10 contractions of 10 second hold (30 per day) in different positions: supine, sitting and standing. The high-intensity PFMT group (n=50) were taught to do six sets, including 10 fast contractions and 10 slow contractions while standing only (120 per day). All received written and verbal instructions to "stop the flow of urine and shorten the penis while continuing to breathe". After surgery, all participants were followed-up every two weeks by a physiotherapist for the duration of the study. The primary outcome measure was pad weight measured at two, six and 12 weeks. Sayilan (291) studied the effect of post-robotic prostatectomy incontinence pelvic floor exercises (n=30) versus no exercises (n=30). The control group was given breathing exercises and had the opportunity to ask questions about the surgery. For the treatment group, training started one week before surgery with a PFMT programme and general physical activity. There were few details on the programme, which included supervised physiotherapy starting one week before surgery. The training then took place on the day of surgery, one and two days after surgery, as well as on the day the catheter was removed. Participants also participated in an unsupervised functional training programme, which included feedback with verbal and tactile pointers with transabdominal real-time ultrasound measures at baseline, and at one, three, and six months. Outcome measures were the ICIQ-SF, indwelling catheter (IDC), pad use, with the primary outcome being self-reported continence at six months using the ICIQ-UI.

Quality of the data
The study by Bassi was a small pilot study, which was reported only in abstract form. Recruited men were randomised, but blinding, allocation, ITT and loss to follow-up were not described (287). De Lira used computer-generated randomisation, the assessors were blinded, and there was no loss to follow-up. A small sample size (n=31) reduced the generalisability of this study (288). In a study with a larger sample size, Jalalina *et al*. recruited 60 men from a convenience sample and randomly allocated them to treatment or control groups. Four participants dropped out per group but there was no ITT analysis nor any mention of sample size analysis or *post-*

hoc power analysis. Millios (290) used a minimisation approach to randomisation. The study performed sample size calculations, and loss to follow-up included three participants in usual care and one in the high intensity group, but there was no ITT analysis. Lastly, Sayilan (2018) used randomisation and had detailed sample size calculations with no loss to follow-up, but did not describe blinding, allocation concealment, or ITT, risking bias in the study (291).

Results

The newer studies continue to report variable results. Some studies reported no differences in UI or the ICIQ-SF at three months and concluded that PFMT taught pre-operatively was not useful compared to usual care (287, 288). Three studies (289-291) found that there were significant differences favouring the PFMT group and there were improvements in UI at all time points. The study by Jalanina found statistically significant differences at one, two and three months on both the ICIQ-UI SF and I-QOL in favour of the PFMT group (289). Milios (290) found that high-intensity PFMT improved results and more men were continent at all time points compared to usual care (two weeks: 14% versus 4%, 6/52; six weeks: 32% versus 11%, 12/52; 12 weeks: 74% versus 43%). The weight of the 24-hour pad showed similar statistically significant results. Sayilan reported statistically significantly fewer pads used by the PFMT group at one and six months, and higher incontinence scores on the ICIQ-SF in the control group at three and six months (291).

Summary

There were five new trials added to the previous nine examining a variety of pre- and post-operative PFM training. Most new studies started pre-operatively and continued post operatively, and were compared to usual care. Different regimes of training were assessed and there was a wide variety of outcome measures used (287-291). There is significant heterogeneity in the protocols on how PFMT is taught to men and about the effectiveness of PFMT for post-prostatectomy incontinence. Many studies did not provide a detailed description on how the exercises were taught, and how they progressed or were assessed.

As in previous consultations, these trials found that short- to medium-term benefits to continence as reported in pad tests and self-reported symptoms. None of the new trials reported differences between groups at or after 12 months. Starting PFMT before, or shortly after, surgery continues to be supported if the aim is to attain continence earlier. Studies had small sample sizes, inconsistent outcome measures and varied in method and quality. Discussion is needed on the significance of an earlier return to continence, including benefits for QoL, which has not been studied.

Many studies did not describe the type of PFMT programmes that were studied, and the majority focused on training posterior PFMs (with cues to retain gas). The largest study in this section (290) focused on the anterior PFM and showed that using PFMT produced significant improvement at all time points. Most of the studies included in this update, and previous consultations, assessed or trained the pelvic floor of men via the anus. Prostatectomy destroys the smooth muscle of the prostatic urethra and possibly causes damage to the extrinsic urethral sphincter (292). Assessing the PFM anally or applying strength training protocols to the posterior PFM may not target the muscles that cause post-prostatectomy incontinence as much as a more anterior PFM protocol (cues to stop the flow of urine and shorten the penis) (282). A recent meta-analysis comparing protocols, favouring posterior pelvic floor versus anterior PFM, show that the risk of incontinence is reduced at three months (RR 0.85, 95% CI 0.75 to 0.95) when an anterior PFM approach is used (293). A large randomised clinical trial assessing personalised PFMT programmes is currently underway (294).

Recommendation

Early PFMT either pre-operatively or early post-operatively can be recommended to reduce time to continence after surgery. **(Grade of recommendation: B)**

2.3. PFMT for management of PPI compared to other modalities

2.3.1. PFMT plus or minus PFMT with EStim after radical prostatectomy

Three new trials (295-297) were added to the 11 previously included in this section. Full papers for two of the abstracts reported are available in the previous ICI edition (298, 299). Studies had heterogenous samples. Two studies had three arms: EStim, PFMT and Pilates (295, 299). The data discussed here compare EStim to control treatments. Studies assessing Pilates versus control or PFMT will be discussed in Section IV.2.3.3.

Gomes' 2018 (295) study compared PFMT with anal EStim (n=38) to a group undergoing anal EStim only (n=36) over a 10-week period. Outcome measures included the ICIQ-SF and pad tests, measured at baseline and after four months. Pedrali (299) compared PFMT combined with EStim versus no treatment. The first group (n=31) received 10 weekly individualised PFMT sessions with EStim and a home PFMT programme. The second group (n=31) had no treatment. Outcome measures were pad weight and use and the ICIQ-SF, which were measured at baseline (four weeks post-operatively) and repeated after four months.

Gonzales (296) recruited men to receive physiotherapy consisting of EStim and biofeedback, three days per week for three months (n=30), while the control group (n=30) received no specific treatment. Both groups received a printed guide about PFM exercises. Pad tests and the ICIQ-SF were measured at one, two, three and six months. Laurienzo (298) recruited men who were still incontinent one month after a RP. Three groups were used to assess the effect of EStim and PFMT combined with home exercises (n=42) versus PFMT with three specific exercises (n= 41), versus a control group (n=40), who were given usual post-operative information. Follow-ups assessed the 1-hour pad test, PFM strength, ICIQ-SF and IPSS and took place pre-operatively and after one, three and six months. Wang (297) (abstract only) looked at the efficacy of electrical pudendal nerve stimulation (EPNS) (n=64) versus PFMT with biofeedback and trans anal EStim (n=32). The EPNS group received 60 minutes of stimulation three times per week for eight weeks via long needles inserted near the pudendal nerve. The main outcome measure was the ICIQ-UI SF and secondary measures were pad use and leakage.

Quality of the data

Gomes (2018) (295) developed a study with careful attention to risks of bias, which were reduced with randomisation, allocation concealment and blinding. Four participants were lost to follow-up (three in the EStim group, one in the control group) and ITT analysis was not mentioned. Pedrali's study failed to discuss blinding of participants and ITT analysis. Three participants dropped out of the EStim group, two due to non-attendance and one due to discomfort

caused by the treatment (299). There were no control group dropouts. Gonzales' (2020) (296) study was well powered, but there was no ITT analysis and a dropout rate of 13/60 (five in the electrotherapy group, eight in the control). There was no blinding, concealment of allocation and randomisation was not described. In the Laurienzo trial (2018) (298), participants were blinded and randomised by computer, but ITT was not discussed. Only three participants dropped out per group in this otherwise high-quality study. The study by Wang (2018) had low ROB due to randomisation, blinding of assessors and ITT analysis. Allocation concealment was not discussed. Loss to follow-up was zero (297).

Results

Gomes *et al.* found statistically significant differences in the reduction of the number of pads used between groups (Group 2: 0.77±1v Group 3: 1.48±1.31) and the number of men who achieved continence between the treatment and no treatment groups (Group 2: 67.4±131.88 versus Group 3: 72.88±97.28 p=0.01) (295) favouring the PFMT plus EStim group. Gonzales *et al.* reported statistically significant differences in favour of the EStim and biofeedback group in the one-hour pad test with 64% recovering continence compared to 9%. Wang (297) found no difference between groups for the ICIQ-SF and leakage frequency (p=0.68). However, there was a statistically significant difference comparing baseline to study end within groups (p<0.05). The other two trials reported no benefit of PFMT with EStim compared to no treatment (298, 299), or of EStim compared to PFMT (298). Laurienzo concluded that there was no benefit of adding EStim to PFMT as there were no differences for the one-hour pad test or the QoL score between groups at any time points. However, within group changes were significant over time. Pedrali, similarly found no significant differences in pad weight or use, and ICIQ-SF scores between the EStim and control groups (299).

Summary

The use of EStim with or without PFMT is better than no treatment, but there is no benefit in adding EStim to other types of treatments. **(Level of evidence: 2)**

Recommendation

Adding EStim to a PFMT programme for men with persistent PPI cannot be routinely offered. **(Grade of recommendation: B)**

2.3.2. PFMT with biofeedback after radical prostatectomy

Three new trials were found assessing biofeedback after RP and added to the six previously included trials (300-302). All trials used anal probes to provide the biofeedback. Oh (2020) (300) investigated the effect of a novel biofeedback device for training PFMs. The biofeedback device has a pressure sensor under the perineum and anus that reportedly provides biofeedback to the pelvic floor, which helps strengthen the muscles. There was no description of the PFMT programme that was used, and there was no mention of verifying that participants were able to perform a correct PFM contraction. The intervention group (n=42) used the device with verbal and written instructions on PFMT, and the control group (n=42) received only the verbal and written instructions. Outcome measures were the 24-hour pad test, IPSS and IIEF-5 measured one, two and three months after surgery. Santos (2017) (301) recruited participants up to three months after surgery and compared PFMT to PFMT with biofeedback. This study aimed to assess the impact of adding anal biofeedback (n=8) to PFMT (n=8) using a one-hour pad test. Continence was deemed to be achieved if urine leakage was less than 2g, which was measured at baseline, and after five and nine weeks. Lin (302) compared the effect of PFMT with biofeedback (n=44) to no treatment (n=31) for six months. PFMT was done four times per day, where participants performed 20 PFM contractions and relaxations per session with the aid of a DVD and pamphlet. Biofeedback was provided via an anal probe. The main outcome measure was the one-hour pad test.

Quality of the data

In the study by Oh, randomisation, ITT and loss to follow-up were all detailed. Blinding and concealment of allocation was not described (300). Two participants dropped out from the biofeedback group. In the study by Santos *et al.,* there were no details on randomisation, concealment of allocation or blinding (301). Three participants were excluded due to post-operative complications (two from the intervention group and one from the control group). ITT was not discussed. Lin (302) conducted a quasi-experimental trial with no indication of how participants were randomised. Five were lost to follow-up in the biofeedback group and three in the control group. Blinding, allocation concealment and ITT analysis were not discussed.

Results

Oh (2020) found no statistically significant differences between groups, except in the one-month IPSS scores favouring the biofeedback group (p=0.028) (300). By the end of the study 27 (67.5%) participants in the biofeedback group and 26 (61.9%) participants in the control group achieved continence. In the study by Santos (301), 69% (n=9) of participants attained continence with the other four participants still reporting mild UI. While both groups showed significant improvement, there were no statistically significant differences between groups. Lin (302) also found a reduction in leakage in the second and third months in both groups. There was statisticaly significantly less leakage on the one-hour pad test in the PFMT with biofeedback group for both the two- and three-month follow-ups (two-month PFMT group: 27.68±51.84, control group: 79.44±71.94, three-month PFMT group: 9.27±25.23 control group: 27.11±40.88).

Summary

The three new trials and the six previously reported trials show that adding anal biofeedback to PFMT does not significantly improve outcomes, regardless of the type of biofeedback used. **(Level of evidence: 2)**

Recommendations

The addition of biofeedback to a PFMT programme cannot be routinely offered to men with persistent post-prostatectomy incontinence as it does not seem to add any clear benefit. However, biofeedback may be considered for subgroups of men presenting reduced proprioception **(Grade of recommendation: B)**

PFMT plus or minus Pilates

There were three trials that assessed the effect of Pilates (295, 299, 303): Two were three-armed trials assessing PFMT versus Pilates versus EStim (295, 299). Data on EStim have been separated and are reported in section IV.2.3.1. Au (303) conducted a feasibility RCT to study Pilates combined with PFM exercises and hypopressive exercises (n=25) versus PFM exercises (n=25) alone. 'Pelvic Floor Pilates' employed synergistic contractions of the pelvic floor

with the core. Outcome measures included a 24-hour pad test, QoL score and IPSS measured before surgery and after two, six, 12 and 26 weeks. Pedrali (2016) (299) compared Pilates versus PFMT with EStim versus no treatment. Pilates (n=28) was described as mat Pilates, which was done once per week for 45 minutes in addition to a home Pilates programme. Outcome measures were pad weight and use, ICIQ-SF, measured at baseline (four weeks after surgery) and repeated after four months. In another three-armed trial by Gomes *et al.* (295), Pilates (G1) (n=36) was compared to PFMT plus EStim (G2) (n=38) and a control group (G3). Outcome measures included the ICIQ-SF and pad tests, measured at baseline and after four months.

Quality of the data

In the study by Pedrali (299), participants were carefully randomised, and assessors were blinded, but authors failed to discuss the blinding of participants and ITT analysis. Two participants dropped out of the Pilates group due to attendance issues and none from the control group (299). The study by Au *et al.* reported high dropout rates with six in the Pilates plus group and seven in the PFMT group. Neither the participants nor the assessors were blinded, nor did they use ITT analysis (303). In the trial by Gomes (295), there was concealment of allocation and blinding of evaluators but no mention of ITT analysis. Four participants were lost to follow-up, two from the Pilates group and one from the control group.

Results

The only differences found in the study by Au (303) were between the Pilates group and the PFMT group at 26 weeks with statistically significantly reduced participant-reported leakages on the bladder diaries (RR 0.45 (0.22 to 0.98) favouring PFMT. In the study by Pedrali (299), all groups improved for the main outcome measures from baseline to four months. The only statistically significant between-group differences occurred between the Pilates and the no treatment group in daily pad use and ICIQ-SF in favour of the Pilates group (p=0.01). There were no statistically significant differences between the Pilates arm and the PFMT plus EStim arm in the study conducted by Gomes *et al.* (295). They concluded that Pilates was better than no treatment when looking at the proportion of men not needing to use pads (p<0.05).

Summary

Research does not currently support the use of Pilates over the use of PFMT for men with persistent post-prostatectomy incontinence. However, emerging evidence suggests that Pilates may be more effective than no treatment (295, 299). The use of Pilates in addition to PFMT or as a progression to PFMT requires more research. **(Level of evidence: 2)**

Recommendations

Pilates cannot be recommend over a PFMT programme for men with persistent post-prostatectomy incontinence as there is no evidence of superiority. **(Grade of recommendation: B New)**

Pilates to manage persistent post-prostatectomy incontinence in men may be considered over no treatment **(Grade of recommendation: D New)**

2.4. PFMT compared to or plus alternative interventions for management of PPI

With PFMT becoming the gold standard as first line treatment for PPI, other conservative treatments are being investigated for effectiveness in addition or compared to PFMT. Seven new trials were identified that combined post-operative PFMT with other conservative treatments. Techniques being used to treat PPI vary significantly and are often presented in small studies.

The effectiveness of using an oscillation rod (a flexible pole, which can be set into oscillation, resulting in tuneable, rapidly alternating forces) (304) to train the pelvic floor post RP was the focus of a study by HeyDenreich *et al.* (305). They compared sensorimotor training with an oscillating rod (n=93) to standard PFMT (n=91). The PFMT used was based on a protocol using the external anal sphincter as its focus. Outcome measures were one-hour and 24-hour pad tests and the FACT-PHRQoL, evaluated before and after three weeks of treatment. This is a concealed allocation randomised study, but neither the participants nor the assessors were blinded. There were no dropouts in this study. Both pad tests showed statistically significant differences favouring the novel treatment (one-hour pad test: p=0.008 24-hour pad test p=0.012) as did the Functional Assessment of Cancer Therapy (FACT-P) scores (p=0.017 between groups) (305).

Tanawy added whole-body vibration (n=32) to PFMT (n=32) to manage mild SUI after RP (306). PFMT was taught to both groups with an anterior focus to the exercises. Using the I-VAS, ICIQ-UI-SF and a 24-hour pad test, blinded assessors evaluated continence before treatment, after four weeks of treatment and at the two-month follow-up. This study was randomised but it is unclear if there was concealment of allocation or blinding of the assessors. Two participants dopped out in the vibration group and one in the control group. ITT analysis was not mentioned. At both time points, post-treatment results statistically significantly favoured the treatment group (p<0.001).

Zachovajeviene *et al*. evaluated the effect of postoperative diaphragm muscle training (n=49) and abdominal muscle training (n=49) to PFMT (n=50) on PFM strength and endurance and incontinence after RP (307). Details of the exercise protocols were missing. There was no information on the blinding of assessors and participants, but ITT analysis, randomisation and allocation concealment were included. The dropout rate of 14% (21/148) was equally divided at seven per group. Results of the eight-hour pad test showed a significant reduction in leakage after six months but no difference between the groups (307).

Crowe (308) evaluated the effectiveness of using a video to teach PFM exercises. Only an abstract was available for this study. Both groups (n=60) were provided PFMT by a physiotherapist, and one group was given additional education using an animated video. The Expanded Prostate Index Composite (EPIC-26) score was used to evaluate continence at one and three months. Details of randomisation, allocation concealment or ITT analysis were unavailable, and it is unclear how many of the 9 dropouts were in each group. No differences in the EPIC-26 scores were found between groups (308).

Novick (2014) added BT to PFMT to evaluate if there was any additional supportive value (309). PFMT was not described in this study. The BT group (n=36) was provided a handout and oral explanations on bladder irritants and advice on bowel health. The usual care group (n=32) doing Kegel exercises were given a handout. There was no discussion of allocation concealment and blinding

and ITT analysis were not described. The main outcome measure is the EPIC collected at six and 12 weeks. While both groups improved between weeks six and 12, and no differences were found between the two groups at any time point (309).

Chen *et al.* (310) compared usual care to a protocol that combined several other modalities. PFMT, 'urinary reflex training', BT, EStim and biofeedback were all offered to the training group (n=13) while usual nursing care was described as perineal and urination care (n=12). The main outcome was time to recovery of full continence. The study did not include details on randomisation, allocation concealment and blinding of assessors. There were no participants lost to follow-up and the authors used ITT analysis. Statistically significantly more men were continent at six months in the treatment group than in the usual care group (9/13 versus 3/12). There was no difference in the number of participants who were continent at 12 months.

A study by Zhang *et al.* (311) included men that were still incontinent six months after completing any treatment for prostate cancer. They were provided with either a support group (n=81) or telephone support (n=81) plus PFMT with biofeedback, which was compared to usual care (n=82). It was unclear if the usual care group received PFMT and if the participants were blinded or allocation was concealed. The outcome measure was frequency and volume of leakage on a bladder diary as well the I-PSS. There were 36 dropouts, spread evenly amongst the three groups and data included ITT analysis. After three months, men allocated to either of the PFMT plus biofeedback groups had improved more than the usual care group. This difference was not statistically significant at six months. Both treatment groups rated their UI as less problematic than the usual care group at three and six months.

Summary and recommendations

Using an oscillating rod (305), or whole-body vibration (306) may assist in improving post prostatectomy incontinence**.** More studies are needed. **(Level of evidence 3)**

Using a video in addition to physiotherapy-led PFMT (308) did not add value to treatment. However, research is needed to assess if it is effective for men who cannot access pelvic health physiotherapists. **(Level of evidence 3)** More research is needed on costs and benefits before treatments can be recommended for other LUTS such as urgency in men after prostatectomy.

Finally, there is some early evidence that novel interventions, which activate the PFM or involve support groups, may be beneficial after RP and therefore could be recommended; but data are very limited. **(Level of evidence; 3: Grade of recommendation C New)**

More high-quality studies are needed to determine the costs and benefits of adjunct treatments to PFMT.

2.5. TURP

2.5.1. Pre-operative TURP PFMT

No new studies were found. Little research has been dedicated to UI after TURP as the incidence of UI after TURP is reported to be very low.

2.5.2. Pre-operative versus post-operative TURP PFMT

The study by Anan *et al.* (312) was the only one that assessed the effect of pre- and post-operative pelvic floor exercises to improve continence after holmium laser enucleation of the prostate. Men were randomised to start PFMT one month before surgery (n=36) or to only start PFMT after surgery (n=36); both groups continued PFMT after surgery. PFMT consisted of three minutes of PFM contractions, three times per day. Self-reported continence was the main outcome measure with "fully continent" defined as no pad use. The ICIQ-SF was used to gauge QoL. Both were assessed at one, three and six months. This study only had two participants (one per group) lost to follow-up (312). The authors did not describe blinding, concealment of allocation or ITT analysis. At three months, there was a statistically significant difference in return of continence between the groups in favour of the group starting treatment pre-operatively. By six months there was no difference between the groups with all participants attaining continence, indicating that the pre-operative group attained continence earlier than the post-operative only group. There was no difference in QoL between the groups at any time point (312).

Summary

There continues to be limited evidence on the benefit of starting PFMT pre-TURP versus starting post TURP. Starting PFMT before holmium laser enucleation of the prostate may reduce the time to continence in this population. In the absence of sufficient data from rigorous and well-reported trials, it is unknown if PFMT reduces UI following TURP. **(No recommendation)**

2.5.3. Post-operative TURP PFMT for incontinent men

No new studies were found.

Summary

There is limited evidence on the benefit of PFMT post-TURP.

2.6. PFMT for management of UI after radiation therapy

A new section has been added for this edition on the management of long-term LUTS with PFMT in men who were treated with radiation therapy. There were two studies (313, 314) that assessed a multidisciplinary approach to manage these symptoms. Dieperink *et al.* (313) included PFMT in a programme that also supported men with counselling and whole-body exercises. The usual care offered was a consultation with a physician without further education or support. At the three-year follow-up, the PFMT group (n=72) and the usual care group (n=71) were compared using the EPIC and the SF-12. The abstract, presented by Faithfull *et al.* (314) reported on the impact of PFMT combined with psycho-educational instruction and peer support (n=35) versus usual care (n=31). Outcome measures were self-reported symptoms, QoL and self-efficacy scores.

Quality of the data

Dieperink *et al.* (313, 315) carefully designed their study, describing randomisation, concealment of allocation and blinding of the assessment. It was not possible to blind participants. The study used ITT analysis and 7/79 in the PFMT group and 11/82 in the control group were lost to follow-up in the original study three years earlier (313, 315). The abstract from Faithfull *et al.* (314) does not provide sufficient details to assess the quality of the study.

Results

Neither study found differences between the groups. Urinary scores (314) or the UI domain of the EPIC (313) were not statisticaly significantly different between groups. Dieperink suggested that this lack of long-term effect could be due to the absence of follow-up between the original study, which lasted three months, and the final evaluation at three years (313). Faithfull *et al.* found that coping mechanisms were better in the treatment group (314).

Summary

The effect of PFMT on LUTS in men undergoing radiation treatment requires more research.

2.7. PFMT effect on erectile dysfunction and climacturia

The long-term side effects of RP have been gaining more attention as more men survive longer after a prostate cancer diagnosis. Erectile dysfunction and climacturia or orgasm-associated incontinence can have major emotional and psychological influences.

In a study by Greaerts *et al.* (316), the effect of PFMT 12 months or more after RP was evaluated. Erectile function was assessed with the IIEF and a climacturia questionnaire, which was self-reported after three months of treatment. The treatment group (n=16) received PFMT assisted by EStim, and a home programme. The control group (n=17) did not receive any treatment. Allocation was not concealed, nor were participants analysed by ITT. Significant effects were attained in the treatment group (EF (4.1 (5.6) versus –0.2 (2.4), P= 0.025) climacturia (6/14 versus 0/17, P= 0.004)) (316).

Summary

Long-term side effects of RP, such as climacturia and erectile dysfunction appears to be reduced using PFMT. PFMT could be considered for the treatment of climacturia and erectile dysfunction in men post RP. More research in this area is needed. (**Level of evidence 2, Grade of recommendation: C (New))**

2.8. PFMT for Other LUTS

2.8.1. PFMT for post-micturition dribble (PMD)

No new trials were identified to add to the previously included trials.

Recommendation

Men with PMD could be instructed to perform a strong PFM contraction immediately after voiding or use urethral massage to empty the urethra. **(Level of evidence 3; Grade of recommendation: C)**

Table 42. Table of included RCTs of treatments for UI in men

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Anan (2020) (312)	RCT PFMT pre and postoperatively vs PFMT postoperatively	72	TURP Men with BHP undergoing holmium laser enucleation of the prostate	Participants were instructed to perform PFMT 3x/day for 3 minutes Group 1 (n=36): PFMT started 28 days preoperatively and on the second day after surgery and catheter removal instructions for PFMT Group 2 (n=36): PFMT on the second day after surgery and catheter removal	UI rate was significant lower in G1 when compared to G2 at 3 months follow up (p=0.01). No significant differences at 3 days, 1 and 6 months. 3 days G1: 14/35, G2: 19/35 (P=0.34) 1 month G1: 13/35, G2: 18/35 (P=0.34) 3 months G1: 1/35, G2: 9/35 (P=0.01) 6 months G1: 0/35, G2: 1/35 (P=1.00) ICIQ-SF score: no significant differences at 1, 3 and 6 months between groups. 1 month G1 (n=35): 5.4±4.9, G2 (n=35): 5.6±4.9 (P=0.89) 3 months G1 (n=35): 2.9±3.4, G2 (n=35): 3.8±4.6 (P=0.80) 6 months G1 (n=35): 1.5±2.0, G2 (n=35): 1.5±2.4 (P=0.83)	3 days, 1, 3 and 6 months after surgery	Adverse events: NR Loss of follow up: 2.77% (2/72) G 1: n=1; G2: n=1 Intention to treat: NR
Au (2019) (303)	RCT PFMT + Pfilates and hypopressives vs PFMT	50	Men undergoing radical prostatectomy	Participants were instructed to isolate and maximally contract the PFM with escalating repetition every 2 weeks (starting at 30 repetitions/day) G1 (n=25): PFMT G2 (n=25): PFMT + Pfilates and Hypopressive exercises	Severity of UI measured by 24-hour pad test weight no between-group differences. UI measured by 24-hour pad test no between-group differences. 3-day bladder diary was significant lower in G2 when compared to G1 at 26 weeks follow up (p<0.05) for Total leaks (24h) and Day leak. No significant differences at 2, 6 and 12 weeks for Total leaks (24h) and Day leak. No between-group differences for Night leaks 2, 6, 12 and 26 weeks. FACT-P total score no between-group differences. PORPUS HRQOL and total score were no observed between-group differences. HRQOL IPSS total score: no between-group differences.	2, 6, 12 and 26 weeks after surgery	Adverse events: none Loss of follow up: 26% (13/50) G1: n=6 G2: n=7 Intention to treat: Yes

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Bassi (2018) (Abstract) (287)	RCT PFMT pre and postoperatively vs Usual care	36	Men undergoing robot-assisted radical prostatectomy	G1 (n=22): Participants were instructed to perform PFMT G (n=14): usual care	Pad test, ICIQ-UI, IPSS-QoL and total scores no between-group differences. IPSS-QoL both groups showed significant within group comparison at 4 weeks when compared to baseline. UI no between-group differences at 4 and 12 weeks. Urinary incontinence 4 weeks G1: 19/22 G2: 12/14 12 weeks G 1: 3/22 G2: 2/14	1 week prior to surgery, 4 and 12 weeks after surgery	Adverse events: NR Loss of follow up: NR Intention to treat: NR
Chen (2013) (310)	quasi-RCT Nursing care vs Nursing care + PFMT + rehabilitation	25	Men after radical prostatectomy	G1 (n=13): Nursing care + PFMT (3x/day) + urinary reflex training + bladder training + EStim (daily, 30 minutes) + biofeedback (daily, 30 minutes) over 4 weeks G2 (n=12) conventional nursing care (perineal and urination care)	Urinary incontinence: UI cure significantly improve in G1 when compared to G2 at 6 months follow up (p=0.005). G1: 9/13, G2: 3/12 At 3 months follow-up, 10/13 of G1 recovered continence and at 6 months.13/13 were continent G2 recovered continence slower 4/12 by 3 months, 9/12 at 6 months and 12/12 by12 months.	1-3, 4-6, 7-9 and 10-12 months after radical prostatectomy	Adverse events: NR Loss of follow up: none Intention to treat: Yes
Crowe (2017) (Abstract) (308)	RCT Animated PF model and usual care vs Usual care	60	Men schedule for radical prostatectomy	G1: Usual care + animated PF model G2: Usual care + a prostate cancer DVD Usual care: verbal and written instruction followed by appointment with Pelvic Health Physiotherapist instruction	EPIC-26 for UI assessment: no significant difference between groups at 3 months.	1 and 3 months post-operatively	Adverse events: NR Loss of follow up: 15% (9/60) Intention to treat: NR
Dieperink (2020) (313)	RCT Multidisciplinary rehabilitation vs Usual care	161	Men who underwent radiotherapy and androgen deprivation therapy	G1 (n=79): Multidisciplinary rehabilitation sessions 1 hour each (2 nursing counselling + 2 physical therapy including instructions for home PFMT daily, 3 sessions of 10 repetitions for 8 seconds and if necessary, biofeedback; and exercises for major muscle groups) + usual care 4 and 12 weeks after radiotherapy. G2 (n=82): Usual care (physician consult after radiotherapy).	EPIC-26 UI domain no difference between groups (p=0.242) G1: 7.3(14.9), G2: 4.9(15.8) EPIC-26 disease-specific QoL no difference between groups (p=0.418) G1: 88.61(16.1), G2 86.45(17.1) Moderate-severe urinary problems no difference between groups (p=0.835) G1: 7/72, G2: 6/71	6 months and 3 years after radiotherapy	Adverse events: NR* (adverse events reported are related to ADT or radiotherapy) Loss of follow up: 8% (6/161) Intention to treat: Yes

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Faithfull (2015) (Abstract) (314)	RCT Self-management intervention vs Usual care	66	Men treated with radiotherapy for prostate cancer	G1 (n=35): Self-management (psycho educational instruction, problem solving and goal setting, PFMT instruction, support film provided within a small group over 4 sessions + one-to-one with a nurse specialist + 2 motivational telephone calls) G2 (n=31): Usual care	Urinary symptom scores not statistically significant between groups (p>0.09). QoL no statistically significant differences between groups (p>0.8).	6 months	Adverse events: NR Loss of follow up: NR Intention to treat: NR
Filocamo (2019) (Abstract) (286)	RCT PFMT + indwelling catheter vs PFMT after catheter removal	39	Men post radical prostatectomy	G1 (n=20): supervised PFMT with indwelling catheter in the 3rd post-operative day. Patients instructed to daily PFMT, including after catheter removal. G2 (n=19): supervised PFMT after catheter removal in the 10th post-operative day.	Cured (continent) The difference between the two groups was statistical relevant at 3, 6 and 9 months (p<0.05), was not statistically significant at 1 and 12 months. 1 month: G1: 4/18, G2: 2/17 3 months: G1: 11/18, G2: 4/17 6 months: G1: 15/18, G2: 7/17 9 months: G1: 15/18, G2: 8/17 12 months: G1: 16/18, G2: 14/17 QoL ICS male questionnaire total score The difference between the two groups was statistical relevant at 3, 6, 9 and 12 months (p<0.05). 1 month: G1: 25, G2: 28.57 3 months: G1: 15.41, G2: 19.92 6 months: G1: 13.58, G2: 16.57 9 months: G1: 13.05, G2: 14.75 12 months: G1: 12.09, G2: 14	1, 3, 6, 9 and 12 months after surgery	Adverse events: NR Loss of follow up: 10.25% (4/39) (G1: n=2; G2: n=2) Intention to treat: NR

3. ELECTRICAL STIMULATION

Electrical stimulation (EStim) works by activating the motor fibres of the pudendal nerve, which can result in contraction of the PFMs or the striated peri-urethral musculature, supporting the intrinsic part of the urethral sphincter closing mechanism. For male SUI, EStim could be used to enhance contraction of the PFMs in the same way as female SUI.

EStim can also be helpful in men with detrusor overactivity (DO) or UUI because it can stimulate afferent fibres of the pudendal nerve, decreasing the sensation of urgency and inhibiting parasympathetic activity, which results in a decrease in involuntary detrusor contractions (317, 318). As a stand-alone therapy it is unclear whether EStim enhances continence recovery. It has been postulated that continence is regained more rapidly and the duration of the application of EStim is reduced when PFMT is augmented with EStim (318). EStim is also believed to be more effective in participants who are initially unable to identify and correctly contract their PFMs (317). EStim should be avoided for patients with carcinoma of the bladder or prostate, as EStim may increase abnormal cell activity (319). A previous relevant Cochrane systematic review was updated and contributed to this section (320).

Two types of non-invasive EStim, i.e., anal EStim or transcutaneous electrical nerve stimulation (TENS) are commonly used. The surface electrodes are positioned over the perineal region.

Questions addressed are:
- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control, or no treatment) for treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?

Despite the prevalence of incontinence and LUTS in older men, the only area which has received systematic consideration with respect to EStim is associated with postprostatectomy incontinence (PPI). All prostatectomy types and approaches were considered, including RP (open, laparoscopic, or robotic) for prostatic cancer, or surgery for benign prostatic enlargement (TURP, laser prostatectomy, or less invasive surgeries). Other studies for LUTS such as UUI included men and women.

This section presents the evidence for the use of EStim in the prevention and treatment of PPI in men.

Eligible interventions were non-invasive EStim without implanted electrodes (PTNS and MStim are described in section IV.4). A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed, and no participants with UI due to neurological or cognitive impairment were included.

The primary outcomes were cure rates and improvement rates (the number of men improved, including cure). There was considerable variability in the way these outcomes were measured. Data on health related QoL and adverse effects were also extracted.

The Cochrane review (317) found six RCTs (five full papers and one abstract) on PPI. There was considerable variation in the interventions used, study protocols, types of EStim parameters and devices, study populations and outcome measures. Frequencies of 5 to 20 Hz are usually used for UUI, 20 to 50 Hz for SUI, and for mixed UI around 20 Hz or high and low frequency alternately. The trials were mostly small and generally there was insufficient information to assess ROB. Four trials evaluated the effect of adding PFMT to EStim versus PFMT alone or with biofeedback. There was some evidence that EStim enhanced the effect of PFMT in the short term but not after six months (317, 318). There were, however, more adverse effects (pain or discomfort) with EStim.

Five studies of EStim in men and women, four with UUI and one with SUI, and eleven studies of men with PPI were summarized in the 6th ICI report.

Two new trials were identified for this update and included in this section. The new trials were targeted for PPI.

The EStim parameters and protocols in this section are summarised in Table 43. There was considerable variation in the intervention protocol.

Table 43. Summary of EStim protocols (EStim for men)

Author, year	Current	Current Intensity	Pulse Shape Duration	Frequency	Duty cycle	Electrodes	Treatment duration	Target UI
Laurienzo (2018) (298)	NR	NR Max tolerable intensity	1ms	35 Hz	Rise time 2 sec; on – 6 sec; off 2 sec; standing time 12 sec	anal	20 min, 2x per week for 7 weeks	PPI
Gomes (2018) (295)	NR	NR	1ms	(SUI) 50 Hz (UUI) 4 Hz	NR	anal	20 min	PPI
Gonzalez (2020) (296)	Square wave pulse	Maximum 24mA Max tolerable intensity	300µ	20 Hz	NR	NR	15 min, 3x per week for 3 months	PPI

Abbreviations: EStim: Electrical stimulation; NR: not reported; PPI: post-prostatectomy urinary incontinence; SUI: stress urinary incontinence; UUI: urge urinary incontinence; UI: urinary incontinence

3.1. Prevention

No new trials were identified. There remain no studies on the effect of EStim for prevention of non-post prostatectomy UUI or SUI in men.

3.2. Treatment

Two new trials were added to the 16 RCTs, included in the 6th ICI (295, 296).

3.2.1. Is EStim better than no treatment, placebo, or control for treatment of UI?

Two earlier placebo-controlled trials (one for UUI and one for SUI) did not separate male and female results.

No new trials were identified to add to the sixth ICI reports.

Summary

In the continued absence of sufficient data from rigorous and well-reported trials, it is not known if EStim, as a stand-alone treatment for male UUI or SUI, is better than no treatment, placebo, or control treatments.

3.2.2. Is one EStim approach better than another?

No new trial was identified. No studies comparing EStim protocols were included in previous consultations.

Recommendation

In the absence of data, it is not known if one EStim protocol is better than another for the treatment of UI in men. **(No recommendation)**

3.2.3. Is EStim better than other treatments?

The sixth ICI report summarized three studies: one study compared EStim to magnetic stimulation (Mstim), another study compared EStim to verbal/written instruction on PFMT, and a crossover trial compared EStim to oxybutynin. These studies included men and women with UUI, but there were few men in these three trials.

No new trials were identified.

Summary

A total of three studies were assessed in the sixth ICI report. Due to insufficient data, it is unknown whether EStim is better than another treatment for UI in men. **(Level of evidence 2/3)**

Recommendations

No recommendation can be made.

3.2.4. Does the addition of EStim to other treatments add benefit?

Two new studies (Table 44) were added to the previous 11 studies on EStim plus PFMT in men with PPI, for a total of 13 included studies (295, 296).

One study by Gomes *et al.* (295) compared Pilates (which included PFMT) to PFMT plus EStim, and control (no therapy) in 120 patients with PPI. This was a similar study to that previously reported in the sixth ICI (321). The other study by Gonzalez *et al*. compared EStim plus biofeedback versus control (no treatment) in 60 patients with PPI (296).

Quality of data

Randomisation was achieved using sealed envelopes in one study (295) but was not defined in the other (296). Participants and evaluators were not blinded in either study (296). Statistical analysis was conducted on patients completing the trial for both studies (295, 296). Loss to follow-up was between 5-10% in the Gomez trial (295) and more than 10% in the Gonzalez trial (296). Adverse events were not reported in any studies.

Results

Gomez *et al.* reported that Pilates and the PFMT plus EStim treatment groups achieved a ststistically significantly higher number of fully continent patients than the control group ($P<0.05$). Continence (no pads) rates were 59% in Pilates, 54% in PFMT plus EStim, and statistically significantly greater than the control group (26%) after treatment (295, 322).

Gonzales *et al*. reported statistically significant differences in the 1-hour and 24-hour pad tests between EStim plus biofeedback versus control at three months ($p=0.01$ and $p=0.001$). The continence rates in the 1-hour and 24-hour pad tests were 64% and 44%, respectively, in the EStim plus biofeedback group at three months, and 9.1% and 4.5%, respectively, in the control group at three months. The ICIQ showed statistically significant differences between the two groups at three months ($P=0.001$) and six months ($P=0.0001$), again favouring the intervention group (296).

Summary

Thirteen studies investigated the addition of EStim plus PFMT or biofeedback in men with PPI. The new data did not change the Level of evidence or Grade of recommendation. Data suggest that EStim plus PFMT or biofeedback is superior to no treatment. However, there is no further benefit of EStim when added to PFMT compared to PFMT or Pilates training alone. The safety of using EStim in an area with cancer cannot be guaranteed (319). **(Level of evidence: 2)**

Recommendations

Although a combined intervention including EStim plus PFMT or biofeedback appears to be superior to no treatment, adding EStim to PFMT for men with PPI cannot be routinely offered. **(Grade of recommendation: B)**

Table 44. Summary of data on EStim + another treatment vs the other treatment

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Gomes (2018) (295)	Group 1: Pilates (including PFMT) for 10 weeks Group 2: PFMT+EStim for 10 weeks Group 3 instructions to perform PFMT at home	120	PPI (SUI, UUI, MUI)	Continence (Number of pads/day) (QoL) ICIQ-UI SF	G1(59%). G2(54%) >G3(26%), P<0.05 P<0.01 between Group 1 and Group 3 NS between Group 2 and Group 3	10 weeks after the intervention	104 participants completed the RCT
Gonzalez (2020) (296)	EStim+BF 3 days/week for 3 months vs control (no treatment)	60	PPI 3 months post-surgery	Continence rate in 1-h pad test at 3M Continence rate in 24-h pad test at 3M Results of 1-h pad test at 3M and 6M Results of 24-h pad test at 3M and 6M ICIQ	Estim+BF > control (64% vs 9.1%) at 3 months Estim+BF > control (44% vs 4.5%) Estim+BF > control (P=0.01 and 0.01) Estim+BF > control (P=0.03 and 0.01) Estim+BF > control (P=0.01)	6 months after the 3-month intervention	47 participants completed the study Loss to follow-up: 5 in EStim+BF group 8 in control group

Abbreviations: PFMT: pelvic floor muscle training; EStim: Electrical stimulation; BF: biofeedback; PPI: post-prostatectomy urinary incontinence; SUI: stress urinary incontinence; UUI: urge urinary incontinence; MUI: mixed urinary incontinence; QoL: quality of life; ICIQ-UI SF: International Consultation on Incontinence Questionnaire-Urinary Incontinence Short Form; NS: non-significant; PFMS: pelvic floor muscle strength

4. MAGNETIC STIMULATION (MSTIM)

MStim is a novel noninvasive approach which has been used to manage a number of neurological and psychiatric disorders. In terms of the therapeutic mechanism for male UI, MStim can generate a pulsed magnetic field through an electrified coil, which induces a flow of ions to form eddy currents when the excitable tissue is exposed to the magnetic field. Consequently, human motor nerves are depolarized and produce an action triggering external sphincter contraction (323, 324). Additionally, detrusor relaxation induced by MStim also contributes to male continence (325). Although MStim has been widely used to treat all types of UI in women, there are only limited studies exploring the effect of MStim on male UI secondary to RP. No new studies were identified.

4.1. Prevention

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

4.2. Treatment

A total of three trials (two published, one abstract without data) were identified and only the two published trials were included in the 5th & 6th ICI. No new studies were identified based on current available evidence.

4.2.1. Is MStim better than no treatment, placebo, or control for treatment of UI?

No studies were found addressing this question.

4.2.2. Is one MStim approach better than another?

No studies were found addressing this question.

4.2.3. Is MStim better than other treatments?

No new studies were identified.

4.2.4. Does the addition of MStim to other treatments add benefit?

No new studies were identified.

5. PENILE VIBRATORY STIMULATION

This conservative treatment was included in the 5th edition. Penile vibratory stimulation (PVS) stimulates the pudendal nerve to treat SUI in men post prostatectomy. It has previously been shown to increase the external sphincter pressure in men with spinal cord injury (326, 327) and vibratory stimulation applied to the perineum in healthy women was related to increased external urethral pressure (328). No new trials have been found to add to the small pilot study (329) found in the last edition. No recommendations can be made.

6. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens include BT, timed voiding, habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to suggest that

scheduled voiding regimens, especially BT and timed voiding, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to women, leaving insufficient evidence to comment on effectiveness.

For this edition there were no new trials to add to the 6th edition. In men, behavioural treatment may be just as effective for some LUTS, including UI, as pharmacological therapy. Further studies of high quality are needed before a recommendation for practice can be supported.

7. COMPLEMENTARY AND ALTERNATIVES MEDICINES

There is increasing evidence for the use of CAMs in management of chronic diseases. Basically, CAMs therapy including acupuncture, herbal therapy, massage, yoga, Tai Chi, Qi Gong, meditation, Ayurveda and homeopathy. In the 6th ICI, only a few low-quality trials were identified. Small sample size, absence of objective assessment, and lack of long term follow up were the main limitations. In the 7th ICI, these limitations remain. Three low quality, small sample studies were added to this section.

7.1. Prevention

One RCT examined the effect that participating in a structured yoga programme (n=35) during radiation therapy for prostate cancer had on urinary symptoms versus control (n=33) (330). Unfortunately, there were several ROB in this study with no blinding, allocation concealment or ITT analysis. There was also a large loss to follow up. While the IPSS increased over time in both groups, there was no difference between the groups after 6-9 weeks of yoga (330).

Another RCT looked at a pre-RP exercise programme (n=10) versus usual physical activity (n=10) using the IPSS (331). There were not sufficient details available in this abstract only to assess the ROB. No differences were reported between groups on the IPSS at 6 months after RP (331).

Summary

Yoga and generalised exercise programmes do not appear to impact urinary symptoms after treatment for prostate cancer as measured on the IPSS. **(Level of evidence 3)** Therefore, Yoga may not be routinely offered to all men with urinary symptoms after treatment for prostate cancer. More studies are needed. **(Grade of Recommendation D).**

7.2. Treatment

7.2.1. Acupuncture vs no treatment, sham acupuncture or any other treatment?

7.2.1.1. SUI

No new trials were identified.

7.2.1.2. OAB, UUI, MUI

One non blinded, moderate ROB trial was found observing the application of two weeks of Chinese medicine on the umbilicus + electroacupuncture (n=-42) versus tolterodine (n=41) in the management of OAB after TURP (332). On both outcome measures of UI and OABSS the Chinese traditional medicine group did statistically significantly better. Emerging translated literature suggest that traditional medicine may be of interest in male UI. More research in this field is warranted. **(Level of evidence 3).**

7.2.2. What is the most effective acupuncture protocol?

No new trials were identified.

7.2.3. Other approaches?

No trials were identified.

Table 45. Table of included RCTs for complementary and alternatives medicines in men.

Author, year	Study type/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow-up…)
Exercise							
Ben-Josef (2017) (330)	RCT Yoga vs no yoga	68	Men undergoing 6-9 weeks of external beam radiation therapy	Group 1 (n=35): Yoga during radiation therapy (75 minutes, 2x per week) for 6-9 weeks. Group 1 (n=33): no yoga	IPSS was used to determine the severity of urinary symptoms and urinary QoL, and between-group differences at all follow-ups (p=0.1022) Week 4 Group 1 (n=22): 11.14±5.01 Group 2 (n=28): 13.34±6.82 Final Group 1 (n=22): 10.79±6.7 Group 2 (n=28): 15.04±6.5	4th week of radiotherapy and 1 week after the last treatment session/ external beam radiation therapy	Adverse events: NR Loss of follow up: 26.47% (19/68); Group 1: n=13 Group 2: n=5 Intention to treat: No
Flannigan (2020) (331) Abstract	RCT Aerobic and resistance exercise vs usual physical activity	20	Men diagnosed with prostate cancer and scheduled for a radical prostatectomy	Group 1: combined supervised aerobic and resistance exercise program for 8-12 weeks. Group 1: usual physical activity	There were no significant differences between the start and 6 months after RP regarding IPSS and FACT-P scores.	6 months after radical prostatectomy	Adverse events: NR Loss of follow up: 5% (1/20); Group 1: n=1 Intention to treat: NR
Acupuncture							
Jia (2014) (332)	RCT Electroacupuncture + Chinese medicine vs medication	83	Men who underwent transurethral resection of the prostate	Group 1 (n=42): Chinese medicine on umbilicus (3x per day, 30 minutes) + electroacupuncture (daily, 30 minutes) for 2 weeks Group 2 (n=41): tolterodine 2mg (2x/day) for 2 weeks	UI and OABSS significantly decreased in Group 1 when compared to Group 2 (p<0.05). UI: Group 1 (n=42): 0.8±0.5 Group 2 (n=41): 1.3±0.8 Between group comparison p<0.05 OABSS Group 1 (n=42): 6.6±1.2 Group 2 (n=41): 8.9±2.1 Between group comparison p<0.05	2 weeks after transurethral resection of prostate	Adverse events: NR Loss of follow-up: 0/83 Intention to treat: Yes

Abbreviations: RCT: randomized controlled trial; IPSS: International Prostate Symptom Score; QoL: quality of life; NR: not reported; UI: urinary incontinence; OABSS: Overactive Bladder Symptom Score

8. SUMMARY CONSERVATIVE MANAGEMENT FOR MALE UI

8.1. Lifestyle modification interventions

Prevention

Weight loss through lifestyle changes can be recommended to obese and overweight men with UI, particularly those with type 2 diabetes. **(Grade of recommendation: B)**

Smoking abstinence could be recommended for men with UI. **(Grade of recommendation: C)**

A reduction in caffeine intake could be recommended for men with incontinence symptoms; evidence suggests that the equivalent of two cups of coffee per day (250mg) is associated with UI in men. **(Level of evidence 3: Grade of recommendation: C)**

High vegetable, fruit and vitamin C intake could be recommended to men in the primary and secondary prevention of LUTS, UI and BPH. **(Grade of recommendation: C New)**

8.2. PFMT

Pre-operative instruction in PFMT can be recommended as it facilitate earlier recovery of continence in men undergoing RP **(Grade of recommendation: B)**

Early PFMT either pre-operatively or early post-operatively can be recommended to reduce time to continence after surgery. **(Grade of recommendation: B)**

There does not seem to be any benefit of adding EStim to a PFMT programme for men with persistent PPI and therefore it cannot be recommended routinely. **(Grade of recommendation: B)**

The use of biofeedback does not seem to add any benefit to a PFMT programme for men with persistent post-prostatectomy incontinence and therefore it cannot be recommended routinely. However, biofeedback may be considered for subgroups of men presenting reduced proprioception **(Grade of recommendation: B)**

The use of Pilates does not seem to be superior to a PFMT programme for men with persistent post-prostatectomy incontinence and therefore cannot be recommended for men with persistent post-prostatectomy incontinence. **(Grade of recommendation: B New)**

Pilates may be considered over no treatment to manage persistent post-prostatectomy incontinence in men. **(Grade of recommendation: D New)**

Novel interventions, which activate the PFM or involve support groups, could be beneficial after RP, but data is very limited **(Grade of recommendation C New)**

Long-term side effects of RP, such as climacturia and erectile dysfunction appears to. Be reduced using PFMT. PFMT could be considered for the treatment of climacturia and erectile dysfunction in men post RP. More research in this area is needed. **(Grade of recommendation: C (New).**

Men with PMD could be instructed to perform a strong PFM contraction immediately after voiding,or use urethral massage to empty the urethra. **(Grade of recommendation: C)**

8.3. EStim

Treatment

Although a combined intervention including EStim plus PFMT or biofeedback appears to be superior to no treatment, adding EStim to PFMT for men with PPI cannot be recommended routinely. **(Grade of recommendation: B)**.

8.4. MStim

No recommendation

8.5. Penile vibratory stimulation

No recommendation

8.6. Schedule voiding regimens

No recommendation

8.7. Complementary and alternative medicine

Yoga and generalised exercise programmes do not appear to impact urinary symptoms after treatment for prostate cancer as measured on the IPSS and therefore may not be routinely offered to all men with urinary symptoms after treatment for prostate cancer. More studies are needed. **(Level of evidence 3, Grade of recommendation D)**

V. URINARY INCONTINENCE IN MEN AND WOMEN

1. TIBIAL NERVE STIMULATION

Tibial nerve stimulation (TNS) is a form of peripheral neuromodulation targeted towards symptom relief of OAB and UUI.

Evidence for the use of TNS for the prevention and treatment of UI in adults (study with men and women with results combined) is presented below. Evidence for the use of TNS for the prevention and treatment of neurogenic UI is presented in the section VI.

Questions addressed are:
- Can TNS prevent UI?
- Is TNS better than no treatment, placebo, or control treatments for UI?
- Is TNS better than other treatments for UI?
- Does the addition of TNS to other treatments add any benefit?
- What is the best programme of TNS for UI in adults?
- What is the effect of TNS on LUTS other than UI?
- What factors might affect the outcome of TNS?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see Appendix 1). Trial data reported in conference abstracts as well as full text papers were included. Search dates were from 9th September 2015 to December 31st, 2020.

Eligibility criteria:

1. Reports of RCTs or quasi-randomised trials of TNS, percutaneous or transcutaneous.
2. Adult men and women with UI and/or OAB (with or without urgency incontinence) presentation of data combined for men and women. Trials including women only are presented in section II.6.

Evidence overview
This section was included for the first time in the 6th ICI with no date restrictions on searches applied. A total of 7 RCTs of tibial nerve stimulation (TNS) in adults were identified and one Cochrane systematic review of anticholinergic drugs versus non-drug active therapies for non-neurogenic overactive bladder syndrome in adults (133), in which TNS trials with adults of both sexes only were included. Since then, a further eleven trials and a full report on a previously presented abstract (333) have been added.

Overall, five randomised trials compared TNS with a sham intervention (334-338). Four trials compared TNS with other active treatments for UI: two trials compared percutaneous TNS with different anticholinergics (339, 340), one trial compared percutaneous TNS with injected onabotulinumtoxin-A (341) and one trial compared transcutaneous TNS with transcutaneous electrical nerve stimulation (TENS) of the sacral foramina (342). Three trials compared different stimulation protocols (333, 343, 344). Percutaneous TNS was used in 7 randomised trials (335, 337-341, 344). Transcutaneous TNS was used in 4 trials (333, 334, 336, 342, 343). A direct comparison of transcutaneous and percutaneous TNS for treatment of UI has been undertaken in an adult population (343).

1.1. Prevention
There have been no studies on the effect of TNS for prevention of UUI/OAB in adults.

1.2. Treatment

1.2.1. Is TNS better than no treatment, placebo, or control for treatment of UI?
Five randomised controlled trials in adult men and women address this question. Two RCTs (334, 337) were adequately powered whereas Vohra (2002) (338) and Booth (2013) (336) are both pilot RCTs and Lashin 2020 (335) is an abstract of a small trial and reports no power calculation. See Table 46.

Quality of data
Computerised randomisation was used in four studies (334, 336-338) and not reported in Lashin 2020 (335). Adequate allocation concealment was reported in three (334, 336, 337) and unclear in two (335, 338). Subjects and outcome assessors were blinded throughout in three studies (334, 336, 337), with blinding unclear in two (335, 338). Three studies reported ITT analysis (334, 336, 337); the type of analysis was not reported in two (335, 338). There was no apparent inequality in loss to follow-up across the groups: In the ELECTRIC care home trial (334) 30 transcutaneous TNS and 31 sham residents were lost to follow up at 6 weeks (7 and 4 died from unrelated causes, respectively): 197 transcutaneous TNS and 178 sham resident data was analysed. In the SUmiT trial (337) seven subjects were lost to follow-up in the percutaneous TNS and 5 in the sham group thus 94% and 95% respectively were analysed. Two of the 30 subjects (6.6%), both from the sham group, discontinued in one trial (336), one subject (4.5%) from the control group dis-continued in one trial (338) and no attrition was reported by Lashin (335). Mild or moderate treatment relat-ed adverse events were reported by 2 sham subjects who complained of a heavy sensation/leg pain in ELECTRIC (334) and 6 percutaneous TNS subjects in SUmiT (337). They included ankle bruising (1 of 110, 0.9%) discomfort at needle site (2 of 110, 1.8%) bleeding at the needle site (3 of 110, 2.7%) and tingling in the leg (1 of 110, 0.9%). The Lashin (2020) (335) trial reported pain/discomfort at the needle site in 4 (16%) percutaneous TNS subjects and 2 (8%) sham; bleeding at the needle site in 1 (4%) percutaneous TNS subject and 2(8%) sham; tingling in the leg and ankle bruising in 1 (4%) percutaneous TNS subject and 0 (0%) in sham. No subjects in the transcutaneous TNS trial (336) reported adverse events and presence of adverse events was unclear in one study (338). Two trials were reported as pilots with no sample size calculation (336, 338), in one trial (335) no sample size calculation was provided and two trials were ade-quately powered (334, 337), however the payment of subjects for time and expenses in the SUmiT trial was a potential limitation and the efficacy achieved may not be equivalently reflected in translating to real world practice. ROB of bias was low in three trials (334, 336, 337) and high in two (335, 338).

Results
No study reported cure rates for UI. Four trials reported UI improvements and one trial reported no effect of transcutaneous TNS on UI in residents of care/nursing homes (334). In the SUmiT trial (337) 37.9% percutaneous TNS subjects reported moderate or markedly improved urgency incontinence compared to 22.1% sham subjects (p=0.02). Voiding diary analysis showed percutaneous TNS to be statistically significantly superior to sham in reducing urge incontinence episodes (p=0.002) from a median of 3.0 episodes accompanied by moderate to severe urgency per day at baseline, to a median of 0.3 episodes at 13 weeks (p<0.0001). Lashin (2020) (335) reported statistically significantly improved scores on the

OAB symptom scale in the percutaneous TNS group compared to the sham group at 7 weeks (Homma: 5.9±3.2 PTNS group, 9.6±1.4 sham, p<0.001; Blavais 16.6±3.4 PTNS group, 20.8±2.3 sham, p=0.007); 3months (Homma: 5.8±3.3 PTNS group, 9.2±1.1 sham, p<0.001; Blavais 18.2±4.3 PTNS group, 21.9±2.1 sham, p<0.001) and 6 months (Homma: 5.7±3.0 PTNS group, 9.8±1.8 sham, p=0.001; Blavais 19.2±4.2 PTNS group, 22.0±3.1 sham, p=0.005). In the two pilot trials Booth (2013) reported improved ICIQ-UI SF in 10 of 15 (67%) transcutaneous TNS group and 6 of 13 (46%) sham group (p=0.132, NS); Vohra reported statistically significantly reduced UI in 7 of 11 percutaneous TNS subjects but provided no estimates of effect size. There were no significant differences reported between transcutaneous TNS and sham groups in the ELECTRIC trial (334) in adjusted mean differences (95% confidence interval) of 24-hour volume of UI on pad test at 6 weeks (53ml; CI-22 to 128ml, p=0.164), 12 weeks (70ml; CI-9 to 148ml, p=0.081) or 18 weeks (21ml; CI -60 to 102ml, p=0.605). Data were not reported separately by sex in any of the trials.

In one large trial (337), percutaneous TNS subjects reported statistically significant improvements in over-all bladder symptoms with 54.5% reporting moderate or markedly improved Global Response Assessment (GRA) from baseline compared to 20.9% of sham subjects (p<0.001). A statistically significant difference between the groups in favour of percutaneous TNS was found for the OAB-q quality of life scores (p=0.006) and the SF36 general health survey quality of life scores significantly improved between baseline and 13 weeks for the percutaneous TNS group in the physical (p=0.002) and mental (p=0.049) domain scales. Voiding diaries were improved in 13 of 25 (52%) subjects who received percutaneous TNS (p<0.001) in the Lashin trial (335) but the authors did not specify the measurement time point. One pilot trial (338) reported significant improvements in quality of life (QoL questionnaires not specified and SF-36) but provided no data or figures to support this.

A prospective study to assess long-term outcomes and determine frequency of top-up stimulation sessions required was reported (337). Fifty responders to the original trial underwent a fixed 14-week tapered stimulation protocol, followed by a personal treatment plan aimed at maintaining improvements. Twenty-nine of 50 (58%) completed the outcomes. 77% of these maintained moderate or marked improvement in OAB symptoms at three years with a median 1.1 treatments each month.

Summary

The results of three trials, one rigorous, well-reported trial and two low quality trials, showed that percutaneous TNS is safe and more effective than a sham treatment for improving urgency incontinence in adults with OAB/UUI. There is evidence that effects are sustained for up to 3 years with regular treatment. **(Level of evidence: 1)**

One rigorous, well-reported trial showed that transcutaneous TNS is safe but has no effect on UI (of unspecified type) in older adults living in nursing or care homes. **(Level of evidence: 2)**

Further studies are needed to determine the effectiveness of transcutaneous TNS on OAB/UUI in frail older adults and in other adult populations.

Recommendation

Percutaneous TNS can be offered to men and women (adults) with UUI/OAB who do not achieve satisfactory results from first line lifestyle and behavioural intervention and pharmacological therapy. **(Grade of recommendation: B)**

Transcutaneous TNS cannot be offered to frail older adults as a treatment for UI as there is evidence of no effect **(Grade of recommendation: B New)**

In the adult population with UUI/OAB, Transcutaneous TNS may be a useful option to test earlier in the treatment algorithm, following lifestyle and behavioural interventions and before more invasive therapies are considered.

Table 46. Characteristics of studies comparing tibial nerve stimulation (TNS) with no treatment, placebo or control treatments for UI

Author, year	Comparator groups	N	Study population	Modality details or parameters	Outcomes	Follow up
Vohra (2002) (338)	Treatment group: Percutaneous TNS Active electrode: 34-gauge needle provides sensation. Inactive electrode: calcaneal surface electrode. Control group: Sham TNS Described as 'TNS treatment without nerve stimulation'	22	Adults with urgency frequency syndrome of > 6 months and urodynamic detrusor overactivity Males: not reported Females: not reported Results reported together	Pulse width: not reported Frequency: 20 Hz Intensity: 0.5-10mA according to sensory & motor response. Abbreviations: GRA: Global Response Assessment; UUI: urinary urge incontinence; OABq: Overactive Bladder Questionnaire; SF-36: 36-Item Short Form Health Survey; AUASI: American Urological Association Symptom Index; ICIQ-UI SF: International Consultation on Incontinence Questionnaire on Urinary Incontinence Short Form; PVR: post-void residual urine volume; PPBC: Patient Perception of Bladder condition; DEMqol: Dementia Quality of Life; OABSS: Overactive Bladder Symptom Scores.

1.2.2. Is TNS better than another treatment for UI?

Two trials compared percutaneous TNS with another treatment for UI (Table 47). The other treatment was an oral drug – extended release tolterodine 4mg daily (339) or intra-detrusor injections of botulinum toxin type A [BTX-A] (341). There are no trials comparing transcutaneous TNS with other treatments in the adult population.

Quality of data

In Peters (2009) (339) 1:1 randomisation to percutaneous TNS or tolterodine was implemented using a random block design stratified by investigational site, however the success of allocation concealment was unclear. Sherif (2017) (341) provided no information about randomisation or allocation concealment. Blinding of subjects and clinicians was not possible given the different nature of the interventions with the comparator to percutaneous TNS being an oral medication (339) or intra-detrusor injection of BTX (341). Outcomes were subject reported in both trials and no indication of any assessor blinding was provided. An ITT analysis was not undertaken in either study. No reasons for withdrawal were provided for the 3 participants who dropped out in the Sherif trial (341). In the Peters trial (339), seven subjects (14%) with-drew from the drug group and nine (18%) from the percutaneous TNS group; none due to adverse effects; Adverse effects were mild or moderate in both groups with 14.3% (7 subjects) from the tolterodine arm reporting moderate adverse effects and 16.3% (8 subjects) from the percutaneous TNS group. Percutane-ous TNS related adverse events included leg cramps, intermittent foot/toe pain, generalised swelling, headache, haematuria, inability to tolerate stimulation, worsening incontinence and vasovagal response to needle placement (339). Sherif (341) reported adverse events of post-void residual urine >200ml requiring clean intermittent catheterisation in two patients (6.6%), early postoperative haematuria in three patients (10%) and UTI in two patients (6.6%). Minor localised bleeding and temporary pain were reported by an unspecified number in the percutaneous TNS group. The Peters trial (339) was adequately powered for a non-inferiority margin of 20% in number of voids per 24 hours based on the sample size calculation. No sample size calculation was reported by Sherif (341). Long-term follow-up of percutaneous TNS subjects for nine months after initial treatment completion was reported by both studies (341, 345). The overall ROB for both studies is high.

Results

Data were reported for the whole group with no differentiation by sex in both trials. Peters (2009) (339) reported that the global response assessment (GRA) demonstrated statistically significant subjective as-sessment of bladder symptom change compared to baseline, with 79.5% (35) of the percutaneous TNS group reporting cure (1) or improvement (34) and 54.8% (23) of the tolterodine group reporting cure (2) or improvement (21) (p=0.01). Both groups had improved significantly but there was a statistically significant difference between the groups in favour of the percutaneous TNS. Symptoms of UUI, reported in the void-ing diaries, improved significantly in both groups however there were no between-group differences for these measures. Similarly, quality of life scores showed statistically significant improvements for both treatment groups (P<0.001) but no between-group differences. The percutaneous TNS group reported statistically significantly less dry mouth than the tolterodine group (p=0.01) and a non-significant lower rate of constipation.

Follow-up to determine duration of effect up to 12 months from baseline was offered to percutaneous TNS responders (those who reported a successful response to GRA after 12 weeks) (345). Thirty-three of the 35 responders chose to continue. The GRA showed sustained improvements in 96% at 12 months, with a mean of 21 days between treatment sessions.

Sherif (2017) (341) reported statistically significant improvements in UI episodes, based on 3-day bladder diaries, for those treated with percutaneous TNS at 6 weeks, 3 and 6 months post-treatment (baseline UI episodes 4.7 + 1.01; 6 weeks UI episodes 2.2 + 0.7 P<0.05; 3 months UI episodes 2.6 + 0.7 P<0.05; 6 months UI episodes 3.3 + 0.6 P<0.05; 9 months UI episodes 4.2 + 1.04 NS) and those treated with BTX-A (baseline UI episodes 4.3 + 1.1; 6 weeks UI episodes 1.8 + 0.7 P<0.05; 3 months UI episodes 2.4 + 0.7 P<0.05; 6 months UI episodes 3.1 + 0.5 P<0.05; 9 months UI episodes 3.5 + 1.2; P< 0.05) but statistically significant improvements only extended to 9 months in the BTX-A group . Quality of life, measured by a single ques-tion on the OABSS, was significantly improved in both percutaneous TNS and BTX-A groups at all time points however the improvement was greater in the BTX-A group and the difference between the two groups was statistically significant at 6 weeks and 9 months.

Summary

Two trials compare percutaneous TNS with another treatment for UI. Evidence from a single RCT indicates that percutaneous TNS may be as effective as tolterodine, for urgency UI with an improved side effect pro-file; evidence from a single study comparing percutaneous TNS with BTX-A in the treatment of refractory idiopathic OAB indicates a significant reduction in UI episodes up to 6 months following treatment with percutaneous TNS but that it may be less effective than BTX-A in the management of refractory OAB, alt-hough associated with fewer side-effects. However, study design limitations in both trials suggest caution and further studies are recommended to establish the effects of percutaneous TNS in comparison to other pharmacological treatments. **(Level of Evidence: 2)**

As there were no trials comparing transcutaneous TNS with another active treatment, trials are needed to determine the effects of transcutaneous TNS compared to common anticholinergic drugs used to treat UUI/OAB in adults.

Recommendation

TNS can be considered as an alternative to tolterodine anticholinergic medication for OAB/UUI. (Grade of recommendation: B) There is insufficient evidence available to make further recommendations about TNS in comparison to other treatments for UI.

Table 47. Characteristics of studies of tibial nerve stimulation (TNS) added to other active treatment

Author, year	Comparator groups	N	Study population	Modality details or parameters	Outcomes/results	Follow up
Peters (2009) (339)	Treatment group: Percutaneous TNS Active electrode: 34-gauge needle provides sensation. Inactive electrode: calcaneal surface electrode. 1.2.3. Does the addition of TNS to other UI treatment add any benefit?

One RCT was identified (340) that compared percutaneous TNS with percutaneous TNS plus oxybutynin, for treatment of patients with urodynamically diagnosed detrusor overactivity (DO). One new RCT was identified (342) comparing transcutaneous TNS plus transcutaneous electrical nerve stimulation (TENS) of the sacral foramina (SF) with transcutaneous TNS alone, for first-line treatment of idiopathic OAB (Table 48).

Quality of data

Karademir (2005) (340) reported randomisation following urodynamic studies into percutaneous TNS group or percutaneous TNS plus 5mg daily oxybutynin hydrochloride but no description of method of randomisation or adequacy of allocation concealment, blinding of subjects, clinicians or assessors or type of analysis. Surbala (2014) (342) used computer-generated randomisation and reported on allocation concealment, blinding of assessors and ITT analysis. No subject dropped out in either study. There were no adverse events in Surbala (2014) (342) and in Karademir (2005) (340) adverse events were mild: percutaneous TNS plus drug group - seven reported dry mouth, one blurred vision; percutaneous TNS group – one reported a small haematoma, one local tenderness. There was no sample size calculation in either study, no long-term follow-up and overall ROB was high.

Results

In Karademir (2005) (340) four of five subjects receiving percutaneous TNS only and all five subjects receiving percutaneous TNS and oxybutynin, with urgency UI reported cure on voiding diary. The numbers were too small for statistical analysis. Overall treatment response was defined as patient reported improvement in OAB symptoms of frequency, urgency and urge incontinence by > 35% and occurred in 61.6% percutaneous TNS group and 83.2% percutaneous TNS plus oxybutynin group. The between group difference was not statistically significant. Surbala (2014) (342) reported all stimulation resulted in statistically significantly improved OABSS, UDI-6 and IIQ-7 at 4 weeks. Large effect sizes (> 0.8) were shown for all outcomes, with combined transcutaneous TNS and SF TENS, compared to transcutaneous TNS alone. No UI-specific results were presented.

Summary

The evidence is limited to two small, low-quality trials **(Level of evidence: 2)** which indicate the possibility of additional effects from adding oxybutynin to a programme of percutaneous TNS or parasacral TENS to a programme of transcutaneous TNS.

Large, well-designed trials are needed to establish whether the addition of any anticholinergic drug or other type of EStim enhances the effectiveness of TNS in adults with UUI/OAB.

Recommendation

Based on current evidence on adding oxybutynin to percutaneous TNS and adding parasacral TENS to transcutaneous TNS could be considered for additional benefit, in adults with OAB. (**Grade of recommendation C)**

Further high-quality trials are needed.

Table 48. Characteristics of studies of tibial nerve stimulation (TNS) added to other active treatment

1.2.4. What is the best TNS protocol for UI in adults?

Three RCTs compared different stimulation protocols. Finazzi-Agro (2005) (344) compared weekly and thrice weekly percutaneous TNS, Seth (2018) (333) compared weekly and daily transcutaneous TNS using a novel device and Ramirez-Garcia (2018) (343) compared efficacy of percutaneous TNS and transcutane-ous TNS in adults with idiopathic OAB. Details are provided in Table 49.

Quality of data

Computer-generated online randomisation was used by Ramirez-Garcia (2018) (343) and Seth (2018) (333) with associated allocation concealment. Selection bias is possible in Finazzi-Agro (2005) (344) as random-isation methods were not described. Blinding of subjects or clinicians was not possible within these study designs. Type of analysis was not reported in two trials (333, 344) while ITT analysis was reported in Ramirez-Garcia (343). Outcomes were reported at the end of each treatment protocol but no long-term follow up was reported. Withdrawals were high (29.2 %) in the Seth pilot trial (333), with 8 of the 14 with-drawals being device related, although no significant adverse events occurred. There were no withdrawals in the Finazzi-Agro trial and no adverse events reported. Ramirez-Garcia (343) reported 7 drop-outs (10.3%) and no serious adverse events.

Results

In the Finazzi-Agro trial (344) 4 of 11 (36%) subjects with UI in the weekly percutaneous TNS group and 5 of 11 (45%) subjects with UI in the 3 X weekly percutaneous TNS group reported complete cure after treat-ment. Overall success of >50% reduction in micturition episodes/24 hours or (if incontinent) UI epi-sodes/24 hours was confirmed for 11 of 17 (63%) subjects in the weekly percutaneous TNS group and 12 of 18 (67%) subjects in the 3 times weekly percutaneous TNS group. Subjective improvement was reported after 6-8 sessions, regardless of frequency of delivery. In the Seth trial, 18 of 34 (53%) subjects who com-pleted the 12-week protocol were responders [daily treatment (n=9), weekly (n=9)], rating their improve-ment as moderate to significant on the General Response Assessment (GRA). Statistically significant improvements in ICIQ-OAB (p=0.001) and ICIQ LUTSqol were reported for both daily and weekly stimula-tion groups. There were no differences in ICIQ or bladder diary parameters between those with idiopathic and neuropathic OAB however the proportion of idiopathic OAB GRA responders was 36% (5/14) com-pared to 65% (13/20) in the neuropathic OAB group. Ramirez-Garcia showed non-inferiority of transcuta-neous TNS compared with percutaneous TNS in both urgency and leakage episodes, which reduced by similar amounts in both groups: 23% and 47% in transcutaneous TNS and 14.6% and 60% in percutaneous TNS. Both groups achieved statistically significant mean increases of 21.5 and 22.1 points (P<0.001) in I-QOL with no statistically significant between group difference.

Summary

One small well conducted RCT demonstrates non-inferiority of transcutaneous TNS compared to percuta-neous TNS for reducing urgency UI episodes and improving quality of life. **(Level of evidence: 1b)**

Two small trials indicate that no benefit on outcome is conferred by a more than once weekly stimulation protocol for percutaneous or transcutaneous TNS however it is possible that symptom improvement may be more rapid with a more frequent delivery protocol. **(Level of evidence: 2)**

Larger, rigorous and well-reported trials are needed to confirm the most effective type of TNS, timing and duration of protocols to treat UI.

Recommendation

Percutaneous or transcutaneous TNS can be delivered at least once weekly, and the protocol determined by patient preference. **(Grade of recommendation B New)**

Table 49. Characteristics of studies comparing one protocol of Tibial Nerve Stimulation (TNS) with another for UI

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes	Follow up

1.3. What is the effect of TNS on LUTS other than UI?

No trials were identified that analysed the effect of TNS in adults with other LUTS alone i.e., frequency of voiding, urgency, nocturia and integrated reporting of UI and other LUTS was a feature of all studies. In one RCT comparing efficacy of transcutaneous TNS and percutaneous TNS (343), the primary outcome was reduction in daytime frequency of voiding. This outcome significantly reduced in the transcutaneous TNS group by 1.3 episodes (95% CI 0.5,2.0) (P=0.002) compared to a non-statistically significant reduction in the percutaneous TNS group of 0.4 episodes (95% CI -0.3,1.1) (P=0.213). Similar results were found for number of urgency episodes in 24 hours, which reduced in the transcutaneous TNS group by 2.2 episodes (95% CI 1.1,3.1) (P<0.001) compared to 1.4 episodes in the percutaneous TNS group of (95% CI -0.3,3.1) (P=0.102). Voiding frequency in 24 hours was significantly reduced in the transcutaneous TNS group by 1.6 episodes (95% CI 0.8, 2.5) (P<0.001) compared to 0.8 episodes in the percutaneous TNS group (95% CI -0.1,1.6) (P=0.073). The adjusted analysis of the differences between transcutaneous TNS and percutaneous TNS showed no statistical significance for the primary outcome of daytime frequency of voiding in the per protocol (P = 0.089) or the ITT analysis (P = 0.064).

For percutaneous TNS, in the large, well reported SUmiT trial the percutaneous TNS group reported statis-tically significant improvements in voiding diary symptoms of frequency, night-time voids and voids with moderate to severe urgency, compared to the sham group (Peters 2010). A small pilot trial reported re-duced day and night-time frequency and urgency by 63% after 12 weekly 30-minute percutaneous TNS sessions, although no effect size estimates were provided. The elimination of detrusor overactivity on repeat urodynamic testing was also shown (338).

For transcutaneous TNS, compared with sham, one trial in care home residents (336) reported statistically significantly improved total AUASI scores for 87% of the transcutaneous TNS group compared to 31% sham group (p<0.001).

When comparing percutaneous TNS with 4 mg daily tolterodine, Peters (2009) reported a statistically significant reduction in bladder diary reports of voiding frequency, nocturia, moderate to severe urgency episodes in both groups and no between-group differences.

Self-reported urinary urgency was statistically significantly reduced at 6 weeks, 3 and 6 months by percutaneous TNS and BTX-A but at 9 months only by BTX-A (341).

One trial comparing two percutaneous TNS protocols (344) reported a statistically significant reduction in frequency (P=0.01) for both once and three times weekly treatment regimes. A similar result was reported by Seth (2018) (333) who showed a reduction in 24-hour frequency from 11.5 at baseline to 8.8 at week 12 for both the daily- and the weekly- transcutaneous TNS groups.

1.4. Factors affecting outcomes

None of the included TNS trials addressed the effect of age or any other factor on prediction of outcome of TNS. Effectiveness of transcutaneous TNS on UI in frail older adults resident in care homes was the focus of a large, rigorous trial (334) and a well-reported pilot trial (336) where the mean age was 85 and 84.2 years respectively. The adherence to the transcutaneous TNS was high (85-100%), with no serious adverse effects reported however transcutaneous TNS in the ELECTRIC trial conferred no benefit on volume of UI in this elderly, frail population, 75% of whom were dependent of staff for assistance to use the toilet. A prospective study (346) of prognostic factors for successful percutaneous TNS showed that sex, age, weight, body mass index, indication for percutaneous TNS, duration of symptoms, number and type of previous treatments, number of UI episodes/24 hours, voiding frequency/24 hours and total IQoL scores were all unrelated to the success or not of percutaneous TNS in men and women with OAB, non-obstructive urinary retention or chronic pelvic pain. A low Mental Component Summary Score on the SF-36 was a negative predictive factor for success of percutaneous TNS, both subjectively and objectively. Additionally, patients with OAB who had detrusor overactivity had poorer outcomes than those without, as did those with low bladder capacity at baseline (137). A retrospective chart review of 162 women to identify prognostic factors for successful TNS found that in women treated with percutaneous TNS for refractory OAB, a history of depression/anxiety and severe baseline urgency UI, were positive predictors of a successful percutaneous TNS outcome (347).

These results mean there is no reason to exclude older adults, those with a long symptom history, weight difficulties, anxiety/depression, severe symptoms, or failure of previous treatments and that they should be offered TNS where indicated, except where recognised contraindications to TNS, such as a cardiac pacemaker are present. Only in those patients with poor mental health overall and/or overactive and/or low-capacity bladders at baseline, or who are dependent on others to use a toilet, should the possibility of limited success be considered.

Summary

The evidence on which to base recommendations for best practice in the use of TNS to treat OAB/UUI in men and women remains sparse, for both percutaneous and transcutaneous TNS. However, it is sufficiently robust to support the use of percutaneous TNS when less intensive and invasive behavioural treatment options have **failed (Level of evidence: 1)** and there is the suggestion that percutaneous TNS may be as effective as some drug therapy, making it a viable alternative. **(Level of evidence: 2)**

Only four trials investigated transcutaneous TNS. One large trial showed no effect on UI of unspecified type in older people dependent on staff to use a toilet. **(Level of evidence: 2)** The other three trials showed promising results suggesting further well-designed and reported trials in different adult populations would allow decisions to be made about the place of transcutaneous TNS in the treatment algorithms for OAB/UUI in men and women. **(Level of Evidence: 2)**

A single RCT has demonstrated non-inferiority of transcutaneous TNS compared to percutaneous TNS in decreasing daytime frequency and UUI episodes in men and women with idiopathic OAB. **(Level of evidence: 1b)**

Health economic information is required to establish the cost effectiveness of the different forms of TNS, particularly in comparison to pharmacotherapy.

Based on the included studies percutaneous TNS continues to use a standard protocol regarding stimulation parameters of frequency and session duration. Most studies report using the Urgent PC™ stimulator however the study comparing transcutaneous and percutaneous TNS (343) used an alternative low voltage stimulator (URO STIM). The number of individual sessions, overall duration of programme and timing of delivery protocols remain varied. There is also variation between percutaneous and transcutaneous stimulation parameters This variability re-

flects the limited understanding of the mechanisms of TNS effect, which cannot be assumed to be identical for both percutaneous and transcutaneous routes of delivery. Further investigation is required, for both percutaneous and transcutaneous TNS, to determine the most effective type of stimulation and treatment protocols and further compare the modalities for superior intervention in different populations.

Recommendations for practice:

In adults with OAB/UUI percutaneous TNS is better for improving UUI than no treatment or sham and can be offered to adults with UUI/OAB who do not achieve satisfactory results from first-line lifestyle and behavioural interventions or drug therapy. **(Grade of recommendation: B)**

At least weekly TNS sessions can be offered during an active treatment programme with regular top-ups provided to sustain benefits for up to three years. **(Grade of recommendation: B)**

Transcutaneous TNS can be offered as an alternative to percutaneous TNS for treating adults with idiopathic OAB/UUI. Transcutaneous TNS can be the recommendation of choice and preferred by patients and clinicians as it is a less invasive approach, with reduced related adverse effects. **(Grade of recommendation: B New)**

Transcutaneous TNS cannot be offered to frail older adults with UI who are dependent on others to use a toilet as there is evidence of no effect **(Grade of recommendation: B New)**

Percutaneous TNS can be offered as an alternative to tolterodine for OAB/UUI in adult men and women. **(Grade of recommendation: B)**

Future research directions:

Currently available evidence compares percutaneous TNS with older antimuscarinics. Future rigorous trials should compare percutaneous TNS with other commonly used antimuscarinics and beta 3 adrenergic agonists for efficacy and adverse effect profiles, in men and women with OAB/UUI.

The effectiveness of adding drug therapy to percutaneous and transcutaneous TNS should be further investigated in high quality trials with adults with OAB/UUI.

Trials of new delivery systems for TNS, such as use of implanted tibial nerve stimulators are needed.

Further evidence of the effectiveness of transcutaneous TNS to treat OAB/UUI in adults is needed and its place in the treatment algorithm should be clarified, especially in relation to percutaneous TNS.

Research comparing transcutaneous TNS with all types of drug therapy is required.

Further rigorous and well-reported trials are needed to establish the most effective dose of percutaneous TNS and transcutaneous TNS, including the timing and duration of TNS protocols, stimulation parameters and maintenance regimes.

Cost-effectiveness of percutaneous and transcutaneous TNS needs to be established, especially in relation to other forms of treatment, including drug therapies and botulinum toxin.

Evidence on longer term outcomes of percutaneous and transcutaneous TNS is needed.

VI. NEUROLOGICAL CONDITIONS

Conservative Management of UI in Neurological Patients

UI is commonly reported by patients with neurological disorders and the pattern of lower urinary tract (LUT) dysfunction is influenced by the site of the neurological lesion in the neuraxis. Suprapontine lesions affect the cerebral cortex, subcortical white and grey matter and upper brainstem following stroke, neurodegeneration (e.g., Parkinson's disease (PD), Alzheimer's disease) and neuroinflammation (multiple sclerosis), resulting predominantly in urinary storage symptoms and UUI. The spinal cord is affected by neuroinflammation (multiple sclerosis (MS)), trauma and congenital anomalies (spinal bifida), typically resulting in mixed storage and voiding symptoms. Disorders affecting the conus, cauda equina and peripheral nerves result predominantly in voiding dysfunctions.

This new section reviews the evidence for the effects of conservative management on neurogenic UI. The interventions are grouped into PFMT, EStim (including tibial nerve stimulation and TENS performed in other regions), acupuncture, toilet assistance and multimodal rehabilitation intervention. Eligibility criteria for study participants and outcomes, as well as criteria used to assess ROB in the included studies, are identical to those described in the previous sections. Highest levels of evidence available were reviewed and they are summarized in the different tables in this section. Table 50 provides an overview of the included studies of conservative management for UI in neurological patients. As this is a new section, we limited the assessment of the literature and levels of recommendations to conservative management only.

Table 50. Studies of conservative management for UI in neurological patients

Intervention	Number of studies	Outcomes assessed

Parkinson's Disease	3	
Multiple Sclerosis	4	
Mixed Neurological group	2	
TENS performed in other regions		
Stroke	2 -Positive electrode (second lumbar spinous process), Negative electrode (middle and lower third of junction between posterior superior iliac spine and ischial node) -Positive electrode (second sacral level), Negative electrode (middle and lower third of junction between posterior superior iliac spine and ischial node)	OAB (1), OAB/ urinary incontinence (1)
Mixed neurological group	1 (intravaginal/intra-anal electrical stimulation vs pudendal nerve)	LUTS (1)
Multiple Sclerosis	2	OAB (1), OAB/ urinary incontinence (1)
Acupuncture		
Stroke	Electroacupuncture (6), acupuncture (9)	urinary incontinence (10), LUTS (2), OAB (1), urinary functions (1)
Spinal Cord Injury	Electroacupuncture (1)	urinary incontinence (1), LUTS (1)
Parkinson's Disease	Electroacupuncture (1)	urinary incontinence (1)
Toilet assistance		
Stroke	Bladder training (2), timed voiding (2), systematic voiding programme (1)	urinary incontinence (3), urinary incontinence/ urgency incontinence (1)
Spinal Cord Injury	Bladder training (1)	urinary incontinence (1)
Parkinson's Disease	Bladder training (1)	urinary incontinence, OAB (1)
Multimodal rehabilitation intervention		
Multiple Sclerosis	Bladder management programme (1)	LUTS (1)
Spina bifida	High intensity rehabilitation programme including bladder/ bowel management programme (1)	LUTS (1)

1. PELVIC FLOOR MUSCLE TRAINING

1.1. Prevention

There were no studies identified.

1.2. Treatment

There were 17 RCTs that included PFMT in a study arm (348-367), and the characteristics of these studies are presented in Table 51. The interventions studied were highly variable and usually combined with other modalities of treatment. PFMT alone was only assessed in five studies (348, 350, 358, 361-364). PFMT with intravaginal or intra-anal EStim was evaluated in three studies (350, 351, 357, 365), and with biofeedback in five (350, 353, 355-357, 365). PFMT was combined with other interventions, such as education about pelvic anatomy and function (354, 359, 366), general rehabilitation (359, 360), surface electrical muscle stimulation (348, 360), exercises (i.e., breathing and relaxation exercises) (352), BT (354, 366), intermittent catheterisation (367) medication (349, 353), fluid management (366), and a video about behavioural management (349). The PFMT intervention was either supervised (351, 353-356, 358, 359, 361-364) or performed at home unsupervised (348, 350, 357, 358, 365, 366) (Table 51).

Quality of data

Randomisation was considered appropriate in 12 studies (348, 350, 351, 353, 355-359, 361-364, 366, 367) and could not be determined in the remaining studies. Allocation concealment could be assessed in only two studies and was considered adequate (357, 366). Two studies were double blinded (355-357) and evaluators alone were blinded in four studies (350, 351, 359, 364, 366). Information regarding an ITT analysis was obtainable in only four studies (350, 357, 366) and was performed in two (357, 366). Loss to follow-up was reported in only two studies (350, 355, 356).

Results

Table 51 summarizes the results of these studies. Studies evaluating PFMT in patients with MS and post-stroke demonstrated a significant improvement in UI symptoms when compared to no-treatment (i.e., not related to active LUTS treatment including general education or rehabilitation) or sham treatment (355, 356, 359, 361-363). However, in a cohort of post-stroke men, PFMT was associated with an improvement in PFM strength and function but not LUTS (364). Nonetheless, this study included (364) a small sample size with a long-term follow-up (six months), and although the attendance to weekly PFMT was high, the consistency of the training might not have been monitored. One study, in patients after stroke assessing supervised PFMT, demonstrated improvements in UI severity when compared to unsupervised PFMT at home (358). This finding is in line with PFMT results found in non-neurological female patients with UI (refer to section II.2.3.1).

Studies evaluating the addition of biofeedback to PFMT showed mixed results. Improvement in OAB and UI symptoms was noted in MS patients when the intervention was added to intravaginal or intra-anal EStim (351, 357, 365). However, in a study evaluating a cohort of MS patients (353), no significant improvement in incontinence episodes was observed in those receiving EMG biofeedback and medication. Likewise, in a cohort of women with incomplete spinal cord injury (SCI), no further benefit in continence was seen with the addition of intravaginal or intra-anal EStim, although both treatment groups improved after intervention (350). Other than differences in the population and the addition of intravaginal or intra-anal EStim to the intervention arm, studies that showed benefit presented a much larger sample size than the studies with no benefit.

PFMT as part of a multimodal behaviour therapy in a cohort of patients with PD was found to be more effective in reducing incontinence episodes compared to a control (366).

One of the studies primarily evaluated the addition of mirabegron to a PFMT intervention with behavioural management (349) and was therefore not considered when determining a recommendation. Another study (367) compared PFMT with intermittent urethral catheterisation to plum-blossom needle and was also not considered when determining a recommendation. One further study (352) analysed the efficacy of PFMT and exercises for UI on SCI patients, however, this study did provide information about the type and level of injury.

No serious adverse events were reported in any of these studies. However, one participant in the PFMT group reported soreness in the pelvic area. (350)

Summary

A total of 17 RCTs across different neurological groups, including MS, incomplete SCI, Parkinson's disease, Alzheimer disease and post-stroke, assessed the effects of PFMT on UI, OAB symptoms and/or LUTS against an active, no treatment or placebo comparator.

The interventions that were evaluated and the study designs adopted differed considerably between studies. Data from two well-designed high-quality studies in MS and PD patients (357, 366) (**Level of evidence: 2a)** and most of the other studies (**Level of evidence: 2**) demonstrated a significant improvement in UI symptoms, LUTS and QoL across different neurological groups following supervised or home PFMT combined with biofeedback and also with added active treatments such as intravaginal EStim, BT, and behavioural management. (**Level of evidence: 2**)

Recommendation

PFMT alone or combined with other active treatments is an effective and safe treatment, more effective than no active treatment for managing OAB and related UI symptoms. Therefore, PFMT can be recommended as first line treatment in patients with MS, incomplete SCI, PD, and post-stroke. **(Grade of recommendation: B New)**

These findings need to be investigated further with larger good-quality trials.

Table 51. RCT studies evaluating PFMT

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Bottini (2019) (348)	RCT	Multiple sclerosis and Myelopathy associated with HTLV-I Single centre Brazil	Group 1 (n=10): PFMT at home (2x/week) during 4 months Group 2 (n=10): PFMT at home + electrical stimulation (2x/week, 1 hour) during 4 months	-Overactive bladder version 8 (OABv8): Group 2 showed significant improvement when compared to baseline (p = 0.001) Statistical comparisons between groups are not reported - Qualiveen Instrument: NR	Adverse effects: NR Follow-up: post-intervention (4 months)
Brown (2020) (349) Abstract	RCT	Multiple Sclerosis USA	Group 1 (n=14): PFMT + Mirabegron (25 – 50 mg) + Behavioral management during 10 weeks Group 2 (n=14): PFMT + Placebo + Behavioral management during 10 weeks	- OAB Symptom Composite Score Group 1 was 0.47 (95% CI 0.047 to 0.893, p=0.031) higher than Group 2. Incontinence episodes: no significant difference between groups	Adverse effects: none Follow up: post-intervention (10 weeks)
Elmelund (2018) (350)	RCT	Incomplete spinal cord injury Single centre Denmark	Group 1 (n=17): PFMT (daily) during 12 weeks Group 2 (n=19): PFMT (daily) + intravaginal electrical stimulation (daily) during 12 weeks All participants were trained by a physiotherapist but the intervention was performed at home. The PFMT training included digital vaginal and rectal palpation and EMG biofeedback.	-ICIQ-UI-SF: between group comparison showed no significant difference at 12 and 24 weeks. The within-group analyses showed a significant improvement from baseline at 12 and 24 weeks in the PFMT group -3-day bladder diary/ Daily UI: between group comparison showed no significant difference at 12 and 24 weeks. Daily incontinence episodes showed improvement from baseline at 12 and 24 weeks in the PFMT group. -Pad Test 24h: between group comparison showed no significant difference at 12 and 24 weeks. The within group comparison showed improvement in the Group 2 at 12 weeks and Group 1 at 24 weeks follow-up. -ICIQ-OAB: between group comparison showed no significant difference at 12 and 24 weeks. The within group comparison showed improvement in the Group 2 at 24 weeks -Patient Global Impression of Improvement scale (PGI-I): between group comparison showed no significant difference at 12 and 24 weeks.	Adverse effects: Group 1: soreness in PF area (n=1) Group 2: none Follow up: post-intervention (12 weeks) and 24 weeks

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Ferreira (2019) (351)	RCT	Multiple Sclerosis Single centre Brazil	Group 1 (n=16): Supervised PFMT and intravaginal electrical stimulation (30 minutes 2x/week) during 6 months Group 2 (n=15): home PFMT during 6 months	Qualiveen questionnaire: For general QoL the within-group analyses showed a significant improvement from baseline to 6 months in Group 1. The between group comparison showed significant difference favoring the Group 1. OAB Assessment Questionnaire: The within-group analyses showed a significant improvement from baseline to 6 months in both groups. The between group comparison showed significant difference favoring the Group 1.	Adverse effects: NR Follow-up: post-intervention (6 months)
Gaikwad (2020) (352)	RCT	Spinal cord injury Single centre India	Group 1 (n=14): Conventional exercises (medication, electrical stimulation – 20 minutes and exercises training, timed voiding program and intermittent catheterization) (3x/week, 30-45 minutes) during 4 weeks Group 2 (n=14): PFMT + exercises (3x/week, 30-45 minutes) during 4 weeks	-King's Health Questionnaire significant within and between group difference on incontinence impact, severity measures and symptom severity. -1h Pad Test Significant improvement in Group 1 and 2 (p=0.0288). Group 2 had greater efficacious mean value when compared to Group 1.	Adverse effects: NR Follow-up: post-intervention (4 months)
Klarskov (1994) (353)	RCT	Multiple Sclerosis Denmark	Total patients randomized n=20 Group 1: biofeedback using bladder pressure and surface EMG + supervised PFMT (40 minutes, 2x/week) + medication Group 2: supervised PFMT (40 minutes, 2x/week) + medication	-Number of Incontinence Episodes and pad changes: not reported. -Pad test 60 minutes: not reported. -Visual Analogue Scales for Incontinence: not reported. No difference between groups. However, the authors presented the results from both groups as a whole with significant reduction on the visual analogue scale for UI and significant decrease in the daily number of UI episodes and use of pads on the dairy. There was no difference in the pad test.	Adverse effects: NR Follow up: NR
Lee (2017) (354)	RCT	Alzheimer disease or cognitive impairment Single centre Korea	Group 1 (n=52): supervised PFMT with vaginal palpation and verbal feedback (6 sessions, 60 minutes at 2 weeks intervals) + home exercises + PF Education + bladder training during 12 weeks Group 2 (n=46): PF Education + bladder training	-Frequency volume chart UI: Groups 1 and 2 showed significant within group improvement when compared to baseline ($p<0.05$) at 12 weeks. Significant reduction in Group 1 compared to Group 2 ($p<0.001$). -ICIQ-UI-SF: no significant difference between and within groups at 4 weeks. Group 1 showed significant within group improvement when compared to baseline ($p<0.01$) at 12 weeks. Significant reduction in Group 1 compared to Group 2 ($p<0.001$) at 12 weeks.	Adverse effects: NR Follow up: Follow up: Mid and post-intervention (4, and 12 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Lucio (2011) (355, 356)	RCT	Multiple Sclerosis Single centre Brazil	Group 1 (n=18): supervised PFMT with assistance of vaginal perineometer (2x/week, 30 minutes) + home PFMT (3x/daily) during 12 weeks + home exercises Group 2 (n=17): Introduction of vaginal perineometer without contraction (2x/week, 30 minutes) during 12 weeks	-Pad Test 24h: Group 1 showed significant reduction when compared Group 2 (p = 0.001) -UUI: Group 1 showed significant reduction when compared Group 2 (p<0.0013). -Nocturnal enuresis: Group 1 showed significant reduction when compared Group 2 (p<0.0034). -Overactive bladder version 8 (OABv8): Group 1 showed significant reduction when compared Group 2 (p<0.0001). -ICIQ-UI-SF: Group 1 showed significant reduction when compared Group 2 (p=0.0003). -Qualiveen Instrument: 1) Specific Impact of Urinary Problems on Quality of Life (SIUP): Group 1 showed significant reduction when compared Group 2 (p=0.0001). 2) General Quality of Life: Group 1 showed significant reduction when compared Group 2 (p=0.0443).	Adverse effects: NR Follow up: post-intervention (12 weeks)
McClurg (2008) (357)	RCT	Multiple Sclerosis Multi centre UK	Group 1 (n=37): home PFMT (daily) + EMG biofeedback (1x/week, 15 min) + placebo neuromuscular electrical stimulation (daily, 30 minutes) during 9 weeks Group 2 (n=37): home PFMT (daily) + EMG biofeedback (1x/week, 15 min) + active neuromuscular electrical stimulation (2 parameters: a) correct use of PFM (1x/week, up to 30 min – supervised); and b) inhibition of detrusor overactivity (daily, up to 30 minutes) during 9 weeks	-Leakage episodes per 24h: Groups 1 and 2 showed significant within group improvement when compared to baseline (p≤0.001) at 9, 16 and 24 weeks. Significant reduction in Group 2 compared to Group 1 (p<0.001) at 9 weeks. No significant difference in between group comparison at 16 and 24 weeks. -24h Pad Test: Groups 1 and 2 showed significant within group improvement when compared to baseline (p=0.001) at 9, 16 and 24 weeks. Significant reduction in Group 2 compared to Group 1 (p≤0.005) in all time points. -Incontinence Impact Questionnaire (IIQ) and Urogenital Distress Inventory (UDI): There was a significant superior benefit in Group 2 in the irritative subscale of the UDI at weeks 16 and 24 (p≤0.043).	Adverse effects: none Follow up: post-intervention (9 weeks), 16 and 24 weeks.

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Perez (2020) (358)	RCT	Multiple Sclerosis Multi centre Spain	Group 1 (n=24): Unsupervised PFMT at home (3x/day) during 12 weeks Group 2 (n=24): Supervised PFMT at home (2-3x/day) + 30 min weekly physiotherapist appointment during 12 weeks	-Leakage reduction: Groups 1 and 2 showed significant within group improvement when compared to baseline (p≤0.001) at 12 weeks. No significant difference in between group comparison at 12 weeks. -ICIQ-UI – SF 1)UI severity both groups showed improvement when compared to baseline (p<0.05) at 4, 8 and 12 weeks. No significant difference in between group comparison at 4 weeks. Significant improvement in Group 2 when compared to Group 1 (p<0.05) at 8 and 12 weeks. 2)QoL: Groups 1 and 2 showed significant within group improvement when compared to baseline (p<0.05) at 4, 8 and 12 weeks. No significant difference in between group comparison at 4, 8 and 12 weeks. -OABQ-SF 1)LUTS: Groups 1 and 2 showed significant within group improvement when compared to baseline (p≤0.05) at 4, 8 and 12 weeks. No significant difference in between group comparison at 4, 8 and 12 weeks. 2)QoL: No significant difference in within group comparison at 4 weeks in both Groups and in Group 1 at 8 weeks. Groups 1 and 2 showed significant within group improvement when compared to baseline (p=0.001) at 12 weeks. No significant difference in between group comparison at 4, 8 and 12 weeks.	Adverse effects: NR Follow up: Mid and post-intervention (4, 8, and 12 weeks)
Shin (2016) (359)	RCT	Stroke Single centre Korea	Group 1 (n=18): Supervised PFMT (3x/week, 50 minutes) + PF Education + General rehabilitation – gaiting training and stretching (3x/week, 50 minutes) during 6 weeks Group 2 (n=17): PF Education + General rehabilitation – gaiting training and stretching (3x/week, 50 minutes) during 6 weeks	-Bristol Female Urinary Symptoms Questionnaire Inconvenience (activities of daily living): significant reduction in Group 1 when compared to Group 2 (p<0.01). -Urinary Symptoms: significant reduction in Group 1 when compared to Group 2 (p<0.01).	Adverse effects: NR Follow up: post-intervention (6 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Smilskalne (2009) (360) Abstract	RCT	Stroke Latvia	Group 1: Conventional physiotherapy (5x/week, 1 hour) during 4 weeks Group 2: Conventional physiotherapy (5x/week, 1 hour) + PFMT (5x/week, 30 minutes) during 4 weeks Group 3: Conventional physiotherapy (5x/week, 1 hour) + PFMT (5x/week, 30 minutes) + functional electrical stimulation (5x/week, 15 minutes) during 4 weeks	-Urogenital distress inventory (UDI-6) Comparing results of the Group 1 and 2 the difference is not statistically significant	Adverse effects: NR Follow up: post-intervention (4 weeks)
Tibaek (2005) (361-363)	RCT	Stroke Multi centre Denmark	Group 1 (n=14): Supervised PFMT (1x/week, 1 hour) + home exercises (1-2x/day) during 3 months Group 2 (n=12): Standard program of general rehabilitation without UI treatment	-Number of urinary incontinence episodes 24h: no significant difference within and between groups. -Pads test 24h number and weight: no significant difference within groups. Significant reduction in weight on Group 1 when compared to Group 2 (p=0.013) at 12 weeks. -Incontinence Impact Questionnaire (IIQ): no significant difference within groups in all time points. No significant difference between groups at 6 months.	Adverse effects: NR Follow up: post-intervention (12 weeks) and 6 months
Tibaek (2017) (364)	RCT	Stroke Multi centre Denmark	Group 1 (n=16): Supervised PFMT (1x/week, 1 hour) + home exercises during 3 months Group 2 (n=15): Standard program of general rehabilitation without LUTS treatment	-Danish Prostatic Symptom Score (DAN-PSS-1) 1)Symptom score: Groups 1 and 2 showed significant within group improvement when compared to baseline (p<0.01) at 12 weeks and no significant difference at 6 months. No significant difference between group at 12 weeks and 6 months. 2)Bother score: Groups 1 and 2 showed significant within group improvement when compared to baseline (p=0.01) in both groups at 12 weeks and in Group 2 at 6 months. No significant difference between group at 12 weeks and 6 months. 3)Total score: Groups 1 and 2 showed significant within group improvement when compared to baseline (p<0.01; p=0.03) at 12 weeks and no difference at 6 months. No significant difference between group at 12 weeks and 6 months. -3-day voiding diary: not reported.	Adverse effects: none Follow up: post-intervention (12 weeks) and 6 months

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Vahtera (1997) (365)	RCT	Multiple Sclerosis Single centre Finland	Group 1 (n=40): Intravaginal and intra-anal electrical stimulation (6 sessions/2 weeks; during 10 minutes each frequency) + biofeedback PFMT (1or 2 sessions) + home PFMT (3-5x/week) during 6 months Group 2 (n=40): None	-Leakage of urine in the absence of effort: no significant between-group difference at week 3 and 2 months. Significant reduction in Group 1 compared to Group 2 at 6 months (p<0.05). -Leakage of urine on minimal effort: no significant between-group difference at 2 months. Significant reduction in Group 1 compared to Group 2 at week 3 (p<0.001) and 6 months (p<0.001). -Leakage of urine on heavy effort: Significant reduction in Group 1 compared to Group 2 at week 3 (p<0.001), 2 months (p<0.001), and 6 months (p<0.001). -Volume of urine loss: Significant reduction in Group 1 compared to Group 2 at week 3 (p<0.001), 2 months (p<0.001), and 6 months (p<0.001). -Severity of Lower Urinary Tract Symptoms: no significant between-group difference at week 3, 2 months, and in women at 6 months. Significant between-group difference in men at 6 months.	Adverse effects: none Follow up: Mid and post-intervention (3 weeks, 2 and 6 months)
Vaughan (2019) (366)	RCT	Parkinson's Disease Multi centre USA	Group 1 (n=26): Home PFMT (daily) + bladder training + fluid management + education during 8 weeks Group 2 (n=27): Practice mirrored-shape drawings (1x/day, 15 minutes) during 8 weeks	-Bladder diary UI: no significant difference between groups -ICIQ-OAB/Symptom score: no significant difference between groups -ICIQ-OAB/Bother Score: significant reduction in Group 1 compared to Group 2 (p=0.048) -ICIQ-OAB/Quality of life: significant reduction in Group 1 compared to Group 2 (p=0.037)	Adverse effects: NR Follow up: post-intervention (8 weeks)
Zhang (2019) (367)	RCT	Stroke China	Group 1 (n=30): PFMT + intermittent urethral catheterization during 2 months Group 2 (n=30): Plum-blossom needle (5x/week) + moxibustion (5x/week, 15 minutes) + intermittent urethral catheterization during 2 months	-Frequency of Urinary Incontinence: significantly decreased in both groups (p<0.05). Between group comparison showed a significant improvement in Group 2 (p<0.05).	Adverse effects: NR Follow up: post-intervention (2 months)

2. ELECTRICAL STIMULATION

This section assesses EStim on UI and is divided into tibial nerve EStim, under which transcutaneous TNS and percutaneous TNS will be discussed, and TENS performed in other regions.

2.1. Tibial Nerve Stimulation

2.1.1. Transcutaneous TNS

2.1.1.1. Prevention

There were no studies identified.

2.1.1.2. Treatment

Nine RCTs (146, 368-375) (Table 52) and two non-RCT open label studies (376, 377) (Table 53) were retrieved evaluating transcutaneous TNS in small numbers of participants (ranging from five (375) to 50 (370)). The study design varied considerably and transcutaneous TNS was evaluated alone. However, in one study, transcutaneous TNS was assessed when combined with education about pelvic anatomy and function (371). In another study (372), TTNS was combined with PFMT and biofeedback. Duration of stimulation was 20 minutes (368) or 30 minutes (146, 369-371, 373-375), and the treatment was performed daily (368), thrice weekly (146), twice weekly (369, 370, 372-375), or weekly (371). The length of the intervention lasted for four weeks (370), five weeks (374), six weeks (369, 373, 375), nine weeks (371) and twelve weeks (146, 368, 372). The comparator arm used sham treatment in most studies (146, 368, 369, 373-375), medication (370), general advice/stretching of the lower limbs (373), PFMT and biofeedback (371), or intravaginal EStim (372).

Quality of data

Randomisation was considered appropriate in five studies (146, 368, 369, 372, 374). Allocation concealment was considered adequate in two studies (146, 369). Five studies were double blinded (146, 368, 369, 374, 375), whereas only the assessor was blinded in two studies (371, 372). Information regarding blinding of participants was considered as high ROB in four studies given the nature of the intervention (370-373). Information regarding an ITT analysis was obtainable in only four studies (146, 371, 372, 374) and loss to follow-up was reported in two studies (371, 374) (Table 52).

Results

The results are presented in Tables 52 and 53. Different outcomes were measured in the studies. A significant improvement was reported in most studies, mainly in the intervention arm compared to baseline (368, 370-374). The between group comparisons showed that improvement in bladder-related symptoms (UI, OAB symptoms) and QoL was reported in some studies with PD and MS participants (368, 372). However, most studies showed no improvement compared to the control group (146, 369-371, 373, 374). One of the studies primarily assessed feasibility and did not evaluate efficacy (375). In studies where transcutaneous TNS was compared to sham stimulation (146, 368, 369, 374, 375), a significant improvement was observed only in one study (368) with PD patients. The study presented improvement in the bladder diary and 24-hour outcomes, including night-time urinary frequency, urinary urgency, UUI episodes, use of pads, and questionnaires such as the OAB-V8 and King's Health Questionnaire scores, which were reported three months after the intervention (368). The sample studied was small, although a rationale for powering the study was provided.

No serious adverse effects were reported in any of the studies in the transcutaneous TNS arm. However, one study (369) reported that one participant presented minor skin irritation and other reported ankle cramping. In the study that compared transcutaneous TNS with solifenacin (370), five participants that received the medication reported dry mouth, and two of these dropped out of the study because of this side effect.

Summary

A total of nine RCTs and two non-RCT open label studies assessed the effects of transcutaneous TNS on UI, OAB symptoms and/or UUI compared to an active or sham comparator across different neurological groups including PD, post-stroke, incomplete SCI, MS and mixed neurological participants.

The interventions evaluated and the study designs adopted differed considerably between studies.

Although data from the studies demonstrate a significant improvement in the symptoms of participants after treatment, only one study comparing transcutaneous TNS to a sham treatment (368) demonstrated efficacy in participants with PD. (**Level of evidence: 2**)

Recommendation

Based on the evidence available, TNS to reduce OAB and related UI symptoms in patients with PD MS, incomplete SCI, post-stroke and mixed neurological diseases could be considered. More studies are needed. **(Grade of recommendation: C New)**

Table 52. RCT studies evaluating TTNS

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Araujo (2021) (368)	RCT	Parkinson's Disease Single centre Brazil	Group 1 (n=18): Transcutaneous tibial nerve stimulation (daily, 20 minutes) during 12 weeks Group 2 (n=18): Sham transcutaneous tibial nerve stimulation (daily, 20 minutes) during 12 weeks	Relief of bladder symptoms showed significant between group difference at 12 weeks and 90 days follow-up. No significant difference at 30 days. Number of urgency incontinence episodes showed significant within and between group. Number of pads showed significant within and between group. Overactive bladder version 8 (OABv8) showed significant within and between group. King's Health Questionnaire: - Impact of incontinence showed significant within and between group at 12 weeks. -Severity of urinary symptoms significant within group difference and no between group difference (p=0.089) at 12 weeks.	Adverse effects: NR Follow up: post-intervention (12 weeks), 30- and 90-days follow-up (after intervention).
Booth (2016) (369)	RCT	Stroke UK	Group 1 (n=27): Transcutaneous tibial nerve stimulation (2x/week, 12 sessions, 30 minutes) during 6 weeks Group 2 (n=27): Sham stimulation (2x/week, 12 sessions, 30 minutes) during 6 weeks	The study did not detect any significant difference between groups for number of participants continent after treatment, number of incontinent episodes and health status and quality of life.	Adverse effects: Group 1 and 2: one participant (3.7%) each group had residual urine volume of more than 150ml at the 6-weeks bladder scan. One participant (group unclear) had minor skin irritation and other reported ankle cramping. Follow up: post-intervention (6 weeks) 12, and 26 weeks follow-up
Chen (2015) (370)	RCT	Spinal cord injury China	Group 1 (n=50): Transcutaneous tibial nerve stimulation (30 minutes, 2x/week) during 4 weeks Group 2 (n=50): Solifenacin succinate (5mg, 1x/day) during 4 weeks	Total leakage volume statistical difference within groups at 2 and 4 weeks ($p<0.05$). Incontinence Quality of Life (I-QoL) statistical difference within groups at 2 and 4 weeks ($p<0.05$). No significant improvements between groups	Adverse effects: Group 1: none Group 2: 5 participants had dry mouth (2 drop out because of the side effect) Follow-up: Mid and post-intervention (2 and 4 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Gaspard (2014) (371)	RCT	Multiple sclerosis Single centre Belgium	Group 1 (n=15): Transcutaneous tibial nerve stimulation + PF education (9 sessions, 30 minutes/week) during 9 weeks Group 2 (n=16): PFMT with biofeedback (9 sessions, 30 minutes/week) + home exercises (2x/day) + PF education during 9 weeks	SF-Qualiveen questionnaire score significant difference within groups at 6 months. Frequency of urgency episodes significant difference within groups at 6 months. The study did not detect any significant difference between the 2 groups for quality of life (p = 0.197) and overactive bladder (p = 0.532). Only the Qualiveen fears score varied in favor of the PFMT group at 9 weeks (p = 0.040).	Adverse effects: none Follow up: post-intervention (9 weeks) and 6 months
Lucio (2016) (372)	RCT	Multiple Sclerosis Single centre Brazil	Group 1 (n=10): supervised PFMT with EMG biofeedback + sham sacral neuromuscular electrical stimulation (2x/week) during 12 weeks Group 2 (n=10): supervised PFMT with EMG biofeedback + intravaginal neuromuscular electrical stimulation (2x/week) during 12 weeks Group 3 (n=10): supervised PFMT with EMG biofeedback + transcutaneous tibial nerve stimulation (2x/week) during 12 weeks All participants were instructed to perform PF contractions at home.	24h Pad Test- all groups presented significant reductions in the post-intervention and no difference between group comparison. Overactive bladder version 8 (OABv8): all groups presented significant reductions in the post-intervention and between group: Group 2 improved more than Groups 1 and 3 (p<0.01). Urge urinary incontinence: all groups presented significant reductions in the post-intervention and no difference between group comparison (p=0.83). ICIQ-UI-SF: all groups decreased scores and no statistically significant differences were found among the 3 groups. Qualiveen Instrument Specific Impact of Urinary Problems on Quality of Life (SIUP): significant difference in the post-intervention in Group 2 and no difference in Groups 1 and 3. Between group comparison showed that Group 2 improved more than Groups 1 and 3 (p<0.01). Health Related Quality of Life Ns	Adverse effects: NR Follow up: post-intervention (12 weeks)
Monteiro (2014) (373)	RCT	Stroke Single centre Brazil	Group 1 (n=12): Transcutaneous electrical stimulation of tibial nerve (2x/week, 30 minutes, 12 sessions) during 6 weeks Group 2 (n=12): Stretching session of lower limbs (1-3x/month, 30 minutes, 12 sessions) + general advice during 6 weeks	Urge Urinary Incontinence: Group 1 presented significant difference in the post-intervention at 6 weeks. No between group difference at 6 and 12 weeks. Nocturnal enuresis: No within and between group differences at 6 and 12 weeks.	Adverse effects: none Follow up: post-intervention (6 weeks) and 12 months

Abbreviations: NR: not reported; QoL: quality of life; OABv8: Overactive bladder version 8; TTNS: Transcutaneous tibial nerve stimulation.

2.1.2. Percutaneous TNS

2.1.2.1. Prevention

There were no studies identified.

2.1.2.2. Treatment

There were no RCT studies found, however nine single-arm cohort studies were identified (378-386), evaluating percutaneous TNS in a variable number of participants (ranging from 14-83). The characteristics of these studies are presented in Table 54. In all the studies, 20 Hz stimulation was delivered percutaneously for a duration of 30 minutes, once per week for 12 weeks.

Results

The results are presented in Table 54. Except for one study, most reported improvement of UI symptoms and OAB and/or QoL after percutaneous TNS (378-386). No adverse events were reported in any of these studies.

Summary

A total of nine single-arm cohort studies assessed the effects of percutaneous TNS on UI, OAB symptoms and/or UUI across different neurological groups including PD, MS and mixed neurological participants.

The data demonstrated a significant improvement in symptoms after percutaneous TNS.

However, these observations are based on studies without a comparison group. (**Level of evidence: 3**)

Recommendation

Percutaneous TNS could be considered for UI in neurological patients. Adequately powered well-designed RCTs are needed to confirm the effectiveness of PTNS for neurological patients. **(Grade of recommendation: C New)**

Table 54. Non-RCT studies evaluating PTNS

Author, year	Type of study	Population	Intervention	Outcome	Notes:
El-Senousy (2013) (378)	Cohort	Parkinson's Disease Single centre Egypt	n=33 PTNS: Unilateral needle 5 cm above the medial malleolus and posterior to the tibial edge. Electrical stimulation was performed with pulse width 200 msec frequency of 20 Hz and individualized amplitude equal to 1.5 threshold for evoking toes plantar flexion and/or fanning (1x/week, 30 minutes) during 12 weeks.	Leakage and urge incontinence episodes significantly decrease after PTNS (p=0.001; p=0.04) There was a significant improvement in total IPSS score among patients with moderate disability after PTNS. No statistical difference in patients with mild and severe stages of disability.	Adverse effects: none Follow up: post-intervention (12 weeks)
Finazzi-Agrò (2003) Abstract (379)	Cohort	Mixed neurological patients Italy	n=14 PTNS: A needle was inserted 5 cm cephalad to the medial malleolus. Electrical stimulation was performed with pulse width 200 msec frequency of 20 Hz and adjustable current 0-10mA (1x/week, 30 minutes) during 12 weeks.	Number of leakages per 24h was not statistically significant Effect size: -4.0 (-12.94 to 4.94)	Adverse effects: none Follow up: post-intervention (12 weeks)
Gobbi (2011) (380)	Cohort	Multiple sclerosis Multi centre	n=18 PTNS: Unilateral needle 5 cm above the medial malleolus and slightly posterior to the tibial. A surface electrode was placed on the ipsilateral calcaneus. Electrical stimulation was performed with a current level of 0.5-9 mA using charge-compensated 200 um with a pulse rate of 20 Hz based on each subject's footplantar motor and sensory responses (1x/week, 30 minutes) during 12 weeks.	No statistical differences in the number of patients with UI (p=0.6). Significant improvement in QoL in most domains of the Kings Health Questionnaire (p<0.05). Patient perception of bladder condition (PPBC) significant improvement of LUTS (p=0.003).	Adverse effects: none Follow up: post-intervention (12 weeks)
Kabay (2009) (381)	Cohort	Multiple sclerosis Turkey	n=19 PTNS: Unilateral needle 5 cm above the medial malleolus and posterior to the edge of the tibia. A ground electrode was placed on the ipsilateral extremity. Electrical stimulation was applied using charge-compensated 200 usec pulses with a pulse rate of 20 Hz. Intensity level was then chosen as the intensity immediately under the threshold determining motor contraction (1x/week, 30 minutes) during 12 weeks.	Mean OAB score was statistically significant when compared to before TTNS (p<0.05) Number of leakages per 24h was not statistically significant* Effect size: -3.1 (-12.04 to 5.84)	Adverse effects: none Follow up: 12 weeks

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Kabay (2016) (382)	Cohort	Parkinson's Disease Turkey	n=47 PTNS: Unilateral needle 5 cm above the medial malleolus and posterior to the edge of the tibia. Electrical stimulation was applied using charge-compensated 200 usec pulses with a pulse rate of 20 Hz. Intensity level was then chosen as the intensity immediately under the threshold determining motor contraction during 12 weeks.	Urge incontinence decreased by 3.1 episodes daily (p<0.001) The change from baseline on the ICIQ-SF, OABv8, and OAB-q at 12-week PTNS treatment demonstrated significant difference in symptom severity and health-related QoL (P <.001)	Adverse effects: none Follow up: 12 weeks
Kabay (2017) (383)	Cohort	Multiple sclerosis Turkey	n=21 PTNS: Unilateral needle 5 cm cephalad from the medial malleolus and posterior to the edge of the tibia, placing the ground electrode ipsilateral extremity. Electrical stimulation was applied using charge-compensated 200 usec pulses with a pulse rate of 20 Hz. Intensity level was then chosen as the intensity immediately under the threshold determining motor contraction (1x/week, 30 minutes) during 12 weeks. At the end of treatment, unsuccessful patients who did not respond to treatment received a tapering protocol for PTNS to 1 year treatment. The patients from tapering protocol underwent at 14-day intervals for 3 months, 21-day interval for 3 months, and 28-day intervals for 3 months.	Voiding diary parameters of urge incontinence decreased by 3.4 episodes daily (p<0.001) and were sustained for all results from 12 weeks through 12 months follow up. ICIQ-SF, OABv8 and OAB-q demonstrated significant improvement in symptom severity and health related quality of life (p<0.001), and improvement at all time points through 12 months (p<0.001).	Adverse effects: none Follow up: 3, 6, 9 and 12 months
Kabay (2021) (384)	Cohort	Parkinson's Disease Turkey	n=76 PTNS: Unilateral needle 5 cm cephalad from the medial malleolus and posterior to the edge of the tibia, placing the ground electrode ipsilateral extremity. Electrical stimulation was applied using charge-compensated 200 usec pulses with a pulse rate of 20 Hz. Intensity level was then chosen as the intensity immediately under the threshold determining motor contraction (1x/week, 30 minutes) during 12 weeks. At the end of treatment, unsuccessful patients who did not respond to treatment received a tapering protocol for PTNS to 1 year treatment. The patients from tapering protocol underwent at 14-day intervals for 3 months, 21-day interval for 3 months, and 28-day intervals for 3 months	Voiding diary parameters of urge incontinence decreased by 4.2 episodes daily (p<0.001) and were sustained for all results from 12 weeks through 24 months follow up. ICIQ-SF, OABv8 and OAB-q demonstrated significant improvement in symptom severity and health related quality of life at all time points through 24 months (p<0.001).	Adverse effects: NR Follow up: 3, 6, 9, 12 and 24 months

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Tudor (2020) (385)	Cohort	Mixed neurological group UK	N=49 12 once-weekly, 30-min sessions Tibial nerve stimulated with a 34-gauge needle inserted at a 60° angle approximately 5 cm cephalad to the medial malleo- lus and slightly posterior to the tibia at a frequency of 20 Hz and pulse width of 200 μs	Change in ICIQ-OAB total score; median (IQR) −4 (−9.3, 2.5) (p=0.04) Change in ICIQ-LUTSqol total score; median (IQR) − 34 (− 53, 4.8) (p = 0.05) Change in 24-h urinary frequency (BD); median (IQR) − 0.85 (− 2.8, 0.4) (p = 0.3) Change in mean bladder urge score (BD); median (IQR) 0 (− 0.4, 0.2) (p = 0.9) Change in mean number of incontinence episodes (BD); median (IQR) −0.2 (−1, 0.2) (p=0.8)	No significant side effects reported
Zecca (2014) (386)	Cohort	Multiple sclerosis Switzerland	n=83 PTNS: Unilateral needle 5 cm above the medial malleolus and slightly posterior to the tibia. A surface electrode was placed on the ipsilateral calcaneus. Electrical stimulation was applied using a current level between 0.5 and 9 mA with charge-compensated 200 μsec pulses with a pulse rate of 20 Hz based on each subject's foot/plantar motor and sensory responses (1x/week, 30 minutes) during 12 weeks. At the end of treatment, the patients who did not respond to treatment switched to receiving maintenance treatment every 3 weeks for the next 3 months. After, symptoms were evaluated again and those who did not respond to this protocol, received further maintenance therapy every 2 weeks for 3 months.	Bladder diary parameters significantly improved at 24 months (p<0.05).	Adverse effects: none Follow up: 24 months

Abbreviations: PTNS: percutaneous tibial nerve stimulation; LUTS: lower urinary tract symptoms; QoL: quality of life; OAB: overactive bladder; ICIQ-UI-SF International Consultation on Incontinence Questionnaire on Urinary Incontinence Short Form; OABv8: Overactive bladder version 8; ICIQ-OAB: International Consultation on Incontinence Questionnaire on Overactive Bladder; ICIQ-LUTS: International Consultation on Incontinence Questionnaire on Lower Urinary Tract Symptoms; BD: bladder diary; OABq: Overactive bladder questionnaire; IQR: interquartile range.

2.2. TENS performed in other regions

2.2.1. Prevention

There were no studies identified.

2.2.2. Treatment

There were five RCTs identified (387-391) and the characteristics of these studies are presented in Table 55. Electrodes were placed in different areas as indicated in Table 55, and essentially the sacral roots (388, 389, 391) or intravaginal/intra-anal regions (387, 390) were stimulated. The intervention consisted of TENS either daily for 30 (388, 389, 391) to 45 (390) minutes, twice (387), thrice weekly (390) or more (389). The length of the intervention varied: four weeks (390), 10 weeks (389), 60 days (388), 90 days (391) and 180 days (387). The comparator was either usual care (388), EPNS with a needle electrode (390), a differing frequency of stimulation (20 Hz versus 75 Hz) (391), home PFMT (387), sham (389) or no treatment (391).

Quality of data

Randomisation was considered appropriate in four studies (387, 389-391). Allocation concealment was considered adequate in three studies (389-391). Three studies confirmed that the evaluator was blinded (387, 389, 391). Information regarding an ITT analysis was available in two studies (389, 390), and low ROB for loss to follow-up was reported in four studies (387, 389-391). For one study (387), the authors were contacted to confirm possible biases.

Results

The results are presented in Table 55. In all the RCTs, a significant improvement in LUTS was reported after the intervention in participants with mixed neurological diseases, multiple sclerosis and post-stroke (388-391) when compared to usual care (388), PFMT alone (387), sham (389) and EPNS with a needle electrode (390). Improvement in symptoms was also observed following both 20 Hz and 75 Hz stimulation compared to no-treatment, however the 20 Hz group showed a greater benefit when compared to 75 Hz group (391).

No adverse effects were reported in any of the studies.

Summary

A total of five RCTs in stroke, multiple sclerosis and other different neurological populations assessed the effects of TENS on UI, OAB symptoms and/or LUTS. The interventions evaluated and the study designs adopted differed considerably between studies, most used Estim alone and one in combination with PFMT. However, data from all studies demonstrated a significant improvement in all outcomes assessed (**Level of evidence: 2**), when compared to an active treatment including a higher frequency (75 Hz) of EStim, PFMT alone, usual care or no treatment. Data from one well-designed high-quality study (389) in post-stroke patients demonstrated a significant improvement in OAB and UI symptoms when compared to sham,

Recommendation

TENS appears to be an effective and safe treatment for managing OAB and related UI in some neurological groups, including stroke and mixed neurological patients and can be recommended as a first line treatment option. **(Grade of recommendation: B New)**

However, large high-quality RCTs are needed for a definitive conclusion.

Table 55. RCT studies evaluating Transcutaneous electrical nerve stimulation (TENS) performed in other regions

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Ferreira (2016) (387)	RCT	Multiple sclerosis Single centre Brazil	Group 1: Surface electrostimulation - Frequency: 2 Hz with two electrodes positioned on the S4 dermatome-perineum region (2x/week) + PFMT (daily) during 6 months Group 2: home PFMT (2x/week) during 6 months	Qualiveen Questionnaire: The within-group analyses showed a significant improvement from baseline after 6 months in both groups. No difference between groups in general QoL. OAB-V8: The within-group analyses showed a significant improvement from baseline after 6 months in both groups. The between group comparison showed significant difference favoring the Group 1.	Adverse effects: NR Follow-up: post-intervention (6 months)
Guo (2014) (388)	RCT	Stroke Single centre China	Group 1 (n=32): Transcutaneous electrical nerve stimulation (30 minutes 1x/day) during 60 days Group 2 (n=29): Basic therapy during 60 days Positive electrode: second lumbar spinous process Negative electrode: middle and lower third of the junction between the posterior superior iliac spine and ischia node	Overactive bladder symptom score significant difference between group ($p<0.05$).	Adverse effects: None Follow-up: post-intervention (60 days)
Guo & Kang (2018) (389)	RCT	Stroke Multi centre China	Group 1 (n=41) Neuromuscular electrical stimulation (30 minutes, 5x/week) during 10 weeks Group 2 (n=41) Sham neuromuscular electrical stimulation (no active probe, 30 minutes, 5x/week) during 10 weeks Positive electrode: second sacral level on opposite sides of the vertebral column Negative electrode: inside of the middle and lower third of the junction between the posterior superior iliac spine and the ischial node	OABSS: Significant difference between group favoring Group 1. ICIQ-SF: Significant difference between group favoring Group 1.	Adverse effects: None Follow-up: post-intervention (10 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:

International Consultation on Incontinence Questionnaire - Lower Urinary Tract Symptoms Quality of Life score (ICIQ-LUTSqol) significant difference between group (p<0.001).	Adverse effects: NR Follow-up: post-intervention (4 weeks)
Liu (2016) (391)	RCT	Stroke China	Group 1 (n=27): Transcutaneous electrical nerve stimulation – Frequency 20Hz (30 minutes 1x/day) during 90 days Group 2 (n=27): Transcutaneous electrical nerve stimulation – Frequency 75Hz (30 minutes 1x/day) during 90 days Group 3 (n=27): No treatment Positive electrode: second sacral level Negative electrode: middle and lower third of the junction between the posterior superior iliac spine and ischial node	Overactive Bladder Symptom Score (OABSS): Group 1 and 2 presented significant difference in the post-intervention (p<0.05). Significant between group difference in Group 1 vs 2, 1 vs 3 and 2 vs 3 comparison. Incontinence episodes: Group 1 and 2 presented significant difference in the post-intervention (p<0.05). Significant between group difference in Group 1 vs 2, 1 vs 3 and 2 vs 3 comparison.	Adverse effects: None Follow-up: post-intervention (90 days)

Abbreviations: RCT: randomized controlled trial; NR: not reported; OABSS: Overactive Bladder Symptom Score; OABv8: Overactive bladder questionnaire – 8; ICIQ-SF International Consultation on Incontinence Questionnaire on Urinary Incontinence Short Form, ICIQ-LUTS: International Consultation on Incontinence Questionnaire on Lower Urinary Tract Symptoms.

3. ACUPUNTURE

3.1. Prevention

There were no studies identified.

3.2. Treatment

There were fifteen RCTs identified (392-406) and the characteristics of these studies are presented in Table 56. The intervention was highly variable and usually consisted of acupuncture (394, 397, 405, 406) or electroacupuncture alone (393, 399, 401), combined with medication (392, 395, 400, 404), or moxibustion (396, 398), or usual care (402). One study (403) evaluated the addition of ginger-salt-separated moxibustion and medication to the acupuncture protocol and another study evaluated the addition of electroacupuncture to a transperineal urethral sphincter injection of botulinum toxin protocol (400). A sham comparator was used in only one study (399), whereas in the remaining studies an active comparator was used: usual rehabilitation including standard physiotherapy, BT and general advice on fluids intake (393, 394), different types of acupuncture (395, 398, 405), medication (392, 396, 400, 404, 406) or catheterization (397, 401, 402). Two studies evaluated the addition of ginger-salt-partitioned moxibustion to acupuncture (398, 403).

Quality of data

Randomisation was considered appropriate in eight studies (392, 393, 395-397, 400, 401, 403), high-risk in one (398) and could not be determined in the remaining studies. Allocation concealment could be assessed in only two studies and considered adequate (393, 403). Blinding of evaluators could be assessed in only two studies (393, 399) and was double blinded in one (399). Information regarding an ITT analysis was obtainable in only one study (393) and loss to follow up was rated low ROB in twelve studies (393, 395-400, 402-406).

Results

Table 56 summarizes the results of these studies. A significant improvement in UI symptoms was reported in most studies (392-406) but not all reported improvement in symptoms or cure rates (393, 398, 402). Overall, studies that added active treatments to electroacupuncture in participants with PD, SCI and post-stroke(392, 396, 400), and acupuncture in post-stroke participants (398, 402-404) were effective when compared to medication added to other treatment or medication alone, acupuncture alone, and indwelling catheterisation. Furthermore, electroacupuncture (393, 399, 401) and acupuncture (394, 397, 406) alone in post-stroke participants is more effective compared to usual care including standard physiotherapy, BT and general advice on fluids intake, medication, sham, and indwelling catheterization. Two studies (395, 405) comparing different modalities of acupuncture showed that electroacupuncture was superior to acupuncture (395) and acupuncture with elongated needle was superior to acupuncture with filiform needle (405) in post-stroke participants.

No serious adverse effects were reported in any of the studies. However, in three studies (393, 401, 403) reported minor adverse events such as numbness, cramping, vomiting, skin burn, bruises on arms and torso, abdominal pain and low back pain. In one study (393), drop-out was reported due to pain at the needling sites.

Summary

A total of fifteen RCTs across participants with PD, SCI and post-stroke assessed the effects of acupuncture or electroacupuncture on UI, OAB symptoms and/or LUTS against an active or placebo comparator.

The interventions evaluated, and the study designs adopted, differed considerably. The quality of most studies could not be determined and the only study where quality parameters could be assessed (393) did not show a significant improvement in UI symptoms after the intervention.

However, data from the remaining studies demonstrated a significant improvement in symptoms following intervention. (**Level of evidence: 3**)

Recommendation

There is uncertainty regarding acupuncture as an alternative to medication and usual care for managing OAB and related UI in post-stroke, PD and SCI patients.

No recommendation can be made

High quality RCTs with clear reporting and outcome assessment would be beneficial for the recommendation.

Table 56. RCT studies evaluating acupuncture.

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Chen (2012) (392)	RCT	Parkinson's Disease China	Group 1 (n=30): electroacupuncture (1x/day) + Tolterodine orally (1mg 2x/day) with one day break per week during 6 weeks Group 2 (n=30): Tolterodine orally (2mg 2x/day) during 6 weeks	Frequency of UI of 24h: after treatment improved in both groups. Between group comparison showed that Group 1 was superior to the Group 2 ($p < 0.05$)	The adverse reactions in Group 1 were less than those in Group 2. Follow-up: post-intervention (6 weeks)
Chen (2020) (393)	RCT	Stroke Multi centre China	Group 1 (n=16): Electroacupuncture (20 minutes, 1-2x/week) during 4 weeks Group 2 (n=18): Usual rehabilitation (standard physiotherapy, bladder training and general advice on fluids intake) during 4 weeks	OABSS: significant difference between group comparison at week 5 and 8. No significant difference between group comparison at weeks 1, 2, 3, and 4. Number of incontinence episodes: no significant difference between group comparison at week 5 and 8.	Adverse effects: numbness (n=1), pain at the needling sites (n=1 – drop out), cramping (n=1), vomiting (n=1) and low back pain (n=1) Follow-up: week 1, 2 and 3 (during intervention); post-treatment (4 weeks); 1- and 4-weeks follow-up (week 5 and 8)
Chu (1997) (394)	RCT	Stroke China	Group 1 (n=30): Scalp needle embedding acupuncture during 1-2 weeks Group 2 (n=30): Usual care (no acupuncture)	2-week follow-up reported that 16 patients in the intervention group totally regaining normal urine and 12 patients in the intervention group partially regaining normal urine and the number of patients no regaining is 2. Between group comparison showed significant difference (p=0.001).	Adverse effects: NR Follow-up: 2 weeks
Chu (2011) (395)	RCT	Stroke China	Group 1 (n=56): Electroacupuncture (1x/day with one day break per week, 30 minutes) + calcium ion antagon, angiotensin-converting enzyme inhibitor, angiotensin II receptor antagonist, compound thromb-clearing agent (i.v.) during 4 weeks Group 2 (n=55): Acupuncture (1x/day) + Calcium ion antagon, angiotensin-converting enzyme inhibitor, angiotensin II receptor antagonist, compound thromb-clearing agent (i.v.) during 4 weeks	Severity of UI and symptom scores: Within group comparison statistically significant. Number of participants continent after treatment (cured): Between-group comparison statistically significant favoring Group 1.	Adverse effects: The infection rate of the electroacupuncture group was lower than control group Follow-up: post-intervention (4 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Jiang (2020) (396)	RCT	Stroke China	Group 1 (n=30): Jingui Shenqi pills + Suoquan capsules (orally) during 2 weeks Group 2 (n=30): Electroacupuncture (30 minutes) + moxibustion (daily, 6x/week) during 2 weeks	Urinary incontinence (day/night) The two groups showed significant reduction ($p<0.01$). Between group comparison showed decrease in Group 2 ($p<0.05$). Urinary incontinence degree Increase number of cases with UI degree I and II ($p<0.05$). Between group comparison showed increase UI degree I and II in Group 2 ($p<0.05$). Clinical symptoms of urinary incontinence Reduce score of clinical symptoms ($p<0.05$). Between group comparison showed reduction of UI symptoms score in Group 2 ($p<0.05$). Effective rate showed significant difference between group comparison.	Adverse effects: NR Follow-up: post-intervention (2 weeks)
Li (2015) (397)	RCT	Stroke China	Group 1 (n=24): Acupuncture 1x/day with one day break per week, 30 minutes) during 3 weeks Group 2 (n=20): Indwelling catheterization during 3 weeks	American Urological Association Symptom Index (AUASI) significant difference between group comparison favoring Group 1.	Adverse effects: NR Follow-up: post-intervention (3 weeks)
Liu (2006) (398)	Quasi-RCT	Stroke China	Group 1 (n=41): Ginger-salt-partitioned moxibustion + acupuncture (5x/week) during 3 weeks Group 2 (n=41): Acupuncture (5x/week) during 3 weeks	Frequency of urinary symptoms significantly decreased in between group comparison favoring Group 1. Number of patients continent after treatment showed no difference in the between-group comparison.	Adverse effects: NR Follow-up: post-intervention (3 weeks)
Liu (2013) (399)	RCT	Stroke Single centre China	Group 1 (n=35): Electroacupuncture (20 minutes, 1x/day) during 10 days Group 2 (n=36): Sham electroacupuncture (20 minutes, 1x/day) during 10 days	Frequency UI significant difference between group comparison after treatment and 3 months follow-up favoring Group 1.	Adverse effects: NR Follow-up: post-intervention (10 days) and 3 months

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Meng (2015) (400)	RCT	Spinal Cord Injury China	All patients were treated with usual care including indwelling catheterization and PFMT Group 1 (n=20): Electroacupuncture (40 minutes, 6x/week) + botulinum toxin-A (200 IU/4ml via perineum external urethral sphincter) during 4 weeks Group 2 (n=15): Botulinum toxin-A (200 IU/4ml via perineum external urethral sphincter)	Episodes and volume of urinary incontinence showed significant reduction ($p<0.05$). Between group comparison showed decrease in Group 1 ($p<0.05$).	Adverse effects: NR Follow-up: post-intervention (4 weeks)
Song (2013) (401)	RCT	Stroke China	Group 1 (n=136): Electroacupuncture (5x/week) during 4 weeks Group 2 (n=68): Indwelling catheter intervals of 2-4 hours + bladder irrigation + bladder training during 4 weeks	Number of participants continent significant difference between group comparison favoring Group 1.	Adverse effects: Group 1: 45/136 (33%) bruises on arms and torso with full recovery; 17/136 (13%) had abdominal pain post-acupuncture with resolution after warm compress. Follow-up: post-intervention (4 weeks)
Wang (2015) (402)	RCT	Stroke China	Group 1 (n=38): Acupuncture (cycles of 1x/day during 10 days with two day breaks per cycle, 30 minutes during 4 weeks + usual care Group 2 (n=38): Indwelling catheter during 4 weeks + usual care	Effective rate of Urinary Incontinence – cured and occasional UI: between group comparison showed no difference. Degree of UI for general activities and Score of Urinary Incontinence were better in Group 1 than Group 2 in the between-group comparison.	Adverse effects: NR Follow-up: post-intervention (4 weeks)
Wen (2014) (403)	RCT	Stroke China	Group 1 (n=48): Acupuncture (5x/week during 30 minutes) + ginger-salt-separated moxibustion (2x/day during 5x/week) + Medication (0.1g Aspiring and 75mg Plavix) (1x/day) during 4 weeks Group 2 (n=24): Acupuncture (5x/week during 30 minutes) + Medication (0.1g Aspiring and 75mg Plavix) (1x/day) during 4 weeks	Score of Urinary Incontinence was significant decreased in both Groups post-treatment and in Group 1 in between-group comparison.	Adverse effects: skin burn (Group 1: n=2) Follow-up: Post-treatment (4 weeks)
Wu (1999) (404)	RCT	Stroke China	Group 1 (n=40): Eye acupuncture and electriferous scalp acupuncture (daily, 6 days/week) + Medication therapy (Hua Duo Zai shi tablet, Xi bi lin, Nao Fu Kang, vitamins C and E) during 4 weeks. Group 2 (n=40): Medication therapy (Hua Duo Zai shi tablet, Xi bi lin, Nao Fu Kang, vitamins C and E.	Number of participants continent showed significant difference between group comparison favoring Group 1.	Adverse effects: NR Follow-up: NR

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Zhang (1996) (405)	RCT	Stroke Single centre China	Group 1 (n=32): Elongated needle (50 minutes, 6x/week) during 4 weeks Group 2 (n=25): Filiform needle (50 minutes, 6x/week) during 4 weeks	Micturition completely controlled significant difference between group comparison favoring Group 1. Partially controlled urination no significant difference between group comparison. No urination control significant difference between group comparison with increased numbers in Group 2.	Adverse effects: NR Follow-up: Post-treatment (4 weeks)
Zhang (2002) (406)	RCT	Stroke China	Group 1 (n=36): Acupuncture (daily for 7 times) Group 2 (n=28): Mannite and other medicines to do general treatment with the partial foment on the bladder.	Number of participants continent (cured)- significant difference in group comparison favoring Group 1.	Adverse effects: NR Follow-up: NR

Abbreviations: RCT: randomized controlled trial; UI: urinary incontinence; OABSS: Overactive Bladder Symptom Score; PFMT: pelvic floor muscle training; NR: not reported.

4. TOILET ASSISTANCE

4.1. Prevention

There were no studies identified

4.2. Treatment

There were seven RCTs identified (407-414) across participants post-stroke, PD and incomplete SCI, and the characteristics of these studies are presented in Table 57. Different interventions were studied including BT (408, 410, 412), timed voiding (409, 411), and prompted voiding (413, 414). One study evaluated the addition of moxibustion to BT compared to BT alone (407).

Quality of data

Randomisation was considered appropriate in only three studies (407, 412-414) and could not be determined in the remaining studies. Allocation concealment was unclear in all studies. The evaluator was blinded in one study (412). Information regarding an ITT analysis was obtainable in one study (413, 414) and loss to follow up was rated low ROB in four studies (407, 408, 410, 411).

Results

Table 57 summarizes the results of these studies. A significant improvement in UI symptoms in participants post-stroke, PD and incomplete SCI was reported in some studies that added other treatments to the toilet assistance programme compared to routine nursing, biofeedback, and conservative advice including fluid management (407, 410, 412) and greatest improvement was observed at 12 weeks in participants with PD (412). Three studies (408, 411, 413, 414) with active interventions added to the toilet assistance programme compared to usual care, such as checking for urinary tract infection, overflow incontinence, containment and some toileting schedule, and a toilet assistance programme alone in post-stroke participants did not demonstrate improvement. One study (409) in post-stroke participants comparing the toilet assistance programme alone with other active treatments did not show any statistically significant difference.

No serious adverse effects were reported in any of the studies. However, one study (413, 414) reported the following adverse events: fall, urinary tract infections and bladder catheterizations.

Summary

A total of seven RCTs across participants post-stroke, PD and incomplete SCI assessed the effects of toilet assistance on UI, OAB symptoms and/or LUTS. The interventions that were evaluated, and the study designs adopted, differed considerably between studies. The quality of many studies could not be determined. Data from three studies provided evidence for safety, efficacy and improvement in UI. (**Level of evidence 3)**

Recommendation

Based on the evidence available, toilet assistance regimens could be recommended for treatment for managing OAB and related UI in post-stroke, PD and incomplete SCI patients**.** Further trials are needed. **(Grade of recommendation: C New)**

Table 57. RCT studies evaluating toilet assistance

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Chen (2016) (407)	RCT	Incomplete spinal cord injury	Group 1 (n=42): Bladder training + comprehensive rehabilitation treatment – 20 minutes and exercises training during 8 weeks Group 2 (n=42): Bladder training + umbilical moxibustion during 8 weeks	Daily number of urinary incontinence Significant reduction in both groups after treatment. Between group comparison showed significant difference favoring Group 2. LUTS score Significant reduction in both groups after treatment. Between group comparison showed significant difference favoring Group 2. LUTS Quality of Life Significant reduction in both groups after treatment. Between group comparison showed significant difference favoring Group 2.	Adverse effects: NR Follow-up: post-intervention (8 weeks)
Feng (2012) (408)	RCT	Stroke Single centre China	Group 1 (n=30): Bladder training + standing training + emotional care during 60 days Group 2 (n=30): Routine treatment + nursing during 60 days	UI cure no significant difference between group comparison. Occasional UI no significant difference between group comparison	Adverse effects: NR Follow-up: post-intervention (60 days)
Gelber (1997) (409)	RCT	Stroke USA	Normal urodynamic studies Group 1 (n=10): Void on request Group 2 (n=8): Timed voiding Bladder hyperreflexia Group 1 (n=10): Timed voiding Group 2 (n=9): Oxybutynin	Number of UI episodes per day: no statistical significance between groups.	Adverse effects: NR Follow-up: Each month of treatment for 1 year
Gong (2013) (410)	Quasi-RCT	Stroke China	Group 1 (n=30): Biofeedback + Routine nursing Group 2 (n=35): Water drinking plan + bladder training during 60 days	UI cure: no significant difference between groups. Number of incontinent patients showed significant differene between group comparison favoring Group 2.	Adverse effects: NR Follow-up: NR
Lewis (1990) (411)	RCT	Stroke USA	Group 1 (n=11): Timed prompted voiding + Biofeedback during 2 weeks Group 2 (n=12): Timed prompted voiding during 2 weeks	Number of continent participants and episodes after treatment no significant difference between group comparison.	Adverse effects: NR Follow-up: post-intervention (2 weeks)

Author, year	Type of study	Population	Intervention	Outcome	Notes:
McDonald (2020) (412)	RCT	Parkinson's Disease Single centre UK	Group 1 (n=18): Conservative advice (Advice and instructions to reduce alcohol and caffeine, constipation management and available containment products) Group 2 (n=20): Bladder training (instructions on urge suppression and distraction techniques, coaching PFMT, personalized voiding schedule and video training) + conservative advice during 12 weeks	Incontinence episodes: significant difference between group comparison at 12 weeks favoring Group 2. No significant difference between group comparison at 20 weeks. ICIQ-OAB: -Symptom score significant difference between group comparison at 12 weeks favoring Group 2. No significant difference between group comparison at 20 weeks. -Bother score significant difference between group comparison at 20 weeks favoring Group 2. No significant difference between group comparison at 12 weeks. -Quality of life no significant difference between group comparison at 12 and 20 weeks. -Quality of life interference for daily life significant difference between group comparison at 12 and 20 weeks favoring Group 2.	Adverse effects: NR Follow-up: post-intervention (12 weeks) and follow-up (20 weeks)
Thomas (2014) (413, 414)	Cluster RCT	Stroke Multi centre UK	Group 1 (N=124): Usual continence care (checking urinary tract infection, overflow incontinence, containment and some toileting schedule) Group 2 (N=164): Systematic voiding programme with 3-day bladder diary and comprehensive continence assessment (participants cognitively able: bladder training; participants cognitively impaired: prompted voiding) + usual continence care Group 3 (N=125): Systematic voiding programme with supported implementation (facilitation to assist the process of embedding into practice)	Number of continent participants International Consultation on Incontinence Questionnaire Urinary Incontinence – Short Form (ICIQ-SF) Incontinence Severity Index (ISI) Types of Incontinence: Urge incontinence present; Stress incontinence present Incontinence Quality of Life Instrument (IQoL) (post-treatment; median IQR) No difference between group comparison at all follow-up.	Adverse effects: Number of participants Fall Group 1: 16 Group 2: 11 Group 3: 4 Urinary tract infection Group 1: 13 Group 2: 18 Group 3: 23 Bladder catheterization Group 1: 1 Group 2: 4 Group 3: 1 Follow-up: Post-stroke (6, 12 and 52 weeks)

Abbreviations: RCT: randomized controlled trial; NR: not reported; PFMT: pelvic floor muscle training; UI: urinary incontinence; LUTS: Lower Urinary Tract Symptoms; ICIQ-OAB: International Consultation on Incontinence Questionnaire on Overactive Bladder.

5. MULTIMODAL REHABILITATION INTERVENTION

5.1. Prevention

There were no studies identified

5.2. Treatment

Data from two well-designed studies (415, 416) in participants with MS and spina bifida assessing the effectiveness of multimodal rehabilitation intervention including incontinence treatment with BT, timed voiding, medication, and PFMT associated with cognitive behavioural strategies and psychological adjustments. These interventions were compared with standard outpatient rehabilitation including monitoring by general practitioners and neurologists.

Quality of data

Randomisation and allocation concealment were considered appropriate in all studies (415, 416). Given the nature of intervention in the two studies (415, 416), blinding of participants was rated as high ROB. However, both studies (415, 416) blinded the outcome assessor, employed ITT analysis and were rated as low ROB for loss of follow-up.

Results

Table 58 summarizes the results of these studies. A statistically significant improvement in UI symptoms and QoL in participants with MS and spina bifida was reported in all studies, reaching a clinically important difference. No adverse effects were reported in any of the studies.

Summary

A total of two RCTs of participants with MS and spina bifida assessed the effects of a multimodal rehabilitation intervention on UI symptoms and health related QoL. The interventions were considered homogeneous, and the study designs adopted were similar. One study (415), reported of intervention effectiveness in 12 month follow-up

The studies were considered high-quality with limitations related to blinding of participants. **Level of evidence: 2.**

Recommendation

Based on the evidence available, multimodal rehabilitation interventions in MS and spina bifida patients can be recommended as first line treatment. **(Grade of recommendation: B New)**

Table 58. RCT studies evaluating multimodal rehabilitation intervention

Author, year	Type of study	Population	Intervention	Outcome	Notes:
Khan (2010) (415)	RCT	Multiple sclerosis Single centre Australia	Group 1 (N=40): Individualized inpatient (3h/day – therapy, during 6 weeks) or outpatient (30min 2-3x/week) therapy during 6 weeks + Bladder rehabilitation programme (assessment of bladder type, pattern and function, bladder re-education, behavior management, PFMT, strategies for timed and double voiding, intermittent catheterization techniques, use of prophylactic medication, and strict bowel programme) + Behavioral therapy Group 2 (N=34): Usual care (regular reviews by GP and neurologists)	Significant difference between group comparison in the UDI6, IIQ7 and AUA total score and QoL favoring Group 1.	Adverse effects: none Follow-up: post-intervention (12 months)
Khan (2015) (416)	RCT	Spina bifida Single centre Australia	Group 1 (n=27): Usual care (2-3x/week, 30 minutes) during 6 weeks + bladder management (assessment of bladder type, pattern and function, bladder re-education, behavior management, PFMT, timed/double voiding, catheter care and medication review) + Bowel programme + skin and pressure care education sessions + cognitive behavioral therapy for an additional 4-6 weeks beyond the usual care Group 2 (n=27): Usual care - physical reconditioning programme, wheelchair/seating evaluation, task reacquisition skills and whole-body adaptive techniques (2-3x/week, 30 minutes) during 6 weeks	Significant difference between group comparison in the UDI6, IIQ7 and AUA and QoL favoring Group 1.	Adverse effects: none Follow-up: post-intervention (3 months)

Abbreviations: RCT: randomized controlled trial; PFMT: pelvic floor muscle training; GP: general practitioner; UDI6: Urogenital Distress Inventory; IIQ7: Incontinence Impact Questionnaire; AUA: American Urological Association Symptom Index; QoL: quality of life.

APPENDIX 1

7th ICI – conservative treatment in adults – terms used to search the Cochrane Incontinence Specialised Register

The updated literature search covered from September 9th, 2015 to December 31st, 2020 inclusive (ie from the date of the last search for the 6th ICI to the 7th ICI search cut-off date of December 31st, 2020) according to the following search methods. The searches were conducted between March 1st to 9th, 2021 inclusive. We did not impose any language or other limitations on any of the searches described below.

Please find below details of the search terms used to search the Cochrane Incontinence Specialised Register for each section of this chapter. The Register is maintained in EndNote X8.2 (1) and all searches are of the 'Keywords' field (which contains the Cochrane Incontinence Specialised Register controlled vocabulary terms).

Lifestyle interventions for urinary incontinence (UI)
design.rct* OR design.cct*
AND
topic.urine*
AND
intvent.lifestyle*

PFMT for prevention or treatment of UI and/or faecal incontinence (FI) in childbearing women
design.rct* OR design.cct*
AND
intvent.prevent.pfe* OR intvent.prevent.pfmt* OR intvent.prevent.physicaltherapies OR topic.urine.incon.prevent. OR topic.urine.incon.prevent.postpartum. OR topic.faecal.incon.prevent. OR topic.faecal.incon.prevent.PostObstet. OR topic.urine.incon.postobstetric* OR topic.faecal.incon.postobstetric* OR topic.urine.incon.preg* OR topic.urine.incon.stress.postnatal. I. INTRODUCTION

The function of the lower urinary tract (LUT) is to store and periodically release urine. It is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. These structures form a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; 2015; Andersson and Wein, 2004; see, Andersson and Michel., 2011]. Recently, Abelson et al. [2018] reviewed current understanding of the development, function, and biology of the LUT in females and males on a cellular level with focus on sex differences. Malfunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in detrusor underactivity (DU) and underactive bladder (UAB). A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2012].

In the treatment of LUT disorders, many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [see, Andersson 2016; Andersson et al., 2017; Peyronnet et al., 2018; Abreu-Mendes et al., 2020; De Nunzio et al., 2020].

In this report, we update the recommendations from the 2016 International Consensus meeting [Andersson et al., 2017]. The most relevant information obtained since the last meeting is briefly reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. We have used a modification of the Oxford system **(Table 1)** for our clinical drug recommendations **(Table 2).** The terminology used is that recommended by the International Continence Society (ICS) [Drake 2018).

Table 1. ICI assessments 2008: Oxford guidelines (modified)

Levels of evidence
Level 1: Systematic reviews, meta-analyses, good quality randomized controlled clinical trials (RCTs) Level 2: RCTs, good quality prospective cohort studies Level 3: Case-control studies, case series Level 4: Expert opinion
Grades of recommendation
Grade A: Based on level 1 evidence (highly recommended) Grade B: Consistent level 2 or 3 evidence (recommended) Grade C: Level 4 studies or " majority evidence" (optional) Grade D: Evidence inconsistent/inconclusive (no recommendation possible) or the evidence indicates that the drug should not be recommended

Table 2: Drugs used in the treatment of LUTS/OAB/ DO. Assessments according to the Oxford system (modified)

	Level of Evidence	Grade of Recommendation
Antimuscarinic drugs		
Darifenacin	1	A
Fesoterodine	1	A
Imidafenacin	1	A
Solifenacin	1	A
Tolterodine	1	A
Trospium	1	A
Drugs with mixed actions		
Oxybutynin	1	A
Propiverine	1	A
Beta-AR antagonists		
Vibegron	1	A
Mirabegron	1	A
Drugs acting on membrane channels		
Calcium antagonists	2	D
K-Channel openers	2	D
Antidepressants		
Imipramine	3	C
Duloxetine	2	C
Alpha-AR antagonists		
Alfuzosin	3	C
Doxazosin	3	C
Prazosin	3	C
Terazosin	3	C
Tamsulosin	3	C
Silodosin	3	C
Naftopidil	3	C
PDE-5 Inhibitors+		
(Sildenafil, Taladafil, Vardenafil)	1	A
COX-inhibitors		
Indomethacin	2	C
Flurbiprofen	2	C
Toxins		
Botulinum toxin (neurogenic)***	1	A
Botulinum toxin (idiopathic)***	1	A
Capsaicin (neurogenic)**	2	C
Resiniferatoxin (neurogenic)**	2	C
Other drugs		
Baclofen*	3	C
Hormones		
Estrogen	2	C
Desmopressin#	1	A

+(male LUTS/OAB); * intrathecal; ** intravesical; *** bladder wall; #nocturia (nocturnal polyuria), caution hyponatremia, especially in the elderly!

1. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d'Urologie. There were no restrictions on the inclusion of publications by language; publications in languages other than English were translated into English. The literature searches were completed by early summer of 2021.

II. BLADDER PHYSIOLOGY/ PATHOPHYSIOLOGY

1. CENTRAL NERVOUS CONTROL

In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (Figures1-4). In infants, the central pathways seem to be organized as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999; Beckel and Holstege, 2011; Lovick, 2016]. Studies in humans and animals have identified areas in the brainstem and diencephalon (Figure 5) that are specifically implicated in micturition control, including Barrington's nucleus also known as the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons of the Onuf's nucleus via inhibitory interneurons in the medial sacral cord. Other structures involve in micturition control are the cerebellum [Bastied and Herbaut, 2020] and the periaqueductal grey (PAG) [Zare et al., 2019]. Cerebellum modulates the micturition reflex, participates to the bladder sensory-motor information processing, and is involved in the reflex micturition modulation through direct or indirect pathways to major brainstem or forebrain centres. The PAG receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths 2007; 2011; Griffiths et al., 2008; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008; Deruyver et al., 2016; Groenendijk et al 2021].

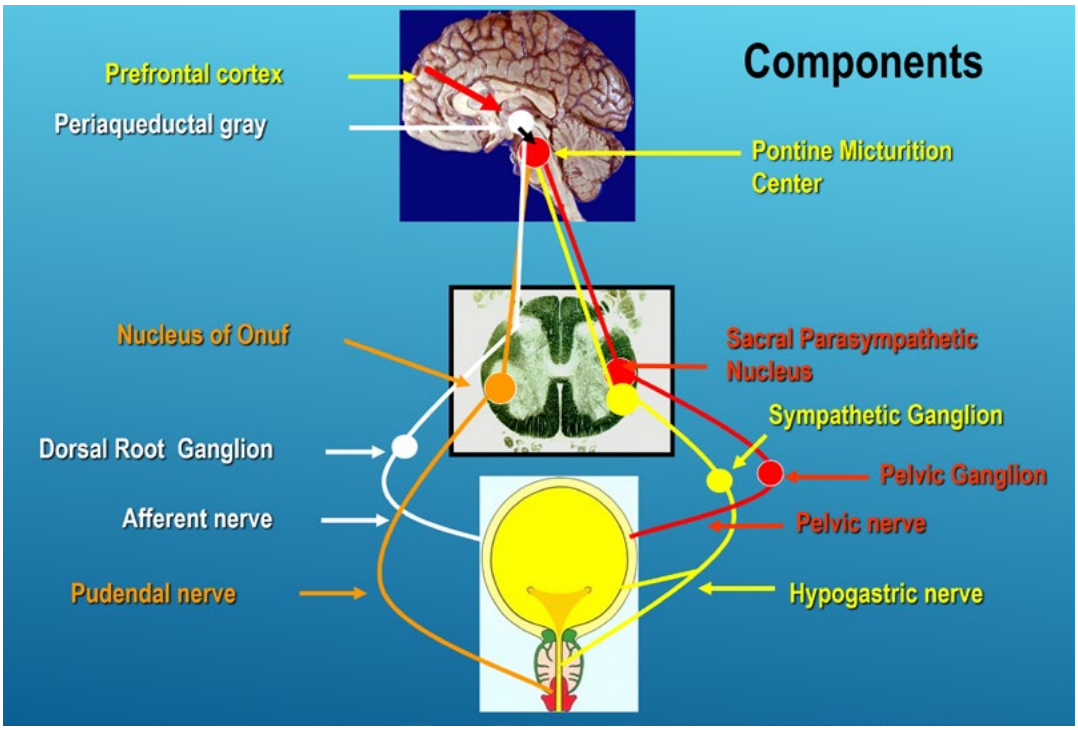

Figure 2: Components of the micturition reflex

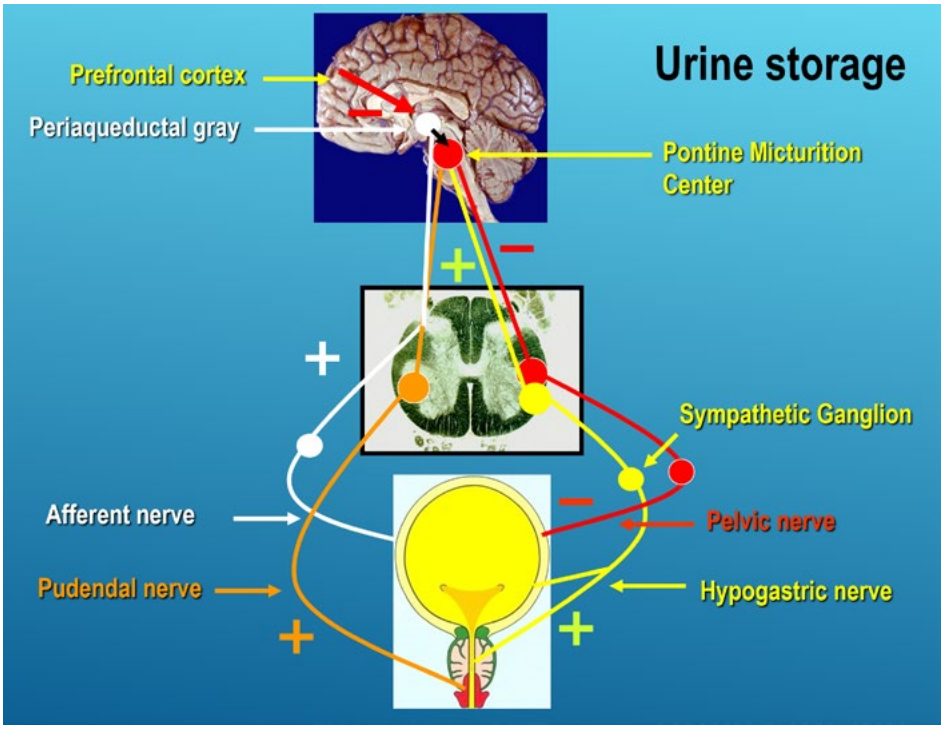

Figure 3: Reflex activity during urine storage

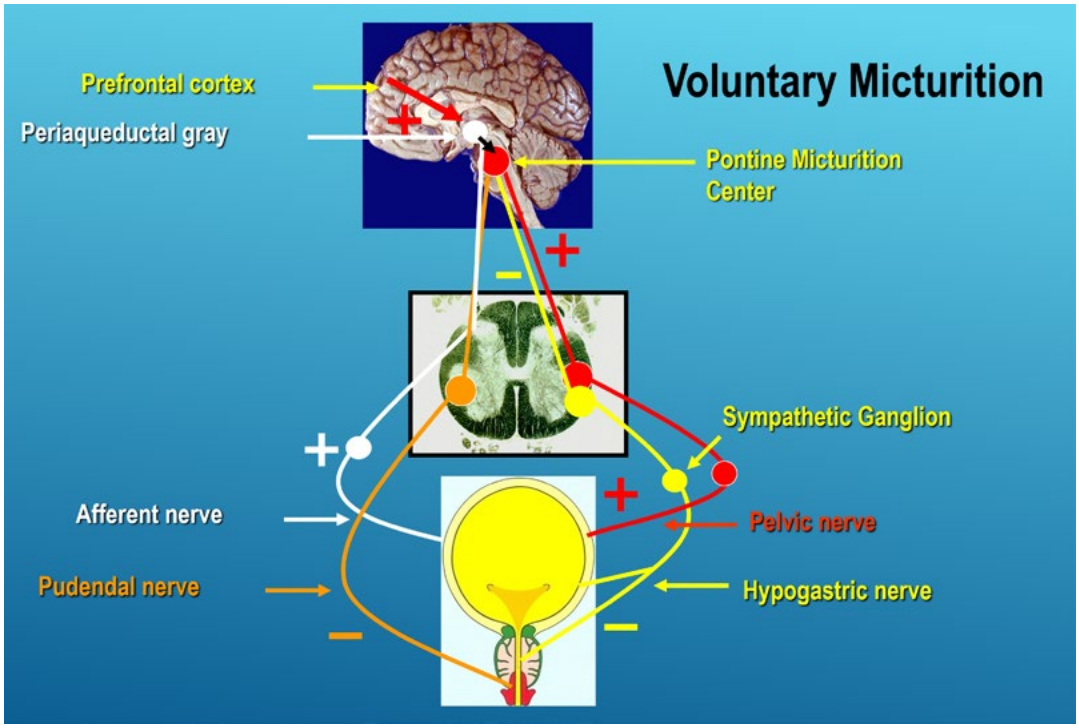

Figure 4: Reflex activity during voluntary micturition

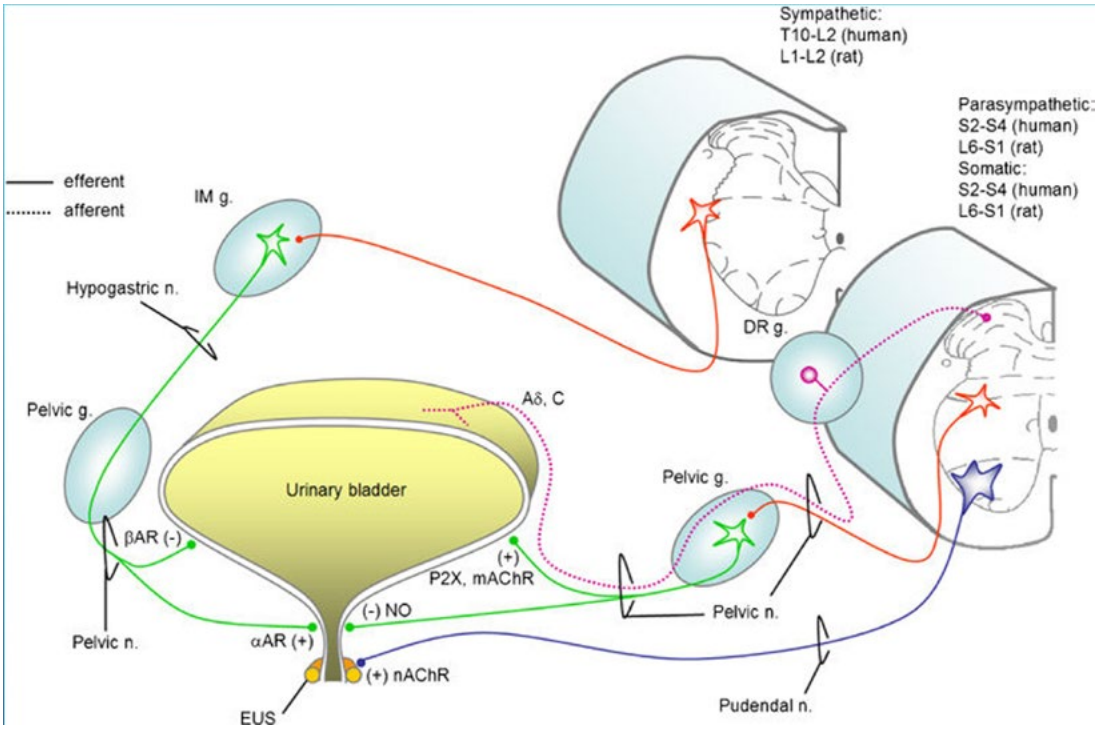

Figure 5: Peripheral innervation of the LUT

2. PERIPHERAL NERVOUS CONTROL

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in parasympathetic, sympathetic, somatic, and sensory nerves (**5**) [de Groat et al., 1993; Beckel and Holstege, 2011; Kim 2019; Ikeda 2021]. These nerves are parts of reflex pathways, which either keep the bladder in a non-contracted state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of *parasympathetic* neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 (**5**) [de Groat et al., 1993; Beckel and Holstege, 2011; Kim 2019; Ikeda 2021]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Hashimoto et al., 1993; Werkström et al., 1995].

Most of the *sympathetic* innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoraco-lumbar region (T10-L2) of the spinal cord (**5**) [Beckel and Holstege, 2011]. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Andersson, 1993; De Groat et al., 1993; Ikeda, 2021].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra (shown in animals and man, see [Andersson, 1993; Ikeda, 2021]. However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues *in vitro*, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

The *somatic* innervation of the urethral rhabdosphincter and of some perineal muscles (for example compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve (**5**) [Beckel and Holstege, 2011; Ikeda 2021]. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in the region called Onuf´s (Onufrowicz's) nucleus.

Most of the *sensory* innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia (Kanai and Andersson, 2010; De Wachter, 2011; Ikeda 2021). In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Andersson 1993]. The most important afferents for the micturition process are myelinated Ad-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Ad-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990]. Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed "silent fibres" [de Groat and Yoshimura, 2001; 2015].

3. BLADDER CONTRACTION

Mammalian detrusor contractions are generated by a transient rise of the intracellular Ca2+ concentration ([Ca2+]), initiated by intracellular release of Ca2+ from stores and/or Ca2+ influx via L-type and T-type Ca2+ channels (**6**). Co-ordinated contraction of the bladder is evoked by parasympathetic post-ganglionic fibres releasing ACh and ATP, and driven by descending fibres, emerging at sacral levels S2-S4, Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle and can be blocked by atropine [Andersson and Arner, 2004]. Atropine resistance, i.e., contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Sjögren et al., 1982; Andersson, 1993; Bayliss et al., 1999; Rouget et al., 2014].

Such atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Andersson and Wein, 2004; Kennedy et al., 2007]. ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G-protein-coupled receptor family (P2Y). Seven P2X subtypes and eight P2Y subtypes have been identified. In several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001; Ford and Cockayne, 2011; Burnstock. 2013; Ford and Undem., 2013; North and Jarvis, 2013; Andersson, 2015]]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that $P2X_1$ receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. $P2X_3$ receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves. In $P2X_3$ knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006; Ford and Cockeyne, 2011; Burnstock, 2013]. These data indicate that purinergic receptors are involved in mech anosensory signaling in the mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders and has been reported to occur in hypertrophic bladders [Sjögren et al., 1982], interstitial cystitis [Palea et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established [Andersson, 2006; Fry and McCloskey, 2021**].**

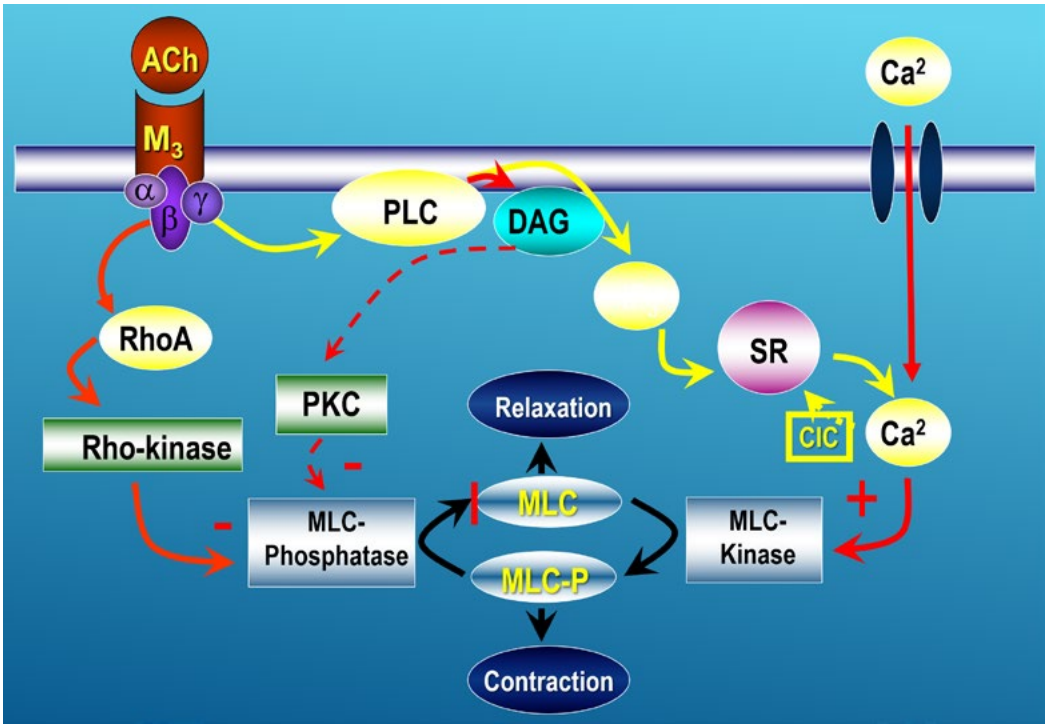

Figure 6: Pathways involved in acetylcholine induced bladder contraction

In the isolated bladder strips from both animals and man local bladder wall small spontaneous contractions can be observed. In isolated whole bladders these contractions are mirrored by small transient increases of intravesical pressure. These pressure movements are not co-ordinated; they are autonomous, with a non-neurogenic origin and thus intrinsic to detrusor smooth muscle itself, but they can be modulated or initiated by stretch of the bladder wall and by local factors. In pathologically changed animal bladders in vivo large pressure variations can occur. Several theories, not mutually exclusive, have been advanced for the origin of such spontaneous contractions: myogenic, neurogenic or urotheliogenic and have been extensively discussed [Fry and McCloskey, 2019]. Characterisation of these spontaneous contractions is important to understand how normal bladder compliance is maintained during filling and the pathophysiology of detrusor overactivity [Fry and McCloskey, 2019].

The urothelium can release neurotransmitters and modulators such as acetylcholine, ATP, nitric oxide, prostaglandins, neuropeptides and nerve growth factor [Guan et al., 2017; Sellers et al., 2018]. In addition, several studies have reported the existence of an urothelium-derived unknown inhibitory factor in the urinary bladder. These factors exert both excitatory and inhibitory effects in modulating urinary tract motility and may also affect function and growth of smooth muscle cells and afferent nerves. The urothelium of the human proxima urethra can generate sensory input through a cross-talk between paraneuronal cells releasing serotonin embedded in the urethral urothelium and sub-urothelial sensory fibers experssing 5HT receptors (**7**) [Coelho et al, 2018].

It has been pointed out [Sellers et al., 2018] that the morphology and function of the urothelium undergo changes with aging and in many pathophysiological conditions. It cannot be excluded that the urothelium may contribute to the therapeutic effects of established drugs to treat lower urinary tract dysfunction and may also serve as a target for novel therapeutics.

4. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2012]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome (8). The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. (2006), using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13 % in men and 14.7% in women [Herschorn et al., 2008]. In a Finnish study, taking into account bother, the prevalence of *clinically meaningful OAB,* was was much lower than reported in these studies [Vaughan et al., 2011].

OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO; urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004; Peyronnet et al., 2019]. DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, supersensitivity to acetylcholine of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways, as can be seen in various neurological disorders, such

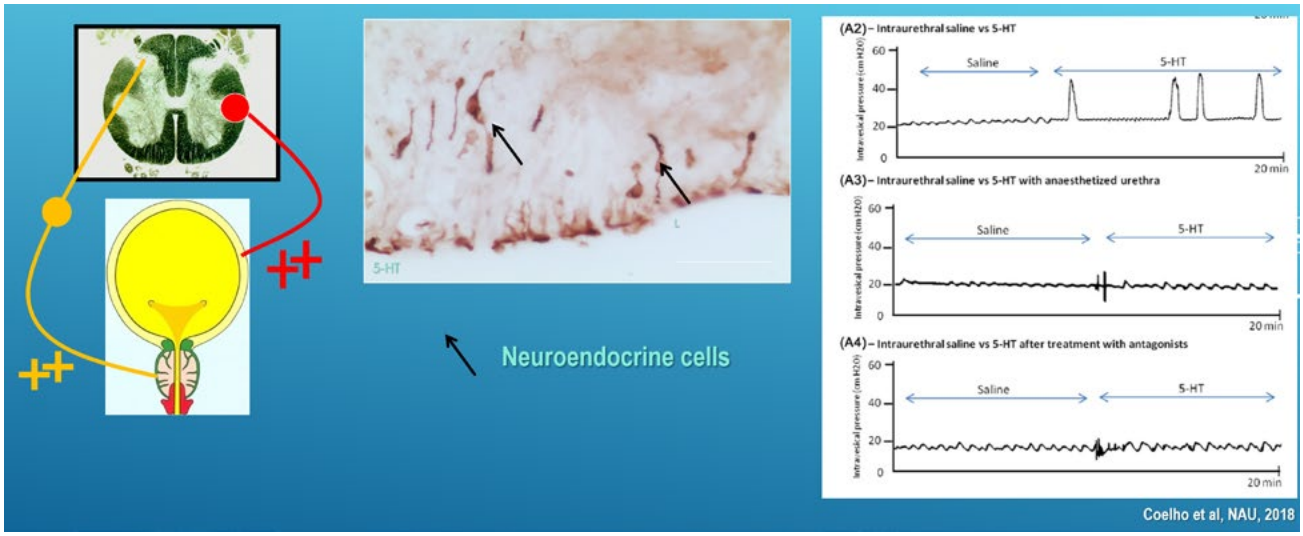

Figure 7: The urethral-bladder reflex initiated by neuroendocrine cells releasing 5HT. From Coelho et al. 2018 Nov;37(8):2389-2397

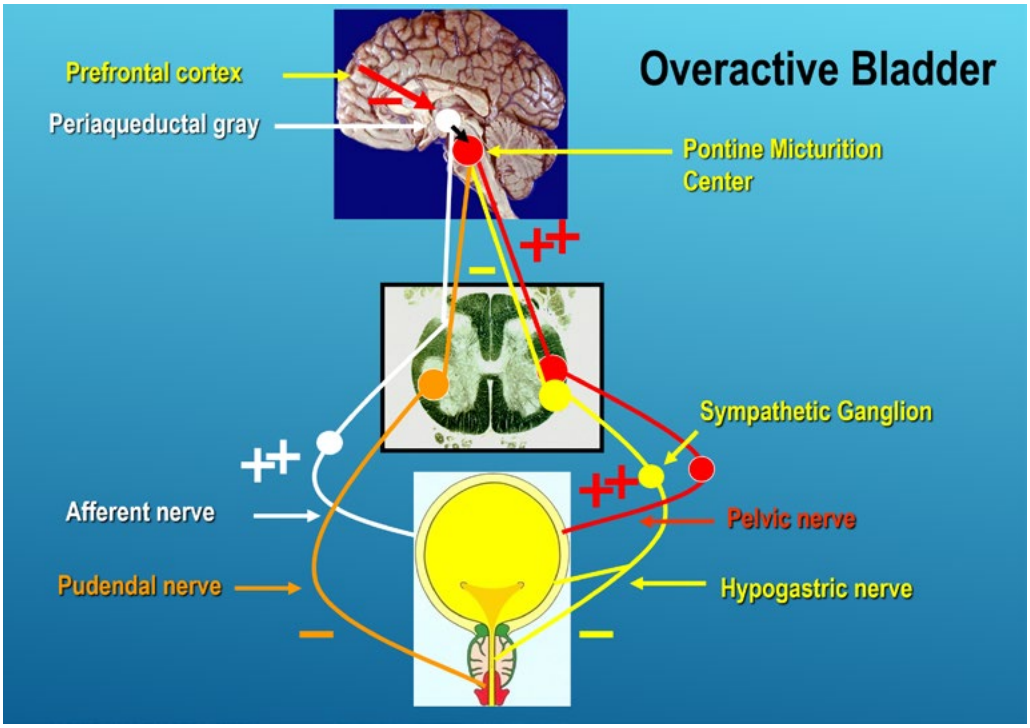

Figure 8: Reflex activity in the overactive bladder

as multiple sclerosis, cerebrovascular disease, Parkinson's disease, brain tumors, and spinal cord injury [Andersson and Pehrson, 2003; Apostolidis et al. 2018; Hamid et al 2018; Sakakibara, 2019; Peyronnet et al., 2019]. The pathophysiologies of OAB refractory to treatment include occult neurogenic bladder, undetected bladder outlet obstruction, urethral-related OAB, urothelial dysfunction with aging, chronic bladder ischemia, chronic bladder inflammation, central sensitization, and autonomic dysfunction [Chen and Kuo, 2018]. The urinary microbiota may contribute to the sensitization of afferents nerves by releasing excitatory compounds including ATP [Abbasian et al, 2019]

Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g., prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g., diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2012].

III. BLADDER PHARMACOLOGY

1. MUSCARINIC RECEPTORS

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former play a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g., in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors (Abrams and Andersson, 2007). Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder but can also be formed and released non-neuronally by the urothelium (Kummer and Krasteva-Christ, 2014; Yoshida et al., 2008). Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M_{1-5} (Caulfield and Birdsall, 1998). Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M_1, M_3 and M_5 on the one hand and the subtypes M_2 and M_4 on the other. The former prototypically couple via pertussis toxin-insensitive G_q proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive G_i proteins to inhibition of adenylyl cyclase and modulation of several ion channels (Caulfield and Birdsall, 1998).

Sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder (Abrams et al., 2006; Hegde, 2006), studies at the protein level, e.g. based upon radioligand binding, have typically detected only M_2 and M_3 receptors, with the former dominating quantitatively (Abrams et al., 2006; Andersson, 2011b; Goepel et al., 1998; Hegde, 2006; Mansfield et al., 2005). The results of radioligand binding studies in tissue homogenates are probably dominated by the expression of subtypes in detrusor smooth muscle. However, muscarinic receptors have also been detected in the urothelium, where M_2 and M_3 subtypes also dominate (Bschleipfer et al., 2007; Leonhäuser et al., 2019; Ochodnicky et al., 2012; Zarghooni et al., 2007). Muscarinic M_3 receptor protein has also been reported in bladder interstitial cells (Grol et al., 2011). On the other hand, muscarinic receptors can also exist pre-junctionally where they modulate neurotransmitter release. Pre-junctionally inhibitory receptors in the bladder have been classified as M_2 in the rabbit and rat, and M_4 in the guinea-pig, rat and human, and a mixture of M_2 and M_4 in the mouse (Andersson, 2011a; D'Agostino et al., 1997; Trendelenburg et al., 2005), whereas pre-junctional facilitatory receptors appear to be of the M_1 subtype in the rat and rabbit urinary bladder, but have also been detected in human bladders (Braverman et al., 1998a). The muscarinic facilitatory mechanism seems to be upregulated (M_3 receptors) in overactive bladders from chronic spinal cord transected rats.

While the detrusor expresses far more M_2 than M_3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M_3 receptor based on organ bath experiments with subtype-selective agonists and antagonists (Chess-Williams et al., 2001; Fetscher et al., 2002; Hegde et al., 1997; Kories et al., 2003; Schneider et al., 2004a; Schneider et al., 2004b; Witte et al., 2011) or on knock-out mice (Ehlert et al., 2007; Matsui et al., 2002; Matsui et al., 2000; Stengel et al., 2002). Under physiological conditions M_2 receptor-selective stimulation causes little contraction (Schneider et al., 2005b) but rather appears to act mainly by inhibiting β-adrenoceptor-mediated detrusor relaxation (Ehlert et al., 2007; Hegde et al., 1997; Matsui et al., 2003). It has been proposed that M_2 receptors can also directly elicit bladder contraction under pathological conditions (Braverman et al., 2006; Braverman et al., 1998a; Braverman et al., 1998b; Braverman and Ruggieri, 2003; Braverman et al., 2002) but such observations have not been confirmed by other investigators using distinct methodological approaches (Schneider et al., 2005a; Schneider et al., 2005b). Studies in the bladder (Cernecka et al., 2014; Michel and Sand, 2009) and in several other tissues (Dale et al., 2014) have observed that β-adrenoceptor agonists including β_3-selective agonists are less potent and/or efficacious in causing relaxation when tested against muscarinic agonists as compared to a variety of other contractile stimuli. Thus, muscarinic receptors make it harder to cause relaxation than other contractile stimuli, an effect apparently involving both M_2 and M_3 receptors (Witte et al., 2011).

Based upon the prototypical signalling pathway of M_3 receptors (Caulfield and Birdsall, 1998) and the presence of phospholipase C stimulation by muscarinic agonists in the bladder (Kories et al., 2003), it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C (Ouslander, 2004). While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs

largely independent of phospholipase C (Frazier et al., 2007; Schneider et al., 2004a; Schneider et al., 2004b; Wegener et al., 2004). Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase appear to contribute to muscarinic receptor-mediated bladder contraction in a major way (Frazier et al., 2008).

The functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e., by investigating the effects of urothelium removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction (Birder, 2010; Dalghi et al., 2020; Sellers et al., 2018). Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) (Andersson et al., 2009). Muscarinic receptor blockade in urothelial cells may also reduce ATP release induced by stretch (Young et al., 2012). Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established.

Assuming an involvement of muscarinic receptors in physiological *voiding* contractions of the bladder, numerous studies have explored whether an overactivity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors (Stevens et al., 2006). However, the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive (Michel and Barendrecht, 2008). This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during *bladder filling* (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions (Rapp et al., 2005; Yoshida et al., 2001; Yoshida et al., 2008). These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies (Buser et al., 2012; Chapple et al., 2008; Novara et al., 2008; Reynolds et al., 2015; Shamliyan et al., 2008).

2. β-ADRENOCEPTORS (β-ARS)

The body of the bladder receives a relatively sparse innervation by noradrenergic nerves. The density of noradrenergic nerves increases markedly toward the bladder neck, where the smooth muscle receives a dense noradrenergic nerve supply, particularly in the male [Gosling et al., 1999]. Noradrenergic nerves also occur in the lamina propria of the bladder, only some of which are related to the vascular supply. Their functional significance remains to be established [Gosling et al., 1999].

In the human detrusor, b-ARs dominate over a-ARs with an order of abundance of $b > a_2 >> a_1$ with the amount of a_1-ARs too small for a reliable quantification; the situation is different in the trigone, and may differ between species for both [Michel & Vrydag, 2006). Accordingly, the primary detrusor response to noradrenaline is relaxation. Even if the a-ARs have no significant role in normal human detrusor contraction, there is evidence from animal models that this may change after, for example, bladder outlet obstruction, parasympathetic decentralization, and in overactive bladders.

The relaxant effect of noradrenaline on the detrusor can be exerted both pre- and postjunctionally [Åmark, et al., 1986]. Stimulation of a_2-ARs on cholinergic neurons may lead to a decreased release of acetylcholine. b-ARs including b_3-AR also exist prejunctionally, including those on cholinergic neurons, but their functional role has remained controversial [Okeke, Gravas, & Michel, 2017]. Since b-ARs dominate over a-ARs post-junctionally in the bladder [Andersson & Wein, 2004; Nomiya & Yamaguchi, 2003], noradrenaline relaxes the detrusor through stimulation of b-ARs. b-AR agonists are considered to stimulate adenylyl cyclase to increase cAMP. In turn, cAMP activates protein kinase A to mediate the biological effects. However, it remains unclear whether this signaling pathways mediates detrusor relaxation [Frazier, Peters, Braverman, Ruggieri, & Michel, 2008]. Both normal and neurogenic human detrusors express b_1-, b_2-, and b_3-AR mRNAs, but relaxation of human detrusor is mediated predominantly if not exclusively by b_3-AR [Igawa, Aizawa, & Michel, 2019; Michel & Vrydag, 2006]. However, other b-AR subtypes may be involved in other species, for instance b_2-AR contribute to relaxation in rat detrusor and even dominate in mouse detrusor [Yamazaki, et al., 1998; Propping, et al., 2016]. These findings suggest b-AR, and particularly b3-AR, stimulation as a way of promoting bladder relaxation during filling. However, this does not necessarily mean that this mechanism is active during normal filling. The importance of the sympathetic input for human bladder function is controversial. Sympathectomy has no distinct effect on bladder filling, and neither has blockade of b-ARs [Andersson & Wein, 2004]. The sympathetic nervous system may not be essential for urine storage in humans. However, if released noradrenaline contributes to bladder relaxation during filling, it may be through stimulation of both b_2- and b_3-ARs.

2.1. Expression of β-ARs in the bladder

2.1.1. mRNA level

All three β-AR subtypes are expressed at the messenger RNA (mRNA) level in the urinary bladder [Michel & Vrydag, 2006]. While initial studies on relative abundance of subtype mRNA have indicated that $β_3$-AR account for more than 95% of all β-AR mRNA in the human detrusor [Nomiya & Yamaguchi, 2003], a later study based on whole bladder rather than detrusor reported a comparable expression of all three subtypes [Uhlen et al., 2015]. A similar abundance of all three subtypes has also been reported in rat bladder (Barendrecht et al., 2009a). In situ hybridization studies have localized expression of $β_3$-AR mRNA in the human detrusor [Takeda et al., 1999]. However, the predictive value of $β_3$-AR mRNA for presence of functional receptor protein remains uncertain.

2.1.2. Protein level

The detection of AR subtypes can in principle be based on radioligand binding (including autoradiography) studies or on antibody-based approaches. Radioligands with high affinity and specificity for $β_3$-AR became available only recently (van Wieringen, et al., 2013). Other radioligands preferentially label b_1- and b_2-AR, which depending on assay conditions have technically been challenging to interpret [Schneider & Michel, 2010] or failed to detect b_3-AR [Michel & Vrydag, 2006; Schneider & Michel, 2010]. The latter studies suggested that b_2-ARs are much more abundant than b_1-ARs.

Antibody-based approaches including immunohistochemistry have the potential for high selectivity in detecting AR subtypes and mapping them to distinct morphological structures. Thus, most reported β-AR subtype antibodies lack specificity or have not been tested for it under stringent conditions. Some antibodies have been proven to have some degree of selectivity for β_3-AR [Cernecka, et al., 2012; Chamberlain et al., 1999; Guillaume et al., 1994] but the degree of selectivity is only moderate and may depend on application being used (i.e., histochemistry vs. immunoblotting) and limited to certain species. Moreover, even minor differences in applied methods may lead to differences in detecting β-AR subtypes [Jositsch et al., 2009].

This is illustrated by recent immunohistochemistry studies in the human bladder: Despite using the same antibodies, some investigators detected β_3-AR in smooth muscle fibres and, to a lesser extent, in urothelium and suburothelium [Silva et al., 2017], whereas others found them colocalized with the vesicular acetylcholine (ACh) transporter and primarily in nerve fibres in the mucosa and muscular layers of the bladder but not in urothelium or smooth muscle [Coelho,et al., 2017]). Based on other antibodies, others reported β_3-AR expression to a greater extent in urothelium than smooth muscle of the human bladder and also in sub-urothelial myofibroblast-like cells, intramural ganglions, Schwann cells and intramural nerves [Limberg et al., 2010]. Thus, the localization of β_3-AR in the human bladder remains at least partly controversial. This is unfortunate because a robust understanding of the cell types expressing β_3-AR in the bladder could guide an understanding which cell types contribute to the clinical effects of β_3-AR agonists.

2.2. Roles of β-ARs in the bladder physiology and pathophysiology

The physiological voiding in humans, and perhaps dogs [Frara et al., 2021] is predominantly mediated by muscarinic M_3 receptor, which differs from rodents where other transmitters contribute to a major degree; however, additional mediators may also such as ATP may also play relevant roles in humans under pathophysiological conditions [Ouslander, 2004]. Limited evidence indicates that pathophysiological states do not cause major changes in β-AR subtype mRNA expression in the detrusor [Barendrecht et al., 2009b; Nomiya & Yamaguchi, 2003]. Accordingly, relaxant effects of β_3-AR in samples of patients with BOO and BOO with detrusor overactivity (DO) were similar [Svalo et al., 2013], which is in line with findings from various animal models [Michel & Barendrecht, 2008].

2.2.1. Detrusor smooth muscle

β-AR-mediated relaxation of the human detrusor is mediated predominantly, if not exclusively, by β_3-AR; however, this appears to be species dependent with similar contributions of β_2- and β_3-AR involved in rats and β_2-AR even dominating in mouse [Michel & Vrydag, 2006; Propping et al., 2016]. Such species differences can complicate extrapolation from animal data to humans. In addition to causing smooth muscle relaxation, β-AR agonists can also counteract contraction elicited by stimulation of other receptors such as muscarinic receptors [Ehlert et al., 2007; Klausner, et al., 2009]. In this regard, studies in rat bladder show β-AR agonists are more potent and more effective against any contractile stimulus other than muscarinic agonists [Cernecka, et al., 2014; Michel & Sand, 2009]. Similar observations have been made in several other smooth muscle preparations [Dale et al., 2014]. Accordingly, β_3-AR agonists may preferentially inhibit detrusor contractions by pathological stimuli such as bradykinin, but largely be sparing those mediated by muscarinic receptors involved in physiological voiding [Igawa, Aizawa & Michel, 2019].

2.2.2. Urothelium

The urothelium plays an active role in the regulation of bladder function: it senses input from its environment by virtue of express-

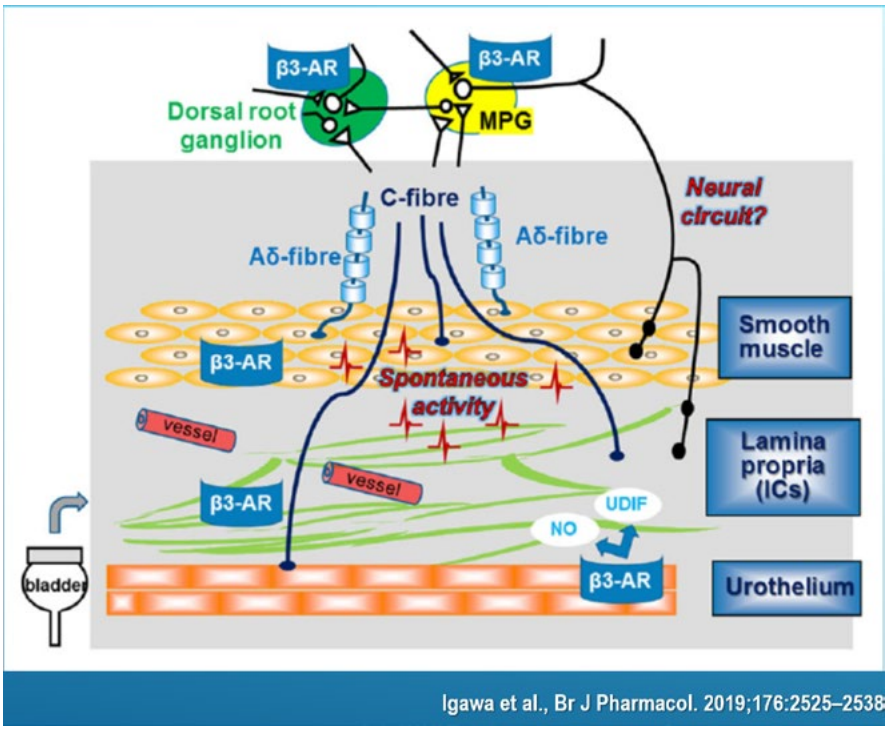

Figure 9: Expression of β3-ARs and possible mechanism that might be involved in the afferent pathway and modulation of spontaneous activity in the bladder. Reproduced with permission from (Igawa et al Br J Pharmacol, 2019; 176: 2525-2538).

ing receptors for various stimuli and releasing neurotransmitters in response to those stimuli [Birder & Andersson, 2013; Sellers, Chess-Williams, & Michel, 2018]. All three β-AR subtypes are expressed in the urothelium at the mRNA level [Ochodnicky et al., 2012; Otsuka, et al., 2008; Tyagi, et al., 2009]. Based on immunohistochemical studies, β_3-AR may be more abundant in the urothelium than in the detrusor (**9**); nonetheless, it may be functionally less important as compared to urothelial β_2-AR, which appears more relevant for the regulation of urothelial function [Sellers et al., 2018]. The stimulation of urothelial β_3-AR leads to release of nitric oxide (NO) to modulate afferent nerves and release of urothelial-derived inhibitory factor to modulate detrusor function (Fig 9) [Igawa, Aizawa & Michel, 2019].

2.2.3. Suburothelial interstitial cells

The bladder suburothelium consists of various cell types including microvessels, sensory nerve endings and interstitial cells (ICs, **9**). A similar level of β_3-AR expression at the protein level in ICs and detrusor has been suggested [Otsuka et al., 2013], but these data are difficult to interpret based on poor validation of the antibody being used. Suburothelial ICs may be a possible origin of spontaneous contractile activity of the mucosa, for instance in guinea pigs and pigs [Igawa, Aizawa & Michel, 2019]. It has been proposed that hyperactivity of bladder afferent nerves may at least partly result from spontaneous contraction of the mucosa, and that β_3-AR agonists can inhibit spontaneous contractile activities by acting on ICs [Aizawa et al., 2017]. This would be consistent with the observation that the β_3-AR agonist mirabegron lowered non-voiding contractions (NVCs) in rats with BOO [Gillespie et al., 2012]. However, these data would not align with observations that β_3-ARs in the human bladder were primarily located in smooth muscle with a more limited expression in the urothelium and suburothelium [Silva et al., 2017]. While these conflicting data need to be resolved, most findings are in line with a theory in which a urothelium-associated sensory web links bladder sensory function (**Fig 9**) [Apodaca, 2004].

2.2.4. Afferent nerves

Two types of afferent nerve fibres are found in the bladder, which differ in morphology, localization and function [Christie et al., 2021]: The myelinated Aδ-fibres appear to dominate in the detrusor and may mainly be involved in physiological sensing of bladder filling. In contrast, the unmyelinated C-fibres are found in the detrusor and the lamina propria (including ICs) and are largely involved in the sensing of pathophysiological signals [de Groat, 2004; Gabella & Davis, 1998; Ouslander, 2004; Vera & Nadelhaft, 2000]. Morphological studies suggest a presence of β_3-ARs in bladder afferent nerves [Coelho et al., 2017) as well as in the major pelvic ganglion (MPG) in rats [Eastham, et al., 2015]. Functional studies in normal rats demonstrated that mirabegron can inhibit the mechanosensitive Aδ-fibres, which may be related to suppression of the bladder micro-contractions [Aizawa, Homma & Igawa, 2012]. Furthermore, afferent activities of both Aδ- and C-fibres were intermittently enhanced by propagation of bladder myogenic micro-contractions in BOO rats [Aizawa et al., 2017]. These findings suggest a possibility of involvement of β3-AR on neural circuits in the regulation of afferent outflow and sensation [Igawa, Aizawa, & Michel, 2019] (**9**).

2.2.5. Bladder vasculature

It is increasingly recognized that hypoperfusion of the bladder may play a causative role in functional disorders of the lower urinary tract [Michel, Chess-Williams, & Hegde, 2015; Thurmond, Yang, & Azadzoi, 2016], which makes blood vessels supplying the bladder as a potential target for the treatment of LUTS. Although the regulation of vascular tone has traditionally been attributed to β_2-AR, β_3-AR can contribute to such regulation in various vascular beds [Bhadada, et al., 2011]. Accordingly, initial reports indicate that β_3-AR agonists can improve bladder function in animal models of LUTS based on experimental atherosclerosis and ischemia [Bayrak et al., 2015; Sawada et al., 2013]. Whether this at least partly reflects direct effects on bladder perfusion or a generally beneficial effect of β_3-AR agonists on bladder function, remains to be explored.

2.2.6. Possible roles in pathophysiology of OAB

Most studies using isolated detrusor strips have reported a potency of mirabegron for causing relaxation in the low micromolar range [Igawa & Michel, 2013]. On the other hand, plasma concentrations observed upon therapeutic doses of mirabegron do not exceed 100 nM [Krauwinkel et al., 2012].This discrepancy may propose that the cellular target of β3-AR agonists in the treatment of OAB may not be the detrusor small muscle cells [Eastham, et al., 2015] but rather a different cell types, including urothelial cells, interstitial cells, efferent, afferent neurons, the major pelvic ganglion and/or blood vessels supplying the urinary bladder [Okeke, Gravas & Michel, 2017].

Mirabegron had high potency for inhibiting the nerve-evoked contraction and ACh-release in human bladder preparation, with EC_{50} value of 123 nM and 129 nM, respectively [D' Agostino, Maria Condino & Calvi, 2015],which are more potent than those producing direct relaxation of human detrusor smooth muscle. Moreover, a recent immuno-histochemisty study on human bladder tissue indicated that *β*3-ARs are expressed only on cholinergic nerve fibres, but are not present on urothelial or smooth muscle cells [Coelho, et al.,, 2017]. These findings may lead to the hypothesis that β3-AR agonists act, at least in part, by inhibiting ACh- release from cholinergic, most probably parasympathetic, nerve terminals through a prejunctional mechanism [Coelho, et al., 2017].

However, another study showed a controversial finding that *β*3-ARs are diffusely distributed among detrusor smooth muscle cells, but are not present on cholinergic nerve fibres, while adenosine A1 receptor predominantly expressed on cholinergic nerve fibres [Silva et al., 2017]. Furthermore, both isoprenaline and mirabegron decreased ACh-release induced by electrical field stimulation in human detrusor preparation, which was prevented by *β*3-AR antagonists and DPCPX, an adenosine A1 antagonist [Silva et al., 2017]. These findings suggest that the decrease in ACh-release induced by isoprenaline or mirabegron did not necessarily occur via *β*3-ARs located in the nerve ending but rather indirectly by intermediate formation of adenosine and subsequent activation of A1 inhibitory receptors (**Fig 10**). However, it remains to be clarified whether such inhibition of ACh-release occurs exclusively indirectly via adenosine formation and A1 adenosine receptor activation or whether it may also involve a neuronally expressed *β*3-ARs. Nevertheless, β3-AR agonists would preferentially inhibit pathologically increased detrusor tone during bladder filling over physiological detrusor contraction during voiding and enable to inhibit an increased cholinergic tone in OAB [Igawa, Aizawa, & Michel, 2019].

It has been demonstrated in women with OAB that an increase in localized contractile activities (micro-contractions) developed during occurrence of urinary urgency without apparent increasing intravesical pressure [Drake, et al., 2005]. Cystometric studies in a decerebrated rat model demonstrated that intravesical administration of mirabegron increased inter-voiding intervals and compliance and decreased the amplitude of non-voiding contractions [Sadananda, et al., 2013].

Studies with monitoring bladder mechanosensitive single-unit afferent activities (SAAs) in rats revealed that the afferent activities of both A*δ*- and C-fibres decreased after mirabegron-adminis-

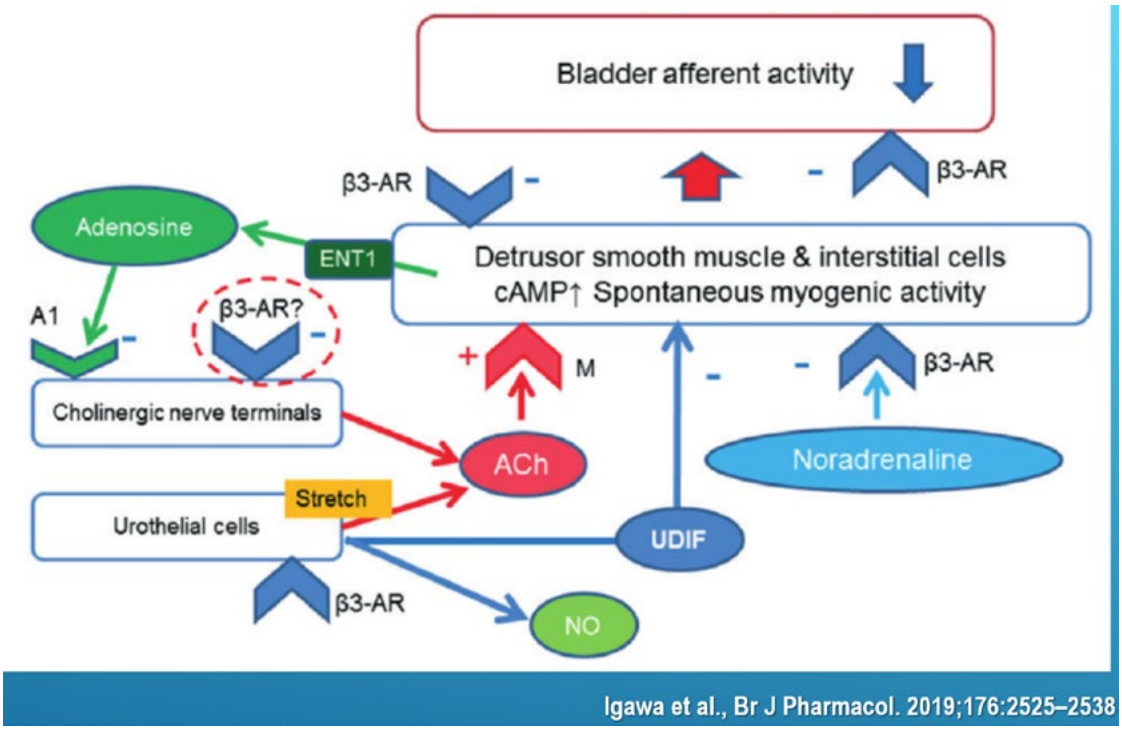

Figure 10: Hypothetic mechanism of mirabgron's inhibitory action on ACh-release through the A1 receptors. Reproduced with permission from (Igawa et al Br J Pharmacol, 2019; 176: 2525-2538).

tration in a dose-dependent manner, which was more remarkable for Aδ-fibres than C-fibres; moreover, such inhibition of afferent activities appeared to synchronize with the decrease in bladder pressure fluctuation (micro-contractions), whereas bladder compliance did not change significantly from the base-line value [Aizawa, Homma & Igawa, 2012]. These authors further confirmed in an isovolumetric condition that mirabegron at 0.3 mg/kg suppressed micro-contractions concomitantly with Aδ-fibre activity but not C-fibre activity with [Aizawa, Homma & Igawa, 2015]. Another β3-AR agonist, CL316,243 (10 μg/kg intravenously) similarly decreased Aδ-fibre, but not C-fibre, activities during bladder filling with saline. Intravesical instillation of prostaglandin E_2 (PGE_2) significantly increased C- but not Aδ-fibre activities. Pretreatment with CL316,243 inhibited the increase in C-fibre activities induced by PGE_2 [Aizawa, et al., 2010]. A recent study with similar monitoring bladder mechanosensitive SAAs in rats with BOO showed a higher number of micro-contractions and lower SAAs of Aδ-fibres, but SAAs of both Aδ- and C-fibres were intermittently enhanced by micro-contractions. These pathophysiological findings may contribute to the development of OAB associated with BOO [Aizawa et al., 2017].

Taken all together, the possible mechanisms of action exerting inhibition of urgency by β3-AR agonists may include: 1) relaxing detrusor muscle-decreasing bladder tone, 2) inhibiting micro-contractions/Aδ-fibre activity, 3) inhibiting urotheliogenic afferent activation-C-fibre activity (**Fig 11**) [Igawa, Aizawa, & Michel, 2019].

3. β-ARS IN THE URETHRA

While we are not aware of studies demonstrating b-AR mRNA expression in the urethra, recent immunohistochemical studies have suggested the presence of β3-ARs in the human female urethra, which was found in the epithelial layer of all parts but highest in the mid urethra [Kummeling et al., 2020]. This finding provides a mechanistic basis for reports that b3-AR agonists, including mirabegron, a clinically used one, can cause relaxation of the urethral smooth muscle of several animal species and humans [Alexandre et al., 2016; Yamanishi, et al., 2003]. How such in vitro findings relate clinical observations in patients with LUTS remains to be determined.

4. β-ARS IN THE PROSTATE

All three β-AR subtypes appear to be expressed in the prostate at the mRNA and protein levels, but precise quantitative information on their relative contribution is lacking [Michel & Vrydag, 2006]. While earlier studies concluded that relaxation of human prostate was primarily mediated by β_1- and β_2-AR, more recent findings with mirabegron suggest a role for β_3-AR [Calmasini et al., 2015]. Such findings could provide a mechanistic basis for ongoing evaluation of β_3-AR agonists in the treatment of LUTS suggestive of benign prostatic hyperplasia.

5. IN VIVO STUDIES

Most *in vivo* studies of β_3-AR agonists on bladder function have been performed in rats and mice. They have demonstrated increases of bladder capacity with little effect on micturition pressure or the residual volume [Fujimura et al., 1999; Hicks et al., 2007; Kaidoh et al., 2002; H. Takeda et al., 2002; Woods, et al., 2001,Takasu et al., 2007].

However, the cellular target underlying such effects remains unclear because of the following dilemma: With very few exceptions, the reported potency of mirabegron to relax isolated bladder strips

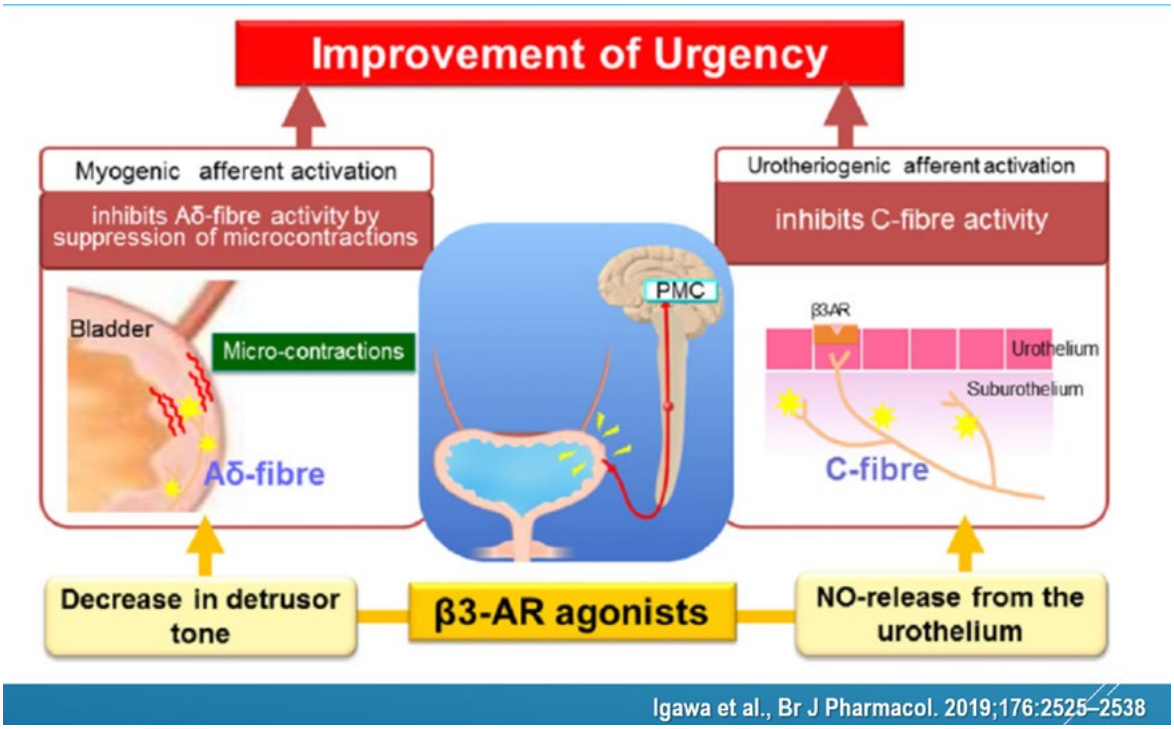

Figure 11: Hypothetic mechanisms involved in urgency-improvement by β3-AR agonists. Reproduced with permission from (Igawa et al Br J Pharmacol, 2019; 176: 2525-2538).

is in the low micromolar range [Igawa & Michel, 2013], whereas plasma concentrations observed upon therapeutic doses of mirabegron typically are less than 100 nM [Krauwinkel et al., 2012]. This led to proposals that the primary cellular target of mirabegron (and perhaps β_3-AR agonists in general) may not be detrusor smooth muscle [Eastham et al., 2015]. Potential alternative targets include the urothelium, ICs, efferent and afferent nerves, the major pelvic ganglion and/or blood vessels supplying the urinary bladder. All of these proposals are intriguing and have some degree of plausibility. However, it remains unclear whether mirabegron has a potency for those targets that is more in line with its therapeutic plasma levels. Of note, the list of potential targets is not necessarily mutually exclusive and rather could be a combination of several of them. This will require additional investigation, a situation which also applies to identifying the true cellular target of muscarinic receptor antagonists in the treatment of OAB [Andersson, 2004].

IV. DRUGS TO TREAT OVERACTIVE BLADDER SYMPTOMS/DETRUSOR OVERACTIVITY

It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (Table 2). Helfand and co-workers showed that in a cohort of 7,244,501 patients over 45 years with an OAB diagnosis, 24.4% of these were treated mainly with antimuscarinic agents; 75.6% went untreated. Only 25.6% of those treated were men [Helfand et al., 2010]. As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

1. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS (MUSCARINIC RECEPTOR ANTAGONISTS)

Since the last edition of this section a limited number of studies have been added to the literature. Clinically important information has been updated in the clinical use section below. For the individual antimuscarinic agents, selected studies have been identified and presented and where updated information is available and relevant, has been added. A more exhaustive and detailed selection of individual studies is presented in the previous iteration of this book (Incontinence, 6th edition). Finally, where drugs have essentially become obsolete, they have been removed e.g., atropine, propantheline bromide and flavoxate but can be reviewed in the previous edition, if required. Comparison of individual antimuscarinics with other modalities of managing overactive bladder have not been included and in general the number of studies in this area are small. Cost effectiveness of antimuscarinics has also not been included due to the different healthcare systems around the world, however, a recent article has reviewed the available literature [Giannitsas and Athanasopoulos, 2015] and a further study looking at a UK health system has been published [Hakimi, Kelleher et al., 2018]. Furthermore, combination pharmacotherapy of antimuscarinics with other agents will be discussed in another section in this chapter.

1.1. Pharmacology

1.1.1. Mechanism of action.

Muscarinic receptor antagonists (antimuscarinics) bind to muscarinic receptors to prevent their activation by agonists including the endogenous agonist acetylcholine (ACh) [Caulfield and Birdsall, 1998]. This occurs throughout the entire body. Acetylcholine is released from three types of neurons: those within the CNS, the motor neurons innervating skeletal muscle, and parasympathetic nerves; moreover, ACh can be formed by and released from non-neuronal sources such as the urothelium [Yoshida, Masunaga et al. 2008]. While ACh released from motor neurons acts on nicotinic receptors, that from parasympathetic nerves and non-neuronal sources largely acts on muscarinic receptors; ACh released within the central nervous system acts on both types of receptors.

ACh released from parasympathetic nerves plays a major role in the execution of voiding by contracting muscarinic receptors on detrusor smooth muscle cells. While release of ACh from parasympathetic nerves is assumed to occur largely during the micturition phase of the voiding cycle, non-neuronally released ACh can also be released during the storage phase, which makes it a candidate to cause non-voiding contractions [Andersson, 2011, Sellers, Chess-Williams et al., 2018].

It had long been believed that antimuscarinics reduce OAB symptoms blocking muscarinic receptors on detrusor smooth muscle cells [Sellers and Chess-Williams, 2012]. However, muscarinic receptors on various other cell types including the urothelium and afferent and efferent nerves may also contribute to the control of

urine storage and micturition [Andersson, 2004]. For instance, muscarinic antagonists can modulate the activity of both C- and Ad-type afferent nerves [Andersson, 2011; Michel 2015] (Figure 9). A role for muscarinic receptors expressed in the urothelium in the regulation of physiological voiding, and even more so that of OAB/DO has been suggested [Andersson, 2011; Sellers and Chess-Williams, 2012; Birder and Andersson 2013; Michel 2015], such role has not been firmly established.

The competitive antagonism exerted by clinically used antimuscarinics implies that their effects can be overcome by the massive release of ACh occurring during micturition; this may explain why antimuscarinics in clinically used doses have little effect on voiding contractions [Finney, Andersson et al., 2006] the others mainly report bladder capacity, frequency and sensation of urgency. Nonetheless, (acute) urinary retention can occur, however, it is rare in humans in doses typically applied for the treatment of OAB/DO (**Fig 12**).

1.1.2. Pharmacodynamic properties

Antimuscarinics can be classified based on their relative affinity for subtypes of muscarinic receptors. While most antimuscarinics bind with similar affinity to all five muscarinic receptor subtypes, darifenacin exhibits a moderate and oxybutynin and solifenacin a minor selectivity for the M_3 subtype, i.e., the subtype predominantly mediating contraction of detrusor smooth muscle [Glavind and Chancellor, 2011; Yamada et al., 2018]. The clinical relevance of subtype-selectivity may be limited because the most frequent AE (dry mouth and constipation) are also mediated by M_3 receptors. An exception may be increased heart rate, which is largely mediated by M_2 receptors [Glavind and Chancellor, 2011]. However, elevation of heart rate typically is very minor with therapeutic doses of all antimuscarinics used in the treatment of OAB/DO [Rosa, Baccino et al., 2018]. Thus, none of the clinically used antimuscarinics exhibits relevant selectivity for the bladder as compared to other organs upon oral administration.

The antimuscarinics can be divided chemically into tertiary and quaternary amines [Guay, 2003; Abrams and Andersson, 2007]. While trospium is a quaternary amine, all other clinically used antimuscarinics are tertiary amines. Tertiary amines are more lipophilic and for this reason exhibit penetration into the brain [Callegari, Malhotra et al., 2011; Yamada, Ito et al. 2018]; however, this is compensated in some cases, e.g., darifenacin, by active transport out of the brain, for instance by transport via the product of the MDR1 gene. In contrast, quaternary amines exhibit lower oral bioavailability [Guay, 2003], but exhibit little passage through the blood-brain-barrier [Staskin et al., 2010]. This may have implications for the ability of antimuscarinics to impair cognition, which has been documented for all members of this drug class to some extent – except for trospium [Müderrisoglu et al., 2019].

1.1.3. Pharmacokinetic properties

The antimuscarinics used in the treatment of OAB/DO differ considerably in their absorption and ability to penetrate into the brain [Callegari et al., 2011, Yamada et al. 2018], but also in their routes of metabolism and excretion [Guay, 2003; Witte et al. 2009]. Such differences impact the extent and variability of absorption, with quaternary amines typically exhibiting smaller and more variable oral bioavailability. They also determine the potential for drug-drug-interactions and their restrictions of use in patients with impaired hepatic or renal function **(Table 3).** They also impact the half-lives of the various drugs after becoming systemically available, ranging from 2-3 h for oxybutynin to 45-68 h for solifenacin. Moreover, the metabolism of some antimuscarinics leads to metabolites that are pharmacologically active, with the metabolites sometimes exhibiting a different pharmacological profile than the parent compound [Michel and Hegde, 2006]); examples of the latter include fesoterodine, oxybutynin and propiverine.

The main pathways of metabolism of antimuscarinics involve cytochrome P450 enzymes, specifically CYP2D6 and CYP3A4 [Guay, 2003; Witte et al. 2009]. Considerable differences exist in the fraction excreted renally in unchanged or otherwise pharmacologically active form ranging from <1% for oxybutynin to 16% for fesoterodine. Such renal excretion raises the possibility of exposing the bladder to the antimuscarinic not only via the blood stream but also from the luminal side, particularly because some antimuscarinics can be reabsorbed from the bladder to become systemically available again [Krause et al., 2013]. However, no evidence is available that differences in renal excretion of active compound have clinical consequences. These differential routes of metabolism and excretion lead to specific recommendations for each drug related to dosing choices or even contraindications in patients with hepatic or renal impairment and/or those with concomitant medication affecting the metabolism (**Table 3**).

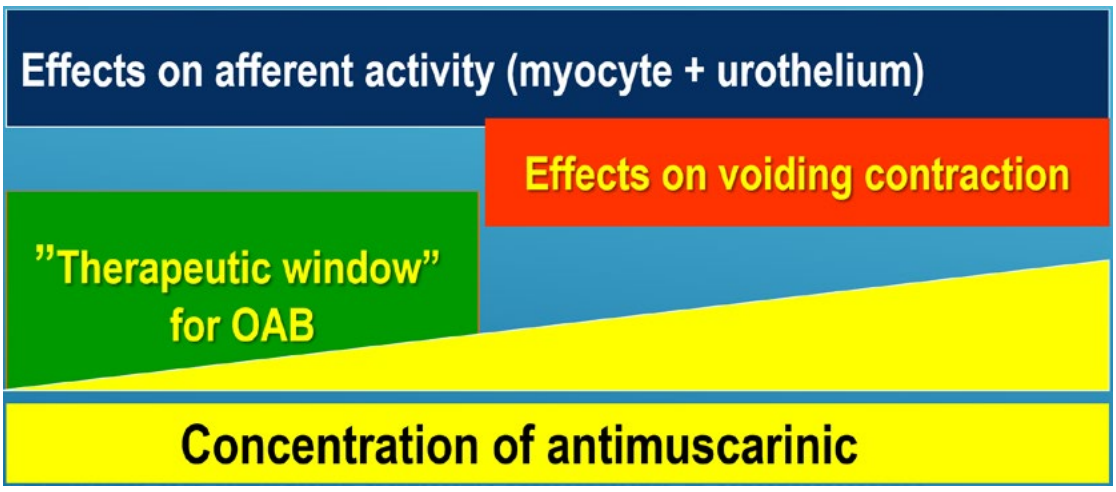

Figure 12: Concentration-dependent effects of antimuscarinics

Table 3: Impact of renal or hepatic impairment and of comedications on dosing recommendations in Europe and the US as based upon regulatory authority-approved summary of product characteristics/package insert. If recommendations differed between countries, the more conservative recommendation is listed. IR, immediate release; ER, extended release; max, maximally. All dosages refer to total daily doses. Unless otherwise noted, the recommendations relate to all available formulations of a given drug. Reproduced with permission from (Witte, Mulder, et al. 2009)

Drug (recommended daily dose)	Renal impairment	Hepatic impairment	Comedications
Darifenacin (7.5/15 mg)	caution	Child Pugh A: none, but risk of increased exposure Child Pugh B: max 7.5 mg, if benefit outweighs risk Child Pugh C: not recommended	CYP2D6 inhibitors: starting dose 7.5 mg, titrate to 15 mg if well tolerated Moderate CYP3A4 inhibitors: starting dose 7.5 mg Potent CYP3A4 inhibitors: do not use
Fesoterodine (4/8 mg)	Mild/moderate: start with 4 mg, increase dose cautiously to 8 mg Severe: 4 mg"	Child Pugh A: start with 4 mg, increase to 8 mg with caution Child Pugh B: max 4 mg Child Pugh C: not recommended	CYP2D6 inhibitors: start with 4 mg Potent CYP3A4 inhibitors: max 4 mg
Oxybutynin (5-30 mg)	Caution	Caution	Potent and moderate CYP 3A4 inhibitors: caution
Propiverine (5/15 IR/30 mg ER)	Max dose 30 mg	Child Pugh A and B: no advice on dose adjustments Child Pugh C: not studied"	Potent CYP 3A4 inhibitors: no studies available but in vitro data point to possible interactions
Solifenacin (5/10 mg)	Mild/moderate: no adjustment Severe: max 5 mg	Child Pugh A: caution Child Pugh B: max. 5 mg Child Pugh C: not recommended	Potent CYP 3A4 inhibitors: max 5 mg
Tolterodine (1/2/4 mg)	Mild/moderate: no data Severe: max 2x1 mg IR or 2 mg ER	max 2x1 mg IR or 2 mg ER	CYP2D6 inhibitor: none potent CYP3A4 inhibitors: max 2x1 mg IR or 2 mg ER
Trospium (40 mg)	Mild/moderate: caution Severe: max 20 mg	Child Pugh A, B and C: caution	-

Darifenacin is metabolized via CYP2D6 and CYP3A4, but the resulting metabolites are considered not to contribute to the clinical effects [Skerjanec, 2006]; about 3% of are excreted renally as active drug [Michel and Hegde, 2006; Witte et al., 2009]. Accordingly, caution should be applied in patients with renal impairment. Hepatic impairment with Child-Pugh A scores, results in an increased exposure but does not result in a need for dose adjustment. If hepatic impairment reaches Child-Pugh B, doses should be limited to 7.5 mg/day and the drug should only be used if anticipated benefit outweighs the risk. It should not be used in patients with Child-Pugh C. In the presence of CYP2D6 inhibitors, the starting dose should be no higher than 7.5 mg/day and it should only be up-titrated to 15 mg/day if the lower dose was well-tolerated. Concomitant use of potent CYP3A4 inhibitors can increase exposure to darifenacin 10-fold and is not recommended.

Fesoterodine is metabolized by non-specific esterases to the pharmacologically active 5-hydroxmethyl tolterodine; the latter is partly excreted renally (16% of administered dose), but partly also metabolized further by CYP2D6 and CYP3A4 [Michel and Hegde, 2006; Witte et al., 2009]. Accordingly, fesoterodine should be started at a dose of 4 mg/day in patients with renal impairment and increased to 8 mg/day with caution in those with mild-moderate renal impairment; the dose should be limited to 4 mg/day in those with severe renal impairment. In patients with hepatic impairment with Child-Pugh A, it should be started at 4 mg/day and increased to 8 mg/day only with caution. In Child-Pugh B, the dose should be limited to 4 mg/day, and fesoterodine is not recommended in patients with Child-Pugh C. In the presence of CYP2D6 inhibitors, treatment should start at 4 mg/day, in the presence of potent CYP3A4 inhibitors 4 mg/day should be the maximum dose.

Oxybutynin undergoes marked first-pass metabolism in the liver upon oral administration; while one of the resulting metabolites is inactive, the other metabolite formed by CYP3A4 is the pharmacologically active N-desmethyl-oxybutynin, which is mainly responsible for the observed clinical profile after oral administration [Michel and Hegde, 2006]. It is postulated that N-desmethyl-oxybutynin is more prone to cause antimuscarinic AE and that this may explain why some oral modified release and transdermal formulations of oxybutynin

may be better tolerated [Michel, 2002; Michel and Hegde, 2006]. In contrast, renal excretion in active form of oxybutynin and N-desmethyl-oxybutynin combined accounts for <1% of administered dose. Accordingly, oxybutynin should be used with caution in patients with renal or hepatic impairment and in those with co-medication with moderate or potent inhibitors of CYP3A4 [Witte et al., 2009].

Propiverine undergoes extensive first-pass metabolism yielding three main, active metabolites among which M5 appears most relevant; these metabolites exhibit a qualitatively and quantitatively distinct pharmacological profile – not only regarding muscarinic receptors but also additional targets such as L-type Ca^{2+} channels and α_1-adrenoceptors [Michel and Hegde, 2006]. These metabolites are partly generated by CYP3A4, and partly by flavin monoxygenases. Less than 1% of an administered dose is excreted renally as unchanged compound. In patients with impaired renal function, the daily dose should not exceed 30 mg; no advice exists on dose adjustment in patients with hepatic impairment, and no clinical studies are available related to an interaction with CYP3A4 inhibitors; however, in vitro data point to possible interactions [Witte et al., 2009].

Solifenacin undergoes extensive hepatic metabolism, partly by CYP3A4, but the metabolites are either considered pharmacologically inactive or to exhibit only low abundance [Michel and Hegde, 2006]. Accordingly, no dose adjustment is required with mild-moderate renal impairment, whereas the dose should be limited to 5 mg/day with severe renal impairment [Witte et al., 2009]. In patients with hepatic impairment, caution should be applied with Child-Pugh A, the dose be limited to 5 mg/day with Child-Pugh B, and use is not recommended with Child-Pugh C. In the presence of potent CYP3A4 inhibitors, the dose should be limited to 5 mg/day.

Tolterodine undergoes hepatic metabolism by CYP3A4 to yield N-desalkyl-tolterodine and by CYP2D6 to yield the pharmacologically active 5-hydroxymethyl-tolterodine (5-HMT) [Michel and Hegde, 2006]. Less than 1% of an administered dose is excreted renally as tolterodine, but 5-14% as 5-hydroxmethyl-tolterodine; the renal excretion in active form is much lower in subjects who are poor metabolizers for CYP2D6. The metabolism of 5-hydroxmethyl-tolterodine is described above for fesoterodine. While dosing recommendations are available for mild-moderate renal impairment, the dose should be limited to 2 mg/day in severe renal impairment or in hepatic impairment or in the presence of potent CYP3A4 inhibitors; no dose adjustment is required in the presence of CYP2D6 inhibitors [Witte et al., 2009].

Trospium undergoes only minor metabolism and is largely excreted in unchanged form in faeces upon oral administration, reflecting the limited oral bioavailability of this drug [Michel and Hegde, 2006]. The pathways of metabolism of absorbed trospium are not fully defined by cytochrome P450 enzymes apparently play only a minor role. About 3.5% of administered dose is excreted renally in unchanged form. Accordingly, caution should be applied in patients with mild-moderate renal impairment, and doses be limited to 20 mg/day in severe renal impairment. Caution should also be applied in patients with hepatic impairment. Dose adjustment in the presence of comedications are not required.

1.2. Clinical Use

Several muscarinic receptor antagonists are available for the treatment of OAB/DO. The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. The randomized controlled trials (RCTs) for some of the antimuscarinics, underlying their approval by the regulatory authorities, have been performed in some cases more than 20 years ago. Some drugs have never been approved in this indication or are no longer in wide clinical use because of unfavorable benefit/risk ratios. These include compounds such as atropine, emepronium, propantheline, and flavoxate; information on these drugs is not included below, but can be found elsewhere [Andersson et al. 1999, Andersson et al., 2017].

Antimuscarinics as a class are effective in the treatment of OAB/DO by reducing symptoms and improving OAB-related quality of life (QoL); clinically noticeable improvements often manifest with 1-2 weeks after initiation of treatment [Chapple et al., 2008; Novara et al., 2008; Wang et al. 2014]. No major difference of efficacy has been observed between compounds, between men and women or between younger and older patients. While urgency is the defining symptom of OAB [Abrams et al., 2002; D'Ancona et al., 2019], approval by regulatory authorities has been based on their effects against incontinence and frequency. Interestingly, antimuscarinics as a class appear more effective against these two OAB symptoms than against urgency, although also some degree of improvement of urgency has also been demonstrated [Chapple et al., 2008; Novara et al., 2008; Wang et al., 2014]. In contrast, antimuscarinics exhibit only little improvement of nocturia relative to placebo in RCTs [Schneider et al., 2009; Cornu et al., 2012], although some exceptions have been reported [Michel and de la Rosette, 2005; Weiss et al., 2013]. A consistent improvement of nocturia is seen in observational studies for instance with darifenacin [Schneider et al., 2010], propiverine [Oelke et al., 2011], solifenacin [Witte et al., 2009] or tolterodine [Michel et al., 2005], possibly reflecting at least partly a placebo effect. More detailed information on specific studies for the individual antimuscarinics has been summarized in the past [Andersson et al., 1999; 2017].

The efficacy of antimuscarinic drugs relative to placebo had been questioned [Herbison et al., 2003]. The authors stated that anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo but the benefits maybe of limited clinical significance. Since that study, large meta-analyses of studies performed with the 'at the time' most widely used drugs [Chapple et al., 2005; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al., reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality [Novara et al., 2008]. The review concluded that ER formulations should be preferred to the IR ones and that with IR formulations, dose escalation might yield some improvements in the efficacy but with significant increase in the AE. Reviewing information from more than 12,000 references, Chapple et al., based their conclusions that "antimuscarinics are efficacious, safe, and well tolerated treatments" on 73 RCTs selected for their meta-analysis [Chapple et al., 2005]. There were significant differences between the antimuscarinics in rates of withdrawal and rates and range of adverse events and efficacy outcomes.

The most frequent AEs observed with antimuscarinics in the treatment of OAB/DO include dry mouth and constipation (**Fig 13**). Most RCT and specific studies with head-to-head comparisons of multiple antimuscarinics were neither designed nor powered for AEs as an endpoint. Analysis of specific AEs such as dry mouth, constipation or blurred vision has been reported but is also difficult to interpret because sample sizes often were insufficient for clear differentiation. Another hard tolerability-related endpoint is withdrawal due to AE, but again incidences mostly were too low with the given sample sizes to allow clear differentiation. With these limitations in mind, meta-analyses of tolerability have been reported [Chapple et al., 2008; Maman et al., 2014]. Two general trends appear from these analyses. Firstly, immediate-release oral oxybutynin appears

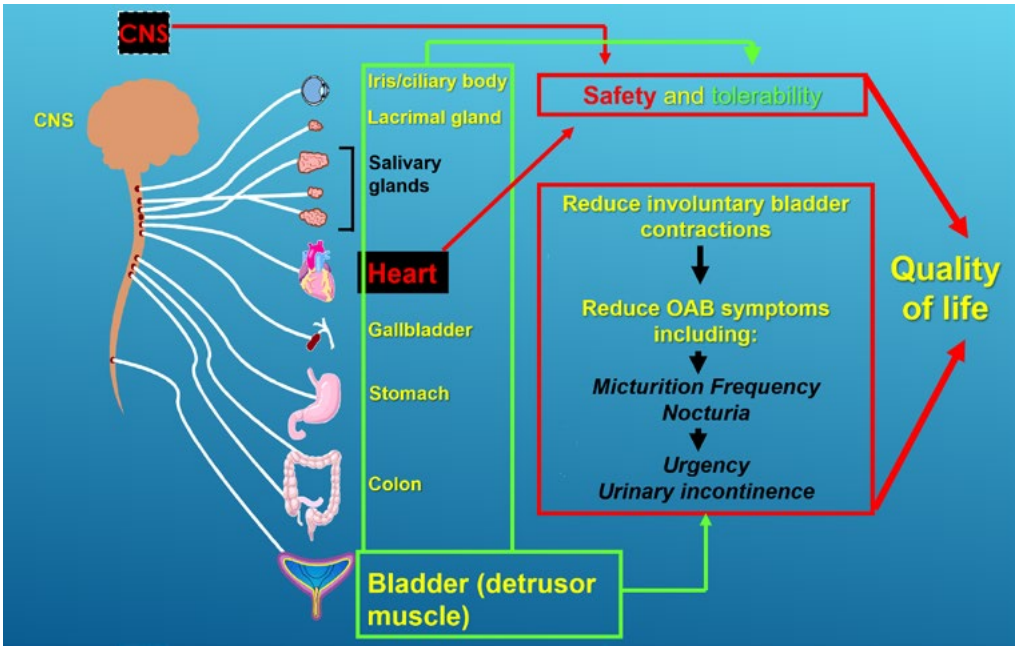

Figure 13: Adverse effects of antimuscarinics

to have the highest incidence of AE. Second, slow-release, extended-release and transdermal formulations appear to have fewer AE than immediate-release formulations.

While effects on heart rate could be expected upon use of antimuscarinics based on mechanistic considerations [Brodde and Michel, 1999], increases in heart rate or cardiovascular AE in general have rarely been observed; when they occurred, increases in heart rate typically were only minor, i.e., not exceeding 2-3 beats/min [Rosa et al., 2018] The clinically used antimuscarinics do not increase QT intervals to a meaningful extent [Rosa et al., 2018].

Impairment of cognition is a typical AE of antimuscarinics, whether administered for the treatment of OAB/DO or other indications. The risk for cognitive impairment upon administration of antimuscarinics increases with total exposure over time, defined as number of drugs with antimuscarinic properties and total number of doses for each of them [Ancelin et al., 2006; Herbison et al., 2003]. A recent population based longitudinal prospective cohort study examined the cumulative effect of anticholinergics (tricyclic antidepressants, 1st generation anti-histamines and bladder antimuscarinics) and the risk of dementia [Gray et al., 2015]. The authors found a dose dependent relationship for the development of dementia and Alzheimer's disease and noted the anticholinergic indication was not relevant to the development of dementia. Cumulative anticholinergic dose was measured utilizing the total standardized daily doses (TSDD) in this study and for dementia, adjusted hazard ratios for cumulative anticholinergic use compared with non-use were 1.23 (95% CI, 0.94-1.62) for TSDDs of 366 to 1095; and 1.54 (95% CI, 1.21-1.96) for TSDDs greater than 1095. Moreover, Dmochowski et al., recently conducted a systematic review and meta-analysis assessing at least 3 months of anticholinergic use and the impact on cognitive function and risk of dementia [Dmochowski et al., 2021]. The risk of incident dementia increased with increasing exposure and 2 studies from the meta-analysis reported an increase risk of dementia with ≥ 3 months use of bladder antimuscarinics (adjusted odds ratio 1.21 to 1.65). Barthold et al. (2020) recently published a large retrospective mediclaims based study involving > 71,000 individuals assessing whether bladder selectivity of the antimuscarinic used effected impact on dementia and Alzheimer's disease. The authors compared solifenacin and darifenacin vs fesoterodine, flavoxate, oxybutynin, tolterodine, trospium (non-selective) and found an increased risk of Alzheimer's and other dementia related disorders in general but with no difference between the groups. In general the RCTs of antimuscarinics used in the treatment of OAB/DO typically were not designed to capture adverse effects on cognition, but such effects have been reported for all members of this drug class [Yamada et al., 2018; Müderrisoglu et al., 2019], except for trospium which does not penetrate the blood-brain-barrier [Staskin et al., 2010]. The incidence of cognitive impairment upon use of different antimuscarinics is difficult to quantify, but preclinical models [Yamada et al., 2018], indirect clinical comparisons [Müderrisoglu et al., 2019] and direct head-to-head studies in volunteers [Kay and Granville, 2005] all suggest that the risk is highest with oxybutynin in its immediate-release formulation. Limited data indicate that cognitive impairment caused by antimuscarinics may largely be reversible upon discontinuation of treatment [Müderrisoglu et al., 2019].

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. [2012] analyzed 86 trials, 70 with parallel and 16 with cross-over designs (31,249 adults). They concluded that when the prescribing choice is between oral immediate release oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. ER preparations of oxybutynin or tolterodine might be preferred to immediate release preparations because there is less risk of dry mouth. Comparing solifenacin and immediate release tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy but has higher risk of withdrawal due to adverse events and higher risk of dry mouth. Kessler et al., analyzed 69 trials enrolling 26'229 patients with OAB where the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses [Kessler et al., 2011]. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and

trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first choice drugs to start the treatment of OAB, except for oral oxybutynin dosages of ≥ 10 mg/day, which may have more unfavorable adverse event profiles.

The durability of the effects of antimuscarinics is not known and the relapse rate of symptoms after discontinuation of treatment has not been systematically studied. In 173 women with OAB symptoms for >6 months, Lee et al., studied in a prospective, randomized, open-label, trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6-months [Lee et al., 2011]. The relapse rate was 62%, and the request for treatment was 65%, indirectly suggesting an efficacy of treatment. None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenacin, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as a first-line treatment for all OAB/DO patients. Optimal treatment should be individualized, based on the patients' co-morbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

Several studies have documented that the persistence with prescribed antimuscarinic therapy for overactive bladder is low [Basra et al., 2008; Sears et al., 2010; Wagg et al., 2012]. The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. [analysed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period [Wagg et al., 2012]. At 12 months, they found that the proportions of patients still on their original treatment were: solifenacin 35%, tolterodine ER 28%, propiverine 27%, oxybutynin ER 26%, trospium 26%, tolterodine IR 24%, oxybutynin IR 22%, darifenacin 17%, and flavoxate 14%. The longest mean persistence was reported for solifenacin (187 days versus 77 − 157 days for the other treatments). Goodson et al., in a large retrospective cohort study assessed 26,775 patients and found that 39% persisted with antimuscarinics at 1 year [Goodson et al., 2018]. Using extended release tolterodine as a reference, better persistence rates were observed for solifenacin (RR = 1.08, 95% CI = 1.03-1.13) and fesoterodine (RR = 1.25, 95% CI = 1.09-1.43), and a lower rate for IR tolterodine (RR = 0.90, 95% CI = 0.85-0.94). Patient factors associated with higher persistence rates included older age, male sex, and comorbidities such as multiple sclerosis, Parkinson's disease, and diabetes. Similar trends in other healthcare systems have been reported [Mauseth et al., 2013; Kalder et al., 2014]. Gomes et al., compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs [Gomes et al., 2012]. This was a retrospective cohort study of Ontarians aged 66 years and older and the exact formulations of the drugs were not stipulated. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, $p < 0.0001$). The median time to discontinuation of oxybutynin and tolterodine was 68 and 128 days, respectively. Vouri et al. [2019] suggested in an elderly population that persistence was better for patients who were initiated on oxybutynin extended-released (ER), tolterodine, trospium, darifenacin, solifenacin, or fesoterodine when compared to oxybutynin IR ($p < 0.001$). Another systematic review concluded that persistence rates regardless of antimuscarinic was generally poor, with median rates 12-39.4% at 12 months and 6-12% at 24 months [Veenboer and Bosch, 2014]. Risk factors for discontinuation included younger age group, use of IR formulations and oxybutynin. A UK retrospective study has suggested that persistence is better for beta 3 agents such as Mirabegron when compared to other antimuscarinics used to treat overactive bladder [Chapple, Nazir et al., 2017]). The median time-to-discontinuation was significantly longer for mirabegron (169 d, interquartile range [IQR] 41-not reached) compared to tolterodine ER (56 d, IQR 28-254; adjusted hazard ratio [HR] 1.55, 95% confidence interval 1.41-1.71; $p<0.0001$) and other antimuscarinics (range 30-78 d; adjusted HR range 1.24-2.26, $p<0.0001$ for all comparisons). Lua et al., in a large commercial claims database study suggested adherence to antimuscarincs was better in men and worse in the obese [Lua, Pathak et al., 2017].

Antimuscarinics are recommended in treating OAB when lifestyle interventions and dietary modification have failed. However, many guidelines would recommend when one antimuscarinic fails due to lack of efficacy or poor tolerability that a second and even third should be tried. A recent retrospective medicine and pharmacy claims analysis in the US linked to a one-time patient survey of members with OAB-wet was recently reported with the specific aim of assessing antimuscarinic treatment patterns and outcomes [Chancellor, Yehoshua et al., 2016]. A total of 620 patients were finally included after exclusions. Patients cycled through 1-6 different antimuscarinics. In general adherence to the medication was poor and 35% of the population used ≥ 2 antimuscarinics. Moreover, UI episodes and burden was fairly consistent despite antimuscarinic cycling and whether patients continued or discontinued their medication. Discontinuation rates were high being 71% of the whole population at study end. Approximately 89% of patients continued to be bothered by their bladder symptoms and requested additional help, whether they remained on antimuscarinics or not. The study suggests that antimuscarinic cycling does not have a positive impact on patients in terms of UI. As a result, alternative therapies should be sought for patients who have failed 1-2 antimuscarinics. It seems logical that if there is inadequate efficacy with 1 antimuscarinic that the maximum dose should be trialed in those with a flexible dosing option. In those where tolerability is an issue switching to an alternative muscarinic is also reasonable. However, thereafter treatment should be escalated to include non-antimusacrinic options.

The use of antimuscarinics to treat the storage component of lower urinary tract symptoms in combination with other classes of drugs is increasing. Furthermore, the evidence base to support this is also expanding. Details of the use of antimuscarinics in combination with β_3-AR agonist agents to treat refractory OAB, in combination with alpha blockers and 5 alpha reductase inhibitors to combat lower urinary tract symptoms attributable to benign prostatic enlargement are covered in later sections of this chapter.

1.3. Antimuscarinics with "specific" action

Below data on the different antimuscarinics are presented. These drugs are assumed to selectively block muscarinic receptors (motivating the term "specific"). The information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug. Grades of recommendation are demonstrated in Table 2.

1.3.1. Darifenacin hydrobromide

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metabolised in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range [Skerjanec, 2006]. UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites of which only UK-148,993 is said to have significant anti-muscarinic activity. However, available information suggests that various me-

tabolites of darifenacin contribute little to its clinical effects [Michel and Hegde, 2006]. The metabolism of darifenacin by CYP3A4 suggests that co-administration of a potent inhibitor of this enzyme (e.g. ketoconazole) may lead to an increase in the circulating concentration of darifenacin [Kerbusch, Wählby et al., 2003]. Darifenacin is a relatively selective muscarinic M_3 receptor antagonist. In vitro, it is selective for human cloned muscarinic M_3 receptors relative to M_1, M_2, M_4 or M_5 receptors. Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day.

The clinical effectiveness of the drug has been documented in several RCTs [Haab, Stewart et al., 2004; Steers, Corcos et al., 2005; Zinner, Susset et al., 2006] including in those > 65 years of age [Chapple, DuBeau et al., 2007]. The time to effect with darifenacin was analyzed in a pooled analysis of efficacy and safety data from 1,059 patients participating in three double-blind 12-week studies [Khullar, Foote et al., 2011]. Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days after beginning administration.

A review of the pooled darifenacin data from the three phase III, multicentre, double blind clinical trials in patients with OAB has been reported [Chapple, Steers et al., 2005]. After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, –8.8 [–68.4%; placebo -54%, P<004]; 15 mg, –10.6 [–76.8%; placebo 58%, p<0.001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo.

The results were confirmed in other RCTs, including a pooled analysis of three phase III studies in older patients (≥65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile[(Foote, Glavind et al., 2005]. A 2-year open label extension study of these studies, confirmed a favorable efficacy, tolerability and safety profile [Haab, Corcos et al., 2006], including in those > 65 years of age [Hill, Elhilali et al., 2007].

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams, Kelleher et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer, Kelleher et al. 2008].

1.3.2. Fesoterodine fumarate

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by non-specific esterases [Malhotra, Guan et al., 2008]. This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney, Pandita et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008]. The bioavailability of fesoterodine, averaging 52%, was independent of food intake and the drug may be taken with or without a meal. Peak plasma concentration of 5-HMT is reached at 5 h following oral administration and has a half-life of 7–9 h [Malhotra, Guan et al., 2008]. The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function due to the combination of renal excretion and hepatic metabolism of 5-HMT [Malhotra, Guan et al., 2008; de Mey, Mateva et al., 2011]. Two doses exist at 4mg and 8mg, allowing flexible dosing.

A multicenter, double-blind, placebo-controlled trial with tolterodine extended release (ER) 4mg, and fesoterodine 4 and 8mg enrolled 1132 patients [Chapple, Van Kerrebroeck et al., 2007]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8 mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER 4mg. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs [Khullar, Rovner et al., 2008]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and UUI as recorded by 3-day bladder diary, offering the possibility of dose titration. Subsequently the Eight Trial, a large randomised double-blind placebo-controlled trial compared fesoterodine 8 and 4mgs (n=1745) [Chapple, Schneider et al., 2014]. At 12 weeks UUI, urgency, micturition frequency, diary dry rates, PPBC, UPS and OAB-q scores were significantly better with fesoterodine 8mg compared to 4mg or placebo. Dry mouth and constipation rates were 26.1% and 4%, 12.9% and 1.5%, 3.4% and 1.8% in the fesoterodine 8mg, 4mg and placebo groups, respectively, suggesting that although higher dose of fesoterodine may improve outcomes this comes at the cost of more AEs [Chapple, Schneider et al., 2014].

In another randomized trial assessing flexible-dosing of fesoterodine, statistically significant improvements at week 12 in the mean number of micturition per 24 h and in both UUI and urgency episodes were seen compared to placebo (all P<0.05) [Dmochowski, Peters et al., 2010]. Those taking fesoterodine had improved PPBC and UPS scores at weeks 2,6, and 12 weeks. Interestingly, 63% and 73% in those taking fesoterodine and placebo, respectively opted for dose escalation at week 2. A systematic review of all flexible dosing trials with fesoterodine (10 met the inclusion criteria) suggested 51-63% opted for dose escalation. Escalators in general had more significant OAB symptoms, worse bother and worse QoL at baseline when compared to non-escalators [Wyndaele, Schneider et al., 2014].

A pooled analysis of 2 phase III trials confirmed superiority of fesoterodine 8mg to tolterodine ER 4mg with regards to patient reported outcomes [Ginsberg, Schneider et al., 2013]. This study also assessed outcomes by gender. In women fesoterodine 8mg was superior to tolterodine at 12 weeks in UUI, urgency, micturition episodes, diary dry rates, PPBC, UPS and OAB-q scores. In men superiority with fesoterodine 8mg was only demonstrated for severe urgency and the symptom bother domain of the OAB-q. In women dry mouth rates were 29%, 15%, 6%, constipation rates were 5%, 4%, 2%, urinary retention rates were <1%, <1%, 0% for fesoterodine 8mg, tolterodine ER 4mg and placebo, respectively. In men dry mouth rates were 21%, 13%, 5%, constipation rates were 5%, 3%,

1% and urinary retention rates were 2%, <1%, 2% for fesoterodine 8mg, tolterodine ER 4mg and placebo, respectively [Ginsberg, Schneider et al., 2013].

Nitti et al., determined whether the presence of DO in patients with OAB and urgency urinary incontinence was a predictor of the response to treatment with fesoterodine in a phase 2 randomized, multicentre, placebo-controlled trial [Nitti, Rovner et al., 2010]. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms.

Kelleher et al., evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome [Kelleher, Tubaro et al., 2008]. Pooled data from two randomized placebo-controlled phase III studies were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine extended release (tolterodine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all King's Health Questionnaire (KHQ) domains, ICIQ-SF scores, and bladder related problems were observed at months 12 and 24 compared to baseline [Kelleher, Dmochowski et al., 2012]. The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

Longer term effects were analysed in a pooled analysis of 2 open label extension studies which demonstrated sustained improvement in OAB with fesoterodine [Sand, Heesakkers et al., 2012]. Mean duration of exposure was 21 months with 51% of patients receiving fesoterodine for ≥ 24 months. 77% elected to remain on fesoteroding 8mg during the open label extension. Discontinuations were seen in 51% before the 24-months visit with insufficient clinical response, adverse events or withdrawal of consent being the main reasons for stopping treatment. Significant improvements were seen in UUI, urgency and micturition epsiodes over the study period compared to open label baseline. The most common adverse events were dry mouth and constipation.

A post-hoc analysis of 2 fixed dose trials, stratified by age, suggested fesoterodine 4 and 8 mg doses were efficacious compared to placebo in those < 75 years of age, but only fesoterodine 8mg in those ≥ 75 years of age [Kraus, Ruiz-Cerda et al., 2010]. As a result, the SOPHIA trial recruited patients ≥ 65 years of age with at least 30% of the population being older than 75 years of age, in this flexible fesoterodine dosing placebo-controlled study [Wagg, Khullar et al., 2013]. At week 4, 52% and 66% opted for dose escalation in the fesoterodine 4mg and placebo groups, respectively. At week 8 de-escalation was allowed and occurred in 4% and 3% in the fesoterodine and placebo groups, respectively. Urgency, severe urgency, micturition and nocturnal micturition episodes, as well as pad use significantly improved in the fesoterodine group compared to placebo at 12 weeks. However, in the 46% who were OAB wet no significant difference in UUI episodes were demonstrated between the groups. Patient reported outcomes using the TBS, PPBC, UPS, OAB-S were significantly greater in the fesoterodine group compared to placebo. Age stratification ie less than or greater than 75 years of age did not alter the results. Mini mental state examination did not change from baseline to end of study and was not different between groups. Dry mouth and constipation rates were 33.9% vs 5.3% and 8.9% vs 2.5% in the fesoterodine and placebo groups, respectively. Central nervous system adverse events occurred very rarely and 6 patients went into retention (5 in the active arm). The authors concluded that fesoterodine was tolerated well and was efficacious in an elderly population [Wagg, Khullar et al., 2013]. Subsequently Wagg et al., have published on a 12-week open label extension of this trial [Wagg, Khullar et al., 2014]. Of the original 655 patients in the SOPHIA trial, 581 completed the open label extension with approximately half the population being male. Significant improvements were observed in bladder diary measures as well as patient reported outcome measures in those that originally had placebo who switched to fesoterodine and efficacy was maintained in those that were originally treated with fesoterodine by study end. Treatment withdrawal due to emergent adverse events were 9.1% in those switched to fesoterodine from placebo and 1.3% in those that continued with fesoterodine [Wagg, Khullar et al., 2014]. Dubeau et al., looked at the use of fesoterodine with dose escalation / de-escalation design vs placebo in a vulnerable elderly population with complex co-morbidities [Dubeau, Kraus et al., 2014]. Patients had to have moderate bladder problems based on PPBC, UUI 2-15 episodes, daytime frequency ≥ 8, vulnerable elderly score (VES-13) of ≥ 3 and a MMSE ≥ 20. The proportion of patients who completed the study were similar in both groups. Approximately 50% of the population were greater than 75 years of age and both groups had complex patients with functional impairment and polypharmacy. Significant reductions in daytime micturition, daytime and nocturnal urgency, UUI episodes per 24 hours and a reduction for the need of absorbent products was seen with fesoterodine compared to placebo. A greater proportion reported improvements in their bladder condition based on PPBC and OAB-q scores and satisfaction were better in the fesoterodine group compared to placebo. In the fesoterodine group 9.3% vs 5% in the placebo group discontinued treatment due to adverse events. Dry mouth and constipation rates were 23.5% and 11%, respectively, in the fesoterodine group. Urinary retention occurred in 3.2% in those treated with fesoterodine but only 3/9 patients were catheterized. No significant changes in MMSE were observed. No significant changes in blood pressure or heart rate were observed in either group until end of study and there were no deaths [Dubeau, Kraus et al., 2014].

When assessing the pooled fixed dosing studies of fesoterodine (n=6689) approximately 1/3 of patients reported a 50% reduction in urgency and roughly 3/4 reported a 50% resolution of incontinence [Wagg, Herschorn et al., 2021]. Furthermore in comparing 14 different agents in managing OAB using multicriteria decision analysis (experts weighted relative importance of favourable and unfavourable effects) and when benefits are judged as more relevant than safety, fesoterodine 4 or 8 mg utilised in a flexible dosing pattern was the favoured drug of choice [Chapple, Mironska et al., 2020]).

The FOXY study assessed the use of oxybutynin 10-20mg and fesoterodine 4-8mg in a randomized double blind crossover trial in children with OAB aged 5-14 years [Ramsay, Naud et al., 2020]. In 60 patient's efficacy was similar for both drugs with documented improvements in bladder capacity. The authors suggested that both drugs were efficacious in the population with acceptable side effect profiles.

1.3.3. Imidafenacin

Imidafenacin (KRP-197/ONO-8025, 4-(2-methyl-1H-imidazol-1-yl)-2,2-diphenylbutanamide) is an antagonist for the muscarinic ACh receptor with higher affinities for M_3 and M_1 receptors than for the M_2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes [Kobayashi, Yageta et al., 2007]. The drug blocks pre- as well as post-junctional muscarinic receptors and was shown to block both detrusor contractions and acetylcholine release [Murakami, Yoshida et al., 2003]. The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary

gland or colon [Yamada, Seki et al., 2011]. In rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect here than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made. Imidafenacin is well absorbed from the gastrointestinal tract and its absolute bioavailability in human is 57.8% [Ohmori, Miura et al., 2007; Ohno, Nakade et al., 2008]. It is rapidly absorbed with maximum plasma concentration occuring 1-3h after oral administration [Ohno, Nakade et al., 2008]. Metabolites in the plasma are produced mainly by first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs [Kanayama, Kanari et al., 2007].

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety/tolerability, and dose-response relationship of imidafenacin [Homma, Yamaguchi et al., 2008]. Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin/day (99 patients), 0.2 mg of imidafenacin/day (100), 0.5 mg of imidafenacin/day (101), or a placebo (101). After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo was observed ($P < 0.0001$). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased dose-dependently. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment due to dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind trial of 781 Japanese patients with OAB symptoms randomized patients to imidafenacin 0.1mg twice daily (n=324), propiverine 20mg once daily (n=310), or a placebo (n=147) [Homma and Yamaguchi, 2009]. After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group ($P<0.0001$). The non-inferiority of imidafenacin compared with propiverine was confirmed for the reduction in incontinence episodes ($P = 0.0014$, non-inferiority margin:14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine ($P = 0.0101$). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group ($P < 0.0001$). However, there were no clinical arrhythmia and clinical arrhythmic events in any of the treatment groups. Similar results have also been published in a population of OAB patients in Korea [Park, Park et al., 2014].

The long-term safety, tolerability, and efficacy imidafenacin 0.1 mg twice daily was studied in Japanese OAB patients [Homma and Yamaguchi, 2008], of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin produced mean changes from baseline in the number of incontinence episodes (-83.51%), urgency incontinence episodes (-84.21%), voiding frequency (-2.35 micturitions/day), urgency episodes (-70.53%), and volume voided per micturition (28.99 mL). There were also significant improvements from baseline in all domains of the KHQ in those who received the treatment and 376 patients completed the 52-week program. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or post-void residual volume. Yokoyama et al., in their comparative long-term study reported equivalent efficacy and better tolerability for imidafenacin compared to solifenacin and lower dicontinuation rates (5.8% vs 13.5%) at study end [Yokoyama, Koide et al., 2013].

Recently in Korea a multi-center non-inferiority phase IV trial of imidafenacin 0.1mg twice daily versus fesoterdine 4mg was conducted [Lee, Park et al., 2013]. No significant differences were observed between the 2 treatments for OAB symptoms or KHQ scores. Dry mouth rates were 39.4 and 37.3% in the imidafenacin and fesoterodine groups, respectively and no statistically differences were shown for adverse events, blood pressure, pulse or residual volume betwen the groups. Furthermore, in a recent study, imidafenacin 0.2mg was shown to be non-inferior to tolterodine 4mg as assessed by bladder diary parameters and the OAB awareness tool [Pushkar, Kasyan et al., 2019]. However, UUI episodes were statistically less with imidafenacin when compared to tolterodine (-1.7 +/- 1.7 vs -1.5 +/- 1.4; P=0.01).

1.3.4. Solifenacin succinate

Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-65 hours [Smulders, Krauwinkel et al., 2004]. It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). It is available in 5mg and 10mg doses which allows for flexible dosing. In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) C_{max} and $AUC_{0\text{-}inf}$ were increased by only approximately 40% and 56%, respectively [Swart, Krauwinkel et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Hegde, Mammen et al., 2004].

A large-scale dose ranging phase 2 trial, comprising men and women, evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple, Araño et al., 2004]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice dai-

ly), or placebo [Chapple, Rechberger et al., 2004]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with placebo (-8%), mean micturitions/24 h were significantly reduced with solifenacin 10 mg (-20%), solifenacin 5 mg (-17%), and tolterodine (-15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Another RCT randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo [Cardozo, Lisec et al., 2004]. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), but not with placebo (-1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs 2.3% with placebo). A 40-week follow up of these studies demonstrated that the favourable profile, both in terms of efficacy and tolerability was maintained over the study period [Haab, Cardozo et al., 2005].

The STAR trial was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week flexible dosing study conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and tolterodine extended release 4 mg once daily in OAB patients [Chapple, Martinez-Garcia et al., 2005]. After 4 weeks of treatment patients had the option to request a dose increase but were dummied throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was “non-inferior” to tolterodine concerning the primary effect variable, micturition freqency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30% and 6.4%, tolterodine 23% and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups. In the SUNRISE trial solifenacin 5/10mg was significantly effective in reducing urgency and urgency bother when compared to placebo with changes noticeable as early as day 3 [Cardozo, Hessdorfer et al., 2008]. In this flexible dosing trial, 591 patients received solifenacin 5mg at 8 weeks, and 46.5% requested a dose increase to 10mg and were further randomized for 8 weeks into solifenacin 5 or 10 mgs [Cardozo, Amarenco et al., 2013]. Those that requested dose escalation had a greater severity of OAB at baseline. Solifenacin 10 mg at end of study compared to week 8 was statistically better than solifenacin 5mg for maximum urgency intensity, total urgency score and micturition frequency. PPBC and treatment satisfaction were not statistically different between the groups. Adverse events were generally low and dry mouth rates were 0.7 and 5.7% for solifenacin 5 and 10 mg, respectively [Cardozo, Amarenco et al., 2013]. In a pooled analysis of four RCTs, solifenacin demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients [Abrams and Swift, 2005].

Another pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (≥ 65 years) patients, and also showed a high level of persistence in a 40 -week extension trial [Wagg, Wyndaele et al., 2006]. Furthermore, a post-hoc analysis of two 12-week, open label, flexible-dosing studies on 2645 patients over 65 years of age with OAB, revealed that solifenacin was associated with improvements in measures assessing patients’ perception of their bladder problems, symptom bother, and aspects of QoL [Capo, Lucente et al., 2011].

Improvement in QoL as assessed by the KHQ has been demonstrated in patients treated with solifenacin [Kelleher, Cardozo et al., 2005]. Data from 2 large clinical trials and an extension study were assessed and statistical improvements compared to placebo were seen in 9 out of the 10 QoL domains. Approximately 2/3 of this improvement in QoL was seen in the first 12 weeks and the remaining third in the extension period (additional 40 weeks), suggesting an improvement over time [Kelleher, Cardozo et al., 2005].

Recently the SONIC trial assessed efficacy and tolerability of solifenacin in patients with neurogenic bladder suffering with multiple sclerosis (MS) and spinal cord injury (SCI) in a prospective randomized phase IIIb/IV parallel group study [Amarenco, Sutory et al., 2015]. Approximately a quarter of the patients were taking muscle relaxants to help with spasticity. Patients were randomized to solifenacin 5mg, solifenacin 10mg, oxybutynin 5mgs three times daily or placebo for 4 weeks after a placebo run-in. The majority of MS patients were female, and the majority of SCI patients were male. The primary endpoint of maximum cystometric capacity was significantly increased with solifenacin 10mg (134 mL) compared with placebo (5 mL). Furthermore, significant improvements were observed with regards to bladder volume at first contraction and at first leak as well as detrusor pressure at first leak. PPBC and I-QoL sub scales significantly improved in favour of solifeancin 10mg compared to placebo. Significant improvements were also seen for oxybutynin compared to placebo, but the trial was not designed to compare outcomes of the different active treatments. The overall incidence of adverse events were low and dry mouth rates were 2.3%, 4.2%, 7.8% and 17% for placebo, solifenacin 5 mg, solifenacin 10mg and oxybutynin 5 mgs three times daily, respectively.

A chart review of 138 children with therapy resistant OAB, treated with solifenacin, increased mean voided volume and improved continence [Hoebeke, De Pooter et al., 2009]. Recently an open labelled study utilizing solifenacin doses 1.25-10mg in children with refractory incontinence was reported [Nadeau, Schroder et al., 2014]. In total 112 girls and 132 boys were included (191 had IDO and 53 NDO) with mean age of 9.2 years at start of treatment. Significant improvements were seen in urodynamic parameters, PPBC, UI episodes with the dry rate being 36%. Treatment outcomes were more successful for IDO than NDO. The majority of patients reported no side effects (n=175). Results from 2 open label studies in paediatric population with NDO suggested solifenacin (2.5mg-10mg) improved maximum cystometric capacity and other urodynamic paraemetrs as well as reduing UI episodes [Franco, Hoebeke et al., 2020]. Solifenacin was generally well tolerated in this study.

1.3.5. Tolterodine tartrate

Tolterodine is is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound, and significantly contributes to the therapeutic effect of tolterodine [Brynne, Stahl et al., 1997; Nilvebrant, Hallén et al., 1997]. Both tolterodine and 5-HMT have plasma half-lifes of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4 % of the dose; 5 – 14% of 5-HMT is eliminated in the urine [Brynne, Stahl et al., 1997]. The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Clemett and Jarvis, 2001]. However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP 2D6 [Diefenbach, Jaeger et al., 2008].

Tolterodine has no selectivity for muscarinic receptor subtypes but is claimed to have functional selectivity for the bladder over the salivary glands [Stahl, Ekström et al., 1995]. In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug. However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated. Animal experiments have suggested that antimuscarinics may affect signaling from the bladder [Andersson, 2011]. Supportive data in humans were found by Vijaya et al., in their randomized, placebo-controlled study [Vijaya, Digesu et al., 2012]. They evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO in comparison to placebo, by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz upon both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz (P-value <0.05).

Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability [Van Kerrebroeck, Kreder et al., 2001] and as such the following section will focus predominantly on the extended release formulation.

In the OPERA study, Oxybutynin extended release (OXY-ER) at 10 mg or TOLT-ER at 4 mg were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours [Diokno, Appell et al., 2003]. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable including adverse events involving the central nervous system.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two) [Sussman and Garely, 2002]. A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the open label design of the study.

Zinner et al., evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency [Zinner, Mattiasson et al., 2002]. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (< 2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

Freeman et al., presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB [Freeman, Hill et al., 2003]. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

Hsiao et al., compared the urodynamic effects, therapeutic efficacy and safety of solifenacin 5 mg versus TOLT-ER 4 mg treatment in women with the OAB syndrome [Hsiao, Chang et al., 2011]. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy and adverse events. Abrams et al., studied the safety and tolerability of tolterodine for the treatment of OAB symptoms in men with BOO and DO [Abrams, Kaplan et al., 2006]. They found that tolterodine did not adversely affect urinary function in these men. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. It was suggested that antimuscarinics can be safely administered in men with BOO on this basis.

The use of tolterodine in paediatric populations have also been analysed in a systematic review [Medhi, Mittal et al., 2013]. Based on 17 studies with differing doses of tolterodine, the authors concluded that tolterodine was efficacious in treating non-neurogenic overactive bladder and was comparable to oxybuynin but had better tolerability. Other studies have suggested efficacy in neurogenic patients [Reddy, Borgstein et al., 2008].

1.3.6. Trospium chloride

Trospium is a quaternary ammonium compound with a biological availability less than 10% [Doroshyenko, Jetter et al., 2005]. The drug has a plasma half-life of approximately 20 h and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim, Yoshimura et al., 2005]. Whether or not it contributes to the clinical efficacy of the drug remains to be established. Trospium is not metabolized by the cytochrome P450 enzyme system [Doroshyenko, Jetter et al., 2005]. It is expected to cross the blood-brain to a limited extent since it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain [Geyer, Gavrilova et al., 2009]. This was demonstrated by Staskin et al., showing that trospium chloride levels in CSF samples were undetectable on Day 10 at steady-state peak plasma concentration concurrent with measurable peak plasma values [Staskin, Kay et al., 2010]. Clinically, trospium seems to have no negative cognitive effects [Chancellor, Staskin et al., 2012]. Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Uckert, Stief et al., 2000].

In a placebo-controlled, double blind study on patients with neurogenic DO, trospium was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure and increased compliance in the treatment group, whereas no effects were noted in the placebo group [Stöhrer, Bauer et al., 1991]. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equally effective; however, trospium seemed to have fewer side effects [Madersbacher, Stöhrer et al., 1995].

A pooled analysis compared the effects of the drug with those of placebo in 517 patients in a urodynamic study of 3 weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum cystometric capacity. Trospium treated patients recorded ‘cure’ or ‘marked improvement’ more often than the placebo group (47.9% vs 19.7%) and the drug was well tolerated with similar frequency of adverse effects as in the placebo group.

In an idiopathic population, 523 patients with symptoms associated with OAB and urgency incontinence were treated with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo controlled trial [Zinner, Gittelman et al., 2004]. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinent episodes 59% compared to placebo (-1.29; 44%). It significantly increased average volume per void (32 ml; placebo: 7.7 ml), and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%). Similar results were seen in a large US multicenter trial with the same design, and including 658 patients with OAB [Rudy, Cline et al., 2006].

In a 12-week, randomised, double-blind, phase IIIb study including 1658 patients with urinary frequency and urgency incontinence, patients received trospium chloride 15 mg TID (n = 828) or 2.5 mg oxybutynin hydrochloride TID (n = 830) initially [Bödeker, Madersbacher et al., 2010]. After four weeks, daily doses were doubled and not readjusted in 29.2% (242/828) of patients in the trospium group, and in 23.3% (193/830) in the oxybuytnin group, until the end of treatment. At study end, there were no relevant differences between the “dose adjustment” subgroups and the respective “no dose adjustment” subgroups (trospium: $P = 0.249$; oxybutynin: $P = 0.349$). After dose escalation, worsening of dry mouth was higher in both dose adjusted subgroups compared to the respective “no dose adjustment” subgroups ($P < 0.001$). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups.

An extended-release formulation of trospium allowing once daily dosing, has been subsequently introduced. In a pooled analysis of 2 large phase III trials (n=1027), trospium chloride extended release 60 mg once daily significantly improved micturition and UUI episodes per 24 hours compared to placebo [Staskin, Rosenberg et al., 2009]. Furthermore, trospium was superior to placebo in OAB symptom composite score, urgency episodes and mean voided volume. Dry mouth and constipation were the 2 commonest adverse events being 10.7% and 8.5% with trospium compared to 3.7% and 1.5% with placebo. The pooled analysis of the long-term extension study (n=667) with extended release once daily trospium chloride 60 mg daily also showed benefit in managing OAB [Zinner, Dmochowski et al., 2011]. Significant improvements were seen in the placebo to trospium group and efficacy maintained in the trospium-to-trospium group by end of study. Approximately 85% of the population felt their symptoms were improved with trospium chloride treatment. Significant improvements in quality of life were also demonstrated when using the KHQ. A sub-analysis of pooled data from randomised placebo-controlled trials has also demonstrated efficacy against placebo for once daily trospium chloride 60 mg extended release in patients aged ≥ 75 [Sand, Johnson Ii et al., 2011]. Trospium ER produced greater improvements in voiding diary parameters, OAB patient global assessment scores and quality of life compared to placebo.

A randomised controlled trial of differing doses of trospium and placebo has also been conducted in a paediatric population of patients with DO (n=58) [Lopez Pereira, Miguelez et al., 2003]. Of those treated with trospium 82% had a positive effect. Approximately ¾ of the responders also demonstrated urodynamic improvement. In general, trospium was well tolerated and in this study dosing between 10-25mg was not statistically different in terms of outcome.

1.4. Antimuscarinics with “mixed” action

Some drugs used for treatment of the OAB or DO have been shown to have more than one mechanism of action. They all have a pronounced antimuscarinic effect and, in addition, an often poorly defined “direct” action on [Hughes, Lang et al., 1992] bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca^{2+} channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action.

1.4.1. Oxybutynin chloride

Oxybutynin is a tertiary amine that is well absorbed and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck, Larsson et al., 1997], but occurs in much higher concentrations after oral administration [Hughes, Lang et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation [Douchamps, Derenne et al., 1988; Hughes, Lang et al., 1992].

Oxybutynin has several pharmacological effects *in vitro*, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur, Peterson et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Nilvebrant and Sparf, 1986; Waldeck, Larsson et al., 1997]. The drug was shown to have slightly higher affinity for muscarinic M_1 and M_3 receptors than for M_2 receptors, but the clinical significance of this is unclear [Nilvebrant and Sparf, 1986; Noronha-Blob and Kachur, 1991]).

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin offer patients improved dosing schedules and side-effect profile whilst maintaining efficacy. An extended-release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are now readily available.

Immediate-release oxybutynin (OXY-IR). Thüroff et al., summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin [Thüroff, Chartier-Kastler et al., 1998]. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24h was 33% (data on placebo not presented). The overall subjective improvement rate was reported as 74 % (range 61%-100%). The mean percent of patients reporting an adverse effect was 70 (range 17%-93%).

Extended-release oxybutynin (OXY-ER). This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours, primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints. Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day [Chancellor, Appell et al., 2001].

In the OBJECT study, the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in reduction in weekly urgency incontinence episodes (OXY-ER from 25.6 to 6.1%; TOLT-IR 24.1 to 7.8), total incontinence episodes (OXY-ER from 28.6 to 7.1%; TOLT-IR 27.0 to 9.3), and frequency (OXY-ER from 91.8 to 67.1%; TOLT-IR 91.6 to 71.5) and both medications were equally well tolerated [Appell, Sand et al., 2001]. In the OPERA study, which was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg), the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency [Diokno, Appell et al., 2003].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al., found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day [Corcos, Casey et al., 2006].

In a multicentre, prospective, observational, flexible-dosing study of realworld clinical practice, the dosage of oxybutynin for each OAB patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12-week treatment period [Yoo, Han et al., 2012]. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5–10 mg/day oxybutynin ER as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment and 89.3% were satisfied.

In many parts of the world the only licensed medicine for use in paediatric OAB is oxybutynin. The FOXY study as discussed in the fesoterodine section has shown efficacy of both fesoterodine and oxybutynin ER in managing paediatric OAB [Ramsay, Naud et al., 2020].

Transdermal oxybutynin (OXY-TDS). Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinent episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR) [Davila, Daugherty et al., 2001]. In another study the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from 5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%) (Dmochowski, Davila et al. 2002). A subsequent study assessed OXY-TDS to placebo and to TOLT-ER [Dmochowski, Sand et al., 2003]. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems. Dmochowski et al., analyzing the combined results of two RCTs concluded that transdermal oxybutynin was shown to be efficacious and well tolerated [Dmochowski, Nitti et al., 2005]. The most common systemic side effect was dry mouth (7.0 % vs placebo 5.3%). Application site er-

ythema occurred in 7% and pruritus in 16.1 %. Cartwright in another study suggested that OXY-TDS was not different to placebo, however, in achieving patient selected goals of therapy [Cartwright, Srikrishna et al., 2011].

Recently the transdermal patch (3.9mg/day) has been shown to be subjectively effective in a small paediatric population but with 35% skin site irritation and 20% discontinuation rate [Gleason, Daniels et al., 2014].

Oxybutynin topical gel. Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. Oxybutynin topical gel (OTG) was approved by the US FDA in January 2009 [Staskin and Robinson, 2009]. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area. The 1 gram application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations and a "favorable" N-desethyloxybutynin metabolite: oxybutynin ratio believed to minimise antimuscarinic side effects [Staskin and Robinson, 2009].

In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks [Staskin, Dmochowski et al., 2009]. The mean number of urge incontinence episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm (P <0.0001). Urinary frequency decreased by 2.7 episodes per day and voided volume increased by 21 mL (versus 2.0 episodes [P = 0.0017] and 3.8 mL [P = 0.0018], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. Similar findings were demonstrated in another large RCT of the gel [Sand, Davila et al., 2012].

A newer 3% topical oxybutynin gel has been assessed in a phase III randomised placebo-controlled trial (randomised n=626) [Goldfischer, Sand et al., 2015]. This product is administered via a metered dose pump dispenser and was hypothesised to have less adverse events. Furthermore, it is made with propylene glycol to help with skin permeation. Two doses of 84mg/day and 56 mg/day of the 3% topical oxybutynin were assessed against placebo gel in this population of patients with urgency and / or urge predominant mixed incontinence. The 84 mg / day dose was statistically better than placebo after 12 weeks in improving weekly UI episodes (primary endpoint) and also daily urinary frequency and urine voided volumes. The lower dose of 56mg / day was not statistically better than placebo. Dry mouth and application site erythema was seen in 12.1% and 3.3% in the 84 mg / day group compared to 5% and 0.5% in the placebo arm.

Other administration forms. Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults, although adverse effects may still occur [Lose and Nørgaard, 2001,; George, Tharion et al., 2007; Guerra, Moher et al., 2008)]

1.4.2. Propiverine hydrochloride

The drug is rapidly absorbed (t_{max} 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter, Ullmann et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound. It is likely these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended-release preparation was shown to be effective and oral absorption of propiverine is site dependent and influenced by dosage form and circadian time– dependent elimination processes [May, Westphal et al., 2008]. Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992, Tokuno; Chowdhury et al., 1993]. The importance of the calcium antagonistic component for the drug´s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al., collected data from 9 randomized studies with a total of 230 patients, and found a 17% reduction in micturitions per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement [Thüroff, Chartier-Kastler et al., 1998]. Side effects were found in 14 % (range 8-42%). In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared (Stöhrer, Mürtz et al. 2007). The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin. Recently the once daily extended-release formulation of propiverine was compared to immediate release propiverine in a trial with 66 patients suffering with NDO [Stohrer, Murtz et al., 2013]. The primary endpoint was change in reflex volume which was improved and comparable between the two formulations. However, continence rates were statistically better in the ER group compared to IR. Adverse events were similar with dry mouth rates 27% and 24% for ER and IR formulations, respectively.

In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Jünemann, Halaska et al., 2005]. It was found that the mean maximum cystometric capacity increased significantly ($p < 0.01$) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups. Madersbacher et al., compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial [Madersbacher, Halaska et al., 1999]. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin.

Yamaguchi et al. conducted a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (n=1584), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo [Yamaguchi, Marui et al., 2007]. There were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg.

Recently the extended-release formulation of propiverine – 30mg was compared to the extended release formulation of tolterodine – 4mg in an non-inferiority trial with approximately 160 patients in each study arm [Leng, Liao et al., 2017]. Statistically more significant reductions were seen for propiverine ER compared with tolterodine ER. Discontinuation rates because of adverse events were more in the tolterodine ER group compared to propiverine ER (7.4% vs 3.1%). Based on the way the study was designed and powered the authors concluded that ER propiverine was non-inferior to ER tolterodine.

A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed [Marschall-Kehrel, Feustel et al.. 2009]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo. Another larger study compared propiverine with oxybutynin and demonstrated equivalent efficacy but a better side effect profile in favour of propiverine [Alloussi, Mürtz et al., 2010].

2. β3-ADRENOCEPTOR (β3-AR) AGONISTS

It has been generally considered that β3-AR agonists can relieve overactive bladder (OAB) symptoms by relaxing detrusor muscle, inhibiting spontaneous contractile activity in the detrusor (*in vitro:* micro-contractions*; in vivo*: non-voiding contractions), and reducing bladder afferent activity (**Fig 11)** [Biers et al., 2006; Takasu et al., 2007; Aizawa et al., 2012; Gillespie et al., 2012; Hatanaka et al., 2013; Igawa & Michel, 2013; Michel & Igawa, 2015; Igawa, Aizawa & Michel, 2019]. While it has been believed that β-ARs induce detrusor relaxation in most species by activation of adenylyl cyclase with the subsequent formation of cAMP, adenylyl cyclase inhibitors had only small if any effects on relaxation responses; in contrast, there is evidence suggesting that in the bladder K^+ channels, particularly BK_{Ca} channels, may be more important in β-AR-mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008].

Potency and efficacy at stimulating cAMP formation via β_1-, β_2-, and β_3-adrenoceptor for each of the compounds mentioned in this section is summarized in **Table 4** [Igawa, Aizawa & Michel, 2019].

2.1. Mirabegron

Mirabegron, a β3-AR agonist approved in Japan, the USA, Canada and Europe, for the treatment of OAB symptoms, is the first of a new class of compounds with a mechanism of action that is different from antimuscarinic agents. The recommended starting dose of

Table 4. EC_{50} values for cAMP formation by β3-AR agonists in CHO cells transfected with human β-AR subtypes

drugs	EC_{50}			references
	β1-AR	β2-AR	β3-AR	
Mirabegron (YM-178)	>10 μM	>10 μM	22.4 nM	(Takasu et al., 2007)
Ritobegron (KUC-7483)	22 μM	2.3 μM	73 nM	(Maruyama et al., 2012)
Solabegron (GW427353)	3.98 μM	1.26 μM	3.98 nM	(Uehling et al., 2006)
Vibegron (MK-4618)	>20 μM	>20 μM	1.1 nM	(Edmondson et al., 2016)

mirabegron is 25 mg in the USA, which can be increased to 50 mg based on individual efficacy and tolerability, and 50 mg in Japan and Europe; the 100 mg dose is not approved for use.

Mirabegron has higher affinity and greater intrinsic activity at β_3- as compared to β_1- and β_2-adrenoceptors **(Table 4)** [Takasu et al., 2007].

Pharmacokinetics

Mirabegron is highly lipophilic and rapidly absorbed after oral administration. The time to maximum plasma concentration (T_{max}) is about 2 hours and the terminal elimination half-life ($t_{1/2}$) is approximately 23–25 hours [Eltink et al, 2012]. Clinically, mirabegron is administered as an extended-release tablet (Oral Controlled Absorption System; OCAS). Steady state was achieved within 7 days of once daily administration, with an accumulation ratio of ~2. Mirabegron C_{max} and $AUC_{0-\tau}$ were similar in older and young subjects. Women exhibited ~40% higher mirabegron C_{max} and $AUC_{0-\tau}$ than men; weight-corrected values were ~20% higher in women [Krauwinkel et al, 2012]. The drug circulates in the plasma as unchanged active compound and as inactive metabolites. Most of an administered dose is excreted in urine, mainly as the unchanged form, and one third is recovered in feces, almost entirely as the unchanged form [Takusagawa et al, 2012a]. It is not known if the drug secreted in the urine will have any effect on bladder function. Theoretically, the drug should be able to pass the blood–brain barrier, but information on possible CNS effects of mirabegron and other β_3-AR agonists are scarce [Füllhase et al, 2011]. Mirabegron is metabolized in the liver via multiple pathways, mainly by cytochrome P450, CYP3A and to a minor extent by CYP2D6 in humans [Takusagawa et al, 2012b, c; Lee et al., 2013], theoretically creating a risk for drug–drug interactions. However, drug interaction studies suggest that mirabegron is not considered a sensitive substrate of CYP3A in vivo, as ketoconazole increased mirabegron exposure by less than 2-fold, suggesting that drugs that are CYP2D6 substrates are not expected to require dose adjustment, except for drugs with narrow therapeutic indices that are significantly metabolized by CYP2D6; caution is advised if mirabegron is co-administered with CYP2D6 substrates with narrow therapeutic indices. The effect of CYP2D6 phenotype on mirabegron exposure is small and likely of limited clinical importance [Lee et al., 2013].

Clinical efficacy and safety for overactive bladder (OAB patients

The effects of mirabegron in men and women with OAB have been summarized in several reviews [Nitti, Khullar, et al, 2013; Chapple et al., 2014; Cui et al., 2014; Rossanese et al., 2015; Chapple et al., 2020], and also in men with both voiding and OAB symptoms [Suarez et al. 2013; Otsuki et al, 2013]. Mirabegron has a documented beneficial effect in the treatment of OAB/DO and seems to have an acceptable side effect profile. Mirabegron seems to have definite advantages over the antimuscarinics with respect to adverse events. Dry mouth and constipation are essentially non-existent in comparison to placebo [Chapple et al., 2014; Cui et al., 2014; Rossanese et al., 2015].

Three large-scale, 12-week, phase III studies conducted in Europe and Australia (SCORPIO) [Khullar et al. 2013] , in the USA/Canada (ARIES) [Nitti, Auerbach, et al., 2013] and in Europe/USA/Canada (CAPRICORN) [Herschorn et al., 2013] have demonstrated the safety, tolerability and superior efficacy of mirabegron at doses of 25 mg (CAPRICORN only), 50 mg (all three studies) and 100 mg (SCORPIO and ARISE) compared with placebo for the treatment of OAB symptoms. Significant improvement of the co-primary endpoints of change from baseline to final visit in mean number of micturitions/24 hr and mean number of incontinence episodes/24 hr versus placebo was demonstrated. These improvements were seen from week 4, the earliest timepoint assessed, and were maintained over time.

Another Phase III trial conducted in Japan [Yamaguchi et al., 2014] confirmed the similar efficacy of mirabegron 50mg once daily for 12 weeks. At final assessment, mirabegron was significantly superior to placebo in terms of mean [sd] change from baseline in number of micturitions/24 h (-1.67 [2.212] vs -0.86 [2.354]; P < 0.001) and mean [sd] change from baseline in number of urgency episodes/24 h (-1.85 [2.555] vs -1.37 [3.191]; P = 0.025), incontinence episodes/24 h (-1.12 [1.475] vs -0.66 [1.861]; P = 0.003), urgency incontinence episodes/24 h (-1.01 [1.338] vs -0.60 [1.745]; P = 0.008), and volume voided/micturition (24.300 [35.4767] vs 9.715 [29.0864] mL; P < 0.001).

The benefit of mirabegron 50 and 100 mg was also evident in patients ≥65 years of age, and in both treatment-naive patients and those who previously discontinued antimuscarinic therapy [Nitti, Khullar, et al., 2013; Chapple et al., 2014]. Responder analyses showed a significant improvement with mirabegron 50 and 100 mg in terms of dry rates, ≥50% reduction in mean number of incontinence episodes/24 hr, and the proportion of patients with 8 micturitions/24 hr at final visit [Chapple et al, 2013]. To further clarify the efficacy and safety of mirabegron in elderly OAB patients a randomised placebo controlled phase IV clinical trial of 12 weeks duration, the Pillar study, was carried out in incontinent patients ≥ 65 years (Wagg et al 2020). Patients were initiated on mirabegron 25 mg, half of which increased at week 4 or 8 to 50 mg on patient or clinician discretion. Primary endpoints, the change from baseline to end of treatment in the mean number of incontinence and micturition episodes in 24h, as well as secondary endpoints, showed clear advantage of mirabegron over placebo. The advantage was also observed in the subgroup of patients ≥ 75 years (Wagg et al 2020). Adverse events were few and in line with previous studies that enrolled younger patients (Wagg et al, 2020, Herschorn et al, 2020). The exposure of the Pillar study population to Mirabegron did not contribute to a drug-related cognitive deterioration evaluated by the Montreal Cognitive Assessment (Griebling et al, 2020). Chapple et al. [2020] recently analysed pooled data from global double-blind,

12-wk studies in patients with OAB receiving mirabegron monotherapy assessed safety, tolerability, and efficacy of mirabegron, placebo, and antimuscarinics, and evaluated differences in baseline characteristics and among subgroups: age <65 versus >65 yr, age <75 versus >75 yr, and men versus women. The results reaffirm the safety and efficacy profiles of mirabegron, solifenacin, and tolterodine in different age groups and both sexes. Drug-related adverse effects were more frequent with antimuscarinics followed by mirabegron and then placebo. As expected, due to anticholinergic effects, dry mouth was more frequent with antimuscarinics versus mirabegron or placebo. Generally, hypertension frequency was similar in the mirabegron, antimuscarinic, and placebo groups. Mirabegron may be a better option than antimuscarinics for those aged >75 yr and also for elderly patients susceptible to constipation.

These data therefore demonstrate a clinically meaningful benefit with mirabegron in the objective endpoints of OAB. However, these studies also indicate that 100 mg does not confer markedly greater efficacy but may have more side effects. Assessment of measures of health-related quality of life and treatment satisfaction showed that patients perceived treatment with mirabegron as meaningful.

In OAB clinical trials of up to 12 months mirabegron appeared to be well tolerated. The most common adverse events (AEs) observed with mirabegron in clinical trials of up to 12 months were hypertension, nasopharyngitis, and urinary tract infection. The incidence of dry mouth was similar to placebo, and was between three and fivefold less than for tolterodine extended release 4 mg. Since dry mouth is the most bothersome AE associated with antimuscarinic drugs and often a reason for treatment discontinuation, the lower incidence of dry mouth would contribute to better tolerability of mirabegron.

Hypertension was the most commonly reported AEs in the pooled 12-week studies occurring in with similar incidence in patients receiving mirabegron 50 mg or placebo (7.5% vs.7.6%) [Michel & Gravas, 2016]. A recent systematic review on the cardiovascular safety of β3-AR agonists also suggested that the cardiovascular safety of mirabegron appears to be acceptable at therapeutic doses and comparable with that of antimuscarinic agents, but also pointed out that data on patients with poorly controlled hypertension, arrhythmia, or cardiac heart failure are currently missing because those patients were excluded from previous studies [Rosa et al., 2016]. As hypertension and diabetes were the two most common cardiovascular comorbidities in the OAB population with prevalence rates significantly higher than in non-OAB gender- and age-matched groups [Andersson et al., 2010], Moreover, there have been reports of hypertensive crisis and cerebrovascular and cardiac events associated with hypertension with a clear temporal relationship with the use of mirabegron [Rosa et al., 2016]. Therefore, US prescribing information concludes that periodic blood pressure determinations are recommended in patients receiving mirabegron; moreover, mirabegron is not recommended in patients with severe uncontrolled hypertension [US Food and Drug Administration, 2015] More recently, severe uncontrolled hypertension even became a contraindication for the use of mirabegron [Michel & Gravas, 2016; Rosa et al., 2016]. Additional clinical data are required for a comprehensive assessment of potential cardiac effects of mirabegron, particularly from real-life settings [Michel & Gravas, 2016].

In a study by Chapple et al. [2013] assessing the 12-mo safety and efficacy of mirabegron, tolterodine was used as active control. There were no significant differences in efficacy between drugs. Mirabegron seems to have definite advantages over the antimuscarinics with respect to adverse events. Dry mouth and constipation are essentially non-existent in comparison to placebo [Chapple et al., 2013; 2014; Cui et al., 2014; Rossanese et al., 2015].

Mirabegron 50 mg and solifenacin 5 mg were compared in OAB patients dissatisfied with previous antimuscarinic treatment. The Beyond study [Batista et al., 2015] was a randomized, double-blind, phase IIIb, noninferiority study that enrolled male and female patients aged ⩾18 years old, with symptoms of OAB for ⩾3 months, who were dissatisfied with their previous antimuscarinic drug due to lack of efficacy. For the primary endpoint, adjusted mean treatment difference (95% CI) in mean number of micturitions/24 h was -0.18 (-0.42, 0.06) and therefore noninferiority of mirabegron to solifenacin was not demonstrated. Both treatments demonstrated clinically meaningful reductions in efficacy variables and were well tolerated, with a lower incidence of dry mouth with mirabegron.

Kakizaki et al [2020] reported the efficacy of mirabegron versus placebo in men with OAB symptoms receiving tamsulosin for LUTS, based on the results of single-blind, 4-wk screening: tamsulosin plus placebo orally once daily; double-blind, 12-wk treatment: patients randomized (n=568) to mirabegron 50mg or placebo, as add-on to tamsulosin in men conducted in Japan and Korea. Mirabegron add-on therapy was superior to placebo in improving the primary endpoint, baseline to end of treatment (EoT) change in the mean number of micturitions/24h, based on a 3-d voiding diary, (adjusted mean difference [95% confidence interval] vs placebo -0.52 [-0.82 to -0.21]) and secondary endpoints, including mean volume voided/micturition (12.08 [6.33-17.84]), OAB symptom score (-0.65 [-1.04 to -0.26]), International Prostate Symptom Score total (-1.19 [-1.94 to -0.44]), storage (-0.78 [-1.13 to -0.43]), quality of life scores (-0.29 [-0.51 to -0.07]), OAB symptom bother (-4.52 [-6.91 to -2.13]), and total health-related quality of life (2.79 [1.13 to 4.44]). Differences, compared with placebo, in urgency, urgency urinary incontinence, and nocturia were not statistically significant. Mirabegron was well tolerated, with no major safety concerns.

Assessment. Mirabegron has a documented beneficial effect in the treatment of OAB and seems to have an acceptable side effect profile. However, periodic blood pressure determinations are recommended in patients receiving mirabegron; moreover, mirabegron is not recommended in patients with severe uncontrolled hypertension.

Clinical efficacy for neurogenic detrusor overactivity and low compliance bladder in adult patients

There are few studies on the efficacy of mirabegron for either neurogenic detrusor overactivity (NDO) or low compliance bladder in adult patients.

Wöllner & Pannek [2016] reported that fifteen patients with NDO treated with mirabegron for a period of at least 6 weeks, showed significant reduction of the frequency of bladder evacuation per 24 h (8.1 vs 6.4, P=0.003), and of incontinence episodes per 24 h (2.9 vs 1.3, P=0.027). Furthermore, urodynamic studies revealed improvements in bladder capacity (from 365 to 419 ml), compliance (from 28 to 45 ml/cm H_20) and detrusor pressure during storage phase (45.8 vs 30 cm H_20). At follow-up, 9/15 patients were satisfied with the therapy.

In a prospective, multicenter, randomized, double-blind, placebo-controlled study on the efficacy and safety of mirabegron 50mg, in 66 patients with NDO suffering from spinal cord injury or multiple sclerosis [Krhut J, et al, 2018] demonstrated a significant increase of volume at the first detrusor contraction (P = 0.00047) and an improvement in bladder compliance (P = 0.0041) in the mirabegron

group compared with the placebo-treated group, whereas the increase in cystometric capacity did not reach statistical significance (P = 0.061). There was a clear tendency to reduced urine leakage (P = 0.056) in the mirabegron group. There were significant changes in all the patient-reported outcomes, favoring the mirabegron group. The incidence of drug-related adverse events was 3.13%.

Welk et al. [2018] reported the results of randomized, double-blind, placebo-controlled study to assess the effects of mirabegron conducted in Canadian patients with neurogenic LUT dysfunction due to spinal cord injury (SCI) or multiple sclerosis (MS). Patients were randomized to mirabegron 25 mg (or an identical placebo) for 2 weeks at which point a dose escalation to mirabegron 50 mg (or an identical placebo) was maintained for 8 weeks. Urodynamics were performed before and after treatment. The primary outcome measure was maximum cystometric capacity (MCC). Sixteen (9 SCI and 7 MS) patients were randomized to mirabegron and 16 (10 SCI and 6 MS) to placebo. At study completion, there was no significant difference in MCC between mirabegron and placebo (MM 305 vs 369 mL, P = 0.20). There was no significant difference in volume at first neurogenic detrusor overactivity (NDO, MM 167 vs 137 mL, P = 0.14) and peak pressure of NDO (MM 69 vs 82 cmH2 O, P = 0.25). There was no significant difference in pad weights or voiding diary parameters. There was a significantly lower symptom burden among those treated with mirabegron (total neurogenic bladder symptom score MM 29 vs 34, P = 0.047).

Due to the limited number of patients and the retrospective nature of these studies, prospective, placebo-controlled studies are required to confirm the beneficial effects of mirabegron on NDO and low compliance bladder suggested by these studies.

Efficacy and safety in children with NDO or OAB

There are some off-label studies to investigate efficacy and safety of mirabegron in children with NDO or OAB.

In their off-label study, Blais *et al*. [2016] gave mirabegron to 58 children with OAB who had shown suboptimal responses to intensive behavioural therapy and medical therapy (with at least two antimuscarinics) or had suffered intolerable adverse effects. Median age at mirabegron initiation was 10.1 years and the drug was given for a median of 11.5 months. Median bladder capacity improved from 150ml to 200ml (p<0.001). Continence improved in 52 of 58, with 13 being completely dry. Median PPBC improved from 4.0 to 2.0 (p<0.001). Eight patients reported mild or moderate side effects. Absence of a placebo group is a limitation of the study.

Fryer et al. [2020] reported their retrospective review of 70 children (50 females), median age 15 [range 8-16] years, commenced Mirabegron 25 mg (n = 29) or 50 mg (n = 41). 37 (53%) were still receiving treatment at 6 months: monotherapy n = 30, and combination therapy n = 7 (Solifenacin n = 4, Desmopressin n = 2, both n = 1). For patients on monotherapy, 6 of 17 (35%) had improvement in NE, 11 of 19 (58%) in DI, 12 of 20 (60%) in frequency, and 8 of 21 (38%) in urgency symptoms. For patients receiving combination therapy, 2 of 6 (33%) had improvement in NE, 2 of 4 in DI (50%), 2 of 4 (50%) in frequency, and 4 of 6 (67%) had improvement in urgency. Reasons for treatment discontinuation (entire cohort) were: ineffectiveness (n = 28), worse symptoms (n = 4) and/or adverse reactions (n = 7), including dry mouth (n = 2), headaches (n = 4), dizziness (n = 1), nausea/vomiting (n = 3), increased seizures (n = 1), and rash (n = 1).

Baka-Ostrowska et al. [2021] reported their open-label, multicenter, baseline-controlled, Phase III study to evaluate the efficacy and safety of mirabegron in children and adolescents (aged 3 to <18 years) with neurogenic detrusor overactivity (NDO) using clean intermittent catheterization. Participants received once daily mirabegron at an adult dose equivalent of 25 mg. Dose was increased to 50 mg equivalent unless there were safety/tolerability concerns. Overall, 86 participants (55 aged 3 to <12 years, 31 aged 12 to <18 years) received treatment; 68 were included in efficacy assessments. A statistically significant increase in maximum cystometric capacity from baseline to Week 24 was observed (87.20 ml, 95% confidence interval: 66.07, 108.33; p < .001); this increase was apparent from Week 4. Significant increases in bladder compliance, bladder volume until first detrusor contraction, average volume per catheterization, maximum daytime catheterized volume and number of dry days per week. Significant decreases in detrusor pressure and number of leakage episodes per day were also observed. Mirabegron was well tolerated in this population with a profile aligned with that in adults.

Park et al. [2019] retrospectively studied clinical and urodynamic parameters in 66 children (under 18 years of age) with spina bifida who were treated for neurogenic bladder with mirabegron 50 mg mirabegron daily for at least 6 weeks either in addition to or instead of antimuscarinic therapy. In both groups post-treatment, incontinence significantly improved. In addition, MCC and compliance significantly increased post-treatment. Six patients reported side effects (constipation, 4.5%; headache, 3.0%; and hypertension, 1.5%) and three patients discontinued treatment.

These off-label studies suggest that the efficacy and safety of mirabegron for treating OAB or NDO in pediatric patients. Prospective, placebo-controlled studies are necessary to confirm these findings.

2.2. Vibegron

Vibegron (MK-4618) is a β_3-AR agonist, potently activates human β_3-AR with an EC_{50} value of 1.1 nM, and vibegron is also highly selective over β_1- and β_2-adrenoceptors versus β_3- adrenoceptors across multiple species (**Table 4**). In contrast to mirabegron, vibegron did not show any stimulating or inhibitory effects on cytochrome P450 enzymes, suggesting a low risk of drug–drug interaction [Edmondson et al., 2016].

The efficacy and safety of vibegron were demonstrated in a phase III study conducted in OAB patients in Japan [Yoshida, Takeda, et al., 2018]. A total of 1232 patients were randomly assigned to one of the four 12-wk treatment groups: vibegron (50mg or 100mg once daily), placebo, or imidafenacin (0.1mg twice daily). The primary endpoint was change in the mean number of micturitions/d at wk 12 from baseline. The secondary endpoints were changes from baselines in OAB symptom variables (daily episodes of urgency, urgency incontinence, incontinence, and nocturia, and voided volume/micturition). Patients taking vibegron 50mg and 100mg orally for 12 wk had significant improvements over the placebo in the primary and secondary endpoints. The proportions of patients with normalization of micturition, resolution of urgency, urgency incontinence, and incontinence were significantly greater than placebo. Vibegron significantly improved QoL with high patient satisfaction. Incidences of drug-related adverse events with vibegron 50mg and 100mg were 7.6%, 5.4%, similar to placebo (5.1%), and less than imidafenacin (10.3%).

A 1-year, multicenter, open-label, non-controlled Phase III trial conducted in Japan confirmed long-term safety and efficacy of vibegron 50mg once daily in OAB patients [Yoshida, Kakizaki, et al., 2018]. After a 1-week observation phase, patients were treated with vibegron for 52 weeks. When the efficacy was insufficient after an

8-week treatment with 50 mg, the dose was increased to 100 mg and maintained for an additional 44 weeks. Among a total of 169 patients receiving one or more doses of vibegron, 118 (69.8%) received vibegron 50 mg for 52 weeks, and the dose was increased to 100 mg in 51 (30.2%) patients. The incidence of drug-related adverse events was 18.1% (21/116) in the vibegron 50 mg group and 11.8% (6/51) in the vibegron 100 mg group. Most frequent drug-related adverse events were dry mouth (3.0%), residual urine volume increased (3.0%), constipation (2.4%) and cystitis (1.8%). Statistically significant changes in overactive bladder symptom variables (daily means of micturitions, urgency episodes, urgency incontinence episodes, incontinence episodes and night-time frequency) from baseline were observed at week 4 and maintained until week 52. The condition of patients who did not respond well to vibegron 50 mg was much improved by increasing the dose to 100 mg. Vibegron improved the quality of life, and the proportion of patients' satisfaction after the treatment with vibegron was high.

A post-hoc analysis of the Japanese Phase III trial to evaluate the efficacy of vibegron on urgency urinary incontinence (UUI) in patients with OAB demonstrated that vibegron, significantly reduced the number of UUI episodes/day and significantly increased the voided volume/micturition in patients with OAB including those with severe UUI, with the response rate exceeding 50%, suggesting that vibegron can be an effective therapeutic option for OAB patients with UUI [Yoshida et al, 2020]. Vibegron administration, OAB duration ≤37 months, mean number of micturitions/day at baseline <12.0 and mean number of UUI episodes/day at baseline <3.0 were identified as factors significantly associated with normalization of UUI.

Another post-hoc analysis of the Japanese Phase III trial also showed that the efficacy of vibegron on nocturia in patients with OAB [Yoshida et al., 2019]. a total of 669 patients with nocturia (≥1 nocturnal void) were included. At week 12, the frequency of nocturnal voiding was reduced from baseline by 0.74 and 0.78, respectively, for the vibegron 50 and 100 mg groups; the reductions were significant when compared with the placebo group ($P < 0.05$ and $P < 0.001$, respectively). The mean volume of nocturnal voids and the volume of the first nocturnal voiding were significantly greater in the vibegron groups than in the placebo group. The vibegron groups showed significant correlations of hours of undisturbed sleep with the changes in the frequency of nocturnal voiding and in the volume of the first nocturnal voiding. Vibegron treatment, no previous treatment with anticholinergics, ≥12 voids per day and hours of undisturbed sleep <180 min significantly contributed to a reduction in the frequency of nocturnal voiding.

Micheson et al., [2019] reported the results of an international, phase IIb, randomized, double-blind, placebo- and active comparator-controlled, two-part superiority trial (2011-2013) in OAB-wet or OAB-dry patients aged 18-75 yr (NCT01314872); Part 1: once-daily oral vibegron monotherapy (3 [V3], 15 [V15], 50 [V50], or 100 [V100] mg), tolterodine extended release 4mg (TER4), or placebo for 8 wk, or combination V50/TER4 for 4 wk and then V50 for 4 wk; part 2: V100/TER4, V100, TER4, or placebo for 4 wk. Overall, 1395 patients were randomized. From baseline to week 8, V50 and V100 significantly decreased average daily micturitions (primary endpoint; least square mean difference [95% confidence interval], -0.64 [-1.11, -0.18]; p=0.007 and -0.91 [-1.37, -0.44]; p<0.001, respectively) and the number of urge incontinence episodes (-0.72 [-1.11, -0.33] and -0.71 [-1.10, -0.32], respectively; both p<0.001) versus placebo. All vibegron doses were well tolerated. The incidence of dry mouth was higher with TER4 than with vibegron monotherapy.

Following this Phase IIb studies, an international Phase III trial (EMPOWUR) confirmed the safety and efficacy of Vibegron 75mg once daily in patients with OAB [Staskin et al., 2020]. Adult patients with OAB with 8.0 or more micturitions per day were randomized 5:5:4 to 75 mg vibegron, placebo or extended-release 4 mg extended-release tolterodine. Up to 25% of patients could have dry OAB (less than 1.0 urge incontinence episode per day). Patients completed 7-day voiding diaries at baseline and weeks 2, 4, 8 and 12. Of 1,518 randomized patients 90.4% completed the trial. At 12 weeks micturitions decreased by an adjusted mean of 1.8 episodes per day for vibegron vs 1.3 for placebo (p <0.001, co-primary end point) and 1.6 for tolterodine. Among incontinent patients urge incontinence episodes decreased by an adjusted mean 2.0 episodes per day for vibegron vs 1.4 for placebo (p <0.0001, co-primary end point) and 1.8 for tolterodine. Moreover, vibegron was statistically significantly superior to placebo for key secondary measures of number of urgency episodes, volume per micturition and proportion of incontinent patients with a 75% or greater reduction in urge incontinence episodes (all p <0.01). Among vibegron treated patients 1.7% discontinued treatment because of adverse events vs 1.1% for placebo and 3.3% for tolterodine. Incidence of hypertension was 1.7% for vibegron and for placebo.

The long-term safety, tolerability, and efficacy of vibegron 75 mg in adults with OAB were evaluated in the 40-week Phase III EMPOWUR extension study [Staskin et al., 2021]. Patients who completed 12 weeks of once daily vibegron 75 mg or tolterodine 4 mg extended release in EMPOWUR continued double-blind treatment; patients who completed 12 weeks of placebo were randomly assigned 1:1 to receive double-blind vibegron or tolterodine. The primary outcome was safety, measured by incidence of adverse events. Secondary outcomes included change from baseline at week 52 in average daily number of micturitions and urgency episodes (OABwet) based on 7-day diary data. Of 506 patients randomized 505 received ≥1 dose of medication, and 430 (85%) completed the study. A total of 12 patients (2.4%) discontinued owing to adverse events. The most common adverse events with vibegron/tolterodine (>5% in either group) were hypertension (8.8%/8.6%), urinary tract infection (6.6%/7.3%), headache (5.5%/3.9%), nasopharyngitis (4.8%/5.2%) and dry mouth (1.8%/5.2%). Improvements in efficacy end points were maintained for patients receiving vibegron for 52 weeks; least squares mean change from baseline to week 52 in micturitions was –2.4 for vibegron vs –2.0 for tolterodine; in urge urinary incontinence episodes –2.2 vs –1.7 (p <0.05); in urgency episodes –3.4 vs –3.2; and in total incontinence episodes –2.5 vs –1.9 (p <0.05). Among patients with overactive bladder wet 61.0% receiving vibegron experienced ≥75% reduction in urge urinary incontinence episodes after 52 weeks of treatment vs 54.4% with tolterodine, while 40.8% vs 34.2% experienced a 100% reduction.

A subpopulation analysis from EMPOWUR assessed the efficacy and safety of vibegron in patients aged ≥ 65 and ≥ 75 years demonstrated that once daily vibegron 75 mg showed rapid onset and robust efficacy versus placebo and was generally safe and well tolerated, consistent with results from the overall population [Varano et al., 2021]. Of the 1463 patients with evaluable efficacy data, 628 patients were aged ≥ 65 years, and 179 were aged ≥ 75 years. After 12 weeks, patients treated with once daily vibegron 75 mg in both age subgroups showed significant improvements from baseline versus placebo in all three symptoms of OAB: daily micturitions (≥ 65 years, $P < 0.0001$; ≥75 years, $P < 0.05$), UUI episodes (≥ 65 years, $P < 0.001$; ≥ 75 years, $P < 0.0001$), and urgency episodes (≥ 65 years, $P < 0.01$; ≥ 75 years, $P < 0.01$). Significant reductions from baseline versus placebo in daily micturitions, UUI episodes, and urgency episodes were observed beginning at week 2 for pa-

tients aged ≥ 65 years treated with vibegron. In patients aged ≥ 65 years, 50.0% of those receiving vibegron versus 29.8% receiving placebo experienced a ≥ 75% reduction in UUI episodes at week 12 (P < 0.0001). Rates of cardiovascular-associated AEs were low for patients receiving vibegron (<2% of patients in either age subgroup) and similar rates in patients receiving placebo. In patients aged ≥ 65 years, hypertension was reported by 1.2%, 3.1%, and 2.9% of patients receiving vibegron, placebo, and tolterodine, respectively; in patients aged ≥ 75 years, hypertension was reported by 1.3%, 3.3%, and 2.1%, respectively.

In the 12-week EMPOWUR trial, treatment with vibegron was associated with significantly greater and clinically meaningful improvement in OAB-q and PGI scores compared with placebo, consistent with improvements in OAB symptoms [Frankel et al., 2020].

Assessment. Vibegron has a documented beneficial effect in the treatment of OAB and seems to have an acceptable side effect profile.

2.3. New developments

Thiagamoorthy et al. [2015; 2016] reviewed "novel and putative" β3-AR agonists for management of OAB, including solabegron, ritobegron, TRK-380, AJ-9677, BRL37344, and CL-316243. There seems to be a number of β_3-AR agonists in the pipeline some of which are under development. However, it is uncertain which, if any, will come to market and be available for the management of OAB.

Solabegron

Solabegron (GW427353) had an EC_{50} value of 1.9 nM in human bladder strips pre-contracted with KCl, whereas isoprenaline had an EC_{50} value of 8.3 mM (**Table 4**) [Uehling et al., 2006; Tyagi et al., 2009]. In a Phase II multicenter, randomized, proof-of-concept trial in 258 women with wet OAB, the drug produced a statistically significant difference in percent change from baseline to Week 8 in incontinence episodes over 24 hr (primary outcome) when compared with placebo (P = 0.025) and was well tolerated [Ohlstein et al., 2012]. Two additional Phase II dose-ranging study with a new formulation have been completed but results have not yet been disclosed (NCT03475706, NCT03594058).

Ritobegron

The selectivity of ritobegron (KUC-7483) for β_3-AR was 301 and 32 times higher than that for β_1- and β_2-adrenoceptors, respectively (**Table 4)** [Maruyama et al., 2012]. In its first Phase III study, ritobegron did not significantly improve the mean number of micturitions per 24 hr compared to placebo. A long-term safety and efficacy study was subsequently withdrawn, and ritobegron does not seem to have been developed further [Thiagamoorthy et al., 2015; 2016]

3. DRUGS ACTING ON MEMBRANE CHANNELS

3.1. Calcium antagonists

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone [Berridge 2008]. Two major groups of calcium channels include the voltage-gated [Caterall et al., 2003] and the store-operated channels [Leung et al., 2008]. While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute

only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type [Frew and Lundy, 1995]) and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2007]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]). In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical installation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Frölich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Naglie et al., 2002]0). It should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction **(Table 2).**

Gabapentin and pregabalin are typically utilised for neuropathic pain [Wiffen et al., 2017; Wiffen et al., 2013]. One potential mechanism of action is through the high affinity binding to $\alpha 2\delta$-1 subunits of the voltage-gated calcium channel [Thorpe and Offord, 2010]. Therefore, some studies have been performed to assess its efficacy in OAB. In a randomised double blind, double dummy placebo-controlled trial of patients with OAB, Gabapentin and solifenacin were compared to placebo utilising flexible dosing regimens [Chua et al., 2018]. Both gabapentin (up to 300mg three times daily) and solifenacin (5 or 10mg) improved mean number of micturitions and urgency episodes compared to placebo but gabapentin was statistically better than solifenacin in improving nocturia. Adverse events were less with placebo and gabapentin compared to solifenacin. In those with neurogenic detrusor overactivity gabapentin was able to improve voiding diary and urodynamic parameters, notably maximum cystometic capacity, volume at first desire to void, volume at first involuntary contraction and maximum detrusor pressure during filling cystometry when compared to baseline [Carbone et al., 2006]. A study in children also suggested that gabapentin could be used as add-on therapy to antimuscarinics and was helpful in improving symptoms in approximately 50% of cases [Ansari et al., 2011]. Finally, in a randomised double-blind placebo-controlled trial evaluated in women with OAB, pregabalin alone twice daily or TOL-ER alone once daily or in combination with normal or half strength dosing was assessed Marecak et al., 2011]. Mean voided volume was significantly greater in standard dose pregabalin / TOL-ER combination (39.5 mL) vs either pregabalin (27.4 mL) or TOL-ER (15.5 mL) alone and in general all treatments were well tolerated.

3.2. Potassium channel openers

Various types of K^+ channels exist and many of them apparently are involved in the regulation of bladder smooth muscle tone [Malysz and Petkov, 2020; Parajuli et al., 2016; Gopalakrishnan and Shieh, 2004]. The opening of K^+ channels typically leads to hyperpolarization of cells and, in the case of smooth muscle, to relaxation. Therefore, various compounds targeting different types of K^+ channels have been tested in vitro, in animals and in patients as possible treatments for OAB/DO. This drug class has been confronted with two key challenges: Firstly, it has proven difficult to identify compounds with marked selectivity for a type of K^+ channel or even spe-

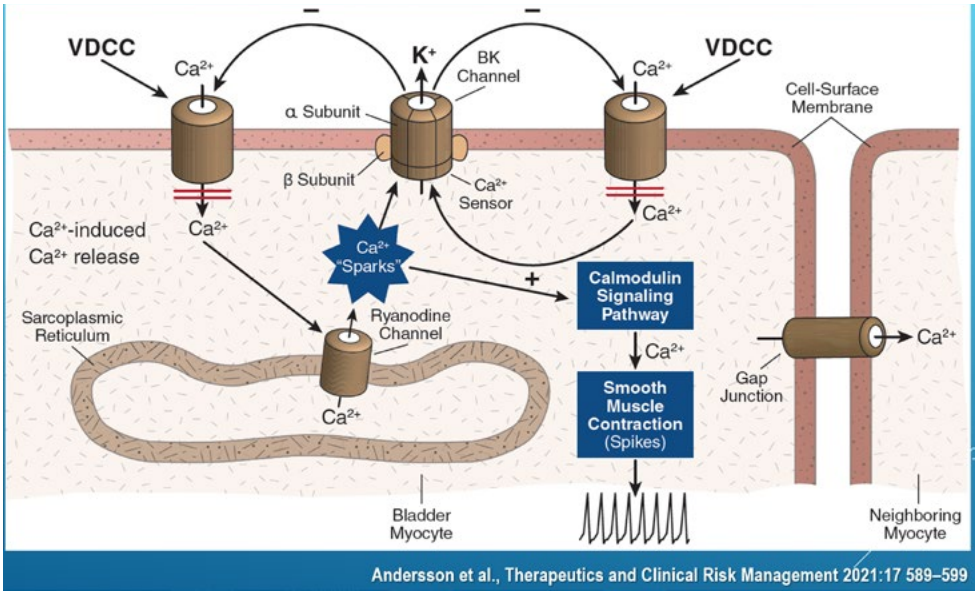

Figure 14: The Maxi K-channel. From Andersson et al., Therapeutics and Clinical Risk Management 2021:17 589–599

cific channel within a family. Second, K^+ channels are also involved in the regulation of smooth muscle and cardiomyocyte function; drug candidates for the treatment of OAB/DO should exhibit efficacy a concentrations/doses that largely lack effects on blood vessels and the heart. Such considerations have sometimes led to clinical proof-of-concept studies that used possibly suboptimal drug doses to avoid cardiovascular side effects. Overall, only few K^+ channel openers with promising animal data have been tested clinically.

an opener of ATP-sensitive K+ channels, has been tested in a phase II study with a daily dose of 25 mg administered for 12 weeks as compared to placebo [Chapple et al., 2004]. Based on >90 patients per arm, ZD0497 showed no relevant benefit for the primary endpoint, mean voided volume, any of the secondary endpoints number of micturitions and incontinence episodes.

Flupirtine has been marketed as a centrally acting, non-opioid analgesic for more than 30 years and is believed to largely act by modulating KCNQ type (K_v7) K^+ channels. Based on positive effects in several animal models has been tested in a phase II study that had planned to be administered 400 mg/day to be uptitrated to 600 mg/day for 12 weeks in comparison to placebo and tolterodine. However, the study was halted prematurely due to unexpected frequent hepatotoxicity of the compound [Michel et al., 2012]. At time of discontinuation, 189 (74, 76 and 39 on placebo, flupirtine and tolterodine, respectively) had at least one efficacy assessment during treatment (full analysis set), but only 88 (38, 32 and 18) had reached the 8-week assessment point without major protocol violations (per protocol set). In the latter, flupirtine was more effective than placebo ($p = 0.03$) for the primary endpoint of urinary frequency but less effective than tolterodine. Due to the small sample sizes upon premature discontinuation, these data are not conclusive. While flupirtine is obviously unsuitable as a treatment for OAB/DO due to its liver toxicity, other agents acting on KCNQ channels remain under investigation.

One type of large conductance, voltage and calcium activated K+ channel, known as big potassium (BK) or Maxi-K channel is expressed highly on urinary bladder smooth muscle cells and regulates bladder function **(Fig 14)**. Modulation of this channel with gene therapy has recently been explored and reviewed [Petkov, 2014]. URO-902 is a 6880-base-pair naked plasmid DNA incorporating a DNA sequence synthesised from mRNA that encodes the human BK channel alpha subunit [Andersson et al., 2021]. In phase 1 studies women with OAB, gene therapy was administered either by direct bladder injection or bladder instillation [Rovner et al., 2020]. No participants withdrew due to AEs (n=34) and no AEs prevented dose escalation. Most AEs were mild and not likely related to the therapy. In the instillation study, there was a trend towards a reduction in involuntary detrusr congractions on urodynamics and mean UUI episodes vs placebo. Furthermore, in those with direct injected gene therapy into the bladder significant reductions vs placebo was seen in urgency episodes ($p=0.036$) and number of voids 1 week post injection ($p=0.044$).

4. α-ADRENOCEPTOR (AR) ANTAGONISTS

The smooth muscle of the bladder base and proximal urethra contains predominantly α-ARs, and contraction of the bladder base and urethra is mediated by α_1 ARs [Andersson, 2021]. There are at least three subtypes of α_1 ARs, designated α_{1A} , α_{1B} , and α_{1D} . The smooth muscle contraction within the human lower urinary tract is mediated largely by the α_{1A} subtype, and the α_{1D} subtype within the detrusor also has a role in contraction.

The use of α1-AR antagonists in the treatment of male lower urinary tract symptoms (LUTS) has been well-studied, and α1-AR antagonists are effective for treating voiding symptoms in men with bladder outlet obstruction (BOO) from BPE, thereby improving bladder emptying and improving urinary incontinence from either bladder overactivity or overflow [McVary et al., 2011].

Epidemiology studies conducted in Europe and in North America have estimated that between 9.7% and 27.2% of men are affected by OAB [Irwin et al., 2011]. Diagnosing OAB in men can be complicated by the presence of the voiding symptoms caused by BOO from BPH. Current European guidelines suggest using oral OAB meds in combination with an α-blocker when symptom relief is insufficient with either drug alone [Oelke et al., 2013].

Several studies in men have shown that antimuscarinics combined with α1-blockers can improve the bladder storage symptoms caused by OAB. Chapple et al randomized 652 men ≥40 years of age with persistent bladder storage symptoms and on a stable dose of α-blocker for ≥1 month to either 4 mg of tolterodine ER and α-blocker (n=329) or placebo and α-blocker (n=323) [Chapple et al., 2009]. After 12 weeks of treatment, men receiving tolterodine ER and α-blocker had significantly greater improvements over men receiving placebo and α-blocker in micturitions/day (-1.8 vs -1.2, p=0.0079), urgency episodes/day (-2.9 vs -1.8, p=0.0010), International Prostate Symptom Score (IPSS) storage subscale (-2.6 vs -2.1, p=0.0370), and OAB-q symptom bother scale (-17.9 vs -14.4, p=0.0086). There were no clinically meaningful changes in either postvoid residual volume or maximum urinary flow rate. The authors concluded that the addition of tolterodine ER to α-blocker therapy further improved bladder storage symptoms. Similarly, Kaplan et al randomized 398 men ≥45 years of age to either 5 mg of solifenacin plus 0.4 mg of tamsulosin (n=203) or placebo plus 0.4 mg of tamsulosin (n=195) [Kaplan et al., 2009]. The primary end point was mean change in micturitions/day after 12 weeks of treatment, and secondary end points included mean change in urgency episodes/day and total IPSS. After 12 weeks, men receiving solifenacin plus tamsulosin saw decreased daily micturitions and urgency episodes; however, only the decrease in urgency episodes reached statistical significance (-2.18 for solifenacin and tamsulosin vs -1.10 for placebo and tamsulosin, p<0.001). On the I-PSS the only significant between group difference was at week 12 in total storage symptoms (-3.15 for solifenacin and tamsulosin vs -2.40 for placebo and

tamsulosin, p<0.006). The authors concluded that while α-blockers may adequately manage voiding LUTS in men, storage LUTS may be improved with the addition of solifenacin. The intermediate-term and long-term impact of combination therapy remains largely unknown because supporting literature is absent. This becomes even more important in light of the high discontinuation rates seen with anticholinergic therapy [Gomelsky et al. 2018].

Recent studies have shown that using β-3 agonists and α-blockers in men with LUTS can improve bladder storage symptoms caused by OAB. Kaplan et al reported on the results of a phase 4 study of 676 men who, after completing a 4-week run-in period of 0.4 mg tamsulosin daily, then entered a 12-week, randomized, double-blind, treatment period where patients received either 25 mg mirabegron or placebo add-on therapy [Kaplan et al., 2020]. At 4 weeks, doses were titrated to either 50 mg mirabegron or placebo. The primary end point was the mean change in micturitions/day, and secondary end points included mean volume voided, mean change in urgency episodes/day, and IPSS score. The study found that tamsulosin plus mirabegron was superior to tamsulosin plus placebo in reducing the mean number of micturitions/day (-2.00 vs -1.62, p=0.039). As for secondary end points, statistically superior results with tamsulosin and mirabegron were seen in mean volume voided/micturition and number of urgency episodes/day, but no significant change was seen in IPSS. The authors concluded that the addition of mirabegron to tamsulosin improved the hallmark symptoms of OAB, urinary frequency and urgency. Ishikawa et al investigated the efficacy and safety of vibegron in men already receiving either α-1 blockers or tadalafil, a PDE5 inhibitor, for men with BPO from BPH and persistent bladder storage symptoms [Ishikawa et al. 2021]. Vibegron 50 mg was administered for 12 weeks to 42 men who were already on either α-1 blockers (n=22) or tadalafil (n=20). The primary endpoint was change in the OAB Symptom Score after 12 weeks of treatment. Of the men on α-1 blockers, 8 men were on silodosin (8 mg/day), 10 men were on naftopidil (50 or 75 mg/day) and 4 men were on tamsulosin (0.4 mg/day). Compared to baseline, the total OAB Symptom Score did significantly decrease after 12 weeks with this combination treatment (6.21 ± 3.12 vs 4.38 ± 2.46; p<0.001). Also, Qmax and PVR did not change after 12 weeks of vibegron use, and no patient discontinued vibegron because of AEs.

Oral OAB drugs are often used with caution in men with LUTS, becaused of the perceived risk of developing AUR. Yet, the risk of AUR from the combination of an α-blocker and an OAB drug (antimuscarinic or β-3 agonist) is very low. Urinary retention was reported in 1.8% of men taking tolterodine ER and α-blocker, which was the same rate reported in men taking placebo and α-blocker. Of the men that took 5 mg solifenacin and tamsulosin, 3% reported urinary retention. Also, urinary retention was seen in 1.7% of men taking both mirabegron and tamsulosin. Furthermore, the increase in PVR seen with combination therapy was low and not clinically significant, and Qmax was not impacted by the addition of either anticholinergics or β-3 agonists [Kim et al. 2017].

There have been several studies evaluating whether better efficacy and/or tolerability is obtained with use of the highly subtype selective α-blockers for male LUTS. Chapple et al. conducted a multicenter double-blind, placebo and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo [Chapple et al. 2011]. A total of 1228 men ≥50 years of age with an IPSS of ≥13 and a Qmax between 4-15ml/s were selected at 72 sites in 11 European countries. The men were entered into a 4-week placebo run-in period. A total of 955 patients were randomized (2:2:1) to either silodosin 8 mg (n=381), tamsulosin 0.4 mg (n=384), or placebo (n=190) once daily for 12 weeks. The primary end point was change in total score of IPSS. The overall efficacy of silodosin was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo (p = 0.013). Also, although both silodosin and tamsulosin showed significant improvements in IPSS storage symptoms compared to placebo (p=0.002), there was no difference between the two. With respect to QOL at 12 weeks, there was no difference between the two α-blockers. Discontinuation rates due to treatment emergent AEs were low in all groups (2.1%,1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). Yet, a major advantage of silodosin is its lack of cardiovascular side effects. Unlike tamsulosin, silodosin has no clinically relevant effect on blood pressure during orthostatic testing. Yamanishi et al evaluated the urodynamic effects of silodosin in 29 men with severe LUTS from BPH [Yamanishi et al., 2010]. After 12 weeks of silodosin treatment, detrusor overactivity (DO) resolved in 40% of patients with DO at baseline, the amplitude of the largest DO contraction decreased from 85.3±35.3 cm H_2O to 37.4±42.9 cm H_2O (p=0.0003), and the bladder volume at initial DO increased from 285.34±112.8 ml to 380.6±136.87 ml (p=0.0003).

Naftopidil is an α-1 blocker with affinity for α_{1D} receptors which are largely concentrated in the bladder within the detrusor smooth muscle, the detrusor vasculature, the urothelium, afferent and efferent nerve terminals and intramural ganglia [Andersson and Gratzke, 2007]. The use of naftopidil in men with LUTS has been shown to improve OAB symptom scores (OABSS) in a study designed to compare efficacy between morning and evening dosing [Sakai et al., 2011]. Naftopidil significantly decreased the OABSS from 7.8±2.6 to 5.0±2.5 in the morning group (p<0.0001) and from 8.6±2.9 to 5.8± 3.3 in the evening group (p<0.0001). Interestingly, there was no significant difference in the incidence of AEs between morning and evening dosing of naftopidil. Matsukawa et al sought to determine the pre-treatment factors related to the improvement of OAB symptoms after α-1 blocker monotherapy in patients with BPE and OAB [Matsukawa et al., 2019]. They did a post-hoc analysis of an open-labeled study comparing silodosin 8 mg daily (n=157) and naftopidil 75 mg daily (n=157). Patients were divided into 2 groups based on the OABSS urgency sub-score after treatment: the good responder group included patients with an OABSS urgency sub-score of <2 at week 12 and the poor responder group had an OABSS urgency score of ≥2 at week 12. The proportion of patients with UUI at baseline was significantly higher in the poor responder group compared to the good responder group (77.4% vs. 55.3%, p < 0.001). In multivariable logistic regression analysis, use of naftopidil, higher OABSS-UUI score, and larger PVR were significant pre-treatment factors related to failure in OAB symptom improvement with α1-blocker monotherapy.

Little has been published on the use of α1-blockers in the treatment of women with LUTS. Low et al randomized 100 women with LUTS to either terazosin 4 mg daily or placebo [Low et al., 2008]. The primary end point was improvement on the IPSS QOL of 2 or <. Of the women receiving terazosin, 80% responded compared to 55% of the women receiving placebo, p <0.02. Recently, Kim et al performed 2 meta-analyses on the use of α1-blockers in the treatment of female LUTS [Kim et al., 2019]. The first analysis compared bladder symptom scores, Qmax and PVR before and after α1 blocker therapy in 8 prospective, open-label studies, and 5 RCTs. The second analysis compared the same variables in 4 RCTs that compared α1 blockers and placebo. The first meta-analysis showed that, women treated with α1 blockers had an improvement in bladder symptoms of 5.85 points (p<0.00001), an increase in Qmax of 3.67 mL/sec (p<0.00001), and a decrease in PVR of 28.46 mL (p<0.00001). In the second meta-analysis, α1-

blockers demonstrated greater symptom relief relative to placebo with a mean difference in symptoms of 1.60 (p=0.004); however, there were no differences in Qmax or PVR between α1 blockers and placebo. Although the authors found that α1-blockers are effective for treating women with LUTS, they stressed that the effect of α1-blockers in this population should be assessed according to underlying cause.

5. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson, 1999; Andersson and Wein, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical treatment approach to increased outflow resistance as found in BPH/BPO (Andersson et al., 1997; 2011¸ 2017). There are presently 11 families of PDEs **(Fig 15**), some of which preferentially hydrolyse either cAMP or cGMP [Uckert et al., 2006, Rahnama'i et al., 2013] (Figure 15).

As a basis for PDE inhibitor treatment of BPH/LUTS, Uckert et al. [2006] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably inhibit the breakdown of cAMP. In vitro, hu-

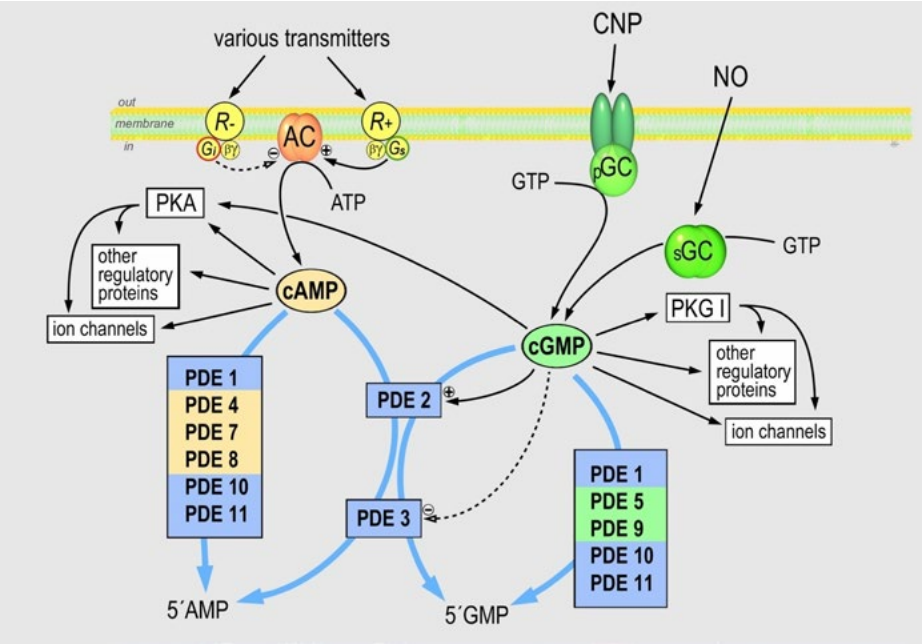

Figure 15: The family of phosphodiesterases

man detrusor muscle responded poorly to sodium nitroprusside, and to agents acting via the cGMP system [Truss et al., 2000]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [Truss et al., 2001]. Significant dose-dependent relaxations were also induced by human cAMP analogues [Truss et al., 2001]. With these studies as a background, Truss et al. presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy [Truss et al., 2000]. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [Truss et al., 2001]. Clinical studies with PDE 1 inhibitors other than vinpocetin (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder [Gillespie and Drake, 2004; Nishiguchi et al., 2007]. Xin et al. [2014] found that that selective pharmacological inhibition of PDE4 increases the frequency of Ca^{2+} sparks and their functionally coupled BK channels, which lead to the attenuation of DSM excitability and contractility and suggested that PDE4 isoforms might be valuable therapeutic targets for the treatment of overactive bladder. In rats with bladder outlet obstruction, Balog et al. [2019] demonstrated that roflumilast (PDE 4 inhibitor) particularly in combination with tadalafil (PDE 5 inhibitor) effectively decreased non-voiding contractions and smooth muscle disruption. Linhares et al. [2020] evaluated in vitro the effect of the combination of the b-AR agonist, BRL 37344, with tadalafil or rolipram (PDE 4 inhibitor) in rats with and without chronic L-NAME treatment. They found that the inhibitory effects of rolipram, but not tadalafil, were enhanced by BRL 3744, and suggested that PDE4 inhibition when associated with $ß_3$-AR stimulation, could represent a potential treatment for overactive bladder.

Several selective PDE 4 inhibitors have been tested clinically for various inflammatory disorders (particularly skin diseases and asthma) [Li et al., 2018] but none seems to have been tested on LUT disorders. Considering the promising preclinical experiences, PDE 4 inhibition with or without combination with other drugs may be a worth further exploration, but clinical studies are needed.

Oger and co-workers showed that PDE5-inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K(+) channel-dependent signalling pathways, with a minor contribution from NO [Oger et al., 2010]. In combination with the alpha-blocker doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle and their combination provided a significant benefit when targeting relaxation of both tissues [Oger et al., 2008].

In-vivo, several studies have indicated a role for PDE5-inhibitors in the regulation of micturition function. Systemic vardenafil reduced both non-voiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord injury rats, indicating potential mechanisms by which PDE5-Is improve storage symptoms in SCI patients [Behr-Roussel et al., 2010]. The effect of vardenafil on OAB-symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (SHR) [Morelli et al., 2009a; Morelli et al., 2009b]. Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment [Morelli et al., 2009b]. Thus, besides relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalfil was shown to increase prostate tissue oxygenation in SHR and human vesicular-deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results

suggest another possible mechanism through which PDE5i exert beneficial effects on LUT symptoms [Morelli et al., 2011; Cellek et al., 2014].

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Arner, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. examined the effects of isoproterenol, prostaglandin E_1 and E_2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra [Morita et al., 1994]. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al.[2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra, and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations. Fibbi et al. [2009] confirmed that the highest expression and biological activity of PDE5 was found in bladder. However, a consistent PDE5 expression and activity was also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fibre afferent activation, it was shown that the NO/cGMP signalling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather on the motor component of the micturition reflex [Caremel et al., 2010]. In obstructed human and rat bladder, He et al. [2020] found an upregulation of NOS isoforms, PDE5 and PDE4A. Obstructed bladder tissue exhibited reduced relaxation responses to sodium nitroprusside but an exaggerated PDE5 inhibition effect. The authors suggested that upregulation of PDE5 could contribute to the lack of effect on Qmax for BPH/LUTS patients treated with PDE5 inhibitors. Agis-Torres et al. [2018], demonstrated a rich PDE4 and PDE4A expression in nerve fibers of the smooth muscle layer of pig and human bladder outflow region. The orally active PDE 4 inhibitor, rofumilast, approved for the treatment of severe chronic obstructive pulmonary disease, produced a much more potent smooth muscle relaxation than that induced by tadalafil. They concluded that PDE4 inhibition and subsequent increased neuronal cAMP facilitates NO- and H_2S-mediated bladder neck inhibitory neurotransmission. Rofumilast also improved bladder function in rats with diabetic [Ding et al., 2019] and obesity-related [Ding et al., 2017] bladder dysfunction. In mice. Ito et al. [2019] showed that ow-dose sildenafil increased bladder compliance, increased pelvic nerve afferent activity, and augmented the bursting activity of the external urethral sphincter. suggested that actions of the PDE5 inhibitor on afferent traffic and sphincter control may contribute to its beneficial actions to restore storage and voiding efficiency in LUT dysfunction. Sildenafil was also shown to selectively inhibit ATP release from nerve terminals innervating detrusor smooth muscle and the urothelium in rats with spinal cord injury [Chakrabarty et al, 2019].

PDE5 degrades cGMP and can thus stop the NO-mediated relaxation of smooth muscle. NO activates its intracellular receptor, soluble guanylate cyclase (sGC), to promote accumulation of cyclic GMP (cGMP), causing smooth muscle relaxation. Inhibitors of PDE5 thus increase tissue cGMP levels and have been approved for treatment of BPH/LUTS suggesting a key role for NO-sGC-cGMP pathway as the key target of PDE5 inhibitor therapy. However, refractoriness to PDE5 inhibitors can develop and alternatives to upregulate cGMP production need to be sought. When NO binds to sGC, it activates its catalytic domain to convert GTP to cGMP, which in turn activates protein kinase G (PKG), phosphorylating multiple downstream proteins. This process can be inactivated by inflammation or oxidative stress associated with different risk factors for BPH/LUTS such as e.g., aging and obesity but can be circumvented by small molecule sGC activators and stimulators which are not structural analogues of cGMP but induce its production in the absence of NO [Monica and Antunes, 2018]. This may be a promising way for treatment for BPH/LUTS patients refractory to PDE5Is.

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of both LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS [Sairam et al., 2002], this observation has been confirmed in several well designed and conducted RCTs.

A number of RCTs are available comparing the effect of PDE5 inhibitors alone to placebo and the combination of alpha-blockers and PDE5 inhibitors vs alpha-blockers alone [Gacci et al 2016; Andersson et al., 2017, Monica and De Nucci, 2019; Pattanaik et al., 2019; Sebastianelly et al 2020]. In these studies, different PDE5 inhibitors and different doses were administered. PDE5-inhibitors significantly improve IPSS and IIEF scores, but not Qmax when compared to placebo. PDE5-inhibitors are generally shown to be safe and well tolerated [Ma et al., 2020].

As discussed above and in several reviews [Andersson et al., 2011; Giuliano et al., 2013; Cellek et al., 2014; He et al., 2020] the mechanism behind the beneficial effect of the PDE inhibitors on BPH/LUTS/OAB and their site(s) of action largely remain to be elucidated. The actions may be multifactorial and He et al. [2020] summarized plausible mechanism as 1) relief of SM tone in prostate and bladder, 2) relaxation of blood vessels so as to increase LUT perfusion and oxygenation, 3) decreasing the activity of afferent nerves in the LUT to modulate the micturition reflex, 4) anti-proliferation effect on bladder and prostate, 5) blunting of intraprostatic inflammation, and 6) anti-fibrotic effect on the bladder.

Improvement of bladder blood flow to the LUT has been suggested [Cellek et al., 2014], and this has been supported by studies in animals with chronic bladder ischemia [Nomiya et al., 2013].,

Currently, tadalafil is the only FDA approved PDE-5 inhibitor for treatment of male LUTS even of e.g, sildenafil and and vardenafil have been shown to be effective. However, there are several other drugs belonging to the same class that are used for treating erectile dysfunction, including avanafil, udenafil, microdenafil, gisadenafil [Gacci et al., 2014], and there are no reasons to believe that they should not be effective in relieving male LUTS. To what extent new molecules with ability to inhibit PDE-5 [Sawant et al., 2015] will be developed for future clinical application remains to be seen.

6. DRUGS ACTING AT THE CNS

6.1. Antidepressants

Some antidepressants have been used in the treatment of urgency urinary incontinence. There is increasing evidence that chronic psychological stress can result in the development of bladder storage symptoms such as urinary frequency, urgency, and urinary incontinence (Chess-Williams et al., 2021). Pro inflammatory cytokines and chemokines are released during periods of chronic stress. In the brain and spinal cord, pro-inflammatory cytokines influence the regulation of micturition pathways by corticotropin-releasing factor (CRF) and its receptors, while peripheral cytokines can directly affect bladder function, thereby causing detrusor overactivity and afferent nerve hypersensitivity. In view of the role of CRF in stress-induced urinary dysfunction, Wrobel et al. (2017) showed that a CRFR-1 antagonist can prevent the development of depressive behaviors induced by stress in a rat model of bladder overactivity. The two most common antidepressants studied in the treatment of bladder overactivity are imipramine and duloxetine.

6.1.1. Imipramine

Imipramine is a tricyclic antidepressant that blocks muscarinic receptors and inhibits norepinephrine reuptake, both of which enhance detrusor smooth muscle relaxation. Also, imipramine inhibits the re-uptake of noradrenaline and serotonin in adrenergic nerve endings to enhance the contractile effects of noradrenaline on urethral smooth muscle [Maggi et al., 1989; Hoebeke et al., 2000], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Although antimuscarinics and beta-3 agonists are currently considered the drugs of choice in the treatment of OAB and urge urinary incontinence (UUI), imipramine has been shows to have in vitro and in vivo effects on the detrusor muscle to improve bladder overactivity [Creed and Tulloch, 1978]. Yet, the early data on the clinical effects of imipramine use alone in adult UUI has been conflicting. Most of these studies attesting to an improvement were either small, poorly designed, and/or uncontrolled [Castleden et al., 1986; Cole and Fried, 1972].

Imipramine has been used in combination with antimuscarinics and alpha-blockers as a treatment for refractory neurogenic detrusor overactivity (NDO) in adults with neurogenic bladder. Natalin et al evaluated prospectively the combination of doxazosin 4 mg at

night, oxybutynin 5 mg BID, and imipramine 25 in the morning [Natalin et al., 2010]. Patients were included if they had poor efficacy with oxybutynin 15 mg/d for at least 3 months and they had NDO demonstrated on urodynamics. There were 17 men and 10 women, and the median follow-up was 15 months (range, 6–38 months). Of the 27 patients, 10 had spina bifida, 5 had MS, 5 had SCI, 4 had vascular brain injury, and 3 had myelitis. After 60 days of triple drug therapy, urodynamics were performed and the mean cystometric capacity (MCC) increased from 200 to 300 cc (p<0.001), and bladder compliance increased from 6 to 20 ml/cm H_20 (p<0.001). Also, 3-day bladder diaries, performed every 6 months, showed decreases in urgency episodes/day and number of voids/day (p<0.001). Adverse events included dry mouth in 37% and constipation in 37%. The authors concluded that triple therapy of oxybutynin, doxazosin, and imipramine may be an effective, easily employed, and well-tolerated treatment option for refractory NDO. Similarly, Cameron et al. [2009] performed a retrospective a retrospective chart review and identified 77 subjects (54 men and 23 women) that were either on antimuscarinics and/or imipramine and alpha-blockers. The etiology of the neurogenic bladder dysfunction was SCI in 49 (64%) or spina bifida in 13 (17%) subjects. Patients underwent urodynamics at baseline and on average 10 months after starting the combination therapy. MCC increased from 160 to 251 ml in the 2 drug group (p=0.002) and from 156 to 263 ml in the 3 drug group (p=0.0006). In addition, bladder compliance increased from a mean of 11.3 to 56.3 ml/cm H2O (p=0.0008) in the 2 drug group and from a mean of 7.2 to 69.6 ml/cm H2O (p<0.0001) in the 3 drug group. There were also improvements in incontinence, vesicoureteral reflux, NDO and detrusor sphincter dyssynergia. The authors concluded that the addition of imipramine and/or an alpha-blocker should be considered in patients with neurogenic bladder in whom anticholinergics alone fail.

In children, imipramine has been known to have favorable effects in the treatment of nocturnal enuresis with success rates up to 70% in some controlled trials [Caldwell et al., 2016]. In a review of 64 tricyclic trials for nocturnal enuresis in 4071 children, Caldwell et al. [2016] concluded that imipramine treatment reduced enuresis by one wet night per week. Although a fifth of the children became dry while on treatment, this effect was not sustained after treatment stopped. Specifically, 96% of children were wet at follow-up after ceasing imipramine versus 97% for placebo. There is evidence that tricyclics combined with anticholinergics may be more effective that tricyclic monotherapy. Specifically, there were about two fewer wet nights per week for children taking imipramine plus oxybutynin compared with imipramine monotherapy. Furthermore, AEs from imipramine use in children include dizziness, headache, mood changes, gastrointestinal complaints, and neutropenia. The authors concluded that there was evidence that tricyclics are effective at reducing the number of wet nights during treatment for nocturnal enuresis in children, but tricyclics do not have a sustained effect after treatment stops, with most children relapsing.

It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giardina et al., 1979]. Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants [Baldessarini, 1985].

6.1.2. Duloxetine

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor **(Fig 16).** Although duloxetine has been well studied in the treatment of SUI, it was shown to increase bladder capacity in a cat acetic acid model through both motor efferent and sensory afferent modulation [Katofiasc et al., 2002]. Wrobel et al. [2020] found that the tested animals presented symptoms of depression, detrusor overactivity, inflammation, and disturbances in neurotrophic factors. Duloxetine improved all changes and the authors suggested that duloxetine may have a potential to become a new treatment option for patients with OAB co-existing with depression.

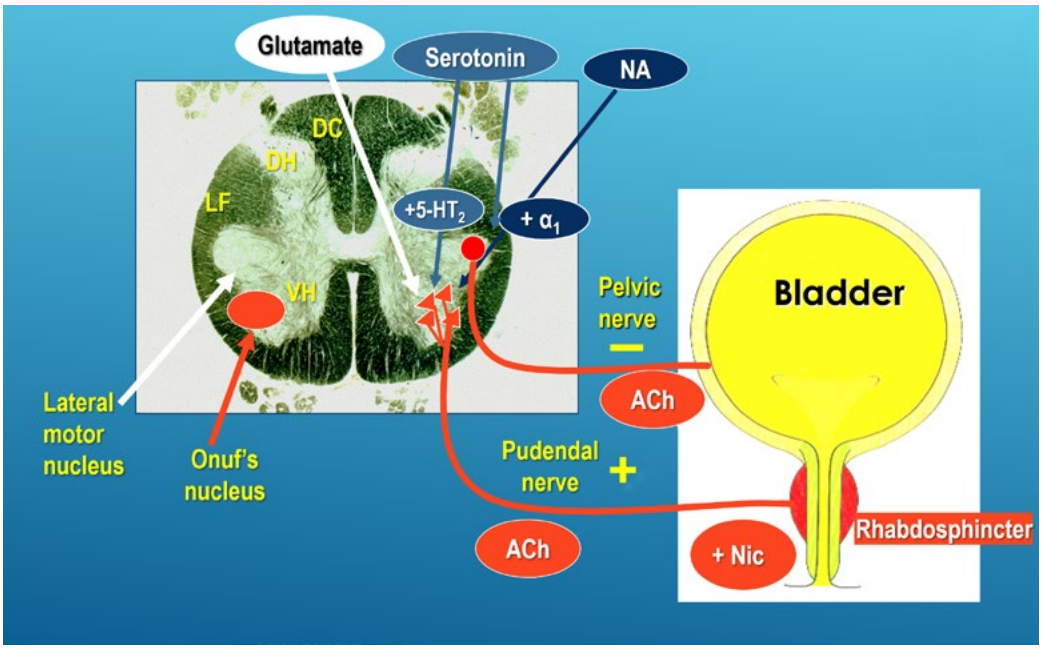

Figure 16: Site of action of duloxetine

Clinical duloxetine use was studied by Steers et al with a 12-week, randomized, placebo-controlled trial evaluating the efficacy and safety of duloxetine women with OAB [Steers et al., 2007]. The study was conducted at 30 sites in the US, Canada, and Australia. A total of 306 women were randomized to either duloxetine at 80-mg/day for 4 weeks and then increased to 120-mg/day for 8 weeks (n=153) or placebo (n=153). These OAB patients underwent urodynamics, and the testing had to demonstrate either DO or urgency which limited bladder capacity to < 400 mL. The primary end point was the mean change from baseline in the number of voids/24 h. Secondary end points included UUI episodes/24 h and scores on the Incontinence Quality of Life questionnaire (I-QOL). After 12 weeks, the number of voids/day was reduced by 1.81 voids in women receiving duloxetine and by 0.62 voids in women receiving placebo, p<0.001. Also, the number of UUIE/day was reduced by 1.12 leaks in women receiving duloxetine and by 0.29 leaks in women receiving placebo, p=0.04. In addition, the I-QOL scores improved by 8.37 points in women receiving duloxetine and by 4.87 points in women receiving placebo, p=0.035. However, nausea was reported in 30.7% of women receiving duloxetine compared to 4.6% of women receiving placebo, p<0.001. Other AEs in those receiving duloxetine included dizziness in 14.4%, insomnia in 13.1%, and fatigue in 10.5%, and all these rates were significantly higher with duloxetine compared to placebo. Study discontinuations due to AEs was 28.1% in those receiving duloxetine compared to 5.2% in those receiving placebo, p<0.001.

Di Rezze et al. [2012] studied the efficacy and tolerability of duloxetine in the treatment of OAB in patients affected by remitting-relapsing MS and secondary progressive MS. They found a statistically significant improvement in bladder disorder, as measured by OAB-Q after duloxetine treatment compared with both basal levels and placebo

In summary, despite the efficacy demonstrated in the Steers RCT with duloxetine over placebo in improving void/day, UUIE, and I-QOL, treatment emergent AEs and discontinuations due to AEs were more common with duloxetine compared to placebo. As such, the safety profile of duloxetine in this study was identical to the safety profile established in women with SUI [Dmochowski et al. 2003]. No further quality studies on the use of duloxetine for OAB have been published. As such, there is no current clinical utility of duloxetine for the treatment of OAB.

6.2. Baclofen

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex in several points along its central pathway [de Groat, 1997; Pehrson et al., 2002]. Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin induced detrusor overactivity, suggesting that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al, 2002]. In spinal intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)-like changes whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions [Miyazato et al., 2008]. After spinal cord injury (SCI), Miyazato et al. [2008] found signs of hypofunction of the GABAergic system (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased) and showed that activation of GABA(A) and GABA(B) receptors in the spinal cord inhibited DO as evidenced by a reduction in non-voiding contractions. GABA(B) receptor activation preferentially reduced DO prior to inhibiting voiding contractions while GABA(A) receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA(B) receptors, *baclofen* has been available for clinical use for more than 60 years [Kent et al., 2020]. Administered systemically or intrathecally in animal models, it has been shown to inhibit pain, including bladder pain [see, Ness et al., 2021]. It has been used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. ADX71441 is a selective positive allosteric modulator of the $GABA_B$ receptor ($GABA_B$ PAM), which is orally available and showed promising effects in animal models of micturition disturbances [Kalinichev et al., 2014]. Further studies of this agent would be of interest.

Baclofen is one of the most effective drugs for the treatment of spasticity following spinal cord injury, traumatic or hypoxic brain injury, and cerebral palsy (Ochs, 1993), and *intrathecal* baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al.[(2000] found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days the volume to first detrusor contraction had increased from 143 ml to 486 ml. In a retrospective chart review, Del Fabro et al. [2018] found that intrathecal baclofen caused a significant reduction of symptomatic episodes of autonomic dysreflexia after spinal cord injury, even in those with additional risk factors for development of autonomic dysreflexia.

In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

7. CYCLOOXYGENASE (COX) INHIBITORS

Prostanoids (prostaglandins and thromboxanes) are synthesized by cyclooxygenase (COX) from a common precursor, arachidonic acid. Prostanoids may be involved in the control of bladder function under normal and pathological conditions, including DO and OAB. Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human bladder muscle, it is still unclear whether prostaglandins contribute to the pathogenesis of unstable detrusor contractions. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Although early clinical studies with nonselective COX inhibitors in patients with DO showed some favourable effects and symptomatic relief, the drugs were not further developed for this indication mainly due to side effects [Cardozo et al., 1980a; Cardozo and Stanton, 1980b; Palmer, 1983]. Nevertheless, combination therapy with alpha blocker and COX-2 inhibitor for male LUTS was recently receiving some attention. Jhang et al. performed a ramdomized controlled study of 82 male patients with clinical BPH, elevated serum PSA (> 4 ng/ml), and significant LUTS (International Prostate Symptom Score [IPSS] ≥ 8) randomly assigned to receive doxazosin 4 mg daily plus celecoxib 200 mg daily (study group) or doxazosin 4 mg daily alone (control group) for 3 months. The improvement in IPSS-voiding was significantly greater in the study group than control group ($p = 0.034$). The PSA level in the study group showed significant improvement after treatment ($p < 0.01$). However, prostate cancer detection rate failed to show any significant difference between the patients whose PSA levels decreased or not (6/21 = 29% vs. 5/24 = 20%, respectively, $p = 0.447$). The changes in Qmax and voided volume after combination treatment were significantly greater in patients with prostatic hyperplasia or inflammation than adenocarcinoma.

Ozdemir et al [2009] compared the efficacy and safety of a combination therapy, doxazosin 4mg plus tenoxicam 20mg, and doxa-

zosin 4mg alone for 6 weeks in 57 patients with LUTS secondary to BPH. The improvements in IPSS, IPSS-QoL, and OABSS were significantly better in patients treated with combination therapy ($P < 0.05$).

Tanaka et al. [2018] evaluated the add-on efficacy of a cyclooxygenase (COX)-2 inhibitor on the chronological changes in urinary function in patients who underwent low-dose-rate prostate brachytherapy. A total of 310 patients with prostate cancer who underwent low-dose-rate-brachytherapy were enrolled. Patients were randomized and allocated to the monotherapy group (tamsulosin alone: 0.2 mg/d) and the combination group (tamsulosin 0.2 mg/d plus celecoxib: 200 mg/d). There was not an additional effect of a COX-2 inhibitor to the action of an alpha-1 adrenoceptor antagonist on concerning the chronological changes in IPSS and OABSS. The use of a COX-2 inhibitor reduced the daytime urinary frequency and postvoid residual after seed implantation.

These findings suggest that COX-2 inhibitors in combination with an alpha blocker may increase the effectiveness of the therapy for LUTS secondary to BPH and prostatic inflammation.

8. TOXINS

Intravesical application of toxins gives the opportunity to use potentially lethal compounds unsuitable for systemic administration to treat bladder dysfunctions. That should be used as a second line treatment, when patients do not respond to oral therapy or do not tolerate their adverse effects. However, it might be expected that progressive patient phenotyping will identify subgroups that may benefit from intravesical therapy without requiring a period of potentially ineffective oral treatment

8.1. Botulinum toxin

Botulinum toxin (BonT) is a neurotoxin produced by *Clostridium botulinum*. Of the seven subtypes of BonT, sub-type A (BonT-A) has the longest duration of action, making it is the most relevant clinically. BoNT/A is available in different commercial forms, with the proprietary names of Botox®, Dysport®, Xeomin®, and Prosigne. Although the toxin is the same, it is wrapped by different proteins which modify the relative potency of each brand. The molecular weights are different. OnabotA is a 900 kDa molecule, abobotulinumtoxinA is approximately 500 kDa and incobotulinumtoxinA, is a 150 kDa molecule [Cruz, 2014]. This was the basis for the introduction of the non-proprietary names onabotulinum toxin A (onabotA), abobotulinum toxin A (abobotA) and incobotulinum toxin A (incobotA) for Botox®, Dysport® and Xeomin®, respectively. Prosigne is the proprietary name of a BoNT/A produced in China, which currently does not have a known non-proprietary name.

The current approved method to estimate the potency of a BoNT/A brand is the mouse LD50 (lethal dose 50%); that is, the mass of toxin (expressed in ng/kg of body weight) that kills 50% of mice. More recently, a cell-based potency assay was approved specifically for onabotulinum toxin assay which uses differentiated human neuroblastoma SiMa cells and replicates all steps in BoNT/A mechanism of action.8 The assay measures the BoNT/A-dependent intracellular increase of cleaved SNAP-25. The EC50, that is, the concentration of toxin required to provoke a response halfway between the baseline and maximum response for OnabotA, is about 1–0.4 U per well [Fernandez-Salas et al., 2012]. Nevertheless, the relative potency of each brand intended for bladder application may require additional investigations, as tissue physiology may alter the effucacy and metabolism of the different BoNT/A. A study in the mice compared the capacity of 1 U of onabotA and 1 U of abobotA injected in the bladder wall to cleave SNAP25. The average number of cleaved SNAP-25 positive fibers was higher after onabotA, suggesting a conversion ratio between onabotA and abobotA around 1:1.6 [Oliveira et al., 2015]. On the other hand, studies carried in the skeletal muscle suggest that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Therefore, without specific dose finding studies for each brand estimated equivalences should be approached with caution.

Innumerous comprehensive reviews have been produced along the years [Dowson et al., 2010; Duthie et al., 2011; Mangera et al., 2011, 2014; Moore et al., 2016]. For references before 2010 the interested reader is invited to read the version of this chapter in the previous edition of this book. Most of the information available about intravesical application of BoNT/A derives from the use of onabotA (Botox®). However, in addition to sub-type A, some studies have investigated the effect of detrusor injection sub-type B, rimabotulinumtoxinB (proprietary names being Miobloc™ or Neurobloc™ according to countries). For further details see below.

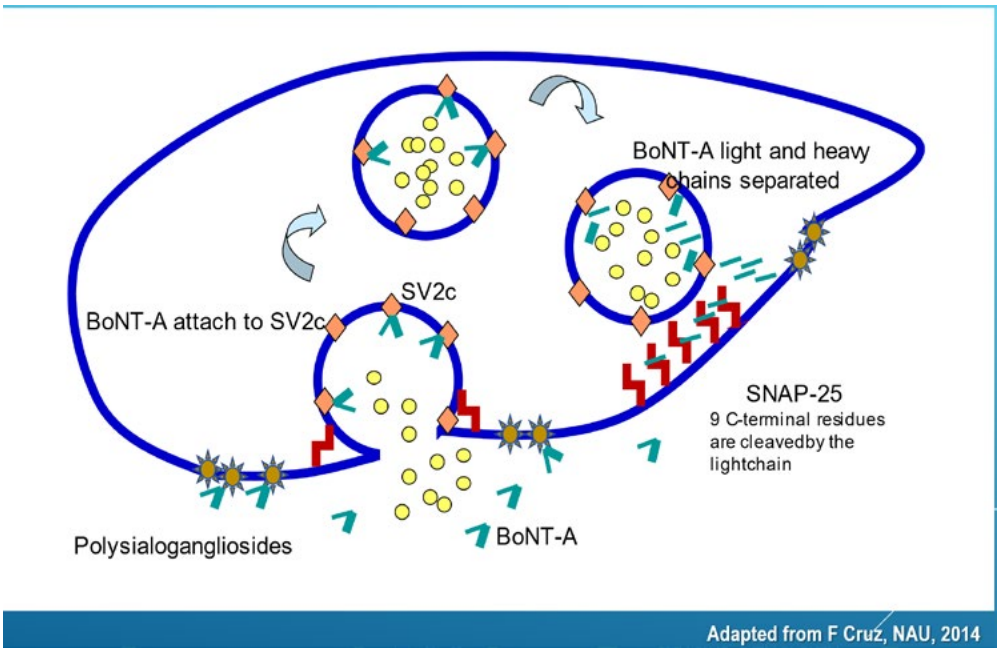

Figure 17: Mechanism of action of BoNT-A

8.1.1. Mechanism of action

This chapter will address the mechanism of action of the subtype BoNT/A, the only one with therapeutic expression in the lower urinary tract. BoNT/A consists of a heavy and a light chain linked by a disulphide bond. As the BoNT/A gene may differ in nucleotides, four A subtypes have been classified based on up to 15% variation in the amino acid composition. The amino acid sequence of the BoNT/A light chain constitutes a catalytic Zn-dependent endopeptidase domain. The heavy chain is subdivided into three portions (HN, HCN, and HCC), but only two have clear functions. The HCC is associated both with the recognition of neuronal-specific areas and toxin internalization. The HN is responsible for translocation of the light chain from synaptic vesicles into the neuronal cytoplasm. In the synaptic cleft BonT/A binds predominately to the isoform C of the synaptic vesicle protein or SV2 (SV2C) [Dong et al., 2006, Dolly, 2014] or to the FGF Receptor 3 [Jacky et al., 2013] by the heavy chain. The importance of the latter toxin acceptor is still unclear.

BoNT/A initially binds polygangliosides, resulting in an increased density of the toxin on the neuronal membrane **(Fig 17)**. This step increases the chance of heavy chain to interact with the protein acceptor SV2, predominately the isoform C (SV2C), expressed in the interior of the synaptic vesicles when they open on the neuronal surface to release the neurotransmitters [Dolly, 2014]. Then, internalization of the synaptic vesicles for recycling carriages BoNT/A into the nerve terminal (**Fig17).** Acidification occurring inside the synaptic vesicles leads to the separation of the two chains. The light chain passes into the cytosol, where it cleaves one of the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin. BonT/A cleaves SNAP-25 in the 9-terminal amino-acids of the C terminal of the protein rendering the SNARE complex inactive [Humeau et al., 2000; Dolly, 2014].

In the human bladder SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sensory fibers and sympathetic [Coelho et al., 2010]. By immunohyscochemistry the expression is by far stronger in parasympathetic nerves. [Coelho et al., 2010].

Following BoNT/A injection in the guinea-pig bladder wall almost all parasympathetic fibers express cleaved SNAP-25 [Coelho et al, 2012a]. The evidence of such cleavage explains the inhibition of ACh release from the rat bladder during electrical stimulation [Smith et al, 2003]. In accordance, the bladder of both normal and SCI animals treated with BoNT/A exhibit less bladder contractions during electrical stimulation of spinal nerves [Ikeda et al., 2012]. Thus, impairment of acetycholine (Ach) release from cholinergic motor nerve endings in the detrusor mimic those described in the striated muscle [Humeau et al., 2000]. However, subsequent events, degeneration of cholinergic endings associated with the accumulation of non-released synaptic vesicles followed by axonal sprouting and cholinergic nerve regeneration reported in the striated muscle [de Paiva et al., 1999] could not been documented in the detrusor [Haferkamp et al., 2004].

About half of the peptidergic sensory fibers of the human bladder express SV2 and SNAP25 [Coelho et al, 2010]. Following BoNT/A injection in the bladder guinea pig they express Cleaved SNAP-25 [Coelho et al, 2012a]. BoNT/A inhibits the spinal cord release of glutamate, substance P (SP) and CGRP from sensory nerves [Purkiss et al., 2000; Aoki et al., 2005; Meng et al.,2007] as well as the release of neuropeptides at the peripheral extremities [Rapp et al., 2006; Lucioni et al, BJU Int, 2008, Ikeda, et al, 2012]. In addition, BoNT/A compromises the trafficking of TRPV1 from intracellular vesicles to the neuronal membrane, as this process is also dependent on SNARE proteins [Morenilla Palao et al. 2004, Shimizu et al, 2012] (**Fig 18**). This explains the decrease in the suburothelial immunoreactivity for TRPV1 (and by analogy P2X3) observed in the human bladder after the toxin injection [Apostolidis et al., 2005]. All these mechanisms may contribute to the observation that BoNT/A reduces firing in bladder afferents [Ikeda et al., 2012].

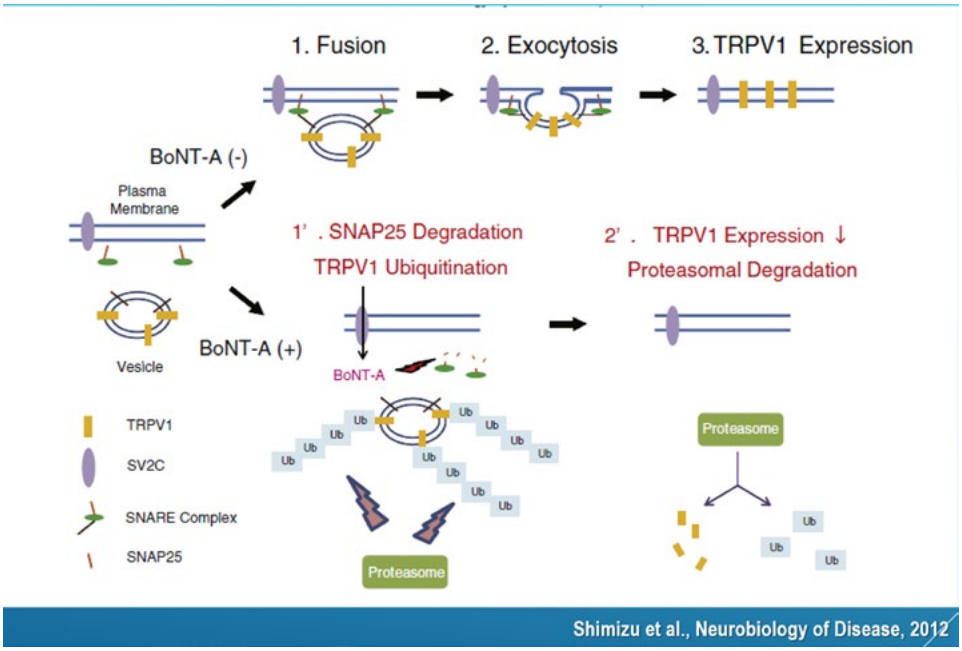

Figure 18: Schematic model of the mechanism by which BoNT-A reduces TRPV1 expression. From Shimizu et al., Neurobiol Dis. 2012 Dec;48(3):367-78

Human bladder sympathetic fibers express SV2 and SNAP-25 [Coelho et al, 2010]. This observation agrees with a decrease in noradrenaline release from the bladder tissue in rats after BoNT/A application [Smith CP et al., 2003].

In the human bladder urothelium SV2 and SNAP-25 expression could not be demonstrated by immunohistochemistry [Coelho et al., 2010]. Immunoblot analysis showed SNAP-25 but not SV2 expression in isolated human urothelial cells. [Hanna-Mitchell et al., 2013]. Another SNARE protein, SNAP 23 was identified in the human urothelial cells by the two methods [Hanna-Mitchell et al.,2013, Cruz, 2014]. BonT/A has been shown to inhibit ATP release from the urothelium in animal models of spinal cord injury [Khera et al.,2004; Vemulakonda et al, 2005, Smith et al., 2008]. BoNT/A does not alter the expression of urothelial sensory protein expression in SCI patients despite inducing a relevant clinical improvement [Chen et al, 2019].

Cleaved SNAP-25 appears rapidly after BoNT/A injection in the guinea-pig bladder, where a robust expression of the inactive protein could be detected already at 12 hours and a maximum intensity was observed at 24 hours. Almost all parasympathetic fibers, both preganglionic and postganglionic, expressed the cleaved SNAP-25 while only half of the sensory and sympathetic fibers expressed the cleaved protein at the same time point. In guinea pigs cleaved SNAP-25 expression was not observed in urothelial cells. [Coelho et al., 2012a; b].

Although all these works and many years of clinical use in multiple clinical conditions suggest a peripheral action of BoNT/A when injected in the bladder [Cruz, 2014]

some studies have proposed that BoNT/A may not be confined to nerve terminals at the injection place. Rather, it was suggested that BoNT/A activity can spread to central neurons by retrograde transport along the first-order neurons and then transferred to second order neurons contacting with the former (transcytosis). However, a study using a highly selective antibody for the cleaved protein (SNAP25-197) combined with markers for Central Nervous System neurons or glial cells contacting the first order neuron excluded that possibility [Cai BB et al, Neuroscience 2017]

Myofibroblasts form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that myofibroblasts act as modulators of bladder activity [Wiseman et al., Apostolidis et al., 2006]. Nevertheless, BoNT/A does not change the expression of connexin 43, [Roosen et al, 2009] questioning an effect of the toxin through the myofibroblasts.

A decrease of the urinary and tissue levels of Nerve Growth Factor (NGF) and Brain-derived Neurotrophic Factor (BDNF) were found in some studies [Giannantoni et al.,2006; Liu et al., 2009, Pinto et al., 2010, Philippova et al, 2020] and not in others [Richter et al, 2017] As neurotrophins have paramount roles for growth, maintenance and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism for BonT/A action in the bladder sensory function.

BonT/A has a long-lasting effect due to the persistence of the enzymatic capacity of the light chain to cleave SNAP-25 given by two leucines amino-acids near its C terminus [Wang et al., 2011]. In the bladder, the duration of the effect surpasses that observed in skeletal muscle. In NDO patients cleaved SNAP-25 was detected up to 11 months after BoNT/A injection [Schulte-Baukloh et al., 2007]. The mechanism for such a long persistence remains unclear. The combined impairment of pre and post- ganglionic parasympathetic neurons, urothelial cells and sensory fibers may however contribute to it.

There is no evidence that repeated injections of BoNT/A into the detrusor muscle cause inflammatory infiltrates, fibrotic activity or apoptosis within the bladder wall [Compérat et al., 2006, Apostolidis et al., 2008, Kessler et al. 2010]. Rather the reverse, one study

demonstrated that NDO patients treated with BonT/A had less fibrosis than non-treated patients [Compérat et al., 2006]. An eosinophilic infiltrate found in bladder biopsies of patients after multiple treatments did not have a clear explanation [Apostolidis et al., 2008].

8.1.2. BoNT/A injection protocols in the bladder.

For bladder injection in NDO and OAB patients, the licenced method of administration is derived from the procedures and doses described in the pivotal studies and is restricted to OnabotA. [Cruz et al, 2011; Ginsberg, 2012, Chapple et al., 2013; Nitti et al., 2013]. AbobotA and IncobotA did not receive yet a specific licence which means that their use is still off-label. The minimum interval for re-injection should be 12 weeks [Cruz et al, 2011; Ginsberg, 2012, Chapple et al., 2013; Nitti et al., 2013].

For NDO patients OnabotA 200 U diluted in 30 ml of normal saline should be distributed by 30 injections points above the trigone above the trigone (1ml saline containing 6.66 U/ml) [Cruz et al., 2011; Ginsberg, 2012]. Concerning OAB, a dose of OnabotA 100 U should be distributed by 20 intradetrusor injections of 0.5 ml each, also above the trigone [Dmochowski et al., 2010c, Chapple et al., 2013; Nitti et al., 2013]. During reconstitution the vials should be stirred but not shaken, as strong movements may break the BoNT/A molecule at the disulphide bond. The injection technique follows therefore that described in the historical descriptions of OnabotA in NDO patients [Schurch et al., 2000 a, b]. Rigid or flexible cystoscopes [Harper et al., 2003], variable brands of flexible 6 Fr injection needle of adequate length and a local anaesthetic agent (4% lidocaine whether or nor alkalinized) [Harper et al., 2003, Pereira-Silva et al, 2020] are used for injections. Colouring the fluid with methylene blue does not increase injection precision and clinical outcomes [Szczypior et al, 2019]

In NDO patients, despite the evidence of the phase 3 trials, Onabot 300 U remained in use, in particular when 200 U failed to produce the desirable effect [see Mangera et al., 2011]. Although the use of high doses might be tried off-label in selected cases one must realize that recent retrospective analysis of NDO cohorts did not find any difference in episodes of bladder evacuation or incontinence episodes in NDO patients that reduced OnabotA dose from 300 U to 200 U [Krebs et al, World J Urol, 2021]. An exception might be SCI or Myelomeningocele patients with low compliant bladders, a low percentage of whom were reported to have symptomatic improvement from a rescue treatment with Onabot 300 U [O´Connor et al, 2020].

AbobotA administration used in several institutions was applied in the bladder wall by technique similar to that licenced for OnabotA. Doses ranging between 500-1000 U of abobotA were injected in 20 above the trigone. The volume of saline at each injection site is commonly 1 ml but volumes so low as 0.25 ml per site were also used [del Popolo et al., 2008; Grise et al., 2010]. Denys et al. [2017a] compared the administration of AbobtA 750 U in 15 points (n=23) and 30 points(n=24) in NDO patients. The reduction on incontinence episodes and improvement of urodynamic parameters were similar for both methods. Two large phase III RCT used 30 injection of 0.5 ml into the detrusor muscle above the trigone to distribute abobotA 600 U, 800 U or saline [Kennelly et al, 2022].

IncobotA detrusor injection was reported in 17 NDO males in doses of 200 and 300 U (10 U/ml). The 20 or 30 injections were delivered throughout the whole bladder, including the trigone. The clinical efficacy was promising and complications were rare, justifying a larger clinical trial [Asafu.Adjei et al, 2020].

The potential advantages of injections in the trigone, the reduction in the number of injection points and, most important, the investigation of methods of administration that might allow the application and passage of BoNT/A through the urothelium have been a matter of study.

The rationale for injecting the trigone is higher density of sensory fibers in this area [Coelho et al, 2017] which makes this injection site particularly relevant for OAB and IC/BPS patients who have an important sensory component in their complains. The suggested risk of ureteral reflux after injecting bladder trigone was never demonstrated, whether OnabotA, abobotA or IncobotA was used [Karsenty et al., 2007; Citeri et al., 2008; Mascarenhas et al., 2008; Pinto et al, 2010, Asafu.Adjei et al, 2020]. A small trial randomised 22 IDO patients to receive abobotA 500 U administration in 20 injections (1ml each) sparing the trigone against 15 off the trigone plus 5 injections in the trigone [Manecksha et al., 2012]. The change from baseline of the OABSS score was greater in the trigone injected group while the mean postvoid residual volumes and clean intermittent self-catheterisation rates were similar between the two groups. One study compared 10 trigonal injections versus 40 detrusor or suburothelial injections of 100 U of OnabotA in IDO patients [Kuo, 2007a]. The 40 detrusor injections brought a more robust and lasting symptomatic improvement. The trigone-only injection protocol was the less effective and durable of the three, although the risk of urinary retention was non-existent [Kuo, 2007a].The suburothelial protocol brought intermediate results, worse than the detrusor but better than the trigone only technique [Kuo, 2007a]. In patients with BPS/IC, onabotA 100 U was injected in 10 sites in the trigone of patients with and without Hunner's lesions. This protocol was not associated with urinary retention or clinically relevant increase of PVR [Pinto, 2010, 2013]. Small RCT comparing OnabotA100 U vs placebo (saline) trigonal injections in BPS/IC patients favoured the toxin group [Pinto et al, 2018]. One study investigated the effect of detrusor plus trigonal injections of OnabotA in SCI patients. A total of 120 patients were randomised to receive 240+60 U in the detrusor plus trigone or 300 U only above the trigone. Incontinence episodes, volumes per void and detrusor leak point pressure improved in both groups although with a small but significant advantage in the group that received the toxin in the two locations [Chen et al, 2020]

The consequences of reducing the number of injection sites while increasing the dose in each injected site has been investigated under the premise that less sites facilitate the administration and may reduce UTIs. One small study in NDO patients concluded that 10 injection sites was quicker and less painful than 30 injections points to deliver OnabotA 300 U and that efficacy of the two procedures was equivalent at 24 weeks [Karsenty et al. 2005]. Interestingly, 30 injection points (30 ml of fluid in total) or 10 injection points (10 ml of fluid in total) caused a similar distribution of the fluid, as determined by MRI, covering 1/3 to 1/4 of the detrusor, respectively [Mehnert et al, 2009].

Two studies investigated further reduction in the number of injection sites in a mixed . IDO and NDO population under treatment with OnabotA ranging between 100 untill 300 U. Injection of the toxin in 1 or 3 injection sites in the posterior bladder wall used a reconstitution volume of 1ml for each 20 U. Avallone et al, [2017]. The other study divided the chosen dose by 3-4 injections at the equatorial line of the bladder of 2 ml each [Martinez-Cuenca et al, 2020]. Administration was easy and the clinical effect was good with a duration exceeding 30 weeks in both studies. However, UTIs occurred in 11.1% in the first and in 24% of the patients in the second study.

Another variable in the injection protocol is the volume of the saline used to reconstitute the toxin. Most studies used 1.0 [Cruz et al., 2011; Ginsberg et al., 2012] or 0.5 mL [Grosse et al., 2005; Schulte-Baukloh et al., 2003, Chapple et al, 2013, Nitti et al, 2013] but volumes of 0.2 mL [Kuo et al., 2004], 0.25 ml [Grise et al., 2010] or even 0.1 mL per injection site [Rapp et al, 2004]. Nevertheless, an experimental study demonstrated the amount of cleaved SNAP-25 induced by a fixed amount of OnabotA was directly related with the volume of the injection [Coelho et al., 2012a]. Thus, more controlled studies designed to compare different number and locals of injection and the volume of each injection are necessary.

BoNT/A does not cross the rat urothelium if instilled in the bladder [Coelho et al., 2012a], obliging caregivers to use bladder wall injections. Therefore, transporters or facilitators for the passage of the toxin are necessary if the injections are to be avoided. For the interested reader we recommend a thorough review of potential methodologies by Tyagi et al, [2017].

Onabot/A instillation in the bladder encapsulated in liposomes was shown to overcome the urothelial barrier in rats and cleave SNAP-25 in nerve terminals [Chuang et al., 2009]. Recently the lipossome encapsulation technology to deliver OnabotA was tested in humans. A small group of 24 patients were randomized to intravesical instillation of Lipotoxin containing 80 mg liposomes and 200 U BoNT-A or normal saline. At 1 mo after treatment, mild improvements in urinary frequency and in urgency episodes were reported in the lipotoxin group. Although no adverse events were reported, the duration of the effect was short lasting [Kuo et al., 2014]. In a RCT with IC patients, liposomal formulated OnabotA 200 U did not show any superiority over saline administration [Chuang and Kuo, J Urol, 2017].

Another form of administration investigated used hydrogel to promote a slow-release of the toxin on the urothelium. A TC-3. OnabotA mixture was assessed in BPS/IC patients. The mixture was safe, but efficacy was short lasting [Rappaport et al, 2018]

Electromotive administration (EMDA) may also help to carry the large botulinum toxin molecule across the urothelium, In 15 children with NDO due to myelomeningocele, a 10F indwelling catheter containing a silver spiral electrode was placed in the bladder, after providing a local transurethral anaesthesia with 2% lidocaine. The bladder was filled with saline and 10 U/kg of abobotA was added. A maximal current of 10 mA (100 mA increment/s) for 15 minutes was applied using abdominal pads [Kajbafzadeh et al., 2011, see also the video demonstration by Sharifi-Rad et al, 2019]. Skin erythema and burning sensation are the only side effects reported with EMDA of the toxin.

Low energy shock waves were investigated in 15 OAB patients to administer OnabotA 100 U previously instilled in the bladder in a volume of saline equivalent to half a bladder capacity. O total of 3000 shocks were delivered during 10 minutes in the supra-pubic area. An improvement in the OAB symptom Score was maintained for 2 months [Nageib et al, 2019].

In the large RCT with NDO antibiotic prophylaxis was used [Cruz et al., 2011; Ginsberg et al., 2012]. However, as many of injected SCI patients relied on some type of bladder catheterisation and presented chronic bacteriuria, the relevance of antibiotic prophylaxis was unclear. In 154 SCI patients undergoing a total of 273 treatments with onabotA bacteriuria was found in 73% (200/273) Those without clinical signs of UTI underwent injections without antibiotic prophylaxis. Following treatment, symptomatic UTI occurred in 7% (5/73) of cases with sterile urine culture and in 5% (9/200) with bacteriuria. These results suggest that routine antibiotic prophylaxis is not required prior to botulinum toxin injection in asymptomatic SCI patients [Leitner et al., 2016]. In patients non-catheterizing at treatment, however, the high risk of UTI recommends that antibiotic prophylaxis should be maintained together with an exclusion of active UTI at the moment of injection. UTI screening after each BoNT/A bladder treatment remains justifiable taking in consideration the high incidence of UTIs in in non-self-catheterizing NDO patients (Mustiple sclerosis, Parkinson´s disease).

For OAB, in large RCT (Tincello et al, 2012, Chapple et al, 2013, Nitti et al, 2013) antibiotic prophylaxis was not obligatory. In a retrospective study of 212 patients, mostly non-neurogenic, the incidence of UTIs after 335 injection cycles do not support the practice of obtaining a preprocedure urine dip in asymptomatic patients [Derisavifard et al, 2020]. However, in real life many centers maintain the use of antibiotic prophylaxis [Hamid et al, 2021]. A retrospective study in more than 100 women concluded that starting antibiotics 1 day before the injection and prolonging for 4 days decreased incidence of UTIs to 22% [Bickhaus et al, 2020].

8.1.2.1. Effect of Bont/A in NDO adult patients.

8.1.2.1.1. BONT/A in SCI and MS

After a small exploratory RCT [Schurch et al., 2005], two large phase 3 studies, as part of the Dignity program investigated the efficacy and safety of Onabot A, 200 U and 300 U against placebo in about 700 patients with NDO. Etiology included spinal cord injury below T1 or multiple sclerosis with an Expanded Disability Status Scale (EDSS) ≤ 6.5 [Cruz et al., 2011; Ginsberg et al., 2012]. Primary outcome measure was the change from baseline in week episodes of urinary incontinence at week 6 after treatment. Secondary outcome measures included the change from baseline in maximum cystometric capacity, maximum detrusor pressure during first involuntary detrusor contraction and quality of life using the I-QOL total score. Both studies yielded similar findings and indicated that 200 and 300 U provided the same effect and had the same duration of action in MS and SCI patients. Further details of the two studies are shown below and in **Fig 19.** In the study by Cruz et al, [2011] the reduction in UI during week 6 was -21.8 in onabotA 200U, -19.4 with 300U and -13.2 with placebo, with 38.0%, 39.6% and 7.6% of patients fully continent, respectively. The Ginsberg study [2012] reported -21, -23 and -9 incontinence episodes per week after 200 and 300 or placebo, respectively. Furthermore, 36% and 41% of patients in the 200 and 300 U groups, respectively, achieved dry status, contrasting with 10% in the placebo arm. Patients could request a retreatment 12 weeks after initial treatment. Median time for saline treated patients was about 90 days days and 250 to 300 days for those treated with 200 or 300 OnabotA, without differences between the two doses. No differences were found between patients with SCI or MS in terms of clinical response to OnabotA. The two doses tested improved similarly detrusor pressure and maximal cystometric capacity. The proportion of patients without IDC was around 60% after OnabotA 200 and 300 groups but only 17.4% after placebo [Cruz et al., 2011; Ginsberg et al., 2012]. Both MS and SCI patients had a significant improvement in quality of life after OnabotA treatment [see also Chancellor et al., 2013]. The improvement of I-QOL total score in MS patients was similar whether patients required or not clean intermittent catheterization (CIC) after toxin administration. Maximal detrusor pressure also decreased significantly [Ginsberg et al., 2012]

When pooled data were analysed by etiology, both MS and SCI patients treated with 200 and 300 U had a greater decrease in urinary

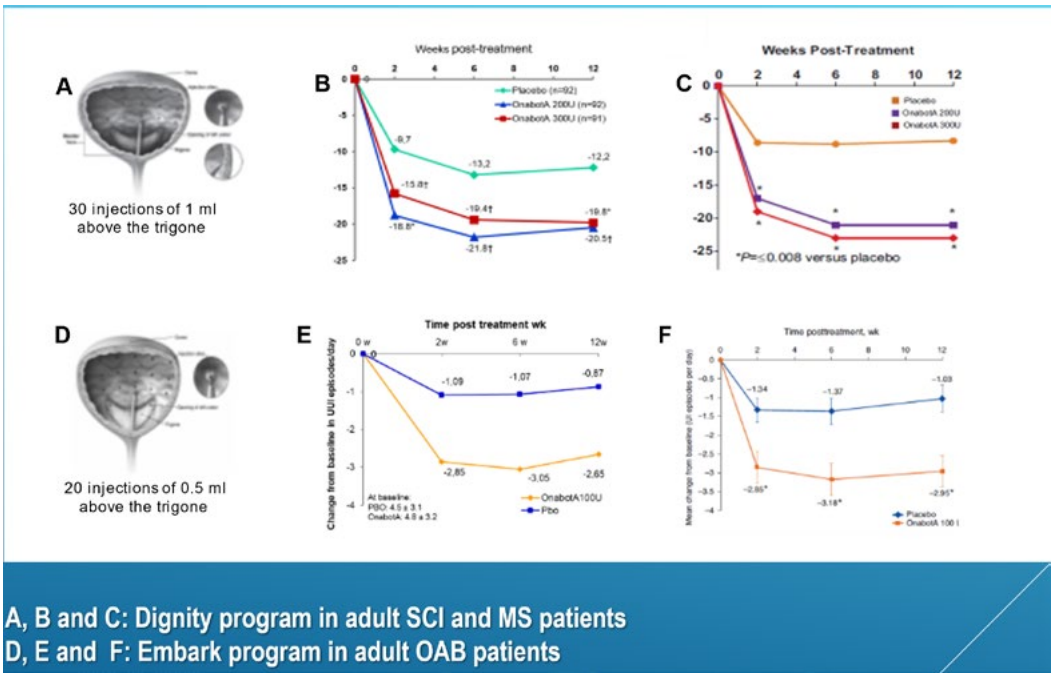

Figure 19: Distribution and effects of OnabotA injections in the detrusor above the trigone for NDO and OAB. From Cruz et al., Eur Urol. 2011 Oct;60(4):742-50, Ginsberg et al., J Urol. 2012 Jun;187(6):2131-9, Chapple et al., Eur Urol 2013, Nitti et al., Urol 2013 Jun;189(6):2186-93

incontinence episodes and more full dryness after treatment than those treated with placebo [Ginsberg et a.l, 2013]. The change in the number of voluntary voids per week was examined only in MS patients, the majority of whom did not use intermittent self-catheterization at study entrance. Following onabotA 200 U treatment, a decrease from baseline of 2 micturitions per day at week 6 and around 3 micturitions per day at week 12 was detected [Ginsberg et al., 2013].

The improvement in incontinence episodes, the proportion of patients fully dry, the urodynamic improvement and median time for re-treatment were similar in anti-cholinergic user and non-user patients [Ginsberg et al., 2013], supporting previous suggestions that SCI and MS patients might stop anti-muscarinic medication after BoNT/A injection [Reitz et al. 2004a, Grosse et al. 2005].

The symptomatic improvement brought by BoNT/A injection in the bladder does not coincide with the moment of injection. In a small open-label prospective study some improvement in urgency, nocturia and frequency could already be demonstrated at 2 days [Kalsi et al., 2008]. In large RCT with SCI and MS patients treated with OnabotA, 200 or 300U, significant decrease in the number of incontinence episodes over placebo were first detected at week 2 after injection [Cruz et al., 2011, Ginsberg et al, 2012].

Doses of OnabotA below 200 U were tested in patients with SCI below T1. Patients (n= 73) with NDO and urinary incontinence episodes received 30 intradetrusor injections above the trigone of onabotA 50 U (n = 19), 100 U (n = 21), 200 U (n = 17) or placebo (n = 16). A linear dose response for incontinence episodes/week was identified with a maximal effect detected with 200 U and no effect observed in patients treated with 50U [Apostolidis et al., 2013]. In real life practice the reduction of OnabotA dose from 300 U to 200U did not decrease clinical and urodynamic efficacy in SCI patients [Krebs et al, 2020]

Antibody formation against OnabotA were not detected during the first treatment cycle of randomised clinical trials [Cruz et al, 2011; Ginsberg et al., 2012]. However, in a large cohort of 414 patients with SCI/disease, 14 tested positive and highly positive [Tiburtius et al, 2020] and seroconversion was associated with a shorter duration of toxin efficacy (< 7 months).

A consequence of BONT/A treatment in NDO patients is the decrease in the incidence of severe urinary tract infections. In 30 SCI patients Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the 6 months before OnabotA 300U, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first 6 month after treatment. In 17 SCI patients that received OnabotA injections for a period of 6 years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a retrospective review of 214 NDO patients followed in 7 German centers, the rate of urinary tract infections in 12 months preceding and in the 12 months following OnabotA was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesico-ureteral reflux [Wefer et al., 2009].

Multiple Sclerosis patients represent a particular subgroup of patients in whom a careful analysis of the efficacy and safety of BoNT/A requires additional attention. First, OnabotA does not increase the risk of MS exacerbation. The annualized event rate in the phase 3 trials was 0.36, therefore in the lower range of the annualized rate known for the general MS population, that varies between 0.2 and 1.2 [Silva et al., 2015]. Second, if voluntary voiding is present before treatment the risk of de novo CIC might represent a drawback. In cohort studies that used OnabotA 300 U, while this dose was effective in improving or curing urinary incontinence, most patients had to initiate CIC [Kalsi et al., 2007; Khan et al., 2011]. The large phase 3 studies [Cruz et al., 2011; Ginsberg, 2012] showed

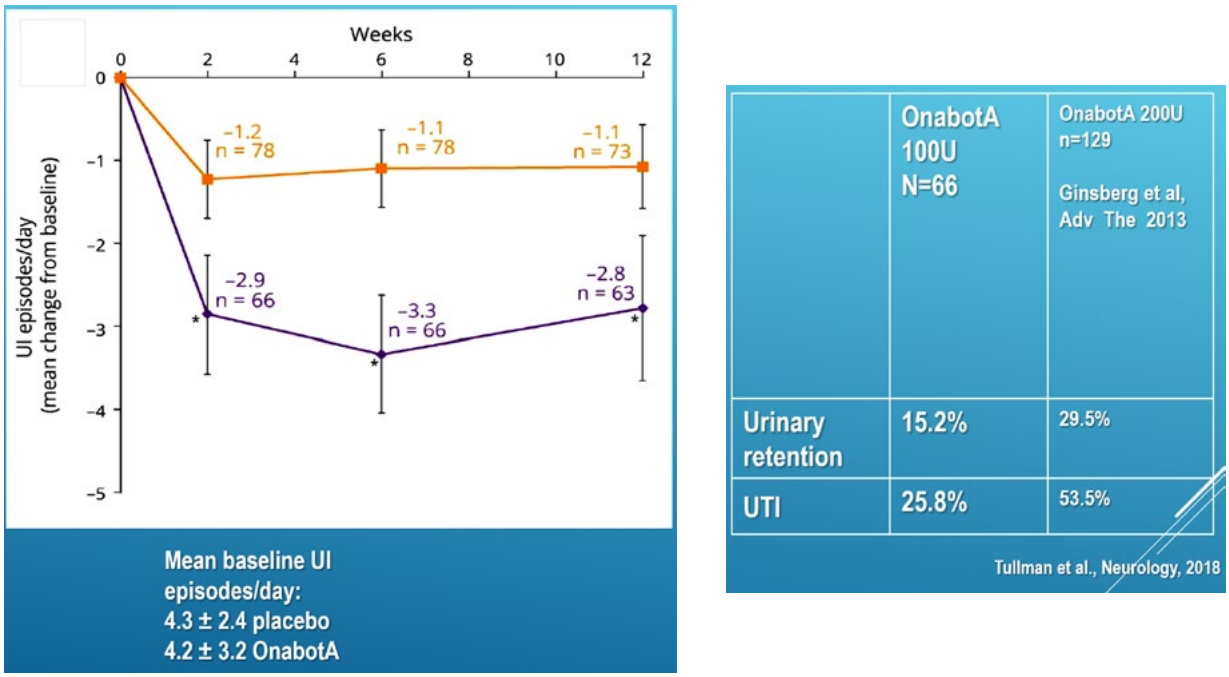

Figure 20: Onabotulinum toxin A 100 U in MS patients with spontaneous voiding is associated with a significant reduction in daily UI and less AE (AUR, UTI). From Tullman et al., Neurology. 2018 Aug 14;91(7):e657-e665

that 200 and 300 had the same efficacy in terms of continence and duration of effect. However, after 200 U about 1/3 of the MS patients started de novo CIC and after 300 U that number exceeded 40%.

Non-randomised studies suggested that OnabotA 100 U might still provide good efficacy while reducing the risk of CIC in non-catheterising MS patients [Mehnert et al., 2010]. The efficacy and safety of this strategy was confirmed by a placebo controlled randomised trial [Tullman et al, 2018, see **Fig 20**]. Injections of 1ml each were carried out in 30 places above the trigone containing onabotA (n=66) or saline (n=78). OnabotA 100U significantly improved UI episodes/day compared with placebo (-3.3 vs -1.1; P<.001) and improved all the key urodynamic parameters like maximal cystometric capacity and maximal detrusor pressure. Improvements in I-QOL total score with onabotA were 4 times higher than placebo. Median duration of effect was 11.9 for OnabotA and 2.9 months for placebo (P<.001). The risk of UTI (25.8%) and de novo CIC (15.2%) after 100 U OnabotA was approximately, half of that observed with 200 U of toxin injections [Tullman et al, 2018].

Although not officially approved for NDO, abobotA has been the object of investigation in a few small comparative clinical trials and from two large phase III trials.

The pooled results from the first treatment cycle of the first two large phase III randomized, double-blind studies are now available [Kennely et al, 2022]. The trials enrolled almost 500 SCI and MS patients with NDO and incontinence regularly performing CIC and refractory to oral medication. Treatment consisted of 30 injection of 0.5 ml into the detrusor muscle above the trigone of abobotA, in a total dose of 600 U or 800 U. One group received only saline. Injections were performed under prophylactic antibiotic. At week 2, 6 and 12 after injections mean incontinence episodes/week were significantly and similarly reduced in both abobotA groups. The reductions at week 6 were -22.7, -23.6 and -12.7 after 600 U, 800 U and saline respectively. Approximately one third of patients in both abobotA groups reported no incontinence episodes compared with only 3% after saline. A significant clinically meaningful improvements in I-QoL increase of bladder capacity and decrease of detrusor pressure occurred with both abobotA doses versus saline [Kennelly et al, 2022].

Several smaller studies had been conducted before. A total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of abobotA 500 U or placebo [Ehren et al., 2007]. Patients in the abobotA arm had a significantly higher cystometric capacity at 6 and 12 weeks, lower maximum detrusor pressure and episodes of urinary incontinence and less consumption of antimuscarinic drugs. Efficacy and safety of abobotA were, additionally, investigated in NDO patients that had abandoned anticholinergic therapy. Two doses, 500 U (n = 39) or 750 U (n = 38) were compared [Grise et al, 2010]. Complete continence at day 30 was observed in 22 patients (56.4%) and 28 patients (73.7%) receiving 500U or 750U. The median delay in the reappearance of leakages was 168 days. Although there was a trend towards a greater improvement with 750 U, no statistically significant differences in terms of clinical and urodynamic variables between the treatment groups were found. Excellent tolerability was reported for both doses.

A single-center retrospective study investigated 750 U intradetrusor injection of abobotA in 81 consecutive patients performing CIC. Six weeks after the first injection, the success rate, defined as a combination of no incontinence episode, a number of catheterizations <8 reported in a 3-day bladder diary and the lack of detrusor overactivity, was reported in 64.2 %. Mean reinjection number was 3.9 and mean interval between reinjection was 8.8 ± 3 months. The clinical efficacy rate after each reinjection (up to fourteen) was at least 86.7 % [Peyronnet et al., 2016].

A phase IIa, enrolled 47 patients with NDO due to spinal cord injury (SCI) or multiple sclerosis (MS). Patients were treated with 15 intra-detrusor injections of abobotA 750 U or the equivalent placebo (n = 16 and 7) or 30 injections of AbobotA 750 U or the equivalent placebo (n = 17 and 7). Change from baseline in mean number of daily incontinence episode frequency at 12 weeks, for abobotA and placebo, respectively, were -3.2 and -1.7 in the 15 injections group and -3.2 and -2.6 30 injections group. Statistically significant improvements in maximum cystometric capacity, maximum detrusor pressure and volume at first contraction were reported in the toxin groups compared to placebo [Denys et al., 2017a].

Incobotulinum toxin A (IncobotA) for NDO was never object of placebo-controlled studies. A small cohort of 17 SCI patients. There were improvements in average daily pads (4.5 to 3.3), daily urinary frequency (9.4 to 4.6), daily incontinent episodes (2.5 to 0.4), CIC volumes (400 to 550 mL) and hours in between CIC (3.6 to 5.2). There were no documented adverse events. Nine of 17 patients (53%) were dry at their first postoperative visit [Asafu-Adjei et al, 2020].

8.1.2.1.2. BONT/A in other neurological conditions

In Parkinson´s disease, a retrospective review of a small cohort of 24 patients treated with OnabotA 100 U (20 injections of 5U/0.5 ml throughout the bladder including the trigone) showed improvement of LUTS in 19 and a complete resolution in 7 cases. The average post-void residual (PVR) increased significantly after the first injection from 17.6 to 125.3 mL Higher pre-injection PVR and male sex decreased the probability of symptomatic improvement and increased the risk of incomplete bladder emptying. After 49 injections, first and subsequent, 5 patients used CIC [Vurture et al, 2018]. A systematic review of 4 small cohorts published before 2018 showed that OnabotA 100 U and 200 U caused robust improvement and LUTS, including a decrease in day and night-time frequency. Although a PVR increase was concluded, no cases of urinary retention were reported [Hajebrahimi et al, 2019]

Concerning adults with myelomeningocele (MMC) A total of 125 patients under onabotA or abobotA treatment (561 intradetrusor injections in variable doses in 14 centers) were retrospectively investigated. The resolution of urinary incontinence occurred in 73.5%. All urodynamic parameters improved significantly compared to baseline, including maximum detrusor pressure (-12 cm H2O), maximum cystometric capacity (86.6 ml) and compliance (8.9 ml/cm H2O). Three cases of muscular weakness were recorded. The success rate was significantly lower in patients with poor compliance while female gender and older age were predictors of success [Peyronnet et al, J Urol, 2018].

OnabotA was successful applied to treat NDO due to transverse myelitis, the criteria for toxin application being the lack of response to oral therapy [Knight et al, 2021]. BoNT/A may also improve storage symptoms and continence in patients who did not respond satisfactory to bladder augmentation. In a small number of patients the toxin was injected both in the detrusor and in the intestinal augment [Martinez et al, 2020].

8.1.2.2. Effect of BONT/A in OAB adult patients

8.1.2.2.1. Effect of BONT/A in predominant OAB female population

The enthusiasm of investigators rapidly produced a reasonable number of pilot studies investigating BoNT/A in patients with IDO refractory to antimuscarinics. Although proper dose-escalating studies capable of defining ideal doses were lacking, investigators opted for the administration of BoNT/A in doses smaller than those initially used in NDO. That is the reason why most pilot studies used either onabot 200 U or abobot 500 U [see also Mangera et al, 2011 and 2014 for historical review] and 4 RCT trials compared onabotA 200 U against placebo [Sahai et al., 2007; Brubaker et al., 2008; Flynn et al., 2009; Tincello et al., 2012]. A small open-label trial showed that urgency, nocturia and frequency improved as soon as 4 days after Onabot 200 U in OAB patients. [Kalsi et al., 2008].

A high incidence of voiding dysfunction associated with the use of onabotA 200U in OAB patients led to the use OnabotA 100 U in one large cohort of 100 patients [Schmid et al, J Urol 2006]. Treatment remained highly effective, and incontinence and urgency sensation disappeared in 86% and 82% of patients, respectively, during an average period of 6 months. Temporary urinary retention only occurred in 4% of the cases, with additional 15% reporting moderate voiding difficulties [Schmid et al, J Urol 2006].

Following the pilot studies two large well designed dose escalating placebo-controlled studies [Dmochowski et al. 2010, Denys et al. 2012] investigated the ideal dose of onabotA in OAB. Dmochowsky et al. [2010] enrolled 313 OAB patients experiencing 8 or more urinary urgency incontinence episodes per week and 8 or more micturitions daily at baseline. Patients were randomized to 50, 100, 150, 200 or 300 U intradetrusor OnabotA, or placebo. Durable efficacy was observed for all groups treated with 100 U dose or higher but in dose response curve doses greater than 150 U contributed minimally to the symptomatic improvement. As the use of CIC was also dose dependent, 100 U offered the best balance between efficacy and safety. Denys et al. [2012] randomised 99 OAB patients to receive a single injection of either placebo or onabotA 50 U, 100 U or 150 U. A >50% improvement versus baseline in urgency and urge urinary incontinence (UUI) in 65% and 56% of patients who respectively received 100 and 150 U. Complete continence was observed in 55% and 50% patients after 100 U and 150 U. The dose of 100 U seemed to offer the best balance between efficacy and increase of PVR.

A few additional studies contributed to defined 100 U as the ideal dose for refractory OAB treatment. Cohen et al. [2009] randomized 44 OAB-dry and wet patients to receive 100 U or 150 U. No significant differences in clinical, QOL improvement or urodynamic outcome measures were noted between the two doses. Altaweel et al. [2011] randomized 11 patients for onabotA 100U and 11 patients to onabotA 200U. No clinical or urodynamic differences were detected between the 2 groups at 3 months follow-up. Urinary retention occurred in 2 patients in the 200 U and in 1 patient in the 100 U arm.

Data from four large placebo-controlled studies and one large observational study are available. Concerning randomised clinical trials, Chapple et al, [2013] and Nitti et al, [2013] enrolled around 85 to 90% women, respectively. Yokyama et al, [2020] enrolled 75% women and Tincello et al, [2012] only women. In the real-life study by Hamid et al, [2021] 85% of the patients were women. So, the following data should be extrapolated to men with precaution.

In the two pivotal phase 3 studies patients were randomized to receive 20 injections of 0.5 mL each above the trigone, containing 5 U per injection with a total of 100 U or only saline [Chapple et al., 2013; Nitti et al., 2013]. These studies enrolled patients with idiopathic wet OAB with ≥3 urgency urinary incontinence (UUI) episodes over 3 days and ≥ 8 micturitions per day and a postvoid residual less than 100 mL who were inadequately managed by anticholinergics. The co–primary efficacy end points were change from baseline in the number of UI episodes and the proportion of patients with a positive

treatment response on the treatment benefit scale (TBS) at week 12. The changes in urinary incontinence are shown in **Fig. 19**.

The Chapple et al [2013] study randomized 277 patients to OnabotA and 271 for saline injection. At baseline the average number of daily UI episodes was above 5 per day. OnabotA significantly decreased UI episodes per day (-2.95 for OnabotA versus -1.03 for placebo). Significant reductions in frequency, urgency episodes per day and nocturia were also observed. Changes in TBS indicate that patients perceived a significant improvement in their condition (62.8% for OnabotA versus 26.8% for placebo; $p < 0.001$). Clinically meaningful improvements from baseline in all I-QOL and KHQ multi-item domains indicated positive impact on quality of life.

The Nitti et al. [2013] study randomised 280 for OnabotA and 277 for saline. In average patients experienced more than 5 episodes of UI per day. At week 12 there were greater decreases from baseline in the mean daily UI in the active group ((–2.65 for OnabotA and –0.87 for Sali, , $p < 0.001$). The percentage of fully dry patients at week 12, was 22.9% after onabotA and 6.5% with saline. The other key OAB symptoms, frequemcy, urgency and nocturia also improved after OnabotA. Of interest, all changes in OAB symptoms detected at week 12 were already present at week 2. A higher proportion of OnabotA treated patients reported a positive treatment response on the TBS vs those on placebo. Large, clinically significant improvements in all I-QOL and KHQ multi-item domain scores were noted after onabotA.

A pooled analysis of these two studies [Sievert et al., 2014] confirmed the effect on incontinence (-2.8 episodes episodes per day, 100% dry or with a 50% improvement in daily incontinence in 27.1% and 60.5%), a decrease in the number of episodes of urgency (-3.30 per day) and a decrease in urinary frequency (- 2.35 per day). The median time to request retreatment was 24 weeks after onabotA and 13 weeks after placebo. Furthermore, the pooled analysis showed that the number of previous anticholinergic drugs does not influence the outcome of OnabotA treatment. The number of prior anticholinergics also did not affect the improvement caused by OnabotA in urinary urgency incontinence episodes per day and in the number of micturitions per day. The rate of satisfaction was also independent from the number of previously used anticholinergic drugs. When analysing the efficacy of onabotA by the reasons why the anticholinergic treatment was stopped, insufficient efficacy or intolerable side effects, the symptomatic improvement and patient satisfaction after OnabotA was similar in the two subgroups and comparable with the results achieved by the overall pooled population [Sievert et al., 2014]. Another post hoc analysis [Drake et al. [2015] concluded that OnabotA is effective regardless of the grade of urinary incontinence at baseline. Patients with < 2, between 2 and 5 or > 5 UUI episodes per day had, respectively, decreases in incontinence episodes of 2.7, 3.0 and 3.8, and a 50% reduction in the urinary incontinence episodes in 56.6%, 66.5% and 56.7% of the patients.

Yokoyama et al [2020] carried out a phase 3, placebo-controlled trial in Japanese patients who were inadequately managed with overactive bladder medications (anticholinergics and/or β3 -adrenergic receptor agonists). Eligible patients were randomized 1:1 to receive a single dose of either OnabotA or placebo into the 20 detrusor sites above the trigone (n = 124 each). OnabotA was reconstituted in 10 ml. In the OnabotA group, there was a significantly greater decrease from baseline in the mean number of daily urinary incontinence episodes compared with the placebo group (2.16), and significantly greater improvement for all secondary end-points that included volume voided per micturition, other symptomatic measures (urinary urgency incontinence, micturition, urgency and nocturia) and patient-reported outcomes. In addition, the percentage of patients fully dry was 19% after OnabotA and 3% after placebo.

A fourth large placebo controlled RCT was conducted in 8 centers in UK (the RELAX study) and randomised a total of 240 women with refractory DO to receive OnabotA 200 U or placebo distributed by 20 bladder wall sites above the trigone (10 U/1ml) [Tincello et al., 2012]. Primary outcome was voiding frequency per 24 h at 6 months. Secondary outcomes included urgency and incontinence episodes and quality-of-life data. A total of 122 women received onabotA and 118 received placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in OnabotA vs 6.0 in the placebo group. Continence was more common after OnabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group.

Hamid et al [2021] carried the first large real-world study in 504 OAB patients receiving OnabotA 100U in everyday clinical practice conditions. Rigid cystoscopy and anesthesia or analgesia with intravesical local anaesthetic liquid/gel was generally preferred. Reductions in UI episodes/day from baseline were observed as early as week 1 (-2.4 ± 3.4) and were maintained at later time points (-3.0 ± 3.9 at week 12). A proportion of 25.5% of patients became completely continent within 1 week and 41.8% at week 12. Pad/liner and diaper usage decreased from 67.7/13.9 in the month prior to baseline to 29.9/4.4 and 23.6/4.3 in the month prior to week 12 and week 52, respectively. The number of patients maintaining oral OAB medication decreased to 5.8%, 2,4% and 1,8% by week 1, 12 and 20, respectively. The median time to patient request for retreatment was approximately 7 months.

Interestingly, a sub-analysis of the dose finding study for onabotA [Dmochowsky et al. [2010] concluded that successful OAB treatment is not related with the existence of detrusor overactivity [Rovner et al., 2011]. Likewise, in a cohort of 5 male and 27 female patients with OAB and without DO, improvement in frequency and urinary incontinence was observed after treatment with onabotA, 100 and 150 U [Kanagarajah et al., 2012]. Thus, in clinical practice there is little reasoning to perform routinely invasive urodynamic tests before recommending OnabotA administration to subjects with OAB symptoms refractory to oral medication.

Studies with AbobotA in OAB are scarce. A prospective study randomised 21 female OAB patients to receive 300 or 500 U of AbobotA injected into 30 sites above the trigone [Sa-Dantas-Bezerra et al, 2018]. From baseline to 12 weeks MCC increased from 185.0 to 270.9 mL (300 U) and from 240.8 to 311.7 mL (500 U). At 12 weeks, 91% of patients were dry in both groups. At 24 weeks, episodes of incontinence had returned in 50% (300 U) and 0% (500 U). Patients were better or much better (PGI-I) in 70% (300 U) and 88.9% (500 U) at 12 w; and 50% (300 U) and 100% (500 U), at 24 w. Therefore, 500 U seems the ideal dose despite the fact that 1 woman required transient CIC.

Elderly OAB patients are a special group for BoNT/A administration. A posthoc analysis of the large phase III studies by Chapple et al., [2013] and Nitti et al., [2013] showed similar efficacy in terms of continence in the subjects below or above 65 years of age. Two studies investigated specifically the effect of the toxin in this OAB population. In one study [White et al., 2008] 21 patients (18 females and 3 males) with a mean age of 81.2 years (received onabotA 200 U in 20 bladder sites. One month after treatment 16 patients (76%)

reported more than 50% improvement in symptoms after 1 injection A significant decrease in the number of daily voids, from 11.4 ± 1.67 to 5.19 ± 0.83 and incontinence pads per day, from 4.0 ± 0.89 to 1.3 ± 0.60, occurred. Mean time to deterioration was 7.12 months. There were no treatment related complications. Liao et al. [2013] investigated the efficacy and safety of intravesical BoNT-A injections in 166 OAB frail elderly, non-frail elderly and younger patients. Frail elderly were defined as individuals >65 years who met three or more of the following criteria: unintentional weight loss, self-reported exhaustion, slow walking speed, weakness, and/or low physical activity. Incontinence improvements were similar among younger, non-frail elderly, and frail elderly patients. However, the risk of large post-treatment PVR urinary volume (>150 mL) was significantly higher in the frail elderly group. Urinary retention occurred in seven frail elderly (11.5%), four (6.3%) in non-frail elderly and one younger (2.4%) patient.

8.1.2.3. BONT/A in OAB male patients

Most trials evaluating OnabotA injections in OAB patients have included predominantly female patients. Therefore, two studies restricted to male subjects merit reference despite their retrospective design. Faure Walker [2019] used doses of 100-300 U of OnabotA in 65 men (mean age 57.1 ± 13 years), with a total of 133 treatments. Using the UDI-6 and IIQ-7 questionnaires, the degree of improvement in men was inferior to that found in women for the same baseline characteristics. Urinary tract infections (UTI) were reported after 29.0% of the treatments. Urinary retention requiring de novo clean intermittent catheterization (CIC) was observed after 42.6% of the treatments without differences between 100 U and 200 U. A low bladder contractility index could be the best predictor of CIC risk. The other study was a review 146 men (mean age 70.1±13.3 years) who were injected only with 100 U [Mateu Arrom et al, 2020]. A positive response to the treatment, assessed by the treatment benefit scale, was reported by 62.3% of men. The incidence of urinary retention, despite the higher age of the cohort, around 70 years, was only 13%. Around 2/3 of the patients had discontinued treatment by the end of followup at 1 year. A higher bladder outlet obstruction index (BOOI) was the only predictive factor for poor treatment response and risk of complications.

8.1.2.4. BoNT/A in NDO and OAB children.

8.1.2.4.1. BoNT/A in NDO children

BoNT/A has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006, Austin et al, 2021]. In this age group the dose of BONT/A should be calculated according to body weight. For onabotA doses ranging between 4 U/Kg [Corcos et al., 2002] and 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] have been used. The maximum suggested for abobotA is 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006; Akbar et al BJU Int 2007].

In the largest randomised clinical trial available so far, three OnabotA 50, 100, or 200 U doses not exceeding 6 U/kg were investigated [Austin et al, 2021]. This was a 48-week prospective, multicenter study which included 113 children (5–17 years) with NDO due to myelomeningocele, transverse myelitis or spinal cord injury inadequately managed with anticholinergics was carried out in children. Toxin was delivered via cystoscopy divided in 20 intradetrusor injections of 0.5 ml excluding the trigone, under general anesthesia/conscious sedation or instillation of local anaesthetic (for children >12 years. Injections were performed under prophylactic antibiotic. Primary endpoint was the change from baseline in daytime UI episodes (**see, Fig 21**). Similar improvements were observed in the 3 dose groups which amount -1.3 UI episodes per day at week 6 after treatment. As secondary endpoints, increases in urine volume at first morning CIC (50 U, 21.9 ml; 100 U, 34.9 ml; 200 U, 87.5 ml;) and decreases in maximum detrusor pressure (50 U, −12.9; 100 U, −20.1; 200 U, −27.3 cmH_2O) favored 200U. The proportion of patients experiencing involuntary detrusor contractions at week 6 was 50 U/61.8%; 100 U/44.7% and 200 U/46.4% also favored the highest dose. Time to request a new treatment raged between 24 and 30 weeks among the three groups. Although the improvement of UI was similar for the three doses the urodynamic changes seem to suggest that the highest dose, 200 U without exceeding 6U/kg should be preferred [Austin et al, 2021].

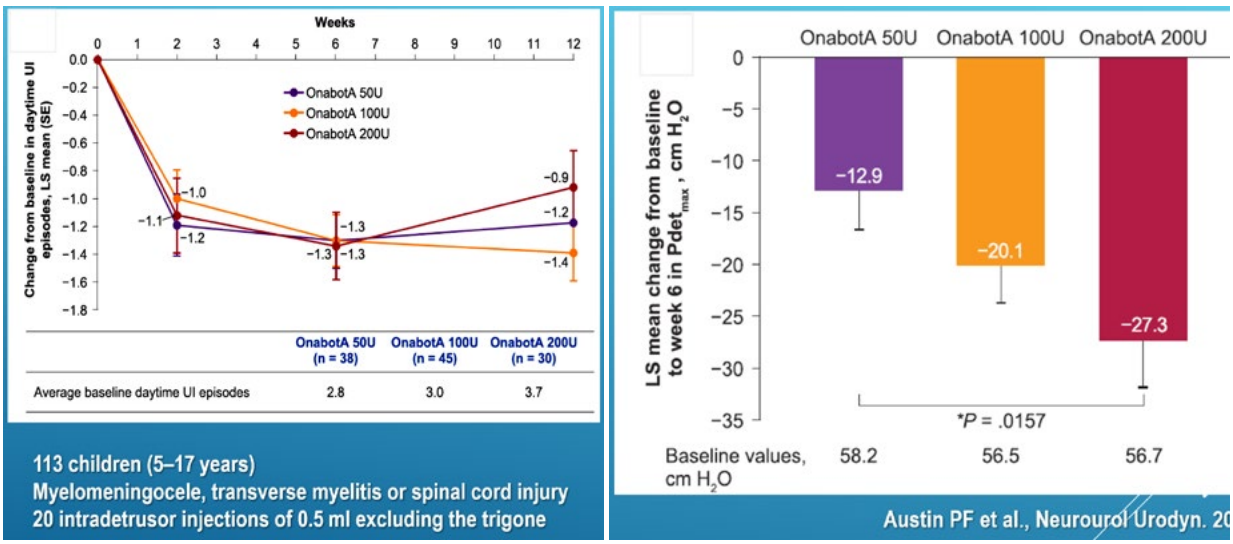

Figure 21: Onabotulinum toxin A 50, 100 and 200 U, (not exceeding 6U/kg), for the treatment of NDO in children. From Austin PF et al., Neurourol Urodyn. 2021 Jan;40(1):493-501

A systematic review made before this study [Mangera et al., 2014] had found a total of 13 studies reported on 368 children receiving BoNTA for NDO but none had a comparator arm. The only parameters reported with consistency between studies were the MCC and MDP, which decreased by between 42 to 59%.

Other studies reviewed in the previous edition of this book are now mentioned below briefly. In 19/26 children (73%) with a mean age of 6,9 years, became completely dry between clean intermittent catheterizations Interestingly vesicoureteral reflux, when present, disappeared or decreased in grade [Kajbafzadeh et al., 2006]. The success rate in terms of continence and cessation of anticholinergic medication may, however, be substantially inferior if irreversible bladder wall changes associated with longstanding detrusor overactivity are present [Altaweel et al., 2006].

As already mentioned, electromotive administration may facilitate BoNT/A administration in children [Kajbafzadeh et al, 2011]. In 15 children with myelomeningocele, electromotive administration of abobotA instilled in the bladder in a dose of 10 U/kg, proved very effective and safe. The mean volume to reflex voiding (99 ± 35 ml to 216 ± 35 ml) and maximal bladder capacity (121 ±39 ml to 262 ± 41 ml) increased substantially while maximal detrusor pressure decreased (75 ± 16 cm H2O to 39 ± 10 cm H2O). Urinary incontinence improved in 12 patients (80%) [Kajbafzadeh et al., 2011]. A small, randomised controlled trial compared AbobotA administration 10 U/Kg in 20 ml using EMDA or a classical injection protocol in 14 and 12 children with myelomeningocele [Ladi-Seyedian et al, 2020]. At 6 and 12 months the dry rate between intermittent catheterizations were 85.7% and 78.5%, respectively, higher than in the classical protocol group (66.6% and 50%).

8.1.2.4.2. BoNT/A in OAB children

To date, five case series that included a total of 135 OAB children have investigated the use of BoNT/A in children with OAB refractory to anticholinergics.

Three studies [Hoebeke et al., 2006; McDowell et al., 2011, Marte et al., 2010] with a total of 99 children of both genders received AbobotA 12 U/kg up to a maximum dose of 480 U studies [Hoebeke et al., 2006; McDowell et al., 2011] or OnabotA 12.5 U with a ceiling at 200U studies [Marte et al., 2010] in multiple bladder sites. A total disappearance of OAB symptoms was variable, between 38% [Hoebeke et al., 2006] and 66% [McDowell et al., 2011]. Time to re-injection varied from 6 months and periods exceeding 1 year.

Two more recent cohorts were identified. In one 39 patients between 5 and 16 years received OnabotA 100U, and 33 were analysed 9 months after treatment. The mean bladder capacity had a robust increase, daily voiding frequency decreased by almost 3 void per days and the mean incontinence episodes decreased from 2.72 ± 1.87 to 1.18 ± 1.13. Nocturia improved in one third of the 14 patients that had nocturia at baseline [Bayrak et al, 2017]. In another, a prospective open labelled uncontrolled study [Edwan et al, 2019], reported on the use of OnabotA 100U in 46 OAB children ageing 4-14 years. Cystometric bladder capacity increased from 194 to 244 ml. LUTS improvement was found, with robust mean decreases in daily frequency (-4.8), incontinence episodes per week (-7.9) and in nocturnal enuresis (-3.1).

Ingham et al [2019] investigated onabotA in 2 doses, 5 units/kg (with a ceiling at 150U), and 10 units/kg (with a ceiling at 300U) in 39 children with a mean age of 13.6 years. Injections were in the submucosa, 10 U per injection site above the trigone. Resolution of LUTS including incontinence after the 1st injection was observed in 11 cases and partial improvement in another 7, making 46% of the patients that got some benefice from the toxin. The mean duration of the effect was 7.6 months. At a median follow-up of 35.4 months 12 (31%) were asymptomatic and off all therapy. The dose of 5U/kg should be the one to start as the higher dose did not show a clear advantage in efficacy.

8.1.2.5. Effect of BoNT/A on quality of life

Bladder injections of BoNT/A in NDO and OAB patients increase quality of life and improve sexual function in women.

All placebo-controlled studies in NDO patients comparing 200 or 300 U [Schurch et al. 2007, Cruz et al., 2011, Ginsberg et al, 2012, Herschorn et al., 2011a,] showed strong increases in the Incontinence-QoL questionnaire score in SCI and MS patients treated with OnabotA. Interestingly, in patients non-catheterizing before treatment, I-QoL scores of those who maintained spontaneous voidings or had to initiate de novo intermittent catheterization were similar [Ginsberg et al., 2012]. Further subanalysis showed that the improvements were in the avoidance, limiting behaviour, psychosocial and social embarrassment domains of the I-QoL [Chancellor et al., 2013]. Responses to the OAB-PSTQ and to the Patient Global Assessment also demonstrated superior mean improvements from baseline in 200 U OnabotA than in placebo treated group [Chancellor et al., 2013].

The study that compared 50 U, 100 U and 200U in NDO children captured the Treatment Benefit Scale and concluded that at week 6 at least 75% of the children across the 3 groups were greatly improved or improved [Austin et al, 2021]

In a study that investigated OnabotA 100 U in non-catheterizing MS patients a strong improvement in I-QoL score, similar to those observed with 200 U, was reported [Tullman et al, 2018]. However, in MS patients voiding spontaneously but maintaining incontinence after a low toxin dose, the administration of a high dose (300U OnabotA) to induce retention combined with CIC might also improve quality of life if dryness between intermittent bladder emptying is achieved [Kalsi et al., 2007, Khan et al. 2011]

Concerning Abobot in NDO patients a single center, double blind, placebo-controlled study [Ehren et al. 2007] randomised 37 patients to abobotA 500 U or placebo. Patients in the AbobotA group showed greater improvement in quality-of-life parameters compared to the placebo group. Improvement in QoL were similar in a study that compared Abobot 500 U versus 750 U in a NDO population of where SCI predominate [Grise et al., 2010]. AbobotA administration of 750U in 15 or 30 points in the bladder of SCI or MS patients increased I-Qol score well above the minimum important difference, without differences between the two methods of administration [Denys et al, 2017a].

In OAB, dose-finding studies [Dmochowski et al. 2010, Denys et al., 2012] showed a sustained improvement in the King's Health Questionnaire score or in I-QoL in patients receiving OnabotA 100 U or higher doses. OnabotA 50U provided inconsistent improvements. In the large phase 3 trials [Chapple et al., 2013, Nitti et al. 2013] significant improvements in the I-QOL total score and in all the three domain scores were observed in the OnabotA 100U but not in the placebo arm. Improvements from baseline in all seven multi-item domains of the KHQ were also greater in the onabotA group. The OAB Japanese population treated with 100U OnabotA had a significant, robust improvement of role limitations and social limitations domains of the KHQ. In the treatment Benefit Scale more than 75% of the patients were greatly improved or improved along the first

12 weeks [Yokoyama et al, 2020]. The RELAX study with 200 U OnabotA [Tincello et al., 2012] showed significant improvement in ICIQ-SF and I-QoL scores. However, authors noticed that in none of the questionnaires the scores were restored to the normal value (0 for ICIQ; 100 for IQOL) [Tincello et al. 2012]. This placebo-controlled trial confirmed therefore the observations of a previous small non-controlled study [Sahai et al., 2009].

Two studies [Miotla et al, 2016, Balzarro et al, 2018] investigated the effect of OnabotA 100U bladder injection on sexual function of 68 OAB women. OAB treatments showed improvement of the sexual function captured by the Female Sexual Function Index (FSFI) questionnaire. In one study [Miotla et al, 2016] over 90% of women reported clinically relevant improvements in all six domains of the FSFI questionnaire.

In OAB children, OnabotA also improved quality of life. A significant change from baseline in the ICIQ-UI short form score was captured Edwan et al [2019]. The patients and their parent's perception of the treatment benefit on the treatment benefit scale also supported the improvement. In fact, 54% described their condition as greatly improved and 30% as improved.

8.1.2.6. Repeated BoNT/A injections

8.1.2.6.1. Repeated injections in NDO patients

Median time for NDO patients due to SCI or MS to request a retreatment was around 300 days after onabotA 200 or 300 U but only 92 days after placebo [Cruz et al., 2011]. Therefore, for patients who respond to BoNT/A a programme of reinjections is inevitable.

Long-term efficacy and safety of repeated onabotA injections was systematically investigated by extension studies of to large phase 3 trials [Cruz et al, 2011, Ginsberg et al, 2012]. Patients on placebo were initially ramdomized to onabotA 200 U or 300 U but further down in the study, following the licensing of 200 U, all patients were converted to this dose. Patients were treated based on their request and fulfillment of prespecified qualification criteria (≥12 weeks since previous treatment and at least 1 episode of incontinence in last 3 days). The final results of patients followed during a 4-year period (from an initial cohort of 392 cases) are available [Kennelly et al., 2017]. Percentage of responders remained high across the six treatments, between 70% and 80%. OnabotA 200U consistently decreased incontinence episodes/day at week 6 across six treatments, reductions ranging from -3.2 to -4.1. More than 80% of the patients achieved a ≥50% and 43 to 56% achieved full dryness. I-QoL total score regularly exceeded 2 times the minimum important difference. Overall, the median duration of each treatment was 9 months. Breaking down the duration, in 52% it was between 6 and 12 months, in 22% was than 6 months and in 26% exceeded 12 months. Further analysis of the patients who completed the 4 year study shows that some patients required 8 re-injections while others requested only 2. Patients who requested less treatment had a trend to have less baseline episodes of incontinence per day. Nonetheless, the daily episodes that were observed in week 6 after each treatment indicated a similar efficacy of OnabotA regardless of the number of injections requested. [Kennely et al, 2015]. This is an interesting point as it may suggest that patient preference for retreatment was not motivated by a different degree of toxin efficacy.

An additional post-hoc analysis of this cohort stratified patients by three responses: <50% (n = 33), 50-74% (n = 23), and 75-100% (n = 139), [Denys et al, 2017b]. The majority of the patients (83.1%) experienced a ≥50% UI reduction after the first treatment and the mean percent reduction in UI remained consistent in subsequent treatments in these groups. However, in those in the low initial response (<50%) one third achieved ≥50% UI reduction in all subsequent treatments. Therefore, as a practical message, a low UI reduction after first treatment does not necessarily predict low response after subsequent treatments.

Real-life studies assessed the persistence of NDO patients in a long-term treatment program with botulinum toxin injection. . A cohort of 199 patients with spinal cord lesions treated with abobotA 500 U to 1000 U was analyzed retrospectively, after 8 years of repeated injections. The intervals of between injections remained constant. Urodynamic improvements, patient satisfaction with treatment and number of pads or other protective devices required were also constant after treatments [Del Popolo et al., 2008]. Intervals exceeded 12 months in 19.5% of the patients, ranged between 10-12 months in 40.2%, was < 10 months in 30.5% and < 6 months in only 10% of the patients [Del Popolo et al., 2008].

In a MS cohort with 137 patients treated with onabotA 300 U, 99 (72%) returned for a second treatment. For third to sixth treatments only 47, 25, 14 and 5 patients returned, respectively. The median interval 2^{nd} , 3^{rd}, 4^{th}, and 5^{th} re-injections ranged between 12 and 13 months. The outcome in terms of continence did not differ among treatments [Khan et al., 2011].

Three studies [Dominique et al, 2019, Baron et al, 2019, Hebert et al., 2020] representing a total of of 375 patients followed for 10 years in real life conditions suggest that around 50% of the patients will abandon the BoNT/A program. Elderly patients, above >50 years, have a higher discontinuation rate than younger, < 50 patients [Hebert et al., 2020]. The most common cause of discontinuation is treatment failure, either primary or secondary, caused by the appearance of adverse events or progression of the neurological disease [Baron et al, 2019]. This latter explanation is particularly relevant for in MS patients. The worsening of the motor capacities will confine a significant number of MS patients to a wheelchair or a bed. Under these circumstances patients might prefer other methods for urine containment. This particular group of MS patients was never well investigated as wheelchair or bed bound cases were excluded from large phase 3 trials. In addition, a significant number of SCI patients may opt for bladder augmentation or urinary diversion.

Long-term success of repeated OnabotA injections was also investigated in 10 children (average age at first injection 11.2 years) with neurogenic detrusor overactivity who had received at least three BTX-A detrusor injections [Schulte-Baukloh et al, 2005]. The relative changes in comparison with the baseline value after the first versus the fifth injection showed a persistent increase in the reflex volume (81% versus 88%) and a progressive decrease in maximal detrusor pressure (7% versus 39%). The results after the third injection were generally similar to those after the fifth injection. No evidence of drug tolerance was detected. Concerning AbobotA [Akbar et al, 2007], 19 patients with myelomeningocele were treated with repeated injections for 3 or more years (20 units/kg, not >400 units). Urodynamic parameters improved and no tolerance developed.

8.1.2.6.2. Repeated injections in OAB patients

Patients participating in the two pivotal phase 3 studies were invited to participate in a long-term, 3 years extension study to determine the efficacy and safety of repeated OnabotA 100 U injections for the management of OAB. The final data were reported by Nitti et al. [2016]. From the initial 839 patients enrolled, 829 received 1 or more treatments and 430 (51.3%) completed the 3.5-year study period. At baseline the mean episodes of UI per day was 5.6 and the I-QOL total score was low. The decrease of UI episodes ranged

between -3.1 and -3.8 episodes per day whether patients received 1 to 6 treatments. The median duration of effect, calculated as the time to requalify to a retreatment was 7.6 months. The duration of effect was 6 months or less in 34.2% of the participants, between 6 to 12 months in 37.2% and greater than 12 months in 28.5% [Nitti et al., 2016]. Improvements in I-QOL scores were consistently 2 to 3 times the minimally important difference, and improvements in KHQ role limitations and social limitations domain scores were 5 to 6 and 3 to 4 times the minimally important difference, respectively. Of importance, 72.9% of patients who achieved or exceeded the minimally important difference for I-QOL after the first treatment maintained the score for all subsequent treatments. However about one third of those who did not achieve that outcome in the first treatment did so in subsequent treatment cycles [Ginsberg et al, 2017].

An open-label extension study of the controlled trial of onabotA 200 IU versus placebo [Tincello et al, 2012] also offered a 5-year extension study period [Owen et al, 2017]. A total of 155 had two and 59 had three injections. Time to symptom return for receiving a second and third injection was 84 and 180 days, respectively and the median inter-injection intervals were 266 and 372 days (range: 134, 1283). No statistically significant differences in symptom outcomes were observed after repeated injections. Although this study used a non-licenced dose of onabotA, it also confirmed the consistent efficacy and duration of action of the toxin [Owen et al, 2017].

Real life studies offer contradictory results concerning persistence on OnabotA OAB program. In a facility with access to flexible cystoscopies and a careful follow-up up to 90% of the patients remained in the program, 93 % would recommend the treatment to a friend and 81% accepted the necessity of a life-long treatment [Malde et al., 2015]. On the other hand, Mohee et al [2013] found that 66.3% of patients discontinued therapy at 36 months. The main reasons for abandonment were UTIs and the need for CIC. In a single-centre retrospective study [Marcelissen et al., 2017] the persistence on treatment among 128 women with at least 5-year follow-up after their first injection and a mean follow-up 97 (60-125) months was only 30 % at the last follow-up visit. Of the 70 % who discontinued treatment, 27 % had insufficient effect and 43 % had tolerability issues. Most patients discontinued treatment after the first (79 %) and second (19 %) injections [Mohee et al., 2013; Marcelissen et al., 2017]. A high rate of adverse events related to the use of high doses of toxin contributed to the low persistence on treatment.

8.1.3. Adverse events after bladder injections of BoNT/A and predictors of response

Most common adverse events related to bladder injection of BoNT/A are urinary tract infection (UTI) and urinary retention requiring CIC.

In studies with a SCI population performing CIC at baseline, the pooled data of the two larger phase 3 trials showed that the incidence of UTI/bacteriuria was similar, around 50%, across placebo, OnabotA 200 U and 300 U treated patients [Cruz et al, 2011, Ginsberg et al 2012, Ginsberg et a.l, 2013]. A low incidence of UTIs was also observed in an AbobotA phase 2a study that enrolled only SCI patients [Denys et al, 2017a] and across the three groups of two recent large clinical trials, which received AbobotA, 600U and 800 U or saline [Kennelly et al, 2022].

In the MS population voiding spontaneously before BoNT/A administration, the rate of UTI was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%) in the study by Cruz et al. [2011] whereas the incidence of UTI was similar, around 50%, after 200 and 300 onabotA doses in the study by Ginsberg et al. [2012]. However, very few complicated UTIs were reported. The incidence of UTI was directly correlated with the dose dependent increase of PVR and necessity of de novo CIC. In MS patients not catheterizing at baseline, Cruz et al., [2011] found an incidence of CIC of 12.2% after saline, 29.5% after 200U, and 42.2% after 300U. In a similar population of MS patients, Ginsberg et al. [2012] reported an incidence of de novo CIC of 10% after placebo, 35% after 200 U and 42% after 300 U. The period of time during which CIC was required after administration of OnabotA 200U was long, >36 weeks in about half of the MS patients [Ginsberg et al., 2013]. In long-term studies with NDO patients most commonly reported AEs were again urinary tract infections and urinary retention. Eventually influenced by patient selection, de novo CIC rates in long-term studies with MS patients decreased progressively as treatments were repeated [Kennelly et al, 2017]. The risk of urinary retention and de novo CIC in MS patients non-catheterising before treatment may be substantially decreased by using a lower dose of the toxin. Using 100U of OnabotA in non-catheterising MS patients de novo CIC (15.2%) and the rate of UTI (25.8%) was half of that observed with 200 U of toxin injections [Tullman et al, 2018].

In OAB, the dose finding study conducted by Dmochowski et al. [2010] showed that the proportion of patients with post treatment PVR of 200 ml or greater was dose dependent. Patients requiring CIC were 0%, 3,6%, 9,1% 12,7% 18,2% and 16,4 after placebo or 50, 100, 150, 200 and 300 U OnabotA injections, respectively, while UTI occurred in 16,3%, 33,9%, 44%, 48.1% and 34.5% patients, respectively.

In OAB large phase 3 trials which used OnabotA 100 U the risks of UTI and urinary retention were low. Chapple et al. [2013] reported an incidence of UTIs during the first treatment cycle of 24.1%. Only 8.8% of patients had an increase of PVR exceeding 200 ml, and 6.9% of the patients initiated CIC. Nitti et al [2013] reported an incidence of UTIs of 15.5% a PVR above 200 ml of 8.7% and de novo CIC of 6.1%. When pooled together and analysed by decades, the incidence of UTIs below the age <40 years was 10%, between 50-60 years 11.8% and >70 was 16.8% [Cruz et al 2017]. Concerning CIC the incidence in the same age groups was 1.1%, 5.3% and 7.2%, respectively, with a mean duration of 3, 88 and 86 days [Cruz et al, , 2017]. In 3 -year extension of these two phase 3 trials, which registered 6 treatment cycles, UTI incidence ranged between 14.4%-17.0% and CIC was necessary in 1%-4.0% The median duration of CIC ranged from 3.1 to 8.3 weeks [Nitti et al., 2016]. In the phase 3 study carried out in Japan, the incidence of UTIs and CIC at week 12 after injection was 13% and 6%, respectively while a PVR > 200 ml was noticed in 6% of the patients at week 2 [Yokoyama et al, 2020]. The studies that investigated the reduction in the number of injection points in the detrusor to facilitate BoNT/A administration still observed a relatively high incidence, 11-24% of UTIs [Avallone et al, 2017, Martínez-Cuenca et al, 2020].

In real life studies with OnabotA 100 U numbers of UTIs show great disparity. Hamid et al [2021] reported 1% UTIs and 0.4% of patients initiating CIC in a total of 504 OAB patients after one single treatment. In retrospective analyses of 103 OAB patients followed for 4 years the incidence of urinary retention was 25% and among patients who did not require catheterization the incidence of UTIs was 20% [Liberman et al, 2018]. In a real-life study with onabotA with 299 patients, mostly women, the incidence of CIC was 2.7% after the first treatment and 3.2% after the second and third treatments. No significant predictors of CIC initiation were found [Kennelly et al, 2018].

Three studies using OnabotA 200 U reported their adverse events. In the RELAX study, UTI occurred in 31% and voiding difficulty

requiring CIC occurred in 16% of cases [Tincello et al., 2012]. In a long-term extension of this study the numbers decreased substantially, due the selection of patients that agreed to continue on treatment [Owen et al, 2017]. In a smaller RCT, CIC was required in 37.5% of [Sahai et al., 2007]. In another small RCT comparing OnabotA 200U vs placebo PVR increased above 200 ml in 43% of the women in the BONT/A group and UTI developed in 75% of these women [Brubaker et al., 2008].

Faure Walker et al [2017] and Mateu Arrom et al [2020] injected only men. The first using OnabotA 100 U and 200 U reported a rate of urinary retention leading to CIC above 40% and an incidence of UTIs among those without retention of 29% among 37 men. The second reported 13% of urinary retentions and 3% of UTIs requiring antibiotics. The reason for the different incidence of adverse events between the two studies is unclear but should have to do with different criteria for male selection and for the definition of UTI and urinary retention.

A thorough investigation showed that formation of toxin-neutralizing antibodies against OnabotA was a rare event in large NDO phase 3 trials [Cruz et al, 2011, Ginsberg et al, 2012]. During long-term extension of these trials, among 388 NDO patients only 1 patient developed antibodies against OnabotA [Kennelly et al, 2013]. The overall incidence of toxin neutralizing antibody formation in large OAB trials was 0.4% [Nitti et al., 2016]. In children treated with AbobotA increment of antibodies against abobotA was shown to be a rare and transient event that was not boost by repeated injections [Kajbafzadeh et al, 2010].

Transient muscle weakness has been reported in some studies with NDO patients. After AbobotA application anecdotal generalised muscular weakness was reported [Wyndaele and Van Dromme, 2002]. Akbar et al., [2007] and Del Popolo et al., [2008] among a total of 243 NDO patients reported 8 cases of hypostenia after abobotA 1000 U injection. In a phase IIa RCT with abobotA 750 U, 3 cases of muscle weakness episodes were reported in two tetraplegic and one paraplegic patient among 15 NDO patients who received the toxin in 15 injection sites [Denys et al., 2017a]. Cruz et al. [2011], among 183 patients treated with OnabotA 200 U or 300 U reported 1 case of muscular weakness in an SCI patient treated with OnabotA 300 U. The reason for the seemingly less cases of transient muscle weakness among OnabotA-treated NDO patients is unclear but might be related with an incorrect ratio conversion and/or to the larger size of the OnabotA molecule which limits its diffusion. Anyway, the recent data of the AbobotA 600 U and 800U trials in NDO patients did not report cases of generalised weakness [Kennelly et al, 2022].

In large OAB trials generalised muscular weakness was not reported after OnabotA 100 U administration [Chapple et al, 2013, Nitti et al, 2013]. Even in geriatric OAB population the administration of OnabotA 100 or 200 U did not cause muscular weakness as investigated by the strength of handgrip test [Wiedemann et al., 2020]

Episodes autonomic dysreflexia in SCI patients during injection were rare. Cruz et al, [2011] reported 2 cases in 183 injected patients and Ginsberg et al. [2012] 7 events in 167 injected patients. Kennelly et al [2022] reported 1 case in more than 500 patients treated.

There is no evidence that repeated BoNT/A injections cause detrusor atrophy or bladder wall fibrosis. Whether onabotA or abobotA were used, repeated injections in NDO patients in the short to medium term did not decrease bladder compliance which would presumably be the case if fibrosis were to develop [Reitz et al., 2007; Del Popolo et al., 2008]. Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008].

The capacity to predict the response of OAB patients to BoNT/A injections was recently the object of a systematic review that identified 17 studies reporting predictive factors for poor response published between 2006 and 2020 [Abrar et al, 2020]. These were cohort studies with predominantly level 3 evidence. Factors including male gender, frailty, comorbidity, increasing age, smoking, baseline leakage episodes, and various urodynamic parameters (bladder outlet obstruction index (BOOI), high pretreatment maximum detrusor pressure, and poor bladder compliance) were proposed as predictors of nonresponse. In predicting CIC use, factors identified were male gender, the presence of comorbidities, increasing age, number of vaginal deliveries, hysterectomy, and urodynamic parameters (bladder capacity, postvoid residual volume, projected isovolumetric pressure value, bladder contractility index, and BOOI). Female gender, males with their prostates in situ, and CISC were suggested to increase UTIs after BoNT/A.

Hematuria may occur after toxin injection in the bladder wall of OAB or NDO patients but in most of the times is mild in nature and does not require any active treatment [Ginsberg et al, 2013, Sievert, et al, 2014, Cruz and Nitti, 2014].

8.1.4. Clinical comparisons of different BoNT/A brands and switch between them

The doses indicated for each brand of botulinum toxin type A cannot be used interchangeably. Moreover, inappropriate storage of the vials, incorrect toxin reconstitution, or incorrect technique of administration, including the type of needle used may contribute to differences outcomes [Karsenty et al., 2014]. A 5-fold variation of the number of neurons expressing cleaved SNAP-25, the end-product of botulinum toxin A activity, after 1 injection of a fixed dose of OnabotA was recently shown in experiments conducted in bladder rodents [Oliveira et al., 2017].

A study compared two different brands of BonT/A, Onabot A 200 or 300 U against the Chinese BoNT/A Presigne in the same dosage. Improvement in MCC was significantly greater with OnabotA (Botox) versus Prosigne (+103.3% vs. +42.2%). Continence was achieved by week 12 in 16 OnabotA recipients (76.2%) and in 10 Presigne recipients (47.6%) [Gomes et al., 2010].

A retrospective case-control study investigated the clinical and urodynamic outcomes in 211 NDO patients [Peyronnet et al, 2017] treated in three consecutives eras with onabotulinum toxin 300 U (2004-2006; 80 patients), abobotulinum toxin 750 U (2007-2011; 78 patients) or onabotulinum toxin 200 U (2011-2014; 53 patients). Patients treated with abobotulinum toxin 750 U had higher success rate compared to those who received onabotulinum toxin 200 U (65.4% vs. 41.5%). In contrast, there were similar success rates in abobotulinum toxin 750 U and onabotulinum toxin 300 U groups (65.4% vs. 65%) but with a trend towards longer interval between the first and the second injection in the onabotulinum toxin 300 U group (12.4 vs. 9.3 months).

A randomized, double-blind, non-inferiority study compared IncobotA vs OnabotA detrusor injections in patients with NDO due to SCI or MS performing CIC [Gianantoni et al, 2021]. A total 28 patients received IncobotA 200U and 29 OnabotA 100 U in 30 points. At

week 12, there was no difference in the number of urinary incontinence episodes/day between the two groups. Total score of I- QoL questionnaire, Visual Analog Scale Scores and urodynamics also did not show differences between the two groups. Adverse effects were similar for both treatments.

Ravindra et al. [2013] reported a retrospective brand comparison in OAB patients. Initially they received onabotA 200 U. Later, due to non-clinical reasons BoNT/A was changed into abobotA 500 U. Under onabotA (n = 101) or abobotA periods (n = 106) patients had similar reductions in frequency, nocturia and daily incontinence episodes. The duration of the effect was similar. However, under abobotA patients had almost twice the rate of symptomatic urinary retention requiring CIC (42% versus 23%).

Switch between brands at the moment is being made on empiric grounds. In particular, the lack of effect of a treatment with a particular brand should not be seen as a compulsory reason for switching to another brand. A sub-analysis of the NDO patients included in the OnabotA pivotal studies who experienced <50% reduction in urinary incontinence episodes following the first onabotA treatment, about 1/3 had a positive response in subsequent injections [Denys et al., 2017b].

Nevertheless, the charts of 57 patients who underwent a switch to AbobotA after failure of OnabotA 200U or 300 U in centers were retrospectively reviewed. After the first injection of AbobotA (mostly 750-1000 U) a significant decrease in number of urinary incontinence episodes per day was observed in 52.63% of patients and all patients experienced a reduction in maximal detrusor pressure (-8.1 cmH20). MCC significantly increased by a mean of 41.2 ml and the proportion of patients without involuntary detrusor contractions increased significantly (from 15.79% to 43.9%). After a median follow up of 21 months, 87% of responders to the switch were still treated successfully with abobotA [Bottet et al, 2018]

The switch may eventually work whatever is the first toxin administered. Peyronnet et al. [2015] reviewed the charts of 58 NDO patients who received either OnabotA or abobotA for the management of NDO. A toxin switch was carried out in 29 patients, whereas the other 29 patients received a reinjection of the same toxin at the same dose. The success rate was higher in patients who switched toxin (51.7% vs 24.1%). Patients who switch from abobotA to OnabotA and those who switch from OnabotA to abobotA had similar success rates (52.9% vs 50%)..

8.1.4.1. Comparison between BoNT/A and other NDO and OAB treatments

BoNT/A has been compared only rarely with other NDO and OAB oral treatments as it is assumed that the toxin introduction should follow the failure of first line pharmacotherapy with antimuscarinics and beta3 agonists.

In SCI patients with NDO, Silva-Ferreira et al [2018] compared oxybutynin 5mg TID or OnabontA 300 U in 78 SCI patients who were under CIC in the last 12 months. Urinary incontinence which was around 8 episodes per day in both groups at baseline, decreased to 5±2 and 3±1 at the end of treatment in the oxybutynin and OnabotA groups, respectively. Also, oxybutynin, in contrast to toxin, could not reduce maximal detrusor pressure to levels below 40 cm H20, indicating an inferior capacity of the antimuscarinic to protect the upper urinary tract.

In OAB, the first large comparison was the Anticholinergic Versus Botulinum Toxin A Comparison Trial (ABC trial) [Visco et al., 2012] **(Fig 22)** that included 249 women with OAB who had 5 or more episodes of urgency urinary incontinence in a 3-day bladder diary. 6-month participants were randomly assigned to one intradetrusor injection of 100 U of onabotA plus daily oral placebo daily or oral anticholinergic medication (solifenacin, 5 mg initially, with possible escalation to 10 mg and, if necessary, subsequent switch to trospium XR, 60 mg) plus one intradetrusor injection of saline. The mean reduction in episodes of urgency urinary incontinence per day, the primary outcome, was similar, 3.3 in the onaboA group and 3.4 in the anticholinergic group. Complete continence was more frequent in the OnabotA than in the anticholinergic group, 27% vs 13%, re-

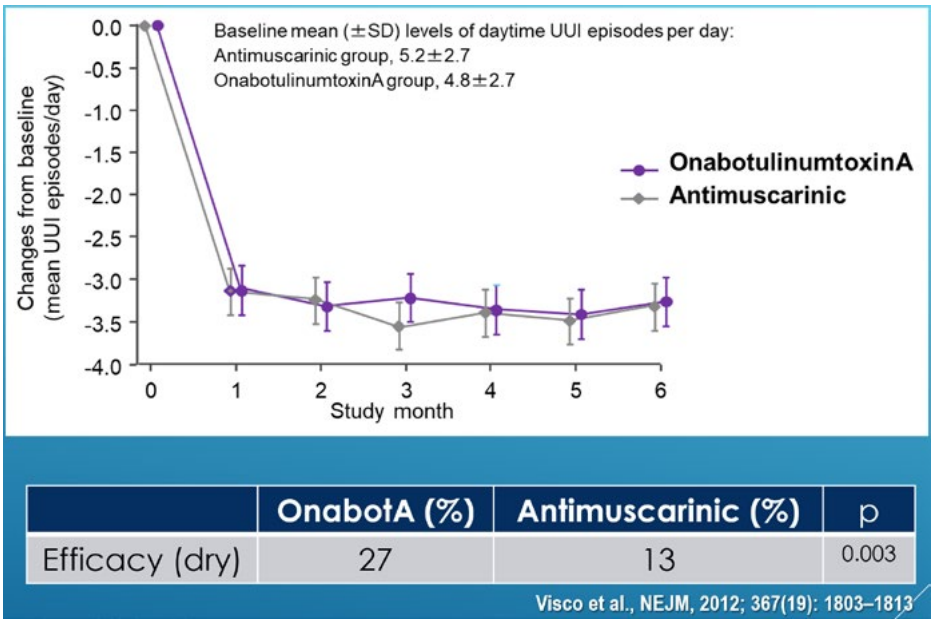

Figure 22: Comparison between Botulinum Toxin A and antimuscarinics. The ABC trial. From Visco et al., NEJM, 2012; 367(19): 1803–1813

spectively. The toxin group had higher rates of catheter use at 2 months (5% vs. 0%, P = 0.01) and UTI (33% vs. 13%) than the anticholinergic group. The latter on the other hand had a higher rate of dry mouth (46% vs. 31%, P =0.02) [Visco et al., 2012].

In contrast, other studies concluded for the superiority of OnabotA over antimuscarinics and beta 3 agonists to improve or resolve OAB wet.

In a study with OAB wet patients, placebo (injection plus oral placebo, n = 60), OnabotA 100 U injection plus oral placebo (n = 145), or oral solifenacin plus placebo injection (n = 151) were compared after 12 weeks [Herschorn et al, 2017]. Co-primary endpoints were change from baseline in urinary incontinence episodes/day and the proportion of patients with 100% reduction in urinary episodes at week 12 after injection. Overall, patients had 4.9 urinary incontinence episodes per day at study entrance. At week 12, mean reduction from baseline was significantly greater with either OnabotA (-3.2) or solifenacin (-2.6) versus placebo (-1.3). In a post-hoc analysis the reduction in urinary incontinence episodes/day was significantly greater with onabotA than with solifenacin. The proportion of patients with 100% reduction in urinary incontinence episodes at week 12 was significantly better for onabotA (33.8%) and solifenacin (24.5%) compared with placebo (11.7%) [Herschorn et al, 2017].

Drake et al, [2017] carried out a network meta-analysis to compare the relative efficacy of onabotA 100 U, and mirabegron and anticholinergics in all licensed doses in OAB adults using 56 RCTs. At a time-point of 12 weeks, patients treated with the toxin had, on average, the greatest reductions in urinary incontinence episodes, urgency episodes, and micturition frequency, and the highest odds of achieving dryness.

The Rosetta study compared OnabotA 200 U against sacral neuromodulation (SNM) (interStim) in refractory OAB wet patients at 6 months [Amundsen et al., 2016] and 2 year [Amundsen et al., 2018] follow-up. The proportion of randomised patients suitable for SNM implant was identical in the two arms. At baseline the OnabotA group (n=190) had 5.4 and the SNM (n=174) had 5.2 episodes of urinary incontinence per day. A 6-months [Amundesen et al, 2016], OnabotA 200 U resulted in a significantly greater mean daily reduction in UUI episodes over 6 months, which averaged 1 episode/day. A significantly greater number of patients experienced a complete resolution (20% vs 4%) or 75% reduction of UUI episodes (46% vs 26%) with OnabotA 200 U treatment than with SNM InterStim. UTIs were more frequent in the onabotA group (35% vs 11%) and the need for CIC was 8% and 2% at 1 and 6 months in the onabotulinumtoxinA group. Neuromodulation device revisions and removals occurred in 3% [Amundsen et al., 2016]. The advantages of onabotA, where no longer observed at 2 years follow-up [Amundsen et al, 2018]. No difference in the decrease of urinary incontinence episodes was found and no differences in incontinence cure or improvement at ≥75% or ≥50% were present at 2 years, although satisfaction and treatment endorsement were higher for the toxin [Amundsen et al, 2018]. Recurrent UTIs remained higher after OnabotA (24% vs 10%) and 6% of the patients required CIC after a second injection. SNM revision and removals occurred in 3% and 9% of the patients, respectively [Amundsen et al, 2018]. Older women with multiple comorbidities and decreased functional and health related quality of life had decreased treatment response and satisfaction with onabotA compared to SNM [Richter et al, 2017].

A survey in 50 OAB patients, with a mean age of 61 years, showed that 74% prefer OnabotA and only 26 % chose SNM as first treatment option. In those who preferred OnabotA 54 % disliked the thought of a foreign body in the back, 45.9 % made the option due to a short waiting list and 43.24 % made the choice based on the quicker onset of benefit. In the SNM group 61.5 % were averse to the potential need for repeated injections and 46.1 % chose SNM to avoid the risk of urinary retention associated with the toxin [Balchandra and Rogerson, 2014].

SNM may be useful in OAB non-responders to OnabotA. In a small cohort with 20 patients 14 (70%) received a definitive implant. One year after implantation, 11 patients were satisfied with SNM [Smits et al, 2013]. The opposite may also be true according to a retrospective multicentre analysis of 62 OAB women who had received either onabotA or abobotA injections after failure of SNM [Baron et al, 2020]. The percentage of success, either resolution or > 50% reduction of urinary incontinence or frequency, was 43.4% after the first injection. CIC was necessary in 36.8%. Overall, 42 patients (55.2%) stopped injections during follow-up [Baron et al, 2020].

8.1.5. Cost-effectiveness of BoNT/A in NDO and OAB.

Economic aspects of BonT/A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, in UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BonT/A treatment was shown to be cost-effective in both NDO and OAB cases [Kalsi et al, 2006]. Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BoNT/A (Botox) compared with standard care [Kalsi et al., 2006]. In Germany a multicenter cost analysisin 214 NDO patients showed that onabotA treatment halved costs for incontinence aids and for urinary tract infection treatment. In patients using incontinence aids, mean costs per patient decreased from €2 to €1 per day, whereas the mean cost of drugs to treat UTIs per patient decreased from €163 to €8 per year [Wefer et al., 2009].

An assessment of costs, from a US payer perspective, extending up to 3 years, was made for 3 interventions, sacral neuromodulation, BoNTA, and augmentation cystoplasty in patients refractory to antimuscarinics. The initial treatment cost was $22,226, $1,313, and $10,252 for sacral neuromodulation, BoNTA, and augmentation cystoplasty respectively. Three years after initiating treatment, the cumulative cost was $26,269, $7651, and $14,337 respectively. Sensitivity analyses revealed that sacral neuromodulation persisted as the most costly intervention [Watanabe et al., 2010]. Also, in NDO patients, break-even point for BoNT/A and augmentation cystoplasty costs may be reached at five years. However, BoNT/A may be substantially more cost-effective if the duration of effect of each injection is superior to 5 months or if the complications associated with augmentation cystoplasty overtake 40% of the patients [Padmanabhan et al., 2011].

For OAB, a study in US over 2 years, concluded that if patients receive 15.6 and 14.3 months of selective and non-selective anticholinergics, respectively, and 2.2 OnabotA injections, the toxin is cost effective, a finding that may change BoNT/A treatment faster into a first line option [Shepherd et al, 2018]. In the Rosetta trial, OnabotA versus SNM , the authors performed a 2-year within-trial assessment of costs and modeled theoretical 5-year costs [Harvie et al, 2020]. The 2-year costs were higher for SNM than onabotA and estimated 5-year costs were still higher for SNM. Harvie et al [2020] concluded that in the US, SMN in its current form is less cost-effective than the toxin in the treatment of refractory OAB.

8.1.6. BONT/A in IC/PBS.

BoNT/ cleaves SNAP-25 in sensory fibers [Coelho et al., 2012a] which inhibits the transmission of noxious sensory input from the bladder [Vemulakonda et al., 2005; Rapp et al., 2006; Lucioni et al., 2008]. Moreover BoNT/A decreases the urinary levels of NGF and BDNF which may contribute to decrease the sensitization of bladder sensory fibers and decrease pain felt by patients during bladder filling [Pinto et al., 2010, 2014]. However, the impact of the findings described below is limited by the fact that most studies are single center, with a small number of patients included, and using different techniques for toxin administration, whole bladder versus trigone. Studies with comparators are scarce. Only one used saline and others maintained in the active arm other forms of treatment which may act as confounders for the outcome.

The first three small pilot studies showed conflicting results. Two, that included a total of 28 patients treated with OnabotA 100 U and 200 U injections in the bladder, including the trigone, reported pain improvement in a large proportion of patients as well as amelioration of urinary symptoms for 3-5 months [Smith and Chancellor, 2004, Giannantoni et al., 2006; 2008]. Importantly, 9 patients experienced moderate to severe voiding difficulties [Giannantoni et al., 2006; 2008] . A third study could not demonstrate any effect of onabotA in 13 IC/PBS patients treated with OnabotA 100–300 U in the bladder [Davies et al., 2006].

Taking in consideration that most of the bladder nociceptors course in the trigone, Pinto et al. [2010] restricted 100 U onabotA injections to the trigone, in 10 sites (10 U/ 1 ml each. Twenty-six women with positive findings at cystoscopy and biopsy were enrolled. All patients reported subjective improvement at 1- and 3-month follow-up in pain, daytime and nighttime voiding frequency, O'Leary-Sant score and QoL. Bladder volume to first pain and maximal cystometric capacity more than doubled. Treatment remained effective in >50% of the patients for 9 months. Retreatment was equally effective in all cases, with similar duration of the effect up to four consecutive treatments [Pinto et al, 2013]. No cases of urinary retention were reported and at urodynamics PVR and bladder contractility index were not impaired [Pinto et al., 2010, Pinto et al, J Urol, 2013]. Interestingly, the improvement in pain may be similar in patients with and without Hunner´s lesions. Kuo and Chancellor [2009] did not find a significant difference in pain intensity between the 2 populations after OnabotA in the whole bladder plus hydrodistention. The symptomatic outcome of trigonal injections of OnabotA 100 U was similar, whether patients had or not Hunner´s lesions [Pinto et al, 2014].

One randomized study compared onabotA 200 U (n=15) or 100 U (n=29) followed by hydrodistention 2 weeks later against hydrodistention only (n=23). The 44 patients that received OnabotA, received the toxin in 40 suburothelial sites, including the trigone [Kuo and Chancellor, 2009]. All participants remained on pentosan polysulphate throughout the study. This and the preliminary hydrodistention inevitably work as a confounder for the results. Nevertheless, the IC/PBS symptom score significantly decreased in all three groups, while pain reduction and urodynamic improvement were only observed at 3 months in the arms that received OnabotA, without any relevant differences between the two doses. A successful result at 12 and 24 months was reported in 55% and 30% of OnabotA treated patients, respectively, compared with only 26% and 17% in the control group [Kuo and Chancellor, 2009].

Three placebo-controlled trials were identified. A multicenter, randomized, placebo-controlled trial randomized 60 patients in a 2:1 ratio to hydrodistention plus 20 suburothelial injections of BoNT-A 100 U) or the equivalent amount of saline above the trigone [Kuo et al, 2016]. A decrease in pain, the primary endpoint, occurred at week 8 (-2.6 ± 2.8 vs. -0.9 ± 2.2) but urinary symptoms captured in a bladder diary, like frequency and nocturia, did not change. The overall success rates were 63% (26/40) in the OnabotA group and 15% (3/20) in the saline group. One case of urinary retention occurred in the OnabotA group [Kuo et al, 2016]. Trigonal only injections of OnabotA 100 U or saline, not associated with any other form of potential treatment, was compared in 10 and 9 IC/PBS women, respectively [Pinto et al, 2018]. A significant greater reduction in pain intensity was achieved with OnabotA (-3.8 ± 2.5 vs -1.6 ± 2.1). The proportion of patients who achieved a 50% or greater reduction in the pain visual analog scale was 60% for onabotA vs 22% for placebo. Important numerical reductions in voiding frequency were also observed with the toxin. UTI developed in 3 patients who received onabotA and in 2 who received saline. No cases of urinary retention occurred [Pinto et al, 2018]. Another small placebo- controlled trial compared periurethral injections of onabotA 50U (n=9) versus saline (n=11) [Gottsch et al, 2011]. The rationale was to investigate the contribution of periurethral somatic afferents to pain. The solution, 2 ml, was injected in the region of the bladder neck, at the 3 o'clock and 9 o'clock positions. No differences between the onabotA and saline were observed at 3-month follow-up in terms of symptoms [Gottsch et al, 2011].

Two metanalyses were identified. One investigated the different treatment options for IC/PBS and concluded that BoNT/A has the highest probability of being the best therapy available at the moment to treat IC/PBS patients [Zhang et al, 2017]. The second meta-analysis identified 12 randomised controlled trials with heterogeneous quality and methodologies. Nevertheless, significant benefits from BoNT/A injections were detected in pain, day-time urinary frequency and Interstitial Cystitis Symptom Index and Problem Index. A clinical insignificant increase in PVR was identified [Giannantoni et al, 2019].

8.1.7. BoNT/A in the Prostate

Apoptosis was reported in rats, dogs, and humans after OnabotA injection in the prostate that affected both the epithelial and stromal components [Doggweiler et al., 1998; Chuang et al., 2005; Chuang et al., 2006a, Silva et al., 2009a]. These findings levered the investigation of BoNT-A for the treatment of benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH). Following ultrasound guided OnabotA 200 U injections consistent decreases in prostate volume, improvement in LUTS were reported. [Maria et al., 2003, Kuo 2005b, Chuang et al., 2005; Chuang et al., 2006b,c Guercini et al., 2005, Silva et al, 2008]. Among 21 frail men on chronic indwelling catheter for at least 3 months, who were not candidates for surgery, 17 (81%) resume spontaneous voiding after OnabotA 200U [Silva et al. 2008]. The duration of prostate atrophy after the single injection of 200U of BoNT-A was found to be about 18 months [Silva et al., 2009b].

A multicenter, double-blind, randomized phase II clinical trial of onabotA 100 and 300 U concluded that both doses caused a 30% improvement from baseline to 3 months in American Urological Association symptom index and/or maximum urinary flow rate [Crawford et al., 2011]. Some serious adverse events were reported, including 3 cases of urosepsis injection. [Crawford et al., 2011]. However, no sexual adverse events were reported [Silva et al., 2011].

These findings were not reproduced, however, in two large RCTs. One enrolled patients with IPSS > 12 and a peak flow rate (Qmax) between 5-15 ml/s [Marberger et al., 2012]. A total of 380 men met the inclusion/exclusion criteria, were randomized (ITT population),

and received treatment via the transperineal (n = 63) or transrectal (n = 311) routes with either placebo (n = 94) or OnabotA 100 U (n = 95), 200 U (n = 94), or 300 U (n = 97).The other [McVary et al., 2014] enrolled 427 men with IPSS score > 14 and Q max between 4 to 15 ml/s. All received initially a sham procedure to exclude cases with a high placebo response during the run-in phase. Then a total of 315 patients were randomized 1:1 to receive a single intraprostatic treatment of OnabotA 200U or placebo. Although in both studies a substantial decrease in IPSS score and increase in Qmax occurred in the OnabotA 200 U groups, the changes were not significantly different from those observed in the saline arm, indicating that they arose from a considerable placebo effect associated with the injection procedure.

The population enrolled in the Marberger et al. [2012] and McVary et al [2014] trials may vary from those usually referred to minimal invasive BPH procedures. As a matter of fact, 51% of the men enrolled in first, although having moderate to severe LUTS had never received treatment with licensed drugs for BPH/LUTS. An exploratory post hoc analysis in the subgroup of patients who had received alpha-blockers showed a significant reduction from baseline in IPSS in the OnabotA 200-U group versus placebo [Marberger et al. 2012]. In the McVary et al. study [2014], 78.3% of the patients were not on alpha-blockers or 5-ARI at the moment they were enrolled in the study. From 313 patients only 68 (21.7%) were currently on treatment, while all the others had meanwhile abandoned oral pharmacotherapy.

Due to these weaknesses, other studies were conducted. A non-inferiority randomized clinical trial compared in BPH patients dissatisfied with oral pharmacotherapy prostatic injection of onabotulinum toxin type A 200 U (n=64) against optimized medical therapy (n=67), that is, any possible drug combination for treatment of BPH/LUTS. The group submitted to toxin injection stopped oral medication 30 days after the procedure [Robert et al., 2018]. Total IPSS at the end of treatment was similar in the two arms, allowing the conclusion that OnabotA is not inferior to optimized medical therapy, in men with BPH/LUTS refractory to initial oral pharmacotherapy. Interestingly, in the onabotA group only 1 episode of acute urinary retention occurred. In contrast, 6 cases were observed in the optimized medical treatment group. A smaller study [[Totaro et al, 2018] randomized 20 consecutive patients to receive intraprostatic OnabotA 200-300 U injection (n = 10) or saline (n = 10). A total volume of 6-8 mL was injected into the transitional zone. At 3 months of follow-up IPSS and PVR were significantly reduced by 55,3%, and 80,6% in the OnabotA arm, respectively. Qmax was increased by 68%. BOOI (bladder outlet obstruction index) decreased by 54%. PROs analysis revealed that 90% of patients treated with OnabotA reported a subjective symptomatic relief and treatment satisfaction and no adverse effects were observed [Totaro et al, 2018].

A curious randomised trial compared intraprostatic injection of OnabotA 200 U against TURP in BPH-patients refractory to oral therapy for more than 6 months [El-Dakhakhny et al., 2019]. The toxin was diluted in 3 mL saline with 1 mL injected in each lobe by transperineal route. At end of the study, 92 patients were available for analysis, 46 in each arm. The IPSS score significantly decreased in all patients with a non-significant difference between the groups. The Qmax increased, whilst PVR and serum PSA significantly decreased after toxin injection. The toxin did not deteriorate erectile function when compared with TURP. Patients who showed deterioration at 12 months were re-evaluated and underwent TURP. Intraprostatic OnabotA spared TURP in >70% of patients [El-Dakhakhny et al., 2019].

By analogy to the rationale of BoNT/A use in IC/PBS, the impairment of prostatic nociceptive fibers by the toxin may be useful to treat pain in patients with chronic prostatitis/chronic pelvic pain syndrome. One randomised clinical trial investigated the effect of intra-prostatic injections of BoNT/A in men 60 men ≥18 years with chronic prostatitis/chronic pelvic pain syndrome refractory to medical therapy [Falahatkar et al, 2015]. Intraprostatic injection of BoNT-A (100 or 200 U of OnabotA according to the prostate volume) or normal saline were carried out by transurethral route. In the toxin group, but not in the placebo group, a marked improvement of pain scores evaluated at the 1-, 3- and 6-month was observed. Also, NIH-CPSI total and subscale scores, the AUA symptom score as well as urinary frequency had significant improvements compared with baseline values. Only two patients developed mild transient gross haematuria, which was managed conservatively [Falahatkar et al, 2015]. Future studies will help to clarify the potential of intraprostatic BoNT/A in chronic prostatitis/chronic pelvic pain syndrome.

8.1.8. BoNT/A in the external urethral sphincter

Patients with external sphincter dyssynergia are frequently put on a program of CIC to empty their bladder. However, some might have difficulty in performing the manoeuvre. An alternative can be to weaken the urethral sphincter in order to facilitate voiding. In the late eighties Dykstra et al, [1988] reported the effect of BoNT/A injection in the rabdosphicter of 10 neurogenic patients with voiding dysfunction. The urethral pressure profile decreased an average of 27 cm. water and post-void residual urine decreased by an average of 146 ml in 8 patients. The toxin effects lasted an average of 50 days. Later, a retrospective study reviewed the charts of 68 patients that received 100 to 200 U of OnabotA in 4 mL divided in equal doses into the four quadrants of the external sphincter [Smith et al, 2005]. Patients reported significant improvement in their detrusor sphincter dyssynergia with decreased postvoid residual urine volume and improved flow. Catheterization to treat urinary retention was required in 41 patients at baseline and only in 7 after OnabotA injection. Post void residual urine volume decreased from 240 ml to 88 ml and maximal voiding pressure decreased from 81to 52 cm H2O. Cases of stress urinary incontinence were rare. Similar results were reported in children [Franco et al, 2007]. A Cochrane review [Utomo et al, 2014] concluded that all available studies were small, of limited quality, and carrying a high risk of bias. Therefore, the evidence of that intraurethral BoNT/A injections improve some urodynamic measures after 30 days in patients with functional bladder outlet obstruction and neurogenic bladder dysfunction should be interpreted with caution. The necessity of reinjection at very short interval (around 3 months) was found a significant drawback. After this review, a retrospective study of 42 neurogenic and 53 non-neurogenic (detrusor underactivity) patients with voiding dysfunction injected with 100 U onabotA into the urethral sphincter was identified [Jiang et al, 2018]. Satisfactory outcomes were reported in 58 (61.1%) patients. However less than half of the patients catheterized or doing CIC could voiding freely. Six cases developed strss urinary incontinence. An open bladder neck during video-urodynamic at voiding was the only predictor for successful outcome. Patients with non-neurogenic voiding dysfunction had a significantly longer therapeutic duration than those with neurogenic voiding dysfunction (9.55 ± 4.18 vs 7.44 ± 2.91 months).

8.1.9. BONT/B protocols in the bladder

Some humans repeatedly injected with BONT-A may show resistance to the toxin. One possibility is the formation of neutralizing antibodies. Although this event is very rare in the case of bladder injections, a minimum interval of 3 months between two BoNT/A injections is generally recommended to decrease its occurrence. If re-

sistance appears, the replacement of BONT-A serotype by BONT-B was investigated [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004b, Hirst et al. 2007]. Empiric doses of BoNT/B were used as there is no ratio conversions for the two serotypes and between BoNT/B brands.

In 3 patients with spinal NDO, bladder injection of 5000 UI [Pistolesi et al., 2004] or 7500 UI [Reitz and Schurch, 2004b] of BONT-B (Neurobloc ®) restored bladder function for 6 months [Reitz and Schurch, 2004b]. Interestingly, 1 patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BONT-A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BONT-B (rimabotulinumtoxinB in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only 1 patient failed to respond and a clear dose-dependent effect, was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which rimabotulinumtoxinB 5000 U were used. Hirst et al. [2007] concluded that Botulinum toxin B is not an effective treatment of refractory overactive bladder due to the short duration of action, in most of the patients not exceeding 10 weeks. The short duration of action for BONT-B at safe doses may, therefore, limit the clinic usefulness of this serotype for lower urinary tract dysfunctions.

8.2. Other toxins

8.2.1. Vanilloids

The rationale for intravesical vanilloid application, capsaicin and resiniferatoxin (RTX), derives from the fact that they desensitize thin type-C sensory fibers after binding TRPV1 the specific vanilloids binding site. In patients with NDO C-fiber desensitization inactivates the sacral micturition reflex [de Groat, 1997]. This sacral reflex emerges in chronic spinal-cord lesions above sacral segments [de Groat, 1997, Cruz et al, 1997a,b] in chronic bladder outlet obstruction [Chai et al., 1998] and in OAB [Silva et al., 2002]. In all conditions an increase in neuronal and urothelial TRPV1 expression was observed in the bladder [Smet et al. 1997, Brady et al., 2004, Liu and Kuo, 2007a] which correlates with urgency sensation [Liu et al., 2007b]. TRPV1 expression decreases after intravesical application of vanilloids [Apostolidis et al., 2005; 2006].

8.2.1.1. Intravesical capsaicin.

Capsaicin was the first vanilloid to be instilled in the bladder as 1-2 mM 30% alcohol solution to treat NDO. Capsaicin was studied in 6 non-controlled [Fowler et al., 1992;1994; Geirsson et al., 1995; Das et al.,1996; Cruz et al., 1997b, De Ridder et al., 1997]. Best clinical results were found among patients with incomplete spinal cord lesions. In the unique controlled study [de Sèze et al., 1998] 10 NDO patients found a significant regression of the incontinence and urge sensation after capsaicin instillation whereas only 1 among the 10 patients who received the alcohol solution had clinical improvement. The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound and no recent studies could be identified.

8.2.1.2. Intravesical Resiniferatoxin

Intravesical RTX application in NDO patients was evaluated in five small open-label studies [Cruz et al., 1997b; Lazzeri et al., 1997; 1998, Kuo 2003] at different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 μM. In selected patients an improvement or disappearance of urinary incontinence and a decrease in daily urinary frequency was reported.

In a placebo-controlled urodynamic study in SCI with NDO patients a significant increase in the volume for first detrusor contraction and maximal cystometric capacity was found in the RTX arm [Silva et al., 2005]. RTX, 600 nM was compared against OnabotA, 300U in a study involving 25 patients with NDO due to chronic spinal cord injury. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity. However, onabotA turned out to be more effective [Giannantoni et al, 2004].

Resiniferatoxin (RTX) has lower pungency [Cruz et al., 1997b], offering the possibility of its instillation not only in NDO patients who lost bladder sensation but also in OAB and PBS/IC patients. A proof-of-concept study with intravesical RTX in OAB patients with IDO showed that intravesical instillation RTX 50 nmol/L was associated with an improvement in volume to first detrusor contraction and maximal cystometric capacity. These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo, 2003; Kuo et al., 2005a].

A specific decrease on urgency was reported in males with prostate enlargement and LUTS in a small non-controlled study [Dinis et al., 2005]. The effect of RTX on refractory OAB was then further investigated in 3 randomized or quasi-randomised clinical trials with contradictory results. Kuo et al. [2006] randomised 54 patients to receive 4 weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle solution, 10% ethanol in saline. At 3 months, patients feeling much better or improved amount to 42.3% and 19.2% in the RTX group and 14.2% and 7.1% in the control arm, respectively. In a quasi-randomised study [Silva et al., 2007] included 23 OAB patients in a 30-day run-in period in which medications influencing the bladder function were interrupted. In the last week of this period patients filled a 7-day bladder diary. Then, patients were instilled with 100 ml of 10% ethanol in saline (vehicle solution) and 30 days later a second 7-day diary was collected. Finally, patients were instilled with 100 ml of 50 nM RTX in 10% ethanol in saline and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 3 months after RTX instillation the number of episodes of urgency decreased to 37 ± 6 [Silva et al., 2007]. In a third study, OAB women were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo and no clinical differences were found at 4 weeks. [Rios et al., 2007].

TRPV1 involvement in pain encouraged the investigation of RTX as a treatment for bladder pain in IC/PBS [Lazzeri et al. 2000, 2004, Chen et al., 2005, Apostolidis et al., 2006; Peng and Kuo, 2007]. However, a randomized, double-blind study in 163 patients with IC/PBS, in which several doses of intravesical RTX (10 nmol/L, 50 nmol/L, and 100 nmol/L) were compared with placebo, failed, however, to show any advantage for the neurotoxin over placebo in terms of overall symptoms, pain, urgency, frequency, nocturia, or average voided volume during 12 weeks of follow up [Payne et al., 2005].

8.2.2. NX-1207.

is a new drug under investigation for the treatment of LUTS associated with BPH [Kunit and Lusuardi, 2014]. It is a new therapeutic protein of proprietary composition with selective pro-apoptotic prop-

erties [Shore, 2010]. The drug is injected directly into the directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to non-regressive prostate shrinkage and both short- and long-term symptomatic improvement. Two US Phase II trials have been performed [Shore, 2010]. Information about the drugs was only available in abstract form and not yet in the peer-reviewed literature. One of them was a multicenter, randomized, non-inferiority study involving 32 clinical sites with 85 subjects and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Allegedly, the mean AUA Symptom Score improvement after 90 days in the intent to- treat group was 9.71 points for 2.5 mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24). Despite these data, the clinical development of this drug was suspended due to the release of negative data coming from a phase III trial run in the US.

8.2.3. PRX302

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by prostate-specific antigen (PSA) [Singh et al., 2007]. The safety and efficacy of PRX302 was evaluated in men with moderate to severe BPH [Denmeade et al.,2010]. The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS >12, a quality of life (QoL) score >3, and prostate volumes between 30 and 80 g. Fifteen patients were enrolled in phase 1 studies, and 18 patients entered phase 2 studies. Subjects received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase 1 subjects received increasing concentrations of PRX302 at a fixed volume; phase 2 subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax), IIEF, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase 1 study and 64% of men in the phase 2 study treated with PRX302 had >30% improvement compared to baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving >1 ml of PRX302 per deposit had the best response overall. There were no deleterious effect on erectile function. Adverse eventswere mild tomoderate and transient in nature. The major study limitation was the small sample size. The promising safety profile and evidence of efficacy in the majority of treated subjects in these phase 1 and 2 studies led to a phase IIb study [Elhilali et al., 2013]. A total of 92 men with an IPSS ≥15, Qmax ≤12 ml/s and prostate volume beween 30 and 100 ml were randomized 2:1 to a single ultrasound guided prostatic injection of PRX302 (0.6 mg per grame prostate) or placebo. Benign prostatic hyperplasia medications were prohibited. The toxin decreased IPSS score by approximately 9-point and increase Qmax by 3 ml/s, both changes being statistically significant when compared to vehicle. Efficacy was sustained for 12 months. PRX302 apparent toxicity was mild, transient, and limited to local discomfort/pain and storage urinary symptoms occurring in the first few days, with no effect on erectile function. No further developments were identified.

9. COMBINATIONS

9.1. Antimuscarinics with α1-AR antagonists

Traditionally, male lower urinary tract symptoms (LUTS) were thought to result from benign prostatic obstruction (BPO) secondary to benign prostatic enlargement (BPE). However, male LUTS can arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosing and appropriately treating men with overactive bladder (OAB) symptoms can be complex and difficult. **α_1**-AR antagonists remain the most widely used pharmacologic agents for the relief of bladder outflow resistance as they relax prostatic and urethral smooth muscle tone, which is the dynamic component of BPO. In contrast, antimuscarinics, which function by competitively blocking muscarinic receptors, are the first-line pharmacologic treatment for OAB. Given the prevalence of combined voiding and OAB symptoms, as well as the finding that the quality of life (QoL) of these patients is affected primarily by the symptoms of OAB, it is logical for this category of patients to be given antimuscarinic drugs.

Several studies have demonstrated the superior efficacy of a combination treatment of an **α_1**-AR antagonist and an antimuscarinic in alleviating symptoms of BPO and concomitant OAB, compared with either monotherapy [Saito, et al., 1999; Lee et al., 2005; Kaplan et al., 2006, MacDiarmid et al., 2006; Kaplan et al., 2013a; van Kerrebroeck et al., 2013a; b Van Kerrebroeck et al., 2013: Drake, Sokol et al., 2016; Matsukawa, Takai et al., 2017). The combination is now the treatment recommended by AUA, EAU, and NICE for men with moderate-to-severe LUTS with predominant storage symptoms.

the therapeutic benefits of combining an antimuscarinic agent (propiverine) with an α_1-AR antagonist (tamsulosin) were compared with an α_1-AR antagonist alone and reported by Saito and colleagues (Saito, Yamada et al. 1999). The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than in the α_1-AR antagonist monotherapy group. The post-void residual (PVR) was unchanged in both groups, and one case (1.5%) of acute urinary retention (AUR) occurred with the combined treatment. Subsequently, Lee et al. (Lee, Choo et al. 2005) compared the safety and efficacy of 8 weeks of combination therapy using propiverine and doxazosin in 211 men with urodynamically confirmed bladder outlet obstruction and OAB symptoms. Compared with doxazosin monotherapy, patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores on the International Prostate Symptom Score (IPSS). Patient satisfaction was significantly higher in the combination group. There was a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

a large-scale, multicenter, randomized, double-blind, placebo-controlled trial (TIMES study) demonstrated the efficacy and safety of tolterodine extended release (ER) alone, tamsulosin alone, and the combination of the two in 879 men with OAB and BPO (Kaplan, Roehrborn et al. 2006). In their primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 (p<0.001 vs. placebo; p=0.001 vs. tolterodine ER; p=0.03 vs. tamsulosin). In their secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia compared with patients receiving placebo. However, tamsulosin monotherapy and placebo did not differ significantly in any diary variables at week 12. Patients receiving tolterodine ER plus tamsulosin showed significant improvements in total IPSS (−8.02 vs. placebo, −6.19, p=0.003) and QoL (−1.61 vs. −1.17, p=0.003). Although patients who received tamsulosin alone reported significant improvements in total IPSS, the differences in total IPSS among patients who received tolterodine ER versus placebo were not significant. A subanalysis (Rovner, Kreder et al. 2008) of data from the TIMES study focused on the urgency perception scale and concluded that the 217 men who received tolterodine plus tamsulosin showed significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as a greater willingness to continue the treatment. Another subanalysis (Kaplan, Roehrborn et al. 2008) of the data examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Those authors concluded that tolterodine ER plus

tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms.

On the other hand, Maruyama and colleagues (Maruyama, Kawachi et al. 2006) reported different results from their prospective, randomized, controlled study in which naftopidil (25–75 mg/day), an α_{1d}-AR antagonist, was administered for 12 weeks alone or in combination with propiverine hydrochloride (10–20 mg/day) or oxybutynin hydrochloride (2–6 mg/day) to 101 men with BPH. In their study, the IPSS and QoL indexes improved significantly in both groups, with no significant differences between the groups. Maximum flow rate (Qmax) and PVR showed improvement in both groups, again with no differences between groups. However, the median post-therapeutic PVR was significantly higher in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, p = 0.021). Significantly more patients had increased PVR relative to unchanged residuals in the combination therapy (22.9%) group than in the monotherapy group (5.0%, p = 0.038). Those authors concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than naftopidil monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased PVR was significantly greater in the combination therapy group than in the monotherapy group.

In caution of increased PVR and aggravated voiding symptoms, combination therapy with a lower dose of an antimuscarinic and α_1-AR antagonist was tried to assess its efficacy and adverse events in men with BPO and OAB. Kang et al. (Kang, Sung et al. 2009) evaluated the efficacy and safety of tamsulosin combined with a low dose of propiverine hydrochloride (10 mg) in comparison with tamsulosin monotherapy in 119 men with prostate volume of 20 ml or greater, IPSS of more than 8, and OAB symptoms. After 3 months of treatment, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index differed significantly between the groups in favor of the combination group. No cases of AUR were recorded in this low-dose study. Those authors suggested that for patients with LUTS due to BPH and concomitant OAB, combination therapy with an alpha-blocker and low-dose anticholinergic could be a reasonable and effective initial therapeutic option.

Another study evaluated the efficacy and safety of low-dose (2 mg) tolterodine ER with an α-blocker compared with a standard-dose (4 mg) tolterodine ER with an α-blocker in 95 men with residual storage symptoms after 4 weeks of α-blocker monotherapy (Kim, Jung et al. 2016). The inclusion criteria were IPSS ≥12, IPSS QoL ≥3, and ≥8 micturition and ≥2 urgency episodes per 24 h. After 12 weeks of treatment, patients in both groups had a significant improvement in their total IPSS scores (−5.5 and −6.3, respectively), micturition per 24 h (−1.3 and −1.7, respectively) and nocturia per night (−0.4 and −0.4, respectively). Changes in IPSS, bladder diary variables, and patient-reported outcomes did not differ significantly between the treatment groups. All interventions were well tolerated. The authors concluded that low-dose tolterodine ER add-on therapy is similar to standard-dose tolterodine ER add-on therapy in terms of efficacy and safety.

The efficacy and safety of solifenacin in combination with tamsulosin have been reported in several large-scale RCTs, including the VICTOR (Kaplan, McCammon et al. 2013)and SATURN (Van Kerrebroeck, Haab et al. 2013)b trials.

The VICTOR trial (Kaplan, McCammon et al. 2013) was a randomized, placebo-controlled study assessing solifenacin 5 mg as an add-on therapy to **α_1**-AR antagonist treatment in men with residual OAB symptoms. Significant reductions in daytime frequency, the primary outcome of the study, were achieved in both the solifenacin and tamsulosin and placebo and tamsulosin groups compared to baseline, but the difference between the two groups was not significant. Solifenacin add-on significantly reduced daily urgency episodes compared to placebo, but that was the only significant efficacy difference between solifenacin and placebo. Seven patients (3%) in the solifenacin group developed retention, with three requiring catheterization, versus none in the placebo group.

The SATURN trial was a phase 2 dose-finding study evaluating the combination of different doses of solifenacin (3, 6, and 9 mg/day) with tamsulosin versus tamsulosin alone in 937 men with voiding and storage LUTS (total IPSS ≥ 13, and Qmax 4.0–15.0 ml/s with a volume voided ≥120 ml) (Van Kerrebroeck, Haab et al. 2013). There were no specific inclusion criteria regarding storage symptoms. Patients were excluded if they had a PVR >200 ml. Decreases in micturition frequency and total urgency and frequency scores and increases in void volume per micturition were significantly greater with increasing solifenacin dosages in the combination groups compared with tamsulosin monotherapy. In a post-hoc analysis, patients with at least two urgency episodes and at least eight micturitions per 24 h at baseline showed clear improvements in storage and QoL parameters with combination treatment over tamsulosin alone. The subgroup of patients with fewer storage symptoms experienced little or no additional benefit from combination therapy compared with tamsulosin monotherapy. Combination therapy was well tolerated, and adverse events were consistent with the safety profiles of each individual compound. Mean PVR volume increased with increasing solifenacin dose, but the changes were not clinically relevant and were not accompanied by an increase in the incidence of retention.

Based on the results from the SATURN trial, those authors expected to establish the most useful clinical dose of combination therapy for further evaluation in the phase 3 study (NEPTUNE) of solifenacin and tamsulosin in males with moderate to severe storage LUTS (van Kerrebroeck, Chapple et al. 2013). The study evaluated the efficacy and safety of a fixed-dose combination (FDC) tablet containing solifenacin plus an oral controlled absorption system formulation of tamsulosin (TOCAS). A total of 1334 men with LUTS/BPH who had moderate-to-severe storage symptoms (two or more urgency episodes per 24 h, eight or more micturitions per 24 h and Patient Perception of Intensity of Urgency Scale grade 3 or 4) were included. Men with ultrasound-estimated prostate weight ≥75g or PVR >150 ml were excluded. Patients were randomized to placebo, TOCAS 0.4 mg, FDC solifenacin 6 mg plus TOCAS 0.4 mg, or FDC solifenacin 9 mg plus TOCAS 0.4 mg. The primary efficacy endpoints were (1) total IPSS and (2) Total Urgency and Frequency Score (TUFS). An FDC met the success criteria if it demonstrated superiority over placebo and noninferiority to TOCAS for total IPSS and superiority to TOCAS for TUFS. After 12 weeks of treatment, reductions in total IPSS and TUFS were observed with both solifenacin 6 mg plus TOCAS (–7.0 and –8.1, respectively) and solifenacin 9 mg plus TOCAS (–6.5 and –7.6, respectively) compared with TOCAS (–6.2 and –6.7, respectively) and placebo (-5.4 and -4.4, respectively). Solifenacin 6 mg plus TOCAS met all the prespecified success criteria for both primary endpoints, and solifenacin 9 mg plus TOCAS met the success criteria compared with placebo but not compared with TOCAS. Both FDCs improved QoL and were well tolerated, with low incidences of AUR. Consequently, a once-daily FDC tablet of solifenacin 6 mg plus TOCAS 0.4 mg intended to treat both storage and voiding symptoms in men with

LUTS/BPH is licensed and available in several countries, including the UK.

Patients completing the 12-week NEPTUNE study were invited into the open-label, 40-week NEPTUNE II extension study to evaluate the long-term (up to 52 weeks in total) safety and efficacy of the solifenacin plus TOCAS combination therapy (Drake, Chapple et al. 2015). For total IPSS, significant improvements from baseline to the end of treatment compared with placebo were achieved with TOCAS (−6.2, p = 0.039), solifenacin 6 mg plus TOCAS (−7.0, p < 0.001), and solifenacin 9 mg plus TOCAS (−6.5, p = 0.006). Solifenacin 6 mg plus TOCAS was noninferior to TOCAS for total IPSS (p = 0.001); improvement was observed with solifenacin 9 mg plus TOCAS compared with TOCAS (p = 0.028), but that was not significant after multiplicity adjustment, and noninferiority was not proven. Improvements in TUFS from baseline to the end of treatment were significantly greater with TOCAS, solifenacin 6 mg plus TOCAS, and solifenacin 9 mg plus TOCAS than with placebo (−6.7, −8.1, and −7.6, respectively; all p < 0.001). Solifenacin 6 mg plus TOCAS was statistically superior to TOCAS alone on TUFS (p = 0.025), but solifenacin 9 mg plus TOCAS was not (p = 0.162). Urinary retention occurred in eight patients, and five cases required catheterization: one case (0.3%) each with TOCAS and solifenacin 6 mg plus TOCAS and three cases (0.9%) with solifenacin 9 mg plus TOCAS.

Responder and health-related QoL (HRQoL) analyses of the NEPTUNE study reported that men treated with an FDC of solifenacin 6 mg plus TOCAS consistently had significantly improved outcomes compared with both the placebo and TOCAS groups (Drake, Sokol et al. 2016). The reduction in total urgency frequency score correlated significantly with the improvement in HRQoL, as defined by the IPSS QoL score, the OAB-q symptom bother score, the overall patient global impression bladder symptoms, and the general health of the patient. The authors expected the positive HRQoL data for the FDC of solifenacin 6 mg plus TOCAS to translate into improved persistence of treatment and possibly increased confidence in prescribing the combined therapy as an initial treatment for moderate-to-severe LUTS/BPH.

More recently, a pilot study evaluated the potential influence of antimuscarinics on morphometric parameters of the prostate in patients with BPE/OAB (Sakalis, Sgas et al. 2018). All five muscarinic receptors are present in the endothelium and smooth muscle cells of small arteries (Walch, Brink et al. 2001). The human prostate expresses muscarinic receptors at densities exceeding those of α1-adrenoreceptors, with a preponderance of the M1 subtype on the prostatic epithelium and a smaller population of the M2 subtype on stromal cells (Ventura, Pennefather et al. 2002, Witte, Chapple et al. 2008). In primary epithelial and stromal cultures of enlarged prostates, M1, M3, and M5 receptors were expressed in the prostatic epithelium, and M2 and M4 receptors were found in the prostatic stroma (Obara, Arai et al. 2000). In cell cultures, carbachol, a muscarinic receptor agonist, stimulated prostatic growth of prostate cancer cells through increased DNA synthesis (Rayford, Noble et al. 1997). This mitogenic response is mediated by M3 receptors. Based on those results, the authors assessed whether solifenacin influenced the growth and vascularity of the prostate in patients with BPE/OAB. For that study, men with prostate volume >30 mL, predominately storage LUTS, urgency episodes ≥3/24 h, Qmax ≥10 mL/s, and PVR ≤100 mL were randomized to receive either tamsulosin or tamsulosin + solifenacin. After 6 months, a reduction in total prostate volume (mean –9.5%) was noted in the combination group, as opposed to an increase in the monotherapy group (+9.2%; P < 0.001). Similar changes were noted in adenoma volume (monotherapy +17.4% vs. combination –12.5%, P = 0.001) and prostate vascularity (monotherapy +149.3% vs. combination –19.8%, P = 0.001). The results of this pilot study suggest that solifenacin might affect the morphometric properties of the prostate, decreasing total prostate and adenoma volume, as well as vascularity. Further study is needed to determine the molecular mechanisms of antimuscarinics in the prostate.

As mentioned earlier, to prevent AUR and increased PVR, a lower dose of antimuscarinics was studied in combination with α_1-AR antagonists in men with BPO and OAB. However, the efficacy of low-dose antimuscarinic therapy in patients with severe symptoms of OAB should be considered. A study evaluated the safety and efficacy of high-dose anticholinergics combined with alpha-blockers as an initial treatment (Lee, Hur et al. 2017). Another study assessed the efficacy of combining two antimuscarinics (solifenacin and trospium) with alpha-blockers.

In the first study, 146 men with total IPSS ≥8, total OAB symptom scores (OABSS) ≥3, OABSS questionnaire number 2 ≥2, and prostate volume >20 mL were randomly assigned to receive 0.2 mg of tamsulosin (Group I, *n* = 44), 0.2 mg of tamsulosin plus 5 mg of solifenacin (Group II, *n* = 55), or 0.2 mg of tamsulosin plus 10 mg of solifenacin (Group III, *n* = 47) for 12 weeks (Lee, Hur et al. 2017). Men with PVR ≥200 mL were excluded. After treatment, the groups receiving both tamsulosin and solifenacin (II and III) showed improvements in storage symptoms significantly greater than those in the monotherapy group (I) in the OABSS and IPSS storage subscores. The total IPSS and IPSS voiding sub-score improved significantly in every group, and the IPSS QoL and Patient Perception of Bladder Condition (PPBC) scores also showed improvements, although not significant ones. Qmax decreased in groups II and III, but not significantly. PVR increased in the combined treatment groups, but that was not significant, either. Dry mouth developed in four (7%) and eight (17%) men in groups II and III, respectively, and one (2%) and three (6%) men dropped out in groups II and III, respectively. Two cases of AUR developed in group III, and one of those patients was withdrawn from the study. Those authors concluded that initially treating men with LUTS with a combination of tamsulosin and solifenacin significantly improves storage symptoms, but dose modification is necessary to prevent adverse events.

Another study assessed the effectiveness of combining solifenacin with trospium and tamsulosin to treat men with severe symptoms of OAB (Kosilov, Loparev et al. 2016). Men initially diagnosed with BPH (8–19 points on the IPSS, residual urine volume ≤ 100 ml) were enrolled in the preliminary stage of the study. During that preliminary stage, men with severe OAB were selected. More than 3 episodes of urinary incontinence/day, IPSS > 19, and OAB-V8 questionnaire score > 32 were considered to be severe symptoms of OAB. The included patients were randomly assigned to the main group (daily combination of 5 mg of solifenacin and 5 mg of trospium with 0.4 mg of tamsulosin) or the control group (tamsulosin 0.4 mg) for 8 weeks. The percentage of patients with severe symptoms of OAB, the first endpoint, was 44%. In the main group, the number of incontinence episodes decreased from 3.4/day to 0.9/day (p < .01), and daytime frequency decreased from 9.2/day to 5.7/day (p < .05). Changes in the parameters in the control group proved to be insignificant. Six patients from the main group (3 dry mouth, 2 hypertension, 1 unknown) and 3 from the control group (2 lack of efficacy, 1 dry mouth) stopped participating in the study. Retention was not reported. The combination of standard doses of trospium and solifenacin with tamsulosin was suggested to be an effective and well tolerated treatment option for the management of severe symptoms of OAB in men.

Besides, in a 52 week extension study (NEPTUNE II), Matsukawa et al.(Matsukawa, Takai et al. 2017) evaluated 1 year efficacy and safety of a combination therapy with an anticholinergic agent and an α1-blocker for patients with BPE and OAB, in comparison with those of α1-blocker monotherapy by conducting a urodynamic study. A total of 120 men with BPE, urinary urgency at least once per week, and an OABSS of ≥3 were randomly assigned to receive 8 mg of silodosin and 20 mg of propiverine or 8 mg of silodosin alone. Changes in parameters from baseline to 1 year after treatment were assessed using IPSS, IPSS-QoL, OABSS, and voiding and storage functions measured by UDS. In the results, although the mean IPSS and OABSS improved significantly in both groups, the combination group showed statistically significant improvement in the OABSS (–3.4 vs. –2.4 in monotherapy, $p = 0.04$), IPSS-QoL (–1.9, –1.2, $p = 0.01$), and OAB-urgency scores (–1.8, –1.2, $p < 0.01$). In storage function, both groups showed significant improvements, but the combination group demonstrated a greater improvement in terms of the disappearance of detrusor overactivity (54.5% vs. 34.2% monotherapy, $p = 0.07$) and bladder capacity (+61 mL, +33 mL, $p = 0.02$).

Those authors concluded that the long-term combination of silodosin and propiverine is a safe and effective treatment for men with BPE and OAB showing urodynamic improvement in the storage phase parameters.

Several systematic reviews and meta-analyses have compared the safety and efficacy of treatments combining anticholinergics and α-blockers with α-blocker monotherapy in men with BPH and OAB (Filson, Hollingsworth et al. 2013) (Hao, Tian et al. 2014) (Gong, Dong et al. 2015). In results from a pooled analysis of 7 placebo-controlled trials, combination therapy produced a significantly greater reduction in the IPSS storage sub-score (Δ -0.73, 95% CI –1.09 to –0.37) and voiding frequency (Δ -0.69 voids, 95% CI –0.97 to –0.41) than monotherapy (Filson, Hollingsworth et al. 2013). Combination therapy also produced a greater reduction in Qmax (Δ -0.59 ml/sec, 95% CI –1.04 to –0.14) and an increase in PVR (Δ 11.60 ml, 95% CI 8.50–14.70). The number of patients who need to be treated with combination therapy to cause 1 AUR episode was calculated to be 101 (95% CI 60–267). Those authors concluded that combination treatment with α-blockers and anticholinergics significantly improved the storage voiding parameters compared with men treated with α-blocker therapy alone. The combined treatment approach was deemed to be safe, with a minimal risk of increasing PVR, decreasing Qmax, or causing AUR. Hao et al. evaluated 18 eligible RCTs in a systematic review including 2106 subjects (52%) in the combination therapy group (antimuscarinic and α-blocker) and 1978 subjects (48%) in the α-blocker monotherapy group (Hao, Tian et al. 2014). The combination group reported significant improvements in storage IPSS (mean difference (MD) = −1.51; 95% CI −2.10 to −0.91, $p < 0.00001$), QoL score (MD = −0.53; 95% CI −0.89 to −0.17, $p = 0.004$), micturitions/24 h (MD = −1.14; 95% CI −1.84 to −0.45, $p = 0.001$), and urgency episodes/24 h (MD = −0.99; 95% CI −1.46 to −0.51, $p < 0.0001$). Q_{max} (MD = −0.05; 95% CI −0.27 to 0.17, $p = 0.64$), total IPSS (MD = −0.88; 95% CI −1.64 to −0.12, $p = 0.02$), and voiding IPSS (MD = 0.40; 95% CI −0.34 to 1.15, $p = 0.29$) did not differ significantly between groups. Worsened PVR was observed only in the combination therapy group (MD = −6.53; 95% CI 3.06–10.00, $p < 0.0002$). Gong et al. performed a meta-analysis of studies that compared tamsulosin and solifenacin combination therapy with tamsulosin monotherapy (Gong, Dong et al. 2015)]. Seven eligible articles were identified with a total of 3063 participants. Combination therapy produced significant improvements in storage IPSS (MD = −0.60; 95% CI −0.81 to −0.38, $p < 0.0001$), QoL (MD = −0.23; 95% CI −0.34 to −0.11, $p < 0.0001$), micturitions/24 h (MD = −0.70; 95% CI −0.86 to −0.55, $p < 0.0001$), and urgency episodes/24 h (MD = −0.26; 95% CI −0.48 to −0.05, $p = 0.018$). The incidence of AEs in the combined therapy group (31%) was similar to that in the tamsulosin monotherapy group (26%). AUR was seldom reported in those studies, and no clinically significant changes in Qmax were reported.

More recently, a systematic review and meta-analysis compared the effectiveness of newer medications for LUTS/BPH (Dahm, Brasure et al. 2017). Six combination therapies of anticholinergics and α-blockers were compared with ABs alone: 1. Darifenacin plus an AB versus an AB alone; 2. Fesoterodine plus an AB versus an AB alone; 3. Oxybutynin plus an AB versus an AB alone; 4. Solifenacin plus an AB versus an AB alone; 5. Tolterodine plus an AB versus an AB alone; 6. Trospium plus an AB versus an AB alone. The safety and efficacy of the combination therapies seemed to be similar among different the antimuscarinics. However, those trials often excluded participants with high PVRs, thereby excluding the patients at highest risk for urinary retention. Furthermore, the applicability of those findings to general medical practice was affected by their use of an assessment of postvoid residuals that is not part of the routine care pathway.

9.2. Antimuscarinics with 5α-reductase inhibitors

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α_1-AR antagonist, a 5α-reductase inhibitor, or a combination of the two. Both α_1-AR antagonists and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance: α_1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, and 5α-reductase inhibitors reduce prostate volume. Several trials have demonstrated the safety and efficacy of combining antimuscarinics with an α_1-AR antagonist in patients with OAB and BPO. However, post hoc analyses of the TIMES study (Kaplan, Roehrborn et al. 2006) suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates (Roehrborn, Kaplan et al. 2008, Roehrborn, Kaplan et al. 2009). Chung and co-workers conducted an open-label, fixed-dose study to assess the safety and efficacy of tolterodine ER in combination with dutasteride in men with large prostates (≥30 g) and persistent OAB symptoms who had been unsuccessfully treated with dutasteride alone (Chung, Te et al. 2010)]. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months, and α1-AR antagonist therapy had failed. All patients were given 4 mg tolterodine ER daily for 12 weeks and had discontinued taking the α1-AR antagonist before the start of the study. After 12 weeks of treatment, the frequency (–3.2/24 h, $p < 0.02$), urgency (19.2%, $p < 0.03$), number of severe OAB episodes (71.4%, $p < 0.05$), and incidence of nighttime voiding (–0.9, $p < 0.003$) had all decreased significantly from baseline. IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 ($p < 0.001$). Storage symptoms decreased from 9.8 to 4.5 ($p < 0.001$). Dry mouth occurred in four (7.5%) subjects, constipation in one (2%), and decreased sexual function in two (3.9%). PVR increased by 4.2 mL, Qmax decreased by 0.2 mL/s, and no patients went into retention. The authors concluded that the combination of tolterodine and dutasteride was safe, effective, and well-tolerated in men with large prostates who had persistent OAB symptoms and LUTS secondary to BPO. Their results indicate that antimuscarinics are safe and effective when used in combination with 5α-reductase inhibitors in certain patients with OAB and BPO. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in patients with persistent OAB symptoms and LUTS secondary to BPO.

Dutasteride was evaluated in terms of OAB symptoms and bladder ischemia in men with BPE (Wada, Matsumoto et al. 2015). After 24 weeks of dutasteride treatment, the bladder vascular resistive index (RI) had decreased significantly, and the IPSS urgency score was significantly improved, from 2.3 ± 1.9 to 1.4 ± 1.4 (P < 0.01). In 20 patients with persistent urgency after dutasteride, RI was less improved than in an additional 10 patients without urgency. Post-treatment bladder outlet obstruction index scores and PdetQmax in patients with persistent urgency were significantly higher than in those without urgency after dutasteride. The authors suggested that the reduction of obstruction and improvement in bladder ischemia might play important roles in the beneficial effects of dutasteride on OAB symptoms. In another study, patients with persistent OAB symptoms after the initial administration of dutasteride were given solifenacin, and IPSS and OABSS were prospectively collected at 4 and 12 weeks (Maeda, Kikuchi et al. 2015). Solifenacin 5 mg significantly reduced the IPSS, OABSS, and OABSS Q3 at 4 (–2.0, – 2.0, –1.0; P <0.05) and 12 weeks (–3.1, –2.7, –1.3; P <0.05).

9.3. Antimuscarinic with β3-adrenoceptor agonists

Because the mechanism of action of β3-adrenoceptor agonists differs from that of antimuscarinics, they might be a useful combination treatment for patients experiencing adverse events or insufficient symptom improvement with antimuscarinics. In addition, combining an β3-adrenoceptor agonist with an antimuscarinic could improve efficacy in the treatment of OAB. Several clinical trials have demonstrated the safety and efficacy of combination therapy using antimuscarinics and β3-adrenoceptor agonists.

9.3.1. Antimuscarinics with mirabegron

SYMPHONY and relevant studies

SYMPHONY was a phase 2, randomized, double-blind, parallel-group, placebo- and monotherapy-controlled trial that evaluated the efficacy, dose-response relationship, and safety/tolerability of solifenacin combined with mirabegron in comparison with placebo and solifenacin 5 mg monotherapy in adults with OAB symptoms (Abrams, Kelleher et al. 2015). A total of 1306 patients were randomly assigned to 12 groups: placebo, 6 combination groups (solifenacin 2.5, 5, or 10 mg plus mirabegron 25 or 50 mg), and 5 monotherapy groups (solifenacin 2.5, 5, or 10 mg; mirabegron 25 or 50 mg) for a 12-week treatment period. The primary endpoint was change from baseline to end of treatment in mean volume voided (MVV) per micturition. All combinations with solifenacin 5 or 10 mg improved MVV significantly more than solifenacin 5 mg monotherapy, and a decreasing trend in the mean number of micturitions per 24 hours was observed with increasing solifenacin and mirabegron doses. Three drug combinations (solifenacin 5 mg plus mirabegron 50 mg, solifenacin 10 mg plus mirabegron 25 mg, and solifenacin 10 mg plus mirabegron 50 mg) demonstrated significant improvements compared with both solifenacin 5 mg and placebo. No severe adverse events were reported, and treatment was generally well tolerated.

In the same study population, changes from baseline to end of treatment were assessed versus placebo and solifenacin 5 mg in patient-reported outcomes (PROs) (OAB-q [Symptom Bother/total HRQoL] and PPBC) and predetermined clinically meaningful improvements in efficacy (e.g., <8 micturitions/24 h). The solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg plus mirabegron 50 mg groups showed significantly improved PPBC versus the placebo and solifenacin 5 mg groups ($p < 0.05$). Significant improvements in the Symptom Bother score were evident for three combinations (solifenacin 2.5 mg plus mirabegron 50 mg, solifenacin 5 mg plus mirabegron 25 mg, and solifenacin 5 mg plus mirabegron 50 mg). Significant improvements in total HRQoL were observed for the solifenacin 5 mg plus mirabegron 50 mg group versus placebo and for three combinations (solifenacin 2.5 mg plus mirabegron 50 mg, solifenacin 5 mg plus mirabegron 25 mg, and solifenacin 5 mg plus mirabegron 50 mg) versus solifenacin 5 mg ($p < 0.05$). In the efficacy responder analyses, two combinations (solifenacin 5 mg plus mirabegron 25 mg, and solifenacin 5 mg plus mirabegron 50 mg) were associated with significant improvements versus solifenacin 5mg in terms of patients achieving complete dryness and achieving ≥ 50% reduction in incontinence episodes per day. The proportion of patients achieving micturition frequency normalization at week 12 was 65.4 and 61.6% with the combinations of solifenacin 10 mg + mirabegron 25 mg and solifenacin 5 + mirabegron 50 mg, respectively, which was significantly greater than in the placebo and solifenacin 5 mg groups ($p < 0.05$). The proportion achieving a major (≥2 point) improvement in PPBC was significantly higher with solifenacin 5 mg plus mirabegron 50 mg than with placebo ($p = 0.038$) and with solifenacin 5 mg + mirabegron 25 mg and solifenacin 5 mg + mirabegron 50 mg than with solifenacin 5 mg ($p = 0.020$ and $p = 0.012$, respectively) **(Table 5)** (Abrams, Kelleher et al. 2017).

SYNERGY and relevant studies

SYNERGY was a phase 3 study that evaluated the safety and efficacy of combinations of solifenacin and mirabegron in comparison with monotherapy and placebo in wet OAB patients with at least 3 urinary incontinence episodes in a 7-day micturition diary (Herschorn, Chapple et al. 2017). A total of 3527 patients was randomly assigned to 6 groups: placebo, 2 combination groups (solifenacin 5 mg plus mirabegron 25 mg or solifenacin 5 mg plus mirabegron 50 mg), and 3 monotherapy groups (solifenacin 5 mg or mirabegron 25 or 50 mg) for a 12-week treatment period. The co-primary endpoints were change from baseline to end of treatment (EoT) in the mean number of urinary incontinence episodes and micturitions per day. All treatment groups demonstrated a reduction in urinary incontinence episodes per day, with a greater reduction in the combination therapy groups than in the monotherapy and placebo groups (reductions of −1.34 for placebo; −1.7 and −1.76 for mirabegron 25 mg and 50 mg, respectively; −1.79 for solifenacin 5 mg; −2.04 for mirabegron 25 mg plus solifenacin 5 mg; and −1.98 for mirabegron 50 mg plus solifenacin 5 mg). However, although the combined solifenacin 5 mg plus mirabegron 50 mg group was superior to solifenacin 5 mg monotherapy for urinary incontinence episodes (mean adjusted difference of −0.2 episodes per day, p = 0.033), the solifenacin 5 mg plus mirabegron 50 mg group did not achieve a significant effect versus mirabegron 50 mg. In terms of micturitions per day, all treatment groups had greater improvements than placebo, with effect sizes for the combination groups (solifenacin 5 mg plus mirabegron 25 mg: –0.85; solifenacin 5 mg plus mirabegron 50 mg: –0.95) higher than those with solifenacin 5 mg (–0.56) and mirabegron (25 mg: -0.36; 50 mg: -0.39) monotherapies. The mean adjusted change in MVV/micturition from baseline to EoT was greater in the combined solifenacin 5 mg plus mirabegron 25 mg (34.84 ml) and solifenacin 5 mg plus mirabegron 50 mg (39.73 ml) groups than in the monotherapy and placebo groups. Improvements in the mean adjusted differences in the MVV/micturition for the combinations were significantly greater than those for monotherapy except for the comparison between solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg. Responder analyses showed odds ratios in favor of the combination therapies versus the monotherapies in the proportion of patients with zero UI episodes (the odds were 31–50% higher in the combination groups) and those achieving micturition frequency normalization (the odds were 30–60% higher in the combination groups). In all, 46% of patients had received previous OAB treatment. A subgroup analysis found a larger effect size in patients who had received prior OAB medication than in treatment-naïve patients in the mean number of incontinence episodes per day (except for the combined solifenacin 5 mg plus mirabegron 25 mg versus mirabegron 50 mg comparison) and in the change in the number of micturitions per day (except for the combined solifenacin 5 mg plus mirabegron 25 mg versus solifenacin 5 mg comparison).

HRQoL was evaluated using OAB-q, PPBC, a treatment satisfaction-visual analogue scale (TS-VAS), and a responder analysis (≥10-point improvement in OAB-q Symptom Bother score, ≥10-point improvement in HRQoL total score, and ≥1-point or ≥ 2-point improvement in PPBC) (Robinson, Kelleher et al. 2018). At 12 weeks, combination treatment (solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg plus mirabegron 50 mg) showed significantly greater improvements in OAB-q [Symptom Bother/total HRQoL] and PPBC than monotherapy, except for the comparison between solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg, The odds ratios significantly favored combination therapy over monotherapy in the proportion of responders with most of the predefined criteria **(Table 6)**.

BESIDE and relevant studies

The BESIDE study, a phase IIIB trial, specifically recruited OAB patients who had not responded to 4 weeks of solifenacin monotherapy (Drake, Chapple et al. 2016). A total of 2174 patients with OAB who remained incontinent despite 5 mg of solifenacin once daily during a 4-week, single-blind, run-in were randomized 1:1:1 to a double-blind daily combination (solifenacin 5 mg plus mirabegron 25 mg, increasing to 50 mg after 4 weeks) (n=727), solifenacin 5 mg (n=728), or solifenacin 10 mg (n=719) for 12 weeks. The primary efficacy endpoint was a change in the mean number of incontinence episodes per 24 h. Key secondary efficacy endpoints were changes in the mean number of micturitions per 24 h and the number of incontinence episodes noted in a 3-d voiding diary. The adjusted change in incontinence episodes per day from baseline to EoT was significantly greater in the combination group (–1.80) than the solifenacin 5 mg group (–1.53). There was also a greater reduction in mean daily micturitions (–1.59 versus –1.14) and 3-day incontinence episodes (4.25 versus 4.87) in the combination group than the solifenacin 5 mg group. The combination treatment was not inferior to solifenacin 10 mg in the key secondary endpoints and was superior to solifenacin 10 mg at improving daily micturitions. All treatments were well tolerated. These results suggest that a combination therapy of mirabegron 50 mg and solifenacin 5 mg could be an alternative to dose escalation of solifenacin in patients with insufficient response to 5 mg of solifenacin alone. The incidence of TEAEs was lowest in the solifenacin 5 mg group (33.1%) and highest in the solifenacin 10 mg group (39.4%); in the combination group, it was 35.9%. The incidence of dry mouth was highest in the solifenacin 10 mg group (9.5%), with the combination group (5.9%) similar to the 5.6% of the solifenacin 5 mg group. In a prespecified subanalysis stratified by age (≥65 yr and ≥75 yr), the combination treatment improved OAB symptoms more effectively than solifenacin monotherapy irrespective of age (Gibson, MacDiarmid et al. 2017).

The proportion of responders who became continent was 46.0% in the combination group, which was significantly higher than in the solifenacin 5 mg (37.9%) and 10 mg (40.2%) groups. Patients receiving the combination were 47% and 28% more likely to achieve zero incontinence, 51% and 25% more likely to achieve a 50% or greater reduction in incontinence episodes per 24 h, and 29% and 12% more likely to achieve normalization of micturition frequency versus treatment with solifenacin 5 mg and 10 mg, respectively. The combination group was superior to the solifenacin 5 mg and 10 mg groups in the OAB-q Symptom Bother score, total HRQoL, and PPBC (details in **Table 3**). According to the responder analysis, statistically significant odd ratios were found in favor of the combination treatment versus monotherapy in the proportion of responders with a 10-point or greater improvement in the OAB-q Symptom Bother score and total HRQoL and a 2-point or greater improvement in PPBC (MacDiarmid, Al-Shukri et al. 2016) **(Table 7)**.

SYNERGY II

SYNERGY II was a phase 3 study of 1829 patients with wet OAB symptoms that demonstrated the safety and efficacy of a combination treatment (solifenacin 5 mg plus mirabegron 50 mg) over 12 months (Gratzke, van Maanen et al. 2018). Overall, 47% experienced ≥ 1 TEAE, and the incidence of TEAEs was slightly higher in the combination group (49%) than in the mirabegron (41%) and solifenacin (44%) groups. A total of 3.7% of the TEAEs were reported to be serious, and only one patient was considered to have possibly treatment-related TEAE (atrial fibrillation in the mirabegron group). Dry mouth was observed more frequently in the combination (6.1%) and solifenacin groups (5.9%) than in the mirabegron group (3.9%). Constipation occurred more frequently in the combination group (3.3%) than the solifenacin (2.3%) and mirabegron (1.0%) groups. Despite the longer treatment period, similar incidence rates for anticholinergic-associated AEs were observed after combination treatment. This study showed that the OAB-q Symptom Bother score and HRQoL total score improved significantly more with combination treatment than with either monotherapy at EoT **(Table 8)**. At EoT, the combination of solifenacin 5 mg and mirabegron 50 mg group was superior to the mirabegron 50 mg and solifenacin 5 mg groups in terms of changes in the number of incontinence episodes per 24 h (vs. mirabegron: adjusted mean difference [AMD]: –0.5, 95% CI –0.7 to –0.2, p<0.001; vs. solifenacin: AMD –0.1. 95% CI –0.4 to 0.1, p=0.002) and in the number of micturitions per 24 h (vs. mirabegron: AMD –0.5, 95% CI –0.8 to –0.2, p<0.001; vs. solifenacin: AMD –0.4, 95% CI –0.7 to –0.1, p=0.004).

MILAI

In Japan, Yamaguchi et al. conducted a multicenter, open-label, phase IV study (MILAI study) to assess the safety and efficacy of mirabegron in combination with solifenacin in OAB patients who had been treated with solifenacin 2.5 mg or 5 mg once daily for at least 4 weeks (Yamaguchi, Kakizaki et al. 2015). If at 8 weeks the patients showed insufficient response to mirabegron 25 mg, were agreeable to a dose increase, and the investigator judged that there were no safety concerns, the mirabegron dose could be increased to 50 mg. In the MILAI study, 223 patients were assigned to one of 4 groups: solifenacin 2.5 mg plus mirabegron 25 mg (n=35), solifenacin 2.5 mg plus mirabegron 50 mg (n=37), solifenacin 5 mg plus mirabegron 25 mg (n=58), and solifenacin 5 mg plus mirabegron 50 mg (n=93) for a 16-week treatment period. The overall incidence of drug-related TEAEs was 23.3%, and all TEAEs were mild or moderate. All treatments produced significant improvements in the OABSS total score, OAB-q-short-form (SF) score (Symptom Bother and total HRQoL score), mean number of micturitions/24 h, mean number of urgency episodes/24 h, mean number of UI episodes/24 h, mean number of urgency UI episodes/24 h, MVV/micturition, and mean number of nocturia episodes/night. In the mirabegron 50 mg groups, the mean OABSS total score, mean OABS-q SF Symptom Bother score, and total HRQoL score were further improved after the dose increased from 25 to 50 mg.

MILAI II

Previous combination studies involved add-on therapy of mirabegron 50 mg in OAB patients who did not respond to anticholinergic monotherapy (Yamaguchi, Kakizaki et al. 2015, Drake, Chapple et al. 2016) or concurrent use of mirabegron and anticholinergics (Abrams, Kelleher et al. 2015, Herschorn, Chapple et al. 2017). Alternatively, the MILAI II study demonstrated the long-term safety and efficacy of antimuscarinic add-on therapy in patients with OABS symptoms who had a suboptimal response to initial mirabegron monotherapy (Yamaguchi, Kakizaki et al. 2019). A total of 647 patients with residual OAB symptoms despite receiving mirabegron 50 mg once daily for at least 6 weeks were randomized to receive a combination of mirabegron 50 mg and solifenacin 5 mg (n=166), propiverine 20 mg (n=161), imidafenacin 0.2 mg (n=161), or tolterodine 4 mg (n=159) for 52 weeks (1:1:1:1 ratio). At week 8, the dose of anticholinergics (except for tolterodine) could be doubled, if a patient had a poor response to the study drugs. If a TEAE occurred after the dose escalation, the dose could be reduced to the original level. Overall, 80.2% of patients experienced at least one TEAE. Furthermore, 46.8% of patients experienced at least one drug-related TEAE, with similar incidences in all groups. Dry mouth (25.2%), nasopharyngitis (21.6%), and constipation (16.5%) were the most commonly reported TEAEs. Dry mouth (31.7%) in the mirabegron plus propiverine group and constipation in the mirabegron plus solifenacin group were slightly higher than found with the other regimens. No notable change from baseline was found for PVR in any group. Significant improvements in OABSS and OAB-q SF were observed at the first evaluation (week 4 for OABSS, week 12 for OAB-q SF) and were maintained throughout the entire 52-week treatment period. Significant improvements from baseline were observed in all of the efficacy parameters assessed using data from patient micturition diaries.

9.3.2. Antimuscarinic with vibegron

Vibegron is a novel, potent, and highly selective β3-adrenoceptor agonist. The efficacy and safety of vibegron were demonstrated in a phase III study conducted in OAB patients in Japan (Yoshida, Kakizaki et al. 2018, Yoshida, Takeda et al. 2018). The efficacy of vibegron in combination with anticholinergics can be predicted from the results of several studies combining anticholinergics with mirabegron, but the evidence is insufficient. One two-part phase IIb study assessed the safety and efficacy of vibegron as a once-daily treatment for OAB patients (part 1) and the safety, tolerability, and efficacy of vibegron administered with or without an antimuscarinic (part 2) (Mitcheson, Samanta et al. 2019). In part 1, patients received once-daily vibegron at 3, 15, 50, or 100 mg, tolterodine ER 4 mg, or placebo for 8 weeks or concomitant vibegron 50 mg plus tolterodine ER 4 mg for 4 weeks and then vibegron 50 mg for 4 weeks. In part 2, patients received once-daily vibegron 100 mg, tolterodine ER 4 mg, vibegron 100 mg plus tolterodine ER 4 mg, or placebo for 4 weeks. The combination of vibegron 100 mg plus tolterodine ER 4 mg decreased the least square mean (LSM) daily number of micturitions and urgency episodes from baseline to week 4 more than tolterodine ER 4 mg or vibegron 100 mg alone; the decrease was statistically significant ($p < 0.05$) versus tolterodine ER 4 mg. Among wet OAB patients, a numerically greater decrease in the LSM daily number of urgency incontinence episodes was observed from baseline to week 4 with the combination of vibegron 100 mg plus tolterodine ER 4 mg versus vibegron 100 mg or tolterodine ER 4 mg alone. Furthermore, a greater decrease in the LSM daily number of total incontinence episodes from baseline to week 4 was observed with a combination of vibegron 100 mg plus tolterodine ER 4 mg than with vibegron 100 mg alone (numerically) or tolterodine ER 4 mg alone ($p < 0.05$) **(Table 9)**.

9.4. Combined antimuscarinics

Although antimuscarinic agents are the first-choice treatment for patients with OAB symptoms, they do not always lead to the desired effects of detrusor stability and continence, especially in patients with spinal cord injury or neurologic diseases such as multiple sclerosis or meningomyelocele. When antimuscarinic treatments fail, invasive procedures such as the injection of botulinum toxin, electrical nerve stimulation, or augmentation cystoplasty are necessary.

Table 9. Change in average daily number of micturitions, urgency urinary incontinence episodes, total incontinence episodes, and urgency episodes from baseline to week 4 in the full-analysis set population

	Placebo	V100	TER4	V100+ TER4	Difference in LSM from V100	Difference in LSM from TER4
Number of micturitions	-1.2	-1.95	-1.16	-2.09	-0.23 (p=0.356)	-0.91 (p<0.001)
UUI episodes	-1.5	-1.71	-1.38	-1.77	-0.17 (p=0.492)	-0.53 (p=0.027)
Total incontinence episodes	-1.73	-1.98	-1.65	-1.98	-0.12 (p=0.626)	-0.51 (p=0.038)
Urgency episodes	-2.35	-2.52	-1.56	-2.68	-0.27 (p=0.400)	-1.27 (p<0.001)

LSM: least square mean, TER4: tolterodine ER 4 mg, UUI: urgency urinary incontinence, V100: vibegron 100 mg

Table 10. Clinical studies of combined antimuscarinic treatments

Study	Patients (n)	Initial antimuscarinics	Combined antimuscarinics	Efficacy results
Amend et al. (Amend, Hennenlotter et al. 2008)	NDO (27)	Oxybutynin 30 mg/day Tolterodine 2×8 mg/day Trospium 3×30 mg	+trospium 45–90 mg +oxybutynin 15–30 mg +tolterodine 4–8 mg	UI episodes decreased: 8.6±2.7 to 1.3±0.9 7.0±1.5 to 0.6±0.7 7.5±2.7 to 2.0±1.5
Nardulli et al. (Nardulli, Losavio et al. 2012)	NDO (12)	Oxybutynin 15 mg/day Oxybutynin 15 mg/day	+trospium 80 mg +solifenacin 10 mg	UI episodes decreased: 5.3to 0.8 4.5 to 1.0
Bolduc et al. (Bolduc, Moore et al. 2009)	NDO (19) OAB (14)	Tolterodine 4 mg	+solifenacin 5 mg +solifenacin 10 mg	UI episodes decreased: 100% in 17 pts > 90% in 14 pts 50–89% in 2 pts
Kosilov et al. (Kosilov, Loparev et al. 2014)	OAB (313)	Trospium 60 mg + solifenacin 20 mg (198) or placebo (115)		Significant decrease in UI episodes compared to placebo
Kosilov et al. (Kosilov, Loparev et al. 2014)	OAB (341)	Trospium 60 mg/day + solifenacin 20 (58) Trospium 30 mg/day + solifenacin 10 (55) Trospium 30 mg/day + solifenacin 10 (62)		Cyclic therapy with high-dose combination showed the most successful treatment without increase in side effects
Kosilov et al. (Kosilov, Loparev et al. 2016)	OAB & BPH (338)	Solifenacin 5 mg + trospium 5 mg + tamsulosin 0.4 mg vs. tamsulosin 0.4 mg		UI episodes decreased: 3.4 (0.8) to 0.9 (0.7)
Wang et al. (Wang, Jiang et al. 2017)	OAB (129)	Any antimuscarinic	+ oxybutynin ER (5–15 mg once a day)	All OAB symptom indexes decreased significantly

In patients who fail to respond or show suboptimal responses to antimuscarinic drugs but tolerate the treatment well, it has been shown that increasing the daily dose can lead to significant improvements in OAB symptoms. A significant decrease in incontinence episodes was observed after doubling the recommended daily doses of trospium chloride and tolterodine to 90 and 8 mg, respectively, in patients with persistent neurogenic detrusor overactivity (NDO) (Horstmann, Schaefer et al. 2006). Another non-invasive approach in patients with refractory NDO or OAB is the combination of two different antimuscarinic drugs, which has been demonstrated to be safe and effective in several clinical studies of patients with NDO (Amend, Hennenlotter et al. 2008, Nardulli, Losavio et al. 2012) or OAB (Bolduc, Moore et al. 2009, Kosilov, Loparev et al. 2014)a; b (Wang, Jiang et al. 2017) **(Table 10).**

Positive results were speculated to result from 1) synergistic activation of different muscarinic receptors or interactions with receptors on different parts of the bladder wall, 2) undiscovered increase in the metabolism of antimuscarinics requiring an increased dose of different antimuscarinic drugs, 3) down-regulation of subdivisions of antimuscarinic receptors under monotherapy that could produce better susceptibility in the other subdivisions when treated by the second drug.

A combined antimuscarinic regimen using tolterodine, oxybutynin, and trospium was evaluated as a non-invasive alternative by Amend and colleagues (Amend, Hennenlotter et al. 2008)] for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dose antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dose antimuscarinic monotherapy. After a 4-week combined regimen, incontinence episodes decreased, and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side-effects were comparable to those seen with normal-dose antimuscarinics.

Kosilov and colleagues found that cyclic therapy of high-dose solifenacin and trospium in elderly men and women with moderate or severe OAB symptoms enabled patients to maintain a longer therapeutic effect with an acceptable level of side effects (Kosilov, Loparev et al. 2014)a. They conducted another study to evaluate the efficacy of cyclic treatment with combined antimuscarinic drugs in elderly men and women with severe OAB symptoms and determined that it appeared to be effective by increasing the compliance level (76–84%). On the other hand, continuous therapy with standard doses of trospium and solifenacin resulted in low adherence and high rates of treatment withdrawal (≥ 66%), despite satisfactory clinical and urodynamic results.

The effectiveness of combination therapy with two different antimuscarinics was also evaluated in patients with severe symptoms of OAB and BPH (Kosilov, Loparev et al. 2015, Kosilov, Loparev et al. 2016). Patients in the experimental group received 2 months of treatment with a daily combination of solifenacin 5 mg, trospium 5 mg, and tamsulosin 0.4 mg. Patients in the control group received only tamsulosin. In the experimental group, the number of episodes of incontinence decreased from a moderate level of 3.4 (0.8) per day to 0.9 (0.7) per day, and most urodynamic indices normalized significantly. In the control group, changes in the urodynamic indices were not significant. The quantity of side effects did not exceed the level that is commonly found in patients receiving antimuscarinic monotherapy. Those authors concluded that a combination of trospium and solifenacin in standard doses is an efficient and safe method for managing severe OAB symptoms in patients with OAB/BPH already receiving tamsulosin (Kosilov, Loparev et al. 2016). However, in patients with OAB/BPH, the efficacy and side effects of combination therapy using different antimuscarinics should be further evaluated.

Wang CC, et al. (Wang, Jiang et al. 2017) evaluated the efficacy and safety of flexibly adding oxybutynin ER in patients with OAB refractory to monotherapy with an initial muscarinic antagonist. A total of 129 patients with persistent symptoms or partial response to 3 months of behavioral therapy and an optimized dose of one antimuscarinic agent were included. At baseline, week 4, and week 12 after the addition of oxybutynin ER (5–15 mg once a day), OAB symptom indexes, PPBC, uroflowmetry, PVR, therapeutic effect, AE, and tolerability were evaluated. Patients continuing combined antimuscarinic therapy were followed for up to 12 months. All OAB symptom indexes decreased significantly at all visits compared with baseline. A total of 32 (24.8%) and 25 (19.4%) patients reported successful therapeutic effect at weeks 4 and 12, respectively. Twenty-four (18.6%) and 44 (34.1%) patients discontinued therapy at weeks 4 and 12, respectively. However, only 31 (24.0%) patients continued the combined medication for up to 12 months. Discontinuation of the combined medication was noted in 28 (21.7%) patients due to AE and in 70 (54.3%) due to a lack of efficacy. The long-term efficacy of the combination of two antimuscarinic agents is thus limited.

9.5. α1-AR antagonists with β3-adrenoceptor agonists

Mirabegron facilitates detrusor relaxation during the storage phase of the micturition cycle and, in contrast with antimuscarinic agents, improves the storage capacity of the bladder without impairing the amplitude of the contraction during the voiding phase of the micturition cycle. In a pooled safety analysis of three phase III studies (Nitti, Khullar et al. 2013), the incidence of urinary retention was infrequent and lower in mirabegron-treated patients than in placebo and tolterodine-treated patients: placebo (n = 7; 0.5%), mirabegron 25 mg (n = 0), mirabegron 50 mg (n = 1; 0.1%), mirabegron 100 mg (n = 0), total mirabegron (n = 1; < 0.1%), and tolterodine (n = 3; 0.6%). The mean change in PVR volume from baseline to the final visit was unremarkable across treatment groups: placebo (−1.6 ml), mirabegron 25 mg (−3.0 ml), mirabegron 50 mg (−0.9 ml), mirabegron 100 mg (−0.7 ml), and tolterodine ER 4 mg (+ 0.1 ml). The proportion of patients experiencing ≥ 150 ml change in PVR volume from baseline was lower in the mirabegron groups than in the placebo and tolterodine groups: placebo (0.7%), mirabegron 25 mg (0%), mirabegron 50 mg (0.3%), mirabegron 100 mg (0.4%), and tolterodine ER 4 mg (0.8%). Although patients with a large PVR or risk of retention were excluded from those studies, as in the antimuscarinic studies of men with BPO, mirabegron can be a reasonable option for treating OAB symptoms and can be used in combination with α_1-AR antagonists in men with OAB and BPO.

Ichihara et al. (Ichihara, Masumori et al. 2015) evaluated the efficacy and safety of add-on treatment with mirabegron for OAB symptoms remaining after α1-blocker (tamsulosin) treatment for BPO. Men with urinary urgency ≥1/wk and a total OABSS ≥3 after 8 or more weeks of treatment with tamsulosin were randomly allocated to receive 0.2 mg of tamsulosin daily or 0.2 mg of tamsulosin and 50 mg of mirabegron daily. Patients with PVRs >100 ml were excluded. After 8 weeks of treatment, the change in total OABSS was significantly greater in the combination group than in the monotherapy group (–2.21 vs. –0.87, p=0.012). The changes in scores for urinary urgency, daytime frequency, IPSS storage symptom sub-score, and QoL were significantly greater in the combination group. The change in PVR was also significantly greater in the combination group, and AUR was observed in 1 patient.

Matsukawa et al.(Matsukawa, Takai et al. 2019) used a urodynamic study to compare the efficacy of fesoterodine and mirabegron as add-on therapies to silodosin in 120 men with persistent OAB symptoms despite silodosin monotherapy. Patients were randomized to receive add-on therapy with fesoterodine (4 mg/day) or mirabegron (50 mg/day) for 12 weeks. At week 12, the fesoterodine (vs. mirabegron) group showed significantly greater improvements in the OABSS-total (–2.8 vs. –1.5, p = 0.004), IPSS-QoL (–1.5 vs. –1.1, p = 0.04), and OABSS-urgency scores (–1.5 vs. –0.9, p = 0.008). Regarding storage functions, although both groups showed significant improvements, the fesoterodine group demonstrated greater improvements in the detrusor overactivity alleviation rate (52.6% vs. 28.9%, p = 0.03). Voiding functions did not deteriorate in either group; no significant inter-group differences were observed. PVRs increased significantly (by 16 mL) only in the fesoterodine group. Those authors concluded that using fesoterodine as an add-on therapy to silodosin was more effective than adding mirabegron to silodosin to improve OAB symptoms and storage functions without deteriorating voiding symptoms or functions.

9.6. α1-AR antagonists with 5a-reductase inhibitors

The Medical Therapy of Prostatic Symptoms Study (MTOPS) and Combination of Avodart® and Tamsulosin study (CombAT) demonstrated the superiority of combinations of α1-AR antagonists and 5-α reductase inhibitors over monotherapy in improving clinical outcomes and preventing symptomatic progression, AUR, and BPH-related surgery (McConnell, Roehrborn et al. 2003, Roehrborn, Siami et al. 2010). Post hoc analyses of MTOPS and CombAT data reported that combination therapy produced a significant improvement in IPSS, QoL, and nocturia (Fwu, Eggers et al. 2013, Oelke, Roehrborn et al. 2014, Roehrborn, Barkin et al. 2014). Discontinuation of 5-α reductase inhibitors after combination therapy was significantly associated with the resumption of combination therapy, progression of BPH, and need for BPH-related surgery (Lin, Liao et al. 2014). Currently, a combination of an α1-AR antagonist and a 5-α reductase inhibitor is recommended by many guidelines for men with bothersome moderate to severe LUTS, a high risk of disease progression or enlarged prostate (prostate volume > 40 mL), and high PSA. The possible disadvantage of combining α1-AR antagonists with 5α-reductase inhibitors is the increased incidence of adverse events from the concomitant effects of both classes of drugs (Fullhase, Chapple et al. 2013, La Torre, Giupponi et al. 2016). Potential side effects (e.g., ejaculation dysfunction with α1-AR antagonists or loss of libido with 5α-reductase inhibitors) might be additive and can negatively affect patient QoL, especially sexual function.

10. FUTURE POSSIBILITIES

Many potential drug targets for the treatment of OAB/DO have been explored in non-clinical and clinical research and have been reviewed elsewhere [Anderssonet al. 2018; Sacco and Bientinesi 2015]. These approaches can be grouped by route of administration such as transperineal, transrectal and transurethral (Andersson 2015) or as drugs acting peripherally or in the central nervous system, but in some cases the site of action remains unclear or.

They can also be grouped by level of evidence, for instance as negative clinical proof-of-concept data, promising animal data not yet tested clinically and targets with positive clinical proof-of-concept data. Details on some of the drugs under discussion are given below as is a critical summary of the current situation.

10.1. Drugs and targets with negative clinical proof-of-concept data

10.1.1. Prostaglandin receptor agonists and antagonists

The major prostaglandins (PG) PGD_2, PGE_2, $PGF_{2\alpha}$, prostacyclin (PGI_2), and thromboxane A_2 work on a family of receptors grouped into DP, EP, FP, IP, and TP subfamilies (Woodwardet al. 2011). Interest in prostaglandin receptors is partly based on increased urinary PGE_2 in OAB patients, but the proposed role as a biomarker of OAB has been questioned (Antunes-Lopeset al. 2014). Additional evidence comes from a demonstration of the presence of multiple prostaglandin receptors in the bladder (Ponglowhapanet al. 2010), prostaglandin receptor knock-out mice (McCaffertyet al. 2008, Molnáret al. 2021), and data with ligands of various prostaglandin receptors in animal models of OAB (Joneset al. 2009, Houet al. 2021). This section focuses on PG receptors as a drug target; enzymes involved in the generation of PGs, specifically cyclooxygenase will be covered in another section.

Intravesical installation of PGE_2 can induce detrusor overactivity (McCaffertyet al. 2008) and urine of patients with OAB contains elevated concentrations of PGE_2 (Antunes-Lopeset al. 2014).

Among the 4 subtypes of EP receptors, EP_1 and EP_3 appear to mediate detrusor contraction, whereas EP_2 and EP_4 mediate relaxation (Houet al. 2021). FP receptors also appear to mediate detrusor contraction, in some cases possibly even those of PGE_2 (Strombergaet al. 2020). PG receptors can also be found in the urothelium (Strombergaet al. 2020, Rahnama'iet al. 2010, Rahnama'iet al. 2012). They may also modulate afferent nerve activity (Schröderet al. 2004).

Based on such findings, the EP_1 receptor antagonist ONO-8539 had entered a double-blind phase II proof-of-concept study randomizing 435 patients to receive placebo or 30, 100 or 300 mg once daily ONO-8539 or 4 mg tolterodine for 12 weeks (Chappleet al. 2014). While tolterodine as positive control reduced micturition frequency (primary endpoint) by 2.18 episodes, the active treatments with all three doses reduced frequency to a similar extent as placebo (1.02, 1.53 and 1.31 as compared to 1.40). These data suggest a small if any role of EP_1 receptor inhibition in the treatment of OAB. While this does not exclude a role for other PG receptor subtypes, apparently no clinical trials for any other PG receptor modulator in OAB are ongoing.

10.2. Drugs and targets with promising animal data

10.2.1. Rho kinase and Rac1 inhibitors

Rho kinase 1 and 2 are essential enzymes in the regulation of smooth muscle contractility because of its involvement in Ca-sensitization (Frazieret al. 2008, Anjum 2018, Liet al. 2020) and also of generating the large compliance of the urinary bladder during filling (Nealet al. 2017). Inhibitors of Rho kinase such as Y 27,632, GSK 269,962 and fasudil inhibit bladder contraction in in vitro preparations from multiple species including rats, mice, guinea pigs and humans. Rho kinase is a potentially attractive target for two reasons: Firstly, rho kinase is involved in contraction elicited by a wide variety of agents including agonists at muscarinic (Frazieret al. 2008), bradykinin (Sand and Michel 2014), tachykinin (Déret al. 2019), sphingosine 1 phosphate (Anjumet al. 2017) or prostaglandin receptors (Molnáret al. 2021). Conversely, agonists relaxing bladder smooth muscle such as β_3-adrenoceptor agonists inhibit rho kinase (Cirinoet al. 2003) and combined administration of a β-adrenoceptor agonist and a rho kinase inhibitor yields greater detrusor strip relaxation (Cerneckaet al. 2015). Moreover, rho kinase

can also be activated by stretch in human bladder smooth muscle cells (Kushidaet al. 2016). Second, the expression and/or function of rho kinase are increased in pathologies associated with DO such as BOO, diabetes or in spontaneously hypertensive rats (Peterset al. 2006, Boopathiet al. 2014, Akaihataet al. 2015, Hanet al. 2015, Baeet al. 2015, Akakpoet al. 2017, Adedejiet al. 2019) and inhibition of detrusor contraction in vitro by rho kinase inhibitors is more pronounced in animal models of OAB or cystitis than in matched controls (Denizaltiet al. 2018). On the other hand, rho kinase expression is regulated in the bladder of aged subjects (Kirschsteinet al. 2014, Kirschsteinet al. 2015). Taken together, these data make rho kinase an attractive target for the treatment of OAB and cystitis.

Considering this background, the effect of rho kinase inhibitors, mostly GSK 269,962 and fasudil or hydroxy-fasudil, has been tested in rodent models of bladder dysfunction. The rho kinase parameters consistently improved cystometric parameters in a variety of OAB models including that induced by acetic acid (Wróbel and Rechberger 2017), retinyl acetate (Wróbel and Rechberger 2016, Wróbel and Rechberger 2017), corticosterone (Wróbelet al. 2018) or chronic bladder ischemia (Akaihataet al. 2018). They were similarly effective in rat models of cystitis as induced by protamine sulfate (Akinet al. 2015) or cyclophosphamide (Wróbelet al. 2017). Although the rho kinase inhibitor fasudil has been approved in some countries for clinical use in indications unrelated to the bladder, apparently no clinical studies of rho kinase inhibitors in bladder dysfunction are currently performed or have been completed.

Rac1 is a monomeric GTPase involved in similar pathways as rho kinase. Inhibitors of Rac1 such as NSC23766 and EHT1864 inhibit bladder contraction in in vitro preparations from multiple species including rats, mice and humans, and smooth muscle-specific knockout of Rac1 has similar effects (Liet al. 2020).

10.2.2. Purinergic system – P2X3 receptor antagonists

Other promising targets seem to be the purinergic [Ford and Cockayne, 2011: Ford and Undem., 2013; North and Jarvis., 2013; Andersson, 2015] and cannabinoid [Ruggieri. 2011; Hedlund, 2014; Hedlund and Gratzke 2016] systems, and different members of the TRP channel family [Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. P2X3-receptor antagonists are currently being developed for treatment of non-bladder diseases, but clinical experiences in bladder disorders have not yet been reported.

10.2.3. Opioid receptor agonists

Opioids primarily exert their effects via opioid receptors, which are subdivided into the subtypes δ, κ and μ (Coxet al. 2015). The nociception/orphanin (NOP) receptors are also considered to be part of the opioid receptor family because of structural and functional similarities to the classic opioid receptors despite low potency of naloxone, whereas sigma receptors are not. While some studies suggest that sigma receptors may play a role in the regulation of bladder function (González-Canoet al. 2020), sigma receptors are not considered here.

Studies in guinea pigs have demonstrated a considerable expression of μ opioid receptors, whereas that of δ or κ opioid or NOP receptors was lower (Zhouet al. 2016). Studies with naloxone and other opioid receptor antagonists suggest that endogenous opioids play a role in the regulation of bladder function in health and disease and for instance may mediate bladder effects of gentle mechanical skin stimulation (Hotta and Watanabe 2015) or of sacral neuromodulation (Zhanget al. 2015, Jianget al. 2016, Bandariet al. 2017, Liet al. 2017); by acting in both ascending and descending pathways, they may also contribute to the micturition reflex (Hotta and Watanabe 2015, Fujimuraet al. 2017). This may in part involve direct effect on transmission of sacral parasympathetic nerves (Chenet al. 2015).

Tramadol is an analgesic drug that is an analgesic drug that is a weak μ-receptor agonist, but its active metabolites are stronger μ-receptor agonists and also act as serotonin and noradrenaline uptake inhibitors (Minamiet al. 2015). Tramadol has been shown to inhibit bladder overactivity in rats caused by apomorphine (Pehrson and Andersson 2003) or upon cerebral infarction (Pehrsonet al. 2003). Tramadol also inhibited micturition in conscious, freely moving rats without bladder dysfunction (Panditaet al. 2003). A published double-blind, placebo-controlled, randomized study on the efficacy and safety of tramadol in 76 patients with idiopathic DO has been retracted (Safarinejad and Hosseini 2014) and no other clinical trials appear to have been performed or ongoing. The preferential μ receptor agonist naltalimide (also known as TRK-130) has shown promise in animal models of OAB (Fujimuraet al. 2014) or cystitis (Fujimuraet al. 2017) but apparently has not progressed to clinical studies. While observations with both the weak agonist tramadol and the antagonist naltalimide are interesting, they are also puzzling as they leave it open whether an opioid receptor agonist or antagonist is more promising for the treatment of bladder dysfunction.

10.3. Drugs and targets with positive clinical proof-of-concept data

10.3.1. Neurokinin receptor antagonists

The tachykinins/neurokinins substance P, neurokinin A (also known as neurokinin α, neuromedin L or substance K) and neurokinin B (also known as neurokinin β or neuromedin K) act on NK_1, NK_2 and NK_3 receptors, respectively (Alexanderet al. 2019). There are major species differences in the recognition profile of non-peptide small molecules for all three receptors, which makes the extrapolation of data from animal experiments to humans challenging.

Neurokinins (Coveñaset al. 2003) and their three receptors are found in various parts of the CNS including those involved in micturition control (Saffroyet al. 2003). Accordingly, neurokinins are modulators of the micturition reflex at the central and peripheral level, which includes effects on afferent transmission to supraspinal sites and descending inputs to the sacral parasympathetic nucleus; these effects make it plausible that tachykinin receptor antagonists should affect micturition in pathological states with little effect on normal bladder function (Lecci and Maggi 2001). Within the bladder, tachykinins in nociceptive cells that are sensitive to capsaicin (Lecci and Maggi 2001). Thus, activation of such cells releases tachykinins, which causes neurogenic inflammation. Tachykinin receptor antagonists including aprepitant, netupitant and serlopitant have been tested in animal models of bladder dysfunction and in patients. Of note, some tachykinin receptor antagonists such as aprepitant and fosprepitant have been authorized for clinical use in combination with other antiemetic agents for the prevention of nausea and vomiting associated with emetogenic cancer chemotherapy (Alexanderet al. 2019).

In a rat cyclophosphamide/lipopolysaccharide cystitis model, aprepitant reduced bladder inflammation, reduced PGE_2 and TNF-α content and expression of NK_1, EP_1, EP_2 and $P2Y_2$ receptors (Zhanget al. 2016). Similarly, aprepitant also improved inflammation, and additionally reduced micturition frequency and bladder enlargement, and increased pain threshold; in contrast to the rat study, expression of NK_1 receptors was not altered (Liuet al. 2019). In randomized,

8-week pilot study in 125 postmenopausal women with OAB with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), 160 mg q.d. aprepitant as compared to placebo significantly improved symptoms of OAB (Greenet al. 2006). Number of micturitions (primary endpoint) was reduced by 10.2 ± 17.9 % as compared to 3.3 ± 16.3% (mean difference -6.8 [95% CI -12.5; -1.1]. Number of urgency episodes was also reduced whereas a reduction in total or urgency incontinence episodes did not reach statistical significance with the given sample size and variability. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. While more than 200 other clinical studies with aprepitant have been or currently are performed in other indications, apparently none of them has a primary or key secondary endpoint related to bladder dysfunction, perhaps reflecting that aprepitant is vulnerable to several drug-drug interactions (Frenklet al. 2010).

Serlopitant apparently is a successor molecule to aprepitant. While no pre-clinical studies for serlopitant have been disclosed, a randomized, a 5-armed, double-blind, multicenter trial with 557 adults with OAB compared 0.25, 1 or 4 mg serlopitant, 4 mg tolterodine ER and placebo during an 8-week study (Frenklet al. 2010). Mean change from baseline of frequency (primary endpoint) was significantly greater for 0.25 (-1.1) and 4 mg (-1.1) serlopitant, and for tolterodine (-1.5) than for placebo (-0.5), but not for 1 mg serlopitant (-0.8), indicating lack of a clear dose-response relationship within the tested dose range. Tolterodine was also more effective than any serlopitant dose for the secondary endpoints of urgency incontinence and particularly for urgency episodes. Serlopitant was generally well tolerated and had a lower incidence of dry mouth (3.3%) as compared to tolterodine (8.8%; placebo 4.6%).

Another NK_1 receptor antagonist, netupitant, blocked excitatory effects on guinea pig L6 and S1 dorsal root ganglion cells (Zhanget al. 2012). Netupitant reduced contractions elicited by a substance P analog in isolated detrusor strips with high potency (mean pK_B D 9.24) without affecting contraction amplitude, as did the experimental NK_1 antagonist L-733,060 (Paleaet al. 2016). In an acetic acid model of OAB in guinea pigs, netupitant increased inter-contraction intervals without affecting the contraction amplitude (Paleaet al. 2016). Intravesical netupitant increased void volume and the interval between micturitions with no effects on bladder pressure (baseline, threshold, peak), but had little effects on wild-type mice (Girardet al. 2016). A phase II, multicenter, double-blind study compared an 8-weeks treatment with 3 doses of netupitant (50, 100, 200 mg q.d.) with placebo in adults with OAB symptoms >6 months (Haabet al. 2014). However, netupitant at any dose was not superior to placebo for change in number of daily micturitions at week 8 (primary endpoint) or secondary endpoints such as urinary incontinence, urge urinary incontinence, and urgency episodes. No further studies of netupitant related to bladder dysfunction have been reported.

In conclusion, animal models suggested that NK_1 receptor antagonists may have a role in the treatment of OAB, but at least the compounds tested clinically until now failed to exhibit superior efficacy relative to placebo and/or tolterodine. An alternative approach could be not to antagonize neurokinin receptors but to reduce neuropeptide release. Cizolirtine is a modulator of substance P and CGRP release in the spinal cord, most likely secondary to increased extracellular levels of noradrenaline and serotonin. A pilot study compared 200 and 400 mg b.i.d. of cizolirtine to placebo in 79 OAB patients (Martínez-Garcíaet al. 2009). Although the decrease in key OAB symptoms of incontinence and urgency episdoes was significantly greater in the active arms, adverse events were frequent (68% and 81% of the patients on cizorlitine 200 and 400 mg as compared to 39% with placebo) and most commonly of gastro-intestinal nature including dry mouth and vomiting. A follow-up study compared 800 mg q.d. cizolirtine with 15 mg oxybutynin and placebo in 135 OAB patients treated for 12 weeks (Zaturaet al. 2010). Cizolirtine was similar to oxybutynin and superior to placebo for endpoints such as number of daily voids and increase in mean voided volume; both were also superior to placebo in fraction of patients achieving fewer than 8 voids, complete dryness, or both over placebo. Cizolirtine caused fewer antimuscarinic but more gastrointestinal (nausea) and neurologic (headache and vertigo) adverse events than oxybutynin. Apparently, no additional studies have been or currently are performed.

10.3.2. Vitamin D3 receptor agonists

Epidemiological studies from multiple countries have reported inverse associations between circulating levels of vitamin D_3 and lower urinary tract symptoms. For instance, urinary flow rate was positively associated with vitamin D_3 levels (Chenget al. 2021). On the other hand, low levels were associated with urinary incontinence (Kilicet al. 2016) and such association was confirmed in other populations and persisted upon multivariate analysis adjusting for factors such as ethnicity or age (OR 1.8) (Vaughanet al. 2011). Moreover, low levels were observed in winter and during that season, but not in other seasons where levels were higher, were associated with higher OAB symptom scores (Yooet al. 2018).

Such associations are plausible based upon the observation that rat and human bladders express receptors for vitamin D (Crescioliet al. 2005). Considering this background, a pilot study reported that vitamin D_3 supplementation improved urgency incontinence (Marklandet al. 2019). Such data spawned research programs on synthetic vitamin D_3 analogs, among which a program on elocalcitol, formerly known as BXL-628 has reported the largest amount of data, not only on bladder and incontinence but also on prostate and BPH.

In human bladder smooth muscle cells, elocalcitol did not alter the expression of rho kinase I or II and neither did upon in vivo treatment of rats; however, treatment with elocalcitol delayed contractile responses in isolated bladder strips (Morelliet al. 2007). On the other hand, treatment with elocalcitol increased expression of L-type Ca^{2+} channels in detrusor smooth muscle (Morelliet al. 2008), which may lead to greater contractile responses based on the role of such channels in bladder contraction (Frazieret al. 2008). Elocalcitol improved bladder function in several rat models of OAB including acetic acid-induced overactivity (Shapiroet al. 2013) or BOO (Schröderet al. 2006, Strenget al. 2012). The latter study also found that a muscarinic agonist became more effective in elocalcitol-treated animals. Elocalcitol has improved bladder function in the cyclophosphamide rat model of cystitis (Shapiroet al. 2013). Another vitamin D_3 analog, maxacalcitol at 30 but not 15 µg/kg/d reduced detrusor overactivity in a retinyl acetate rat model of OAB (Wróbel and Rechberger 2016).

Against this background, a phase IIb, multi-center, double-blind proof-of-concept study has compared elocalcitol doses of 75 and 150 µg/d with placebo during a 4-week treatment in 308 women with overactive bladder and idiopathic detrusor overactivity (Digesuet al. 2012). The primary endpoint of this study was the change in bladder volume at first involuntary bladder contraction from baseline; this endpoint was not met. However, reductions in incontinence episodes and improvements in Patient Perception of Bladder Condition score were observed. Elocalcitol was well tolerated with no difference in adverse events as compared to placebo. Apparently,

no further clinical studies of elocalcitol or other vitamin D_3 analogs are ongoing in OAB or cystitis patients.

10.3.3. Cannabinoid system – exocannabinoids; FAAH inhibitors

The cannabinoid system consists of enzymes involved in the generation of endogenous cannabinoids such as *N*-arachidonoylethanolamine (anandamide) and 2-arachidonoyl glycerol (2-AG) and of receptors on which they act (**Fig 23**). Endocannabinoids are generated after cyclooxygenase formed arachidonic acid that is further metabolized by several enzymes including transacylase and phospholipase D. The two well-defined cannabinoid receptor subtypes are CB_1 and CB_2, but the existence of additional receptors cannot be excluded (Pertweeet al. 2010, Ruggieri 2011). Activation of peripheral CB_1 receptors is typically associated with vasodilation and regulation of via inhibition of neurotransmitter release, whereas activation of CB_2 appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions (Pertweeet al. 2010, Ruggieri 2011, van Diepenet al. 2008). The inactivation of endocannabinoids involves transporters and the enzyme fatty acid amide hydrolase (FAAH). The role of the cannabinoid system in the regulation of bladder function has been explored in healthy animals and models of three diseases, neurogenic voiding dysfunction, particularly in the context of multiple sclerosis, bladder outlet obstruction and other models of OAB, and in cystitis.

Cannabinoid system in normal bladder function

Cannabinoid receptors are found both in the brain and in the periphery including the healthy and diseased bladder (Ruggieri 2011, Hedlund 2014, Hedlund and Gratzke 2016). CB_1 and CB_2 receptors have been identified in all layers of the human bladder including the urothelium (Merriamet al. 2008, Gratzkeet al. 2009, Tyagiet al. 2009, Walczak and Cervero 2011, Ochodnickyet al. 2012, Bakaliet al. 2014). CB_2 receptor expressing nerves in the suburothelium, were found to co-express TRPV1 and/or CGRP, whereas those in the detrusor also expressed the vesicular ACh transporter, indicating that they represent cholinergic neurons.

In isolated detrusor strips from rats, monkeys or humans, the endogenous agonist anandamide and the exogenous agonists CP 55,940 or cannabinor did not affect basal tone or carbachol-induced contractions (Gratzkeet al. 2009, Gratzkeet al. 2010); however, contractions induced by field stimulation were enhanced by anandamide and attenuated by CP 55,940, indicating that these agents act predominantly pre-junctionally in isolated detrusor (Gratzkeet al. 2009, Gratzkeet al. 2010). At least at some stimulation frequencies, cannabinor reduced contraction induced by field stimulation in the presence but increased it in the absence of urothelium (Gratzkeet al. 2010). Similarly, the mixed CB_1/CB_2 agonist arachidonyl-2'-chloroethyl amide did not affect basal but attenuated field stimulation-induced tension of isolated rat detrusor strips (Blahaet al. 2016). In contrast, cannabigerol, Δ9-tetrahydrocannabivarin, cannabidiol and cannabidivarin, but not cannabichromene were reported to inhibit contraction of isolated mouse detrusor induced by acetylcholine; however, none of them inhibited contraction induced by field stimulation (Paganoet al. 2015); similarly, the mixed CB_1/CB_2 agonist Bay 59-3047 was reported to inhibit ACh- or KCl-induced contraction in rat isolated bladder strips (Chenet al. 2018). Whether these differences can be attributed to species or specific compounds under investigation cannot be determined from the present data. In guinea pig bladder, methanandamide and the CB_2-selective agonist 4-quinolone-3-carboxyamide inhibited mechanosensitive afferent fiber activity in an ex vivo preparation, an effect blocked by a CB_2 receptor antagonist (Christie and Zagorodnyuk 2021). Taken together these data indicate that cannabinoids may modulate bladder function in vitro at the levels of smooth muscle, detrusor, afferent and efferent nerves, but these observations were not made universally.

In cystometric studies in rats, anandamide, CP 55,940 and cannabinor increased threshold pressure, but micturition intervals were

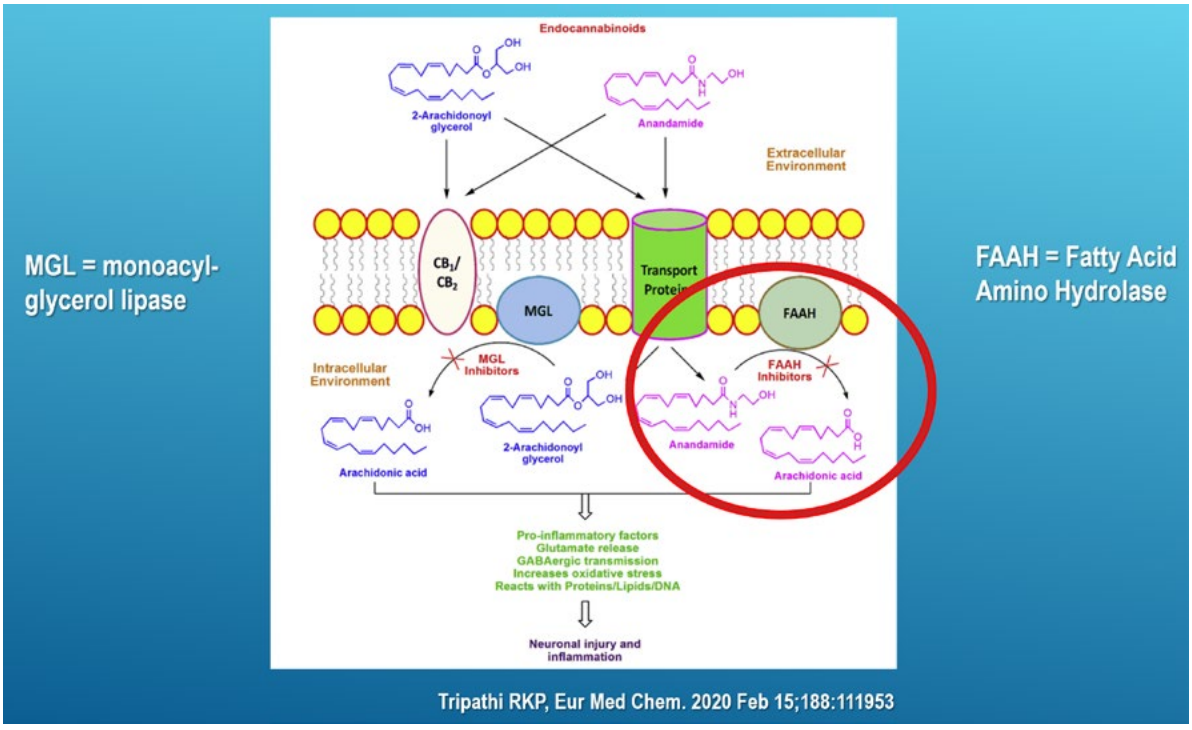

Figure 23: The cannabinoid system. From Tripathi RKP, Eur Med Chem. 2020 Feb 15;188:111953

shortened by anandamide and lengthened by CP 55,940 or a high dose of cannabinor (Gratzkeet al. 2009, Gratzkeet al. 2010). The anandamide transport inhibitor VDM11 also increased threshold pressure in rats and increased inter-contraction intervals in rats (Hondaet al. 2016). These data suggest a consistent effect of cannabinoids on threshold pressure, with effects on micturition intervals being compound specific. On the other hand, administration of the CB_1 antagonist rimonabant or the CB_2 antagonist SR 144,528 induced detrusor overactivity in healthy rats, which was counteracted by an inhibitor of fatty acid amino hydrolyse (FAAH) (Füllhaseet al. 2016). Additional evidence for a role of cannabinoids in the regulation of bladder function comes from proteomic studies comparing potential urinary biomarkers between regular cannabis users and controls (Nedumaranet al. 2017).

Multiple sclerosis

In a mouse model of spinal cord injury, cannabidiol attenuated pro-inflammatory mediators, T cell and infiltration and thermal sensitivity and failed to improve bladder function (Liet al. 2018). Nonetheless, multiple clinical studies have been performed in which patients with multiple sclerosis or other types of neurogenic voiding dysfunction were treated with cannabinoids.

Cannabinoids have been tested in randomized, placebo-controlled trials in multiple sclerosis patients. In the CAMS trial, 630 patients received 4-10 capsules (depending on body weight) of either placebo, a cannabis extract containing 1.25 mg of cannabidiol (CBD), or 2.5 mg Δ^9-tetrahydrocannabinol (THC) for 13 weeks (Freemanet al. 2006). Based on 3-day voiding diaries, placebo, extract and THC reduced number of incontinence episodes by 18%, 38% and 33%, indicating a 25% and 19% reduction relative to placebo ($p = 0.039$). Among secondary outcome parameters, pad tests were also improved by the extract and THC relative to placebo, whereas urodynamic tests and the King's Health questionnaire were not.

Several other studies assessed effects of an oromucosal spray containing a combination of 2.5 mg each of CBD and THC (nabiximols, Sativex®). Following an open-label dose finding study in which urgency, incontinence, frequency and nocturia were improved relative to baseline (Bradyet al. 2004), a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and OAB was performed (Kaviaet al. 2010). While no difference was found between treatment groups for the primary endpoint incontinence and three of the seven secondary endpoints (urgency, I-QOL and voided volume), data in favor of active treatment was observed for frequency, nocturia, overall bladder condition and patient global impression of change. Thereafter, three non-interventional studies were reported with the same preparation: In one study, 433 patients were included of which 349 exhibited a reduction of spasticity of at least 20% after 1 month and 281 after 3 months and continued the study and reported an improvement of spasticity and bladder function (Vermersch and Trojano 2016). Another post-marketing surveillance study in 102 patients observed for 40 weeks; among the 46 patients with assessments, an improvement of IPSS relative to baseline was observed (Paolicelliet al. 2016). A third non-interventional study was small (15 patients) but primarily explore effects on bladder function (Maniscalcoet al. 2018). Treatment was associated with an improvement of the OAB symptom score from 17 at baseline to 12 and a reduction of postvoid residual from 80 to 30 ml; in contrast, various cystometric parameters were not affected.

A meta-analysis of 2 randomized (Freemanet al. 2006, Kaviaet al. 2010) and one open-label trial (Bradyet al. 2004) reported a difference in 0.35 incontinence episodes between active treatment and placebo (Abo Youssefet al. 2017). A broader meta-analysis of 9 randomized studies using various cannabinoids and endpoints found an improvement of bladder function by 0.29 standard deviations for cannabis extracts [CI 0.09; 0.50] and 0.11 standard deviations for cannabinoids [CI 0.0008; 0.20] (Torres-Morenoet al. 2018). Taken together these studies suggest a moderate efficacy of cannabis extracts and cannabinoids in bladder dysfunction associated with multiple sclerosis, but the findings were not sufficiently robust to be detected in all individual studies.

OAB

Cannabinoids have been tested in various, largely rat, models of OAB. Reduced expression of CB_1 and CB_2 receptors in the detrusor was observed in Zucker diabetic fatty rats (Blahaet al. 2016) and fructose-fed rats (Chenet al. 2018), whereas an increased expression of CB_1, but not CB_2 receptors was observed in detrusor and urothelium of BOO rats (Gratzkeet al. 2011). Irrespective of such differences in receptor expression, the tested cannabinoids improved bladder function in all studies. This was observed based on detrusor strip experiments with the mixed CB_1/CB_2 agonist Bay 59-3047 in fructose-fed rats (Chenet al. 2018), and with arachidonyl-2'-chloroethyl amide in Zucker diabetic fatty rats (Blahaet al. 2016). It was also observed in cystometric in vivo experiments in rats with acute installation of the CB_1 agonist WIN 55,212-2 or the CB_2 agonist CB65 (Kimet al. 2017) or cannabinor in BOO (Gratzkeet al. 2011), with peripheral but not intrathecal administration of the CB_1 antagonist AM 251 (Jianget al. 2017) and with CP 55,940 in acetic acid-induced bladder irritation (Bakaliet al. 2016). On the other hand, the CB_1 and CB_2 antagonists AM 281 and AM 630, respectively, diminished the severity of hyperosmolar saline-induced detrusor overactivity (Juszczak and Maciukiewicz 2015)

Endocannabinoids may also work via the GPR55 receptor. One group tested O-1602, a cannabidiol analog and agonist for GPR55, in several rat models of overactivity including spontaneously hypertensive rats (Wróbelet al. 2020), rats with corticosterone treatment (Wróbelet al. 2020) and those exposed to retinyl acetate (Wróbelet al. 2020). In all three models and in one of cystitis (see below), O-1602 reduced detrusor overactivity and improved various parameters of inflammation and oxidative damage.

In conclusion, cannabinoids improved bladder function in all tested OAB models, except when administered intrathecally, indicating that they may mainly act at a peripheral level. To which extent this involves CB_1, CB_2 or GPR55 receptors, remains to be established. Clinical studies in OAB patients have not been reported to our knowledge.

Cystitis

Similar to some of the other bladder pathologies, cyclophosphamide-induced cystitis is accompanied by an up-regulation of CB_1 receptors, without changes of CB_2 receptor expression (Pessinaet al. 2015). In this model, palmitoylethanolamide acting via CB_1 receptors (Pessinaet al. 2015) and the GPR55 agonist O-1602 (Wróbelet al. 2020) improved bladder function. Similarly, in a cyclophosphamide model in mice the CB_2 agonist JWH-133 reduced micturition frequency and inflammation (Liuet al. 2020). The CB_2 agonists beta-caryophyllene and HU 308 also improved bladder function in a lipopolysaccharide-induced cystitis model in mice (Bergeret al. 2019). In contrast, intrathecal arachidonyl-2'-chloroethyl amide was ineffective in acrolein-induced cystitis in rats (Joneset al. 2015), confirming that other cannabinoids had also been inactive upon intrathecal administration in a model of acetic acid-induced bladder irritation (Jianget al. 2017)

In conclusion, cannabinoids improved bladder function in several cystitis models, except when administered intrathecally, indicating that they may mainly act at a peripheral level. To which extent this involves CB_1, CB_2 or GPR55 receptors, remains to be established. Clinical studies in cystitis patients have not been reported to our knowledge.

FAAH

The key enzyme for the degradation of anandamide and other endogenous cannabinoids, is FAAH (**Fig 24**). FAAH is expressed in the mucosa of mouse, rat and human bladder and coexpressed with CB_2 receptors (Strittmatteret al. 2012). Therefore, FAAH inhibitors have been explored as potential treatments in several models of bladder dysfunction. In healthy rats, intravenous or intravesical administration of the FAAH inhibitor oleoyl ethyl amide increased intercontraction intervals, micturition volume, bladder capacity and threshold pressure; while the CB_2 antagonist SR 144,528 abolished all effects of oleoyl ethyl amide, the CB_1 antagonist rimonabant attenuated only those on threshold pressure (Strittmatteret al. 2012).

a peripherally restricted FAAH inhibitor reduced prostaglandin E_2-induced detrusor overactivity and activation of mechanosensitive afferent nerves (Aizawaet al. 2016). In rats with bladder outlet obstruction, oleoyl ethyl amide also reduced detrusor overactivity, and similar findings were obtained the rimonabant or SR 144,528 (Füllhaseet al. 2016).

FAAH knockout mice exhibited greater increases in anandamide upon administration of cyclophosphamide than wild-type animals (Wanget al. 2015). Intravesical NGF caused detrusor overactivity in wild-type mice, which was inhibited by arachidonyl-2'-chloroethyl amide; no effect of NGF was observed in FAAH knock-out mice, but it was restored by the CB_1 antagonist AM 251 (Wanget al. 2015). The FAAH inhibitor URB 937 reduced voiding contractions in lipopolysaccharide-induced cystitis in rats and in the same doses decreased levels of anandamide, but increased those of palmitoylethanolamide (Charrua et al. 2020). Taken together, these animal data suggest that FAAH may be an attractive therapeutic target for bladder dysfunction.

10.3.4. Transient Receptor Potential (TRP) channel family – TRP channel antagonists

TRP channels constitute a large superfamily of cation selective channels. The human TRP family consists of 27 members that are divided in six subfamilies: TRPC (canonical), TRPV (vanilloid), TRPM (melastatin), TRPP (polycystin), TRPML (mucolipin) and TRPA (ankyrin) (Nilius et al., 2007). A particular characteristic of these ubiquitously expressed channels is that a wide range of physical and chemical stimuli can regulate their activation. Thus, TRP channels can act as polymodal cellular sensors that are involved in numerous sensory and homeostatic processes (Deruyver, et al., 2015). TRP channels, including TRPV1, TRPV2, TRPV4, TRM4, TRPM8 and TRPA1, are highly expressed in, but not restricted to, primary afferent neurons, but can also be found in the urothelium, some interstitial cells and detrusor muscle (Andersson, 2019a; 2019b). In the bladder, urothelial expression is well established for TRPM4, TRPV2, TRPV4 and TRPM7, but controversial for TRPA1, TRPV1 and TRPM8. Expression of TRPA1, TRPV1, TRPM8 and TRPC4 is well established on afferent nerves (**Fig. 25**) (Vanneste et al, 2021). In the LUT, TRP channels are mainly involved in nociception and mechanosensory transduction (**Fig 26**) (Vanneste et al, 2021; Andersson, 2019a; 2019b). TRP channels function as molecular sensors in urothelial cells and afferent nerve fibres and can be considered the origin of bladder sensations. TRP channels in the lower urinary tract contribute to the generation of normal and abnormal bladder sensations through a variety of mechanisms (**Fig 26**) and have demonstrated potential as targets for the treatment of LUTS in functional disorders of the lower urinary tract (Vanneste et al, 2021).

However, how these individual channels influence normal and pathological LUT function remains to be established.

10.3.4.1. TRPV1 antagonists

TRPV1 is the best-characterized member of the TRPV subfamily (TRPV1–6) and abundant information on its morphology and function in animal models, and to some extent on the clinical translation of its manipulation, is available (Nilius & Szallasi, 2014). TRPV1 is highly expressed in C-fibres innervating the urinary bladder and urethra in several mammals including rats, mice, and humans (Deruyver, et al., 2015) **(Fig 25; Fig 26).** TRPV1 has been shown to play an integral role in modulating the excitability of bladder afferents and the generation of hypersensitivity, induced by bladder inflammation (Birder et al., 2002).

In several animal models of LUT dysfunction including bladder hyperactivity in mice with lipopolysaccharide (a bacterial toxin)-induced cystitis and in rats with neurogenic bladder overactivity after spinal cord injury, selective TRPV1 antagonists have proven to be promising drug candidates for bladder overactivity and/or inflammation-induced bladder hypersensitivity (Deruyver, et al., 2015). Moreover, it has been reported in six-week-old male mice that social stress can lead to the development of OAB by the induction of TRPV1-dependent an afferent nerve activity, suggesting that TRPV1 channels can be an interesting target also for preventing the development of stress-induced OAB in children (Mingin et al., 2015). In line with these finding in animal models, Zhang et al. (2015) reported increased expression of TRPV1 in the urothelium of 21 female patients with OAB than in nine healthy controls, and the high expression of TRPV1 in the urothelium of the patients was closely correlated to OAB occurrence.

Unfortunately, it became rapidly clear that TRPV1 antagonists cause an increase in body temperature (hyperthermia) and, both in animal models and in humans (Round et al., 2011; Deruyver, et al., 2015), which limits their clinical application. However, Brown et al. (2017) conducted a phase I study I in healthy volunteers on the safety and pharmacokinetics of oral NEO6860, a modality selective TRPV1 antagonist, and found no clinically significant increase in temperature or heat pain threshold/tolerance, but a significant antagonistic effect on intra-dermal capsaicin-induced pain. Whether the new class of TRPV1 antagonists has also a beneficial effect on OAB remains to be clarified.

10.3.4.2. TRPA1 antagonists

As a mediator of inflammation and pain, TRPA1 is considered a potential target in the treatment of visceral hypersensitivity syndromes, e.g. inflammatory bowel disease, OAB, and interstitial cystitis/bladder pain syndrome (IC/BPS). TRPA1 is expressed in the bladder and particularly associated with C-fiber endings in the suburothelium that co-localize CGRP. Agonists acting at the receptor cause bladder overactivity and is suggested to play a role in mechanosensory transduction and in signaling pain (Streng et al., 2008).

A TRPA1 antagonist, HC030031, has been proven effective to ameliorate cystometric parameters in rats with bladder overactivity after spinal cord injury. In these rats, TRPA1 expression in dorsal root ganglia (DRG) was upregulated at the protein and mRNA levels and the effects of the TRPA1 antagonist could be mimicked by TRPA1 RNA knockdown (Andrade et al., 2011). In a visceral pain model, using cyclophosphamide-induced cystitis, HC030031 effectively alleviated cystitis induced bladder hyperalgesia (Deberry et al., 2014). Although these drugs show efficacy in various animal models for bladder pain and hyperalgesia (Ferrer-Montiel, et al., 2012; Kamei et al., 2018), they await clinical validation.

10.3.4.3. TRPV4 antagonists

Functional TRPV4 expression has been shown in bladder urothelial cells in mice, rats, guinea-pigs, and humans [Gevaert, et al., 2007; Deruyver, et al., 2015]. TRPV4 is located predominantly on the surface of the basal urothelial cell layers, in close proximity to the adherence junctions (Janssen, et al., 2011). *In vitro* experiments on cultured urothelial cells showed that cells from TRPV4 KO mice had attenuated Ca2+-influx and ATP release in response to stretch compared with cells from control mice (Mochizuki et al, 2009). Moreover, isolated TRPV4 KO mouse bladders showed reduced stretch-evoked ATP release (Gevaert, et al., 2007). *In vivo,* these KO mice exhibit less frequent voiding [Gevaert, et al., 2007] and larger bladder capacity (Thorneloe, et al., 2008). Moreover, intravesical infusion of GSK1016790A, a potent TRPV4 agonist, can induce bladder hyperactivity in rodents (Thorneloe, et al., 2008; Aizawa et al., 2012) and increase afferent firing of capsaicin-insensitive C-fibres in rats (Aizawa, et al., 2012). Furthermore, systemic administration of the TRPV4 antagonist HC067047 increases bladder capacity and reduces micturition frequency in a mouse model of cyxclophosphamide-induced cystitis (Everaerts, et al., 2010). These findings support the hypothesis that TRPV4 acts as a mechano-sensor in urothelial cells and activates the underlying C-fiber afferent nerves via ATP-release. Further, there is evidence that a co-administration of antagonists to both TRPV4 and TRPV1 can potentiate the effect of each drug and reduce bladder hyperactivity in a rodent model for cystitis (Charrua, et al. 2015).

Interestingly, no significant adverse effects of systemic treatment with the TRPV4 antagonists HC067047 and GSK2193874 have been reported in rodents (Everaerts et al, 2010; Thorneloe, et al., 2012). Recently, two clinical trials of GSK2798745, a highly potent, selective, orally active TRPV4 antagonist, demonstrated its safety and pharmacokinetics in healthy subjects and patients with heart falure and its efficacy for improving pulmonary gas transfer (Goyal et al., 2019; Stewart et al., 202). Although TRPV4 antagonists might eventually precipitate urinary retention (Gevaert et al., 2007), GSK2798745 would be a promssing drug candidate also for OAB.

10.3.4.4. TRPM8 antagonists

TRPM8 is activated by cool temperatures (8–25 °C) and by chemicals that provoke ‘cool’ sensations, such as menthol and icilin. As a cold sensor in the body, TRPM8 is predominantly expressed in a small subpopulation of DRG and trigeminal neurons that do not express TRPV1 (Voets, et al., 2007). TRPM8 expression was shown in a subset of small nerve fibres in the human bladder (Mukerji, et al., 2006) and DRG neurons innervating the rat bladder (Hayashi, et al., 2009).

Lashinger et al. (2008) showed that application of AMTB, a TRPM8 channel antagonist inhibited isovlumetric bladder contractions and bladder nociceptive reflex responses in the rat, suggesting that in addition to cold sensing TRPM8 may also be involved in the afferent control of micturition and nociception. Systemic application of another TRPM8 antagonist, BCTC, reduces cold stress-induced bladder overactivity in rats (Lei, et al, 2013). Ito et al. (2016) showed that TRPM8 have a role in activation of mechanosensitive C-fiber bladder afferent activity recordings in an ex vivo rat model. These experimental findings in animals propose TRPM8 antagonists as a promising therapeutic tool for OAB and hypersensitive bladder disorders.

However, systemic application of TRPM8 antagonists generally decreases deep body temperature (hypothermia) (Almeida, et al, 2012; Ito, et al., 2016), which was believed to limit clinical trials. In contrast to classical TRPM8 antagonists, KRP-2579, a novel TRPM8 antagonist, showed a suppressive effect on acetic-acid- induced bladder overactivity and associated hyperactivity of bladder mechanosensitive C-fibers without affecting deep body temperature in the rat (Aizawa et al., 2018). It has been more recently reported that KRP-5714, another novel TRP M8 antagonist, similarly can improve acetic-acid-induced bladder overactivity and the hyperactivity of mechanosensitive C-fibers of bladder afferents in anesthetized rats (Nakanishi et al., 2020). Moreover, the authors also examined the effects of KPR-5714 on voiding behavior in conscious rats with cerebral infarction and in those exposed to cold in metabolic cage experiments, and found that cerebral infarction and cold exposure induced a significant decrease in the mean voided volume and increase in voiding frequency in rats. Orally administered KPR-5714 dose-dependently increased the mean voided volume and de-

creased voiding frequency without affecting total voided volume in these models (Nakanishi et al., 2020). Furthermore, the combined administration of KPR-5714 and mirabegron or tolterodine tartrate showed the additive effects on bladder overacticity in rats with cerefral infalction or rats exposed to cold temperature, respectively (Aizawa et al., 2021), suggesting that the combination therapy of TRPM8 antagonist and β_3-adrenoceptor agonist or anticholinergic agent can be the potential treatment option for obtaining additive effects in comparison with monotherapy for OAB.

Information on effects of blocking TPM8 channels in humans is scarce. PF-05105679, a selective TRPM8 antagonist, displayed a significant inhibition of pain in the cold pressor test and had no effect on core body temperature in humans. However, an unexpected adverse event (hot feeling) was reported, predominantly perioral which in two volunteers was non-tolerable (Winchester et al., 2014). No clinical trials with TRPM8 antagonists other than PF-05105679 seem not to be available so far.

10.3.4.5. TRPM4 antagonists

The TRPM4 channel is a monovalent cation-selective channel activated by an increase of intracellular Ca2+ (Mathar et al., 2014). It is widely expressed in the body, including rat, guinea pig and human bladder urothelium and detrusor smooth muscle. TRPM4 is implicated in the regulation of many cellular processes e.g., the immune response, insulin secretion, and bladder function (Andersson, 2019a).

In vitro functional studies using guinea-pig detrusor smooth muscle preparations showed that 9-phenanthrol, a selective TRPM4antagonist, reduced spontaneous contractions as well as contractions elicited by carbachol, KCl, and nerve stimulation, indicating that TRPM4 is active at rest, regulates detrusor cell excitability and contributes to contractile activity (Smith et al., 2013a, 2013b; Hristov et al., 2016). Similar investigation using mouse detrusor smooth muscle preparations demonstrated 9-phenanthrol inhibited carbachol-induced contractions but did not inhibit contractions due to intracellular Ca2+ release evoked by the drug, suggesting that TRPM4 channels play a significant role in cholinergic signaling in detrusor smooth muscles at least in mice (Alom et al., 2019). Furthermore, Kullmann et al. (2018) investigating the potential role of TRPM4 in detrusor overactivity following spinal cord transection in mice, found that TRPM4 was upregulated in the urothelium and detrusor smooth muscle after the lesion. The spontaneous contractile activity of detrusor muscle strips in both spinally intact and spinal cord transection mice was significantly reduced.

Even if the preclinical effects of TRPM4 blockade could make the receptor an interesting target for treating detrusor overactivity, no published experiences of TRPM4 antagonists in humans seems to be available.

10.3.4.6. TRPV2 antagonists

TRPV2 is expressed in the umbrella cells of the urothelium, detrusor smooth muscle cells, and nerve fibres within the suburothelium (Yu et al., 2011; Andeersson 2019a). TRPV2 knockout mice exhibit decreased embryonic weight and perinatal viability with surviving adult mice still demonstrating reduced body weight. Behavioural assays and neurophysiological studies failed to demonstrate the necessity for TRPV2 in the detection of noxious heat or mechanical stimulation under normal or pathological conditions. These findings suggest that TRPV2 is important for perinatal viability but is not essential for heat or mechanical nociception or hypersensitivity in the adult mouse (Park, et al., 2011). In primary rat urothelial cells, Ca^{2+} influx was induced by TRPV2 activation, as well as hypotonic stimulation, which can be inhibited by tadarafil, a PDE5 inhibitor. These findings suggest that TRPV2 involves urothelical signal transduction, which can be inhibited by tadarafil (Dong et al., 2018). Increaseed mRNA expression of TRPV2 was reprted in bladder mucosal biopcy sepcimens taken from patients with Hunner type interstitial cystitis as well as patients with bladder pain syndrome, and morever, all symptoms measures correlated with TRPV2 expression (Homma et al, 2013). No study on in vivo LUT function using TRPV2 antagonists seems avaiable so far in either animals or humans. Additional work is needed to determine the role of TRPV2 in bladder function.

10.3.4.7. Summary

Abudant information on preclinical studies from animal experiments and human bladder sepecimens suggests that antagonists for several different types of TRP channels, especially TRPV1, TRPA1, YRPV4, and TRPM8, may be useful for treatment of OAB, DO, and/or bladder pain syndrome. However, so far, the transition from findings from preclinical studies to clinical application has been slow, and presently available information on the use of TRP channel antagonists in humans are restricted to Phase 1 studies on drugs intended to be used in LUT disorders, and thus proof of concept studies in humans are still lacking. (Andersson, 2019b).

10.4. Critical summary

The preceding sections show that approved treatments for OAB have clear limitations: most patients do not achieve a symptom-free state and few patients stay on treatment for long periods. Thus, there is a clear medical need for improved OAB treatments. Other conditions such as IC/BPS or UAB have no approved treatments. Thus, a clear medical need exists for novel and improved treatments of bladder dysfunction.

A critical look at the above data on emerging treatments yields two striking observations: Firstly, there are several instances where animal models looked promising but clinical proof of concept studies failed either entirely or yielded results that do not suggest an improvement over approved treatment. Examples of this include the K^+ channel opener ZD0947 (Chappleet al. 2006), the EP_1 receptor antagonist ONO-8539 (Chappleet al. 2014) or the NK_1 receptor antagonist netupitant (Haabet al. 2014). This raises questions on the translational value of the animal models we use (Erdogan and Michel 2020). A large number of animal models of OAB exist (Fry 2004, Parsons and Drake 2011). Each of them has specific advantages and disadvantages, but none of them is likely to be representative for the entire spectrum of OAB patients. This raises the question how many animal models should be studied to gain sufficient confidence in the finding that warrants proceeding to a clinical proof-of-concept study. While a specific number most likely cannot be determined, it appears wise to use animal models that represent a spectrum of pathologies and animal species. For instance, the

clinical development program for mirabegron had been based on in vivo studies normal animals with volume-induced bladder contractions, in those with acute bladder irritation caused by intravesical prostaglandin E_2 instillation,

with bladder outlet obstruction, with bladder ischemia, with cerebral infarction and in decerebrate rats and involved rats, dogs and monkeys (Michel and Korstanje 2016). Using a broad panel of models and species led to the successful clinical development of a first-in-class new OAB treatment. Robust studies should also include positive controls, such as treatments that are proven to work. This is a standard approach in clinical phase III studies for the European regulatory authorities. Including such positive controls also in animal models will provide early signals whether novel compounds not only work, but whether they are likely to provide benefit over existing treatments. Finally, it is another aspect of using multiple models that it has been estimated that at least 50% of published studies cannot be reproduced (Freedmanet al. 2015), necessitating intensive efforts to improve the robustness of preclinical data.

The second striking observation is that some compounds showed promising results in phase II data but apparently did not lead to full clinical development programs. Examples of this include the NK_1 receptor antagonist serlopitant (Frenklet al. 2010), the tachykinin release inhibitor cizolirtine (Martínez-Garcíaet al. 2009, Zaturaet al. 2010), the vitamin D_3 analog elocalcitol (Digesuet al. 2012), and cannabinoid receptor ligands (Abo Youssefet al. 2017, Torres-Morenoet al. 2018).

Clinicians and scientists may wonder why promising targets such as rho kinases, purinergic receptors or opioid receptors have not led to clinical proof-of-concept studies despite candidate compounds being available for clinical use and a generally acknowledged medical need for improved treatment options. They may also wonder why compounds with positive proof-of-concept data have not proceeded to full clinical development programs. An obvious answer is lack of commercial promise. Given that most OAB drugs currently are or shortly will become available as cheap generic drugs, the investment in a full clinical development program (easily several hundred million dollars) is only considered promising if the novel treatment has a reasonable chance to be better than existing treatments, preferably regarding efficacy (Michel 2020). Accordingly, it appears that major pharmaceutical companies have discontinued discovery and development programs in the field of OAB.

An additional answer could be due to the original definition of OAB as an “initial diagnosis”, mostly likely representing a range of different pathologies (Abramset al. 2002) that may require different treatment approaches. Therefore, it has been argued that it is a key task of future OAB research to identify subsets of patients with specific underlying pathologies (Michel 2020). These can be used to develop corresponding biomarkers that allow identification of such subgroups for inclusion into clinical trials and, eventually for treatment allocation in a physician office. A drug that is highly effective in a small subset of patients may be valuable for that subset but will not look promising in a general OAB cohort. Thus, identifiable subsets of OAB patients will allow more targeted approaches with a reasonable expectation to yield superior success in those subgroups.

V. DRUGS USED TO TREAT OF STRESS INCONTINENCE IN WOMEN

The pathogenesis of stress urinary incontinence (SUI) in women includes any of the following factors: compromised urethral function, damage to urethrovaginal support, and increased abdominal pressure that puts above normal demands on the continence system [Lemack and Carmel, 2021]. In the Research on Stress Urinary Incontinence (ROSE) study, maxial urethral closure pressure (MUCP) was the factor most strongly associated with SUI [DeLancey et al, 2008]. The loss of sphincteric function and the resultant decreased urethral closure pressure can be increased to achieve continence through a variety of pharmacologic pathways [Hillary et al., 2015].

Factors which contribute to urethral closure include urethral smooth and striated muscle tone and the passive properties of the urethral lamina propria, particularly its vasculature. The relative contribution of these factors is still debatable; however, there is evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by noradrenaline [Andersson and Wein, 2004]. Another contributing factor to SUI in postmenopausal women is decreased mucosal function from low estrogen levels. The pharmacological treatment of SUI increases urethral smooth and striated muscle tone either directly or indirectly. The drugs studied in the treatment of female SUI include α-adrenoceptor agonists, β-adrenoceptor antagonists, β-adrenoceptor agonists, and serotonin-norepinephrine uptake inhibitors; however, the relative lack of efficacy and/or adverse events (AEs) from these drugs have limited their clinical use [Andersson, 2021].

Drugs used in the treatment of stress incontinence in women. Assessments according to the Oxford system (modified)

Drug	Level of evidence	Grade of recommendation
Duloxetine	1	B
Imipramine	3	D
Clenbuterol	3	C
Methoxamine	2	D
Midodrine	2	C
Ephedrine	3	D
Norephedrine (phenylpropanolamine)	3	D
Estrogen	2	D

1. α-ADRENOCEPTOR AGONISTS

Several agonists with effects on peripheral α-ARs have been used in the treatment of SUI. Noradrenaline (NA) is an a_1-AR agonist that acts on the human bladder neck [Michel and Vrydag, 2006]. Also, NA has been shown to act centrally by increasing the excitability of the urethral rhabdosphincter within Onuf's nucleus, an effect due to α_1-AR dependent depolarization [Yashiro et al., 2010]. This central action by NA is the mechanism by which SUI is improved with NA reuptake inhibitors. Norephedrine (phenylpropanolamine or PPA) has been the α-AR agonist used most widely for SUI treatment [Andersson, 2021]. The United States Agency for Healthcare Policy and Research Guidelines in 1992 evaluated 8 randomized controlled trials (RCTs) with PPA at a dose of 50 mg twice daily for female SUI [Agency for Healthcare Policy and Research, 1992]. Dry rates with PPA were listed as 0% to 14%, urinary incontinence reductions were 19% to 60%, AEs were 5% to 33%, and dropouts were 0% to 4%. The most recent Cochrane review on the use of α-AR agonists in the treatment of female SUI identified twenty-two RCTs, 11 of which were crossover trials, and 673 women received an adrenergic drug (PPA in 11 trials, midrodrine in 2 trials, and norepinephrine in 3 trials) [Alhasso et al., 2008]. The authors concluded, "there was weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of SUI episodes". Furthermore, over 25% of the subjects reported AEs with α-AR agonists; however, when these were due to AR stimulation, they caused discontinuation in only 4% of the subjects.

Both ephedrine and PPA lack selectivity for urethral α-ARs and both can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson, 2021]. Kernan et al. reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant (95% CI, 1.51 to 182.21; p=0.02) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (95% CI, 0.86 to 11.46; p=0.08) [Kernan et al 2000]. There was no increased risk of stroke in men taking PPA. Although PPA was removed from the market in the United States, it is still used as a SUI treatment in a few countries. Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some had suggested that the sale of these compounds as a dietary supplement be restricted or banned [Bent et al., 2003]. In December 2003, the US FDA decreed such a ban, a move which has survived legal appeal. Recently, Balk et al published a systematic review and network meta-analysis (commissioned by the US AHRQ) of clinical outcomes in women with SUI treated with pharmacotherapy (32 RCTs), and they concluded that there was no difference in cure rates with α-AR agonists compared to no treatment [Balk et al., 2019]. They also found that behavioral therapy was more effective than α-AR agonists (OR, 2.50 [CI, 1.39 to 4.50]). Thus, the effectiveness of α-AR agonists as treatment for SUI in women is moderate at best, and its clinical usefulness remains limited by significant cardiovascular AE.

Many investigators have attempted to develop α-AR agonists with more selectivity for the human urethra. Musselman et al in 2004 reported on a phase 2 study with a peripheral active selective $\alpha_{1A/1L}$-AR partial agonist in 37 women with mild to moderate SUI [Musselman et al, 2004]. Use of the drug after 4 weeks resulted in a lower mean weekly number of SUI episodes compared to placebo (8.4 vs 6.0, p=0.0079); however, despite no difference in blood pressure in the patients given the drug, the drug was not efficacious in subsequent SUI trials. Subsequently, Conlon et al. studied PF-3774076, a partial α_{1A}-AR agonist, in female dogs, and although peak urethral pressure increased dogs and although the drug was selective, subsequent heart rate and blood pressure changes from the drug caused significant concern [Conlon et al., 2009]. Also, Furuta et al. reported that medetomidine, an α_2-AR agonist, inhibited the release of glutamate presynaptically in the spinal cord of female SCI rats [Furuta et al., 2009]. In addition, this α_2-AR agonist potentiated the effects of serotonin/norepinephrine reuptake inhibitors on the EUS, and they proposed that α_2-AR antagonists could be useful as a treatment for SUI; however, this awaits further testing in humans. Finally, Robinson et al. published a phase 2 placebo-controlled trial evaluating PSD503, a topical gel containing phenylephrine 20%, applied vaginally near the urethral sphincter in women with SUI [Robinson et al., 2011]. Only 14 patients were recruited out of a goal sample size of 30. There was a greater median absolute reduction in pad weight gain in patients using topical phenylephrine gel compared to placebo, 22 g vs 10 g. There were no adverse events. Despite the positive effects of PSD503, the poor study accrual suggests that this treatment may not be widely accepted by women.

In summary, it remains to be seen whether increases in urethral tone to a level where patient benefit and long-term compliance is reported can be achieved in the absence of significant cardiovascular events with either full or partial α-AR agonists. Furthermore, none of the α-AR agonist trials reported on whether women who benefitted from treatment continued after the trial period. There is no biological reason to suggest that the desired effect in treating SUI would persist after stopping treatment.

2. β-ADRENOCEPTOR AGONISTS

Although β-AR stimulation results in a decrease urethral pressure [Andersson, 1993], β_2-AR agonists have been reported to increase the contractility of some fast- contracting striated muscle fibers and suppress that of slow contracting muscle fibers [Fellenius et al.,1980]. Some β-AR agonists also cause skeletal muscle hypertrophy, more so in fast twitch than slow twitch fibers [Kim et al., 1992]. Clenbuterol, a selective beta 2-adrenoceptor agonist, was reported to potentiate the field stimulation induced contraction in rabbit isolated periurethral muscle preparations [Kishimoto et al, 1991]. Propranolol suppressed the action of clenbuterol, and the potentiation produced by clenbuterol was greater than that of isoproterenol. These authors were the first to report an increase in urethral pressure with clenbuterol, and they speculated on its potential for the treatment of SUI. Yaminishi et al. studied the contractility of the urethral sphincter of female dogs, and sphincteric fatigue was produced by electrically stimulating the pudendal nerves at 15 V and 20 Hz for 30 to 40 minutes [Yaminishi et al. 1994]. Clenbuterol, given to 17 dogs with sphincteric fatigue, increased the contracting pressure, and propranolol abolished the effect. Clenbuterol had no effect in 9 dogs with non-fatigued urethral sphincters.

These results suggest that clenbuterol act on fast-contracting fibers in the urethral sphincter.

Yasuda et al. described the results of a multicenter, double blind, placebo-controlled trial with clenbuterol in 165 women with SUI [Yasuda et al. 1993]. Women were included if they had 1-2 leaks/day over 3 days and if the urine loss was 2 g or more on a pad test. Patients were randomized to receiving either clenbuterol or placebo daily over 2 weeks. Positive statistical significance was achieved for subjective evaluation of SUI frequency, daily pad usage, and overall global assessment in women receiving clenbuterol compared to placebo. Yet, the difference in baseline pad weights 11.7± 17.9g for clenbuterol and 18.3± 29.0g for placebo) raises questions

about the comparability of the 2 groups. Also, women receiving clenbuterol saw an increase in MUCP of only 3.3 cm H_2O (from 46.0± 18.2 cm H_2O to 49.3± 19.1 cm H_2O). In those receiving clenbuterol, finger tremors were seen in 8/82 (9.8%), and tachycardia was seen in 2/82 (2.4%). The authors concluded that clenbuterol enhanced the striated periurethral sphincter muscle. Ishiko et al. 2000 randomized women with SUI to receive either clenbuterol 20 µg BID, pelvic floor exercises, or both over 12 weeks [Ishiko et al. 2000]. The frequency and volume of SUI and the patient's own impression were used as the basis for the assessment of efficacy. Sixty-one women completed the study, and over half of the patients had mild SUI, defined as < 5 stress leaks/week. No SUI (dry rate) was seen in 76.9% who received clenbuterol (n=13), 52.6% who did exercises (n=19), and 89.5% who did both (n=19), p=0.036. Mild AEs during treatment were reported in 5 patients (numbness and tremor), but none of them were severe enough to discontinue treatment. No subsequent published reports have appeared on the treatment of female SUI with clenbuterol or any β-AR agonist. Larger, well-designed, RCTs investigating the effects of β-AR agonists are needed to adequately assess its potential as a treatment for SUI.

3. β –ADRENOCEPTOR ANTAGONISTS

The theoretical basis for the use of β-AR antagonists in the treatment of SUI is that the blockade of urethral β-ARs may potentiate the effects of noradrenaline on urethral α-ARs. A few studies dating back several decades reported success in treating female SUI with propranolol [Gleason et al. 1974; Kaisary, 1984]. In the Gleason study, the beneficial effects didn't manifest until after 4 to 10 weeks of treatment, a difficult to explain pharmacological phenomenon. Also, Donker and van der Sluis reported that β-AR blockade with iv propranolol and sotalol did not change urethral pressure profile (UPP) in normal women [Donker and van der Sluis 1976]. Although initially suggested as an alternative to α-AR agonists in women with SUI and hypertension, β-AR blockers like propranolol have major potential side effects including heart failure and increased airway resistance. There have been no recently published large RCTs to date supporting the use of β-AR blockers for women with SUI.

4. SEROTONIN-NORADRENALINE UPTAKE INHIBITORS

4.1. Imipramine

Within the urethra, it is thought that imipramine inhibits the re-uptake of noradrenaline and serotonin in adrenergic nerve endings to enhance the contractile effects of noradrenaline on urethral smooth muscle. As such, imipramine has been studied as a treatment for SUI. In an open-label study of 30 women with SUI treated with imipramine 75 mg daily 21women achieved subjective continence, and the mean maximal urethral closure pressure (MUCP) increased from 34 to 48 mm Hg [Gilja et al. 1984]. Furthermore, 35% of the women were reported as cured by pad test. The efficacy of imipramine 25 mg TID was assessed in another open-label study of 40 women with SUI [Lin et al. 1999]. A 20-minute pad test and urodynamics were performed in each woman before and after treatment. After 3 months of treatment, 35% (n=14) were cured and 25% (n=10) improved by ≥50%, resulting in a total of 60% achieving efficacy (95% CI 11.8-75.2). The MUCP was 77 cmH_2O for the treatment success group vs 40 cmH_2O in the treatment failure group (p< 0.0001). The authors concluded that high pre-treatment MUCP served as a predictor of pre-treatment success. More recently, Kornholt et al investigated whether imipramine increased opening urethral pressure [Kornholt et al. 2019]. In a randomized, double-blind, placebo-controlled study of 16 healthy women without SUI where urethral pressure was measured before and 1 hour after receiving either imipramine 50 mg or placebo, imipramine increased urethral pressure by only 6.5 cmH_2O (p=0.07). The authors concluded that the increase in urethral pressure after imipramine was neither statistically significant nor clinically relevant. There have been no recently published RCTs on the use of imipramine in women with SUI.

4.2. Duloxetine.

Duloxetine hydrochloride is another centrally-mediated norepinephrine and serotonin reuptake inhibitor well-studied as a treatment for SUI. Duloxetine was initially studied in a cat model of bladder irritation using acetic acid (Thor and Katofiasc 1995). When these cats were pretreated with duloxetine, urethral sphincteric muscle activity increased 8-fold during bladder storage. This sphincteric effect was reversed by α1-AR and serotonergic antagonists. Serotonin and noradrenaline terminals are particularly dense within the pudendal nerve neurons in Onuf's nucleus in the sacral spinal cord (Fig 17), and activation of these terminals releases glutamate to cause contraction of the urethral rhabdosphincter [Thor and de Groat 2010].

Several RCTs have demonstrated efficacy with duloxetine as a treatment of SUI in women. Dmochowski et al published the first phase 3 RCT of 683 women in North America randomized to either duloxetine 40 mg BID (n=344) or placebo (n=339) for 12 weeks [Dmochowski et al. 2003]. Primary outcome variables included 50-100% decrease in weekly incontinence episode frequency (IEF) and the total score on the incontinence quality of life questionnaire (I-QOL). There was a significant decrease in IEF with duloxetine compared with placebo (50% vs 27%, p < 0.001), and there were significant improvements in quality of life (11.0 vs 6.8, p<0.001). With respect to AE, nausea was seen in 22.7% of women receiving duloxetine versus 2.1% receiving placebo, p<0.001. Nausea was reported in most within 2 days, and the nausea was mild to moderate in severity in 87% of the subjects. Eventually, 6.4% of the women receiving duloxetine discontinued due to nausea. The discontinuation rate for adverse events was 24% for duloxetine compared to 4% receiving placebo, p<0.001. To reduce the risk of nausea, Hashim and Abrams proposed beginning with a dose of 20 mg BID for 2 weeks, then increasing to 40 mg BID [Hashim and Abrams 2006].

A Cochrane review of duloxetine as treatment for women with SUI was performed in 2005, and included 9 primary studies and 6 additional reports related to 1 or 2 of the primary studies [Mariappan et al. 2005]. The definition of treatment response used in most of these studies was a 50-100% decrease in IEF. The authors summarized their results as follows. Subjective "cure" in women receiving duloxetine 40 mg BID was higher than in those receiving placebo (10.8% vs 7.7%, overall RR = 1.42; 95% CI, 1.02-1.98; p = 0.04). Objective cure data, available from only the 1 study by Norton et al which utilized stress pad test, showed no clear drug vs. placebo difference [Norton et al. 2002]. Yet, duloxetine showed greater improvement in I-QOL with the weighted mean difference of .45 for the 80 mg dose (95% CI 2.83-6.18, p<0.00001). With respect to AE, nausea was the most common with an incidence of 23-25%, and nausea was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness, and insomnia. In a subsequent systematic review, the same authors stated that further research was needed to determine if duloxetine was clinically effective and cost effective compared to other

surgical SUI treatments and whether there was sustained efficacy with acceptable tolerability [Mariappan et al. 2007].

Mound et al. (2017) considered the benefits and harms of duloxetine for the treatment of SUI in women. They performed a meta-analysis of 4 placebo-controlled studies, the reports obtained from the European Medicines Agency (EMA). Duloxetine was more successful than placebo in terms of percentage change in weekly UI episodes (mean difference 13.5%) and numeric change from baseline (-2.85) and IQOL total score, but the effect sizes were small. A sensitivity analysis (with removal of one trial) showed that the number needed to treat for a Patient Global Impression of Improvement rating of "much better or very much better" was 8. The number needed to harm was 7 discontinuing because of an AE and 7 (95% CI 6 to 9) for experiencing an activation event (agitation, euphoria, anxiety, mania, irritability, akathisia). There was no report of suicidality or violence, but 2 patients (of 958) experienced a total of 5 serious AE potentially predisposing to suicidality ("the harm outweighed the benefits").

Duloxetine has been studied against pelvic floor muscle training (PFMT) alone and in combination. Ghoniem et al randomized 201 women with SUI to 1 of 4 treatments: duloxetine alone at 40 mg BID (n=52), PFMT (n=50), duloxetine and PFMT (n=52), and sham PT with placebo (n=47) [Ghoneim et al. 2007]. The primary outcome measure was IEF, and other efficacy measures included number of pads used/day and I-QOL scores. Overall, duloxetine with or without PFMT was superior to PFMT alone or placebo, and greater improvements in pad numbers and I-QOL were seen in women receiving both duloxetine and PFMT compared to duloxetine alone. The authors concluded that that the complementary modes of action seen with using duloxetine and PFMT together may result in an additive effect in treating SUI. More recently in 2021, Hagovska et al reported their findings from the DULOXING study where 158 women were randomized to either duloxetine 40 mg BID alone (n=79) or to duloxetine 40 mg BID with PFMT [Hagovska et al. 2021]. The study was conducted over 12 weeks, and primary endpoints involved the assessment of IEF/week and results from the International Consultation on Incontinence Questionnaire short form (ICIQ-SF). The I-QOL and PGI-I were used as secondary measurements. PFMT was performed by a physiotherapist over 5 sessions utilizing lumbopelvic stabilization, and the patient performed pelvic floor exercises 5 times/week for 30 minutes. The physiotherapist checked pelvic floor muscle strength and endurance. After 12 weeks, the groups receiving both duloxetine and PFMT saw a 66.7% decrease in IEF/week and the group receiving duloxetine alone saw a 50% decrease in IEF/week, p<0.001. Also, significant differences (p<0.001) favoring the group receiving duloxetine and PFMT were seen with ICIQ-SF, I-QOL, and PGI-1. There were no significant differences in AEs between the 2 groups. Fatigue was the most common side effect seen, and it was seen in 9.2–9.3% in both groups. Nausea was seen in 3.1-4.6% in both groups. The authors concluded that the addition of PFMT to duloxetine greatly improved SUI symptoms in women.

The conitnued use of duloxetine in women as an alternative to SUI surgery has also been studied. Cardozo et al performed an 8-week placebo-controlled RCT of 109 women with SUI given either duloxetine 40 mg BID (n=55) or placebo (n=54) [Cardozo et al 2004]. All subjects had IEF of 14/week or more, SUI was demonstrated on urodynamics, and all had continence surgery already scheduled. At the end of the study, 20% of the women that received duloxetine were no longer interested in surgical treatment for their SUI. All duloxetine responses were observed within 2 weeks; however, 33% discontinued duloxetine because of AEs with nausea seen as the most common. Duckett et al offered duloxetine 40 mg BID to 33 women with SUI and without prolapse awaiting a tension-free vaginal tape (TVT) operation [Duckett et al 2006]. After 4 weeks of duloxetine use, 24% of the women came off the waiting list; however, 48% discontinued duloxetine because of AEs.

The use of duloxetine to treat SUI in elderly women has been investigated. Schagen van Leeuwen et al. studied the efficacy and safety of duloxetine in women 65 years or older with SUI or stress-predominant MUI [Schagen van Leeuwen et al. 2008]. Women in this 12-week, double-blind study were randomized to either duloxetine starting at 20 mg BID for 2 weeks then increasing to 40 mg BID (n=131) or placebo (n=134). Patients receiving duloxetine had a 52.5% decrease in mean IEF/week compared to patients receiving placebo which had a 36.7% decrease in mean IEF, p<0.001. Furthermore, the responder rate (≥50% reduction in IEF/week) was 57.1% in the duloxetine group and 35.2% in the placebo group, p<0.001. Compared to placebo, duloxetine better improved I-QOL total score (p<0.001) and PGI-I (p<0.001). With respect to AEs during active treatment, there was no statistically significant difference in treatment emergent AEs between the 2 groups, p= 0.210. Nausea was seen in only 7.5% in patients receiving duloxetine versus 3.1% of patients receiving placebo, p=0.169, and this was attributed to the lower starting dose. The authors concluded that duloxetine is safe and effective as a treatment of SUI in elderly women.

Several studies have evaluated compliance with long-term duloxetine use. In a study sponsored by Lilly, Bump et al assessed the maintenance of efficacy of duloxetine 40 mg BID beyond 3 months using data from several long-term, open-label studies [Bump et al. 2008]. Data from 1424 patients enrolled in three 12-week, placebo-controlled clinical trials and their uncontrolled, open-label extensions, and in one uncontrolled, openlabel study were used to assess long-term continuation rates and continued efficacy based on responses to the validated PGI-I scale for up to 30 months. The duloxetine continuation rate at 1 year was 42.5%. After 30 months, only 368 patients remained on treatment. Of those that continued treatment beyond 1 year, 83% of patients at 24 months and 88% of patients at 30 months rated their incontinence in one of the three 'better since starting treatment' PGI-I categories. The authors admitted that the results needed to be interpreted cautiously because many patients discontinued duloxetine and those with better responses were more likely to continue taking the drug. Vella et al reported on a cohort of 228 women prescribed duloxetine and followed beyond 1 year of treatment [Vella et al. 2008]. Seventy-one of the women (31%) continued beyond 4 weeks of treatment, of which 103 stopped because of AEs and 54 stopped because of lack of efficacy. Furthermore, only 12% were taking duloxetine at 4 months, 10% remained on duloxetine at 6 months, and 9% were on duloxetine at 1 year. In addition, the authors reported that 1 year later, 187 (82%) women had either undergone a TVT procedure or were awaiting the procedure. Overall, 56% discontinued due to AEs and 33% stopped due to lack of efficacy. The authors concluded that persistence with long-term duloxetine was low due to poor tolerability and due to the option of effective surgical procedures which offers a more definitive form of treatment.

Duloxetine at a dose of 40 mg BID remains approved in the European Union for the treatment of SUI in women with moderate to severe incontinence (defined as 15 or more episodes per week). The use of duloxetine for the treatment of SUI was withdrawn from the US FDA consideration process, but it is approved for the treatment of major depressive disorder, generalized anxiety disorder, fibromyalgia, diabetic peripheral neuropathic pain, and chronic musculoskeletal pain. Also, the product information for duloxetine contains a "black

box" warning of "increased risk of suicidal thinking and behavior in young adults taking antidepressants for major depressive disorder and other psychiatric disorders", and the product information states that "depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide" [Prescribing Information, revised 2019, Eli Lilly and Company, Indianapolis, Indiana 46285]. AEs for the 6801 duloxetine and 4487 placebo treated patients reported in the product information for duloxetine in the FDA approved treatments mentioned are nausea (24% vs 8%), dry mouth (13 vs 5), fatigue (10 vs 5), somnolence (10 vs 3), insomnia (10 vs 6), constipation (10 vs 4), and dizziness (10 vs 5).

In their review of the medical management of urinary incontinence, Shaban et al concurred with the UK NICE guidelines that duloxetine was an optional second-line treatment for women with SUI not willing or unfit for surgery after discussion of the significant side effects [Shaban et al. 2010]. Robinson and Cardozo expressed similar sentiments by stating that whilst duloxetine may be useful in patients who are reluctant to undergo surgery or who have significant co-morbidities and whilst it may lead to a significant reduction in IEF, the actual 'dry' rates remain considerably lower than following continence surgery [Robinson and Cardozo 2010]. In conclusion, further research utilizing both patient-reported outcomes and cost-effective analysis, is needed to decide how to best incorporate duloxetine into the treatment of women with SUI.

VI. DRUGS USED TO TREAT STRESS INCONTINENCE IN MEN

The pharmacologic treatment of male SUI, most commonly for post-prostatectomy incontinence (PPI), is directed primarily at treating intrinsic sphincteric deficiency as the most important factor maintaining continence in men is sphincteric function [Salvatore et al. 2017]. Unlike in women, loss of urethral support is not a factor in men with SUI. The internal urethral sphincter extends from the

bladder neck through the prostatic urethra. Its function is damaged during prostate surgery, and during radical prostatectomy the internal urethral sphincter is removed. The external urethral sphincter begins distal to the prostate at the membranous urethra and includes the rhabdosphincter (intrinsic skeletal and smooth muscle) and the extrinsic paraurethral skeletal muscle. Damage to the parasympathetic and somatic innervation of the smooth and striated muscle contributes to male SUI after prostatectomy indirectly. Furthermore, compromise of the sphincter support mechanism or post-operative changes such as fibrosis compromises sphincter function.

While the majority of men experience urinary incontinence immediately following prostatectomy, in most this is transient and gradually improves with time. Approximately, 20-27% of men with SUI after prostatectomy achieve immediate continence after urethral catheter removal [Menon et al. 2007]. PFPT recommended as first-line treatment for PPI and performed under the supervision of a physiotherapist with or without biofeedback, is thought to improve urethral stability and increased urethral closure pressure during exertion [Arroyo Fernandez et al. 2015]. Pharmacotherapy for male SUI has been studied as a conservative option before moving onto surgical therapies like artificial urinary sphincter and male sling. Yet, with advancing age there is evidence of rhabdosphincter atrophy and neural degeneration [Burnett and Mostwin 1998]. As such, treatment of male SUI is challenging with drugs that work best with an intact sphincteric apparatus.

Tsakiris et al. published a systematic literature review on pharmacotherapy for male SUI [Tsakiris et al. 2008]. The authors identified nine studies that provided evidence for the use of α-AR agonists, β2-AR agonists, and serotonin-noradrenaline reuptake inhibitors in the treatment of male SUI. Regarding treatment of male SUI with α-AR agonists (ephedrine, phenylpropanolamine, midodrine), all 3 studies were conducted in small populations with a mixture of men and women, and the authors were not able to conclude whether the drugs were effective or not. As for treatment with β2-AR agonists, there was one study of 14 men with SUI after radical prostatectomy treated with clenbuterol 20 mg BID, and 9 men (64%) had improvement in pad scores. [Noguchi et al. 1997]. The drug studied most in the treatment of male SUI is duloxetine.

Kotecha et al searched for articles on the use of duloxetine for the treatment of male SUI published between inception of review to June 2020, and they identified eight studies (n=348 men) for review: 2 RCTs, 1 randomized, non-controlled trial, 4 prospective cohort studies, and 1 retrospective cohort study [Kotecha et al. 2021]. Duloxetine was assessed in two scenarios: (1) early use in two studies (the RCTs) to reduce the time to attain continence following catheter removal after radical prostatectomy and (2) treatment of persistent PPI in six studies after failed PFPT starting at least 6–12 mo after surgery. The primary outcome measures reported in these studies included improvement in urinary incontinence as measured by the number of pads/day, pad weight, dry days, Likert scales, and/or QOL questionnaires. Both RCTs included a comparison arm where patients received either duloxetine and PFPT (n=78) or placebo and PFPT (n=92) [Filocamo et al. 2007] [Alan et al. 2014]. Both RCTs reported an earlier return of continence in those treated with duloxetine and PFPT with dry rates of 78% (compared with 52%) at 4 months and 96.5% (compared with 87%) at 1 year. Only the RCT by Alan et al reported subjective outcomes with the ICIQ-UI SF, and they reported a 48.7% improvement in total score. The other six studies reported that duloxetine was effective in treating PPI, but there was considerable heterogeneity in the outcome measures reported. The mean dry rate of 42% was reported in three studies. In addition, the mean pad number improved by 52%, and the mean 1-h pad weight was significantly improved by 53%. Of the studies with the longest follow-up (9 months), Collado Serra et al noted persistent benefit with duloxetine, with 65% being pad free at 9 months compared with only 37% at 3 months [Collado Serra et al. 2011]. Unfortunately, the lack of a control group meant that the additional benefit of duloxetine above the natural rate of expected continence recovery was unknown. As for AE rates between the eight studies, fatigue, somnolence, and nausea were the most common and reported in 18% of the men. These AEs led to discontinuation of duloxetine in 21%, and the overall discontinuation (due to AEs and lack of efficacy) rate was 38%. The authors highlighted the need for further randomized trials with longer follow-up and consistent outcome reporting measures. Usage of duloxetine for male SUI remains universally off label.

A drug for the treatment of male SUI that demonstrates efficacy and tolerability would be welcome. Yet, larger, placebo-controlled, RCTs with much longer follow-up are necessary to determine the role of pharmacotherapy in men with SUI.

VII. DRUGS TO TREAT UNDERACTIVE BLADDER/ DETRUSOR UNDERACTIVITY

The symptom diagnosis of underactive bladder (UAB) and the urodynamic diagnosis of detrusor underactivity (DU) describe states with a complex pathophysiology and clinical presentation. UAB and DU had been poorly defined in the past (Chapple et al. 2015), but progress towards a consensus has evolved recently (Smith et al. 2020). The identification of UAB and DU has become even more complex by the recognition that underactive and overactive bladder can coexist, with and without detrusor overactivity and underactivity (Mancini et al. 2020). Moreover, UAB can coexist with SUI (Shapiro et al. 2020). Two recent systematic reviews in the field concluded that clinical studies in the field are largely of poor quality (Colaco et al. 2018, Osman et al. 2018).

UAB is characterized by a slow urinary stream, hesitancy, and straining to void, with or without a feeling of incomplete bladder emptying sometimes with storage symptoms (Drake 2018). The International Continence Society has defined DU as a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span (Abrams et al. 2002). While this remains the only generally accepted definition (Osman et al. 2018), it does not provide quantitative guidance. Some authors have proposed more quantitative definitions such as a bladder contractility index of <100 ($P_{det}Q_{max} + 5Q_{max}$), a detrusor pressure at max flow ($P_{det}Q_{max}$) of <30 mm H_2O and a maximum flow rate of <12 ml/sec, and a bladder outlet obstruction index ($Pd_{et}Q_{max} – 2Q_{max}$) of <20 and a Qmax of <12 ml/sec to be indicative of DU (Dan et al. 2020), but there is no generally accepted quantitative definition of DU; rather, it has been proposed to apply context-sensitive definitions (Smith et al. 2020). The International Continence Society defines an acontractile bladder as a detrusor that cannot contract during urodynamic studies resulting in prolonged bladder emptying within a normal time span (Haylen et al. 2010); it has been argued that this unique phenomenon that should be separated from DU (Colaco et al. 2018).

The uncertainty and controversy on the definition of UAB, DU and acontractile bladder has obvious consequences for studies on the prevalence, pathophysiology, and treatment of the condition and also on the validation of animal models thereof. Therefore, it is not surprising that robust knowledge on the of UAB and DU are missing (Osman et al. 2018), but some studies report a prevalence of UAB and/or DU in the range of about 20% (Hartigan et al. 2019, Yamany et al. 2019). However, these data are difficult to interpret because for instance a self-reported difficulty to urinate could result from both UAB or BOO.

1. ETIOLOGY, PATHOPHYSIOLOGY AND ANIMAL MODELS

The main etiological factors of UAB and DU are aging, (long-standing and/or severe) diabetes mellitus, BOO and various neurogenic disorders including injury to the spinal cord, cauda equina and peripheral nerves (Vale et al. 2019, Aizawa and Igawa 2017). Some authors classify UAB occuring in the contrext of physiological aging and that occuring in younger subjects without an identifiable cause as idiopathic (Santos-Pereira and Charrua 2020). Aging is an informative example that a potential cause of UAB may also often have little effect or lead to OAB. Thus, advanced aged is considered as a frequent cause of UAB (Vale et al. 2019, Santos-Pereira and Charrua 2020), but also a risk factor of OAB (Irwin et al. 2006). Moreover, effects of age may manifest differently depending on associated pathologies; for instance, a decreased contractile responsiveness of human detrusor biopsies with age was observed with concomitant BOO or neurogenic voiding dysfunction, but not in biopsies of otherwise healthy individuals (Fry et al. 2011). On the other hand, clinically observed bladder dysfunction in patients with Parkinson's disease was not associated with age upon multivariate analysis (Sammour et al. 2009).

At the cellular and tissue level, contributing factors can be classified into myogenic failure, efferent (motor) nerve dysfunction, afferent nerve dysfunction and brain and spinal cord dysfunction (Aizawa and Igawa 2017); of note, these factors are not mutually exclusive and can coexist (Figures 2, 3, 4 and 5). While most of our knowledge on these factors comes from animal models, factors such as bladder smooth muscle dysfuntion (Fry et al. 2011) or disturbed afferent nerve function (Smith et al. 2015) have also been observed in patients. Similarly, duration of BOO is relevant for the probability to observed OAB or signs of DU in animal models (see below) and, although based on more limited data also in patients (Bosch et al. 2019). Thus, OAB and UAB may not only coexist but may represent different stages of bladder dysfunction with a given underlying pathology (Nomiya et al. 2014). Functional neuroimaging studies in humans studies are beginning to provide insight on central nervous alterations in patients with neurogenic voiding dysfunction (Khavari and Boone 2019). Recent studies also raise the possibility that, similar to other bladder pathologies, the urothelium could also play a relevant role in UAB/DU (Osman et al. 2018).

Animal models of UAB and DU have been selected on the assumed etiologies (Aizawa and Igawa 2017). Aging based models have been reported for rats and mice. A frequent limitation is that rodents should be more than 24 months and at least 18 months old to resemble elderly humans, and generating such animals is resource-intensive. Aged animls have shown features such as impaired contractile responses in isolated detrusor strips and increased collagen disposition (Ito et al. 2015), increased residual urine and decreased voiding efficiency (Ito et al. 2016), shifted pressure-volume relationships and diminished afferent nerve sensitivity (Hotta et al. 1995, Coelho et al. 2019) and a diminished ability to respond to bladder filling with cyclic voiding (Smith et al. 2012).

Various animal models of diabetes exhibit UAB (Daneshgari et al. 2009, Daneshgari et al. 2009). A complication of all models with a more severe diabetic phenotype is that the increased blood glucose levels exceed the renal reabsorption threshold leading to glucose-induced polyuria; they are typically accompanied by an enlargement of the bladder (Arioglu Inan et al. 2018). A second complication is that diabetes models can exhibit both overactive and underactive bladder, with overactivity typically occuring in early and underactivity mostly in later stages of diabetes. Similar to the clinical situation (Mancini et al. 2020), they can also coexist in animal models of diabetes, for instance in the streptozotocin-induced model of type 1 diabetes where an increased residual urine and spontaneous bladder contractions have been observed concomitantly (Christ et al. 2006). Nonetheless, streptozotocin injection remains the most

frequently used animal model of diabetes (Ellenbroek et al. 2018) e>. Goto-Kakizaki rats have been reported to exhibit features of UAB such as reduced voiding pressure, and this was accompanied by a slower conduction velocity of afferent nerves (Aizawa et al. 2013). However, this model also confirms the complexity of studying UAB and DU as in one study residual volume was increased but the contractile responses in isolated detrusor strips were increased (Saito et al. 2008). Zucker diabetic fatty rats exhibited concomitant increases in residual volume and decreases in maximum detrusor contraction velocity (Tatemichi et al. 2015).

Similar to many, but not all animal models of diabetes (Ellenbroek et al. 2018), animal models of BOO typically exhibit a major enlargement of the urinary bladder. A key difference between bladder enlargement in the two pathophysiologies is that BOO is accompanied by bladder fibrosis (Choi et al. 2020), whereas at least in type 1 diabetes model bladder collagen content is reduced (Xiao et al. 2013). The bladder enlargement in BOO is accompanied by a partial denervation of the bladder, which can be observed even within few days of BOO induction (Barendrecht et al. 2007). Rodent models of BOO typically exhibit a decreased voided volume and an increased voiding frequency and residual urine (Hashimoto et al. 2005). Bladders from BOO animals also exhibit an increased collagen disposition, which is accompanied by a greater fraction of smooth muscle cells exhibiting a synthetic phenotype (Matsumoto et al. 2003). However, BOO particularly when examined at early time points after induction of obstruction may exhibit features of OAB such as increased force of contraction (Zeng et al. 2012); contractile responses of isolated detrusor strips have been found to be reduced in some (Schröder et al. 2001), but not other BOO models (Matsumoto et al. 2009).

Based on the multitude of specific causes of neurogenic voiding dysfunction, animal models of UAB based on neurogenic causes are very heterogeneous. As partial denervation of the bladder also is a typical feature of long-standing diabetes (Blaha et al. 2016), animal models of diabetes can also be seen as those of neurogenic voiding dysfunction under some conditions. Examples of other models include spinal cord injury (De Groat and Yoshimura 2010, Salazar et al. 2019), bilateral pelvic nerve injury (Hannan et al. 2017), crush injury to nerve bundles from the major pelvic ganglion (Kim et al. 2013), ventral root avulsion injury (Chang and Havton 2016), and cryoinjury to the serosal side of the organ (Somogyi et al. 2002). Similar to models based on aging, diabetes or BOO, the neurogenic models can exhibit features such as decreased afferent nerve function (De Groat and Yoshimura 2010) and muscle contractility (Kim et al. 2013) or fibrosis (Hannan et al. 2017), but also features incompatible with pure UAB in some cases, for instance increased contractility of isolated detrusor strips (Hannan et al. 2017).

In conclusion, the animal models are as diverse as are the etiologies of UAB/DU. Whether they indeed reflect UAB/DU often depends on specific aspects such as age of the animal or duration of pathology such as diabetes or BOO. In some cases, they concomitantly exhibit features more often associated with OAB. This requires careful consideration of specific aspects of the animal model at hand to determine its translational value for studying phenomena relevant to patients.

2. DIAGNOSIS AND TREATMENT

A recent systematic review concluded that the quality of clinical data on UAB is limited (Osman et al. 2018). No validated symptom scores exist for the diagnosis of UAB (Yamany et al. 2019). While noninvasive measurements such as flow rate, residual urine and emptying efficciency can be useful in the screening for patients with UAB as a cause for their complaints, a clear diagnosis cannot be made without urodynamic assessment to determine factors such as bladder sensation, detrusor pressure or voiding efficiency (Osman et al. 2018). While more studies have become available in recent years, more accurate and practical criteria for the diagnosis of UAB remain to be established.

Particularly in patients with large residual urine, clean intermittent catherization is a therapeutic approach in UAB with the primary aim to prevent damage to the upper urinary tract and the secondary aim to prevent overflow incontinence (Shapiro et al. 2020, Hartigan et al. 2019, Yamany et al. 2019, Cho and Kim 2020, Bayrak and Dmochowski 2019). Behavioral modification may be useful in patients with impaired bladder sensation who do not sense bladder distension (Yamany et al. 2019). Animal studies suggest that caloric restriction may at least partly prevent the development of UAB with age (Ito et al. 2015, Ito et al. 2016).

Another approach to increase detrusor contraction is (intravesical) administration of prostaglandin E_2. However, this has largely been studied in acute post-operative urinary retention, and results have been mixed. While selective EP_2 and EP_3 receptor agonists are under preclinical investigation as potential treatments, prostaglandins are currently not recommended for chronic UAB (Yamany et al. 2019).

While antagonism of muscarinic receptors has been the mainstay of OAB treatment for decades, efforts to treat UAB have focused on the opposite, i.e., providing greater stimulation of such receptors by direct agonists such as bethanechol or indirect parasympathomimectics such as distigmine. While parasympathomimetics typically yielded promising results in animal models (Tatemichi et al. 2015, Hashimoto et al. 2005, Obara and Tanaka 2020), clinical studies have not provided consistent support for their use but have highlighted potential risks associated with such treatments (Cho and Kim 2020, Bayrak and Dmochowski 2019, Barendrecht et al. 2007). Therefore, they are no longer recommended.

An alternative approch to increase detrusor contraction could be the (intravesical) administration of prostaglandin E_2. This has largely been studied in patients with post-operative, acute urinary retention and has yielded mixed results. Data on chronic use in UAB are largely missing (Yamany et al. 2019, Bayrak and Dmochowski 2019) and are insufficient to recommend their use. Specific agonists acting on EP_2 and EP_3 receptors are currently explored in animal models, but have not been tested in clinical studies.

Acotiamide is an approved prokinetic agent in the gastro-intestinal tract and has shown promise in animal models (Singh et al. 2020). Limited, open-label clinical studies in UAB patients showed that it was well tolerated and yielded promising efficacy results. (Bayrak and Dmochowski 2019). Stem cell and gene therapy-based approaches are currently under investigation (Osman et al. 2018, Hartigan et al. 2019, Yamany et al. 2019).

Based on their role in the bladder neck and urethra, α-blockers could potentially be used to reduce bladder outlet resistance and thereby facility voiding particularly if detrusor contractions are weak. While attractive as a concept, only very limited clinical data is available to support this concept and adequately powered, placebo-controlled, randomised, double-blind trials are missing. Therefore, α-blockers are not recommended due to a lack of sufficient supporting evidence (Yamany et al. 2019, Bayrak and Dmochowski

2019). Accordingly, it has generally been concluded that existing pharmacological treatment options are insufficiently effective and/or have too limited data to be recommended (Ladi-Seyedian et al. 2018).

Sacral neuromodulation may have a place in women with non-obstructive urinary retention (Fowlers syndrome), but its value in UAB in general remains unclear (Shapiro et al. 2020, Yamany et al. 2019, Bayrak and Dmochowski 2019). Transcutaneous or intravesical stimulation has been reported to be successful in some patients but the available evidence is too limited for a recommendation. In men with BOO and UAB, surgical removal of the obstruction has largely restored voiding function even if BOO had existed for a long time (Dobberfuhl et al. 2019).

In conclusion, UAB/DU is a condition that appears to be frequent. Treatment modalities proven to be effective and safe in randomized studies are largely missing. Further experimental and clinical research in this area is urgently needed but is hampered by diverse underlying pathologies and unclear definitions.

VIII. HORMONAL TREATMENT OF URINARY INCONTINENCE

1. OESTROGENS

1.1. Oestrogens and the Continence Mechanism

The oestrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intra-vesical pressure at all times except during micturition. The urethra has four oestrogen sensitive functional layers all of which have a role in the maintenance of a positive urethral pressure 1) urothelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of oestrogen receptor, α and β, have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al.,1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause oestrogen receptor α has been shown to vary depending upon exogenous oestrogen therapy [Fu et al., 2003]. In addition, exogenous oestrogens affect the remodelling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that oestrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986], or by using doppler velocimetry and immunohistochemistry staining[Kobata et al., 2008; Yura et al., 2020].

Big Potassium (BK) channels (novel, non-genomic targets for oestrogens), have been shown to play an important role in urinary bladder smooth muscle (UBSM) excitability and contractility [Petkov, 2014; Hanna-Mitchell et al., 2016]. Animal studies have demonstrated a reduction in UBSM excitability via activation of BK channels, mediated by 17β-estradiol [Provence et al., 2015; Kim et al., 2016]. At present the interspecies variation in experimental animal models means that the precise functional role of BK channels in human UBSM remains uncertain [Malysz, Petkov, 2020]. But it is likely that this represents an exciting target for the development of therapeutic interventions in the future.

1.2. Oestrogens for Stress Urinary Incontinence

The role of oestrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results, but this may have been because they were small observational and not randomised, blinded or controlled. The situation is further complicated by the fact that several different

types of oestrogen have been used with varying doses, routes of administration and duration of treatment. Fantl et al. [1996] treated 83 hypo-oestrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine oestrogens, 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study

period the clinical and quality of life variables had not changed significantly in either group. Jackson et al. [1996] treated 57 postmenopausal women with urodynamic stress or mixed incontinence with oestradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit. Weber at al. [2017] conducted a prospective multi-centre trial in Australia, South Africa and the Netherlands, treating 68 postmenopausal women with SUI with vaginal oestriol 1mg/g cream for 6 weeks. At the end of the study period, statistically significant improvements in two out of four subjective domains (Patient's Global Impression of Improvement scale and Urogenital Distress Inventory) were seen. Out of the two objective outcomes measured, only vaginal pH improved significantly following treatment with vaginal oestriol, whereas cough pad tests varied widely.

Two meta-analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of oestrogens to treat all causes of incontinence in post-menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect. In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of oestrogen treatment. They also found that oestrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Oestrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence. Several studies have shown that oestrogen may have a role in combination with other therapies e.g. α-adrenoceptor agonists. In a randomised trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and oestriol (1 mg per day) in 66 patients with post-menopausal stress urinary incontinence. Efficacy was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with oestriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. A further study evaluating the effects of intravaginal oestriol and pelvic floor rehabilitation on urogenital aging in post-menopausal women randomised 206 women with symptoms of urogenital aging into two groups of 103 women each. Subjects in the treatment group received intravaginal oestriol ovules 1 mg once daily for 2 weeks and then 2 ovules weekly for a total of six months together with pelvic floor rehabilitation. Subjects in the control group received only intravaginal oestriol. Prior to treatment 83 (80.6%) of the women in the treatment arm complained of stress urinary incontinence compared to 103 (100%) of the control women. At the end of the study only 22 (21.4%) of the treated patients suffered from stress urinary incontinence compared to 93 (90.3%) of the control group representing a significant improvement in stress incontinence as a result of this combination therapy [Capobianco et al., 2012]. In an extrapolation of this work, triple combination therapy (oestrogen ovule in combination with PFR and Lactobacilli Acidophili) resulted in significantly more improvement in symptoms of stress urinary incontinence [Capobianco et al., 2014].

A more recent systematic review and network meta-analysis confirmed these earlier findings. The analysis compared the effectiveness of pharmacological and nonpharmacological interventions to improve or cure all types of incontinence. 84 randomised trials were identified, of which 32 reported stress urinary incontinence outcomes. The results demonstrated that behavioural therapy (pelvic floor muscle training), either alone or in combination with hormones (vaginal oestrogen), were more effective than hormones alone in achieving cure or improvement. Hormones (vaginal oestrogen) also showed no statistically significant difference in cure or improvement rates compared to no treatment [Balk et al., 2019].

Thus even prior to the reported secondary analyses of the heart and oestrogens/progestogen replacement study (HERS) [Grady et al., 2001] and women's health initiative (WHI) [Hendrix et al., 2005] it was already recognised that systemic oestrogen

therapy alone had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo, 2003].

1.3. Oestrogens for Urgency Urinary Incontinence and Overactive Bladder (OAB)

Oestrogen has been used to treat post-menopausal urgency and urgency incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000]. A double-blind multi-centre study of 64 post-menopausal women with "urge syndrome" failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either sensory urgency or detrusor overactivity. They were randomised to treatment with oral oestriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Oestriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo. Another randomised controlled trial from the same group using 25 mg oestradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a higher complication rate in the oestradiol treated patients (vaginal bleeding). More recently, a prospective study of 37 women with symptoms of overactive bladder demonstrated an improvement in the subjective assessment of night-time frequency and urgency with vaginal oestriol. In addition, objective urodynamic parameters of storage function, i.e., maximum cystometric capacity ($P<0.001$) and first desire to void ($P<0.001$) improved following vaginal oestriol treatment. It is worth noting however, that the parameters of voiding function and the number of patients with detrusor overactivity did not differ significantly with topical hormonal treatment. [Matarazzo et al., 2018].

Vaginal oestrogen therapy has been shown to reduce the incidence of urgency when used after a tension- free vaginal tape (TVT) compared with those not receiving topical vaginal oestrogen therapy (4% vs. 29%, $P = 0.01$) [Zullo et al., 2005].

Symptoms of OAB increase in prevalence with increasing age and lower urinary tract symptoms and recurrent urinary tract infections are commonly associated with urogenital atrophy. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urgency incontinence may be a manifestation of genitourinary syndrome of menopause atrophy in older postmenopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital

atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings and higher serum oestradiol levels (Cardozo et al., 1998).

Overall vaginal oestradiol has been found to be the most effective in reducing patient symptoms although conjugated oestrogens produced the most cytological change and the greatest increase in serum oestradiol and oestrone.

The most recent meta-analysis of intravaginal oestrogen treatment in the management of urogenital atrophy was reported by the Cochrane group in 2012 (Cody et al., 2012) Overall 34 trials including 19676 incontinent women of whom 9599 received oestrogen therapy (1464 involved in trials of local vaginal oestrogen administration). The trials used varying combinations of oestrogen, dose, duration of treatment and length of follow up. The combined result of six trials of systemic administration (oral oestrogen) resulted in worse incontinence than placebo. However, there was some evidence that oestrogen used locally as vaginal creams or pessaries improved incontinence. Overall, there was less frequency and urgency in those women treated with local oestrogen. This confirms the results of an earlier meta-analysis which supports the topical route of oestrogen administration in the treatment of UUI and bladder overactivity [Cardozo et al., 2004]. Thus, theoretically there could be a role for combination treatment with an antimuscarinic agent and vaginal oestrogen in post-menopausal women.

However, the clinical trials which have been reported to date differ in their outcome. Tseng et al. [2009] showed superior efficacy in terms of symptom improvement for the overactive bladder when tolterodine was used with vaginal oestrogen cream as opposed to tolterodine alone. However, Serati et al. [2009] found no difference between tolterodine with or without topical oestrogen in women with symptomatic detrusor overactivity. A subsequent study by Ellington et al. [2016] found that combination therapy resulted in greater symptom relief only when tolterodine was added to single therapy intravaginal oestradiol group at 12 weeks but not the converse. This led them to conclude that the addition of an antimuscarinic may only be necessary if intravaginal oestradiol alone has not conferred sufficient benefit.

A study compared the efficacy and safety of solifenacin succinate versus solifenacin succinate with local oestrogen for the treatment of overactive bladder in 104 post-menopausal women randomised to receive either solifenacin 5 mg daily plus Promestriene vaginal capsules or solifenacin alone. The primary outcome measure was change from baseline to end of treatment in the mean number of voids per 24 hours, quality of life was assessed using the international prostate symptom score and overactive bladder symptoms score questionnaires.

The median decreases in number of voids in 24 hours in the two groups were 5.4 and 4.3 respectively which was not statistically different. The median decrease in urgency episodes was 2.0 and 2.5 respectively. In addition, the quality-of-life scores significantly changed in both groups (both the <0.05). The authors concluded that solifenacin with or without local oestrogen was effective and safe for overactive bladder treatment in post-menopausal women. The addition of local oestrogen improved subjective feelings and quality of life [Jiang et al., 2016].

There has been one study comparing the oestradiol vaginal ring with oral oxybutynin for treatment of overactive bladder [Nelken et al., 2011]. Participants were randomised to receive either the ultra-low dose oestradiol vaginal ring or oral oxybutynin for 12 weeks.

The primary outcome was a decrease in the number of voids in 24 hours. Secondary outcomes were quality of life questionnaires, vaginal pH levels and vaginal maturation index. Fifty-nine women were enrolled, 31 were randomised to receive oxybutynin whereas 28 received the oestradiol vaginal ring. Women who received oxybutynin had a mean decrease of 3.0 voids per day and women who received the vaginal ring had a mean decrease of 4.5 voids per day with no significant difference between the groups. There was a significant improvement in urogenital distress inventory and incontinence impact questionnaire scores in both groups with no significant difference in improvement between the two groups, thus ultra-low dose oestradiol releasing vaginal ring and oral oxybutynin seemed to be similarly effective in decreasing the number of daily voids in post-menopausal women with overactive bladder.

Similarly, a small study where 23 women were randomised to either combination therapy with fesoterodine and topical vaginal oestrogen, or fesoterodine alone, showed no statistically significant difference between groups after 12 weeks of treatment. Again however, the improvement in the combination therapy group in all primary outcome measures of this study, was greater than in the single therapy group [Chughtai et al., 2016].

1.4. Evidence Regarding Oestrogens and Incontinence from Large Clinical Trials.

The HERS study included 2763 post-menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of oestrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were close included. Participants were randomly assigned to 0.625 mg of conjugated oestrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged, or worsened. The results showed that incontinence improved in 26% of the

women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo group worsened compared with 39% of the hormone group (P=0.001). This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinence episodes per week increased by an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group (p< 0.001). The authors concluded that daily oral oestrogen plus progestogen therapy was associated with worsening urinary incontinence in older post /menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women's Health Initiative (WHI) was a multi-centre double blind placebo controlled randomised clinical trial of menopausal hormone therapy in 27347 postmenopausal women, age 50-79 years, enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year [Hendrix et al., 2005]. The women were randomised based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine oestrogen (CEE) plus 2.5 mg per day of Medroxyprogesterone Acetate (CEE+MPA), whereas those who had undergone hysterectomy received oestrogen alone (CEE). At one year hormone therapy was

shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% continence interval) CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urge urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.49; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus, based on this secondary analysis of data from a huge study conjugated equine oestrogen alone or in combination with medroxyprogesterone acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996 39436 post-menopausal women aged 50-75 years who reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased amongst post-menopausal women taking hormones compared to women who had never taken hormones (oral oestrogen: RR1.54 95% CI 1.44, 1.65; transdermal oestrogen: RR1.68, 95% CI 1.41, 2.00; oral oestrogen with progestin: RR1.34, 95% CI 1.24, 1.44; transdermal oestrogen with progestin: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta-analysis of the effect of oestrogen therapy on the lower urinary tract has been performed by the Cochrane Group [Cody et al., 2012] and is notable as the conclusions are starkly different from those drawn from the previous review [Moehrer et al., 2003]. Overall, 34 trials were identified including 19676 incontinent women (1464 involved in trials of local administration) of which 9599 received oestrogen therapy.

Systemic administration (of unopposed oral oestrogens – synthetic and conjugated equine oestrogens) resulted in worse incontinence than placebo (RR1.32; 95% CI: 1.17-1.48). Although this is heavily influenced by the size of the WHI study [Hendrix et al 2005]. When considering combination therapy there was a similar worsening effect on incontinence when compared to placebo (RR1.11; 95% CO: 1.04-1.08). There was some evidence suggesting that the use of local oestrogen therapy may improve incontinence (RR0.74; 95% CI: 0.64-0.86) and overall, there were 1-2 fewer voids in 24 hours and less frequency and urgency. The authors conclude that local oestrogen therapy for incontinence may be beneficial although there was little evidence of long-term effect. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition, they reported that there are too few data to comment reliably on the dose type of oestrogen and route of administration.

2. GENITOURINARY SYNDROME OF MENOPAUSE

Following a consensus conference held in 2013 the Board of Directors of the International Society for the Study of Women's Sexual Health (ISSWSH) and the Board of Trustees of the North American Menopause Society (NAMS) acknowledged the need to review terminology associated with genitourinary tract symptoms related to menopause [Portman et al., 2014]. They agreed on the term Genitourinary Syndrome of Menopause (GSM) as a more accurate all-encompassing and publically acceptable term than vulvo-vaginal atrophy. As well as genital symptoms this covers the urinary symptoms of urgency, dysuria, and recurrent urinary tract infections. It has long been appreciated that these symptoms respond well to

Table 11

Name of Drug	Type of Oestrogen	Dose (dose in mg for comparison)	Formulation
Vagifem	Oestradiol hemihydrate	10microgram (0.01)	Tablet
Estradiol	Oestradiol hemihydrate	10microgram (0.01)	Pessary
Vagirux	Oestradiol hemihydrate	10microgram (0.01)	Tablet
Estring	Oestradiol hemihydrate	7.5microgram/24hr (0.0075/24hr)	Vaginal ring
Femring	Oestradiol acetate	0.05mg/24hr 0.1mg/24hr	Vaginal ring
Imvexxy	Oestradiol	4microgram (0.004) 10mincrogram (0.01)	Vaginal inserts (ovules)
Premarin Vaginal	Conjugate equine oestrogen	0.625mg/g	Cream
Ovestin	Oestriol	1mg/g	Cream
Imvaggis	Oestriol	0.03mg	Tablet
Gynest 0.01%	Oestriol	100microgram/g (0.1)	Cream
Blissel	Oestriol	50microgram/g (0.05)	Cream

low dose local (intravaginal) oestrogen therapy given long term to post-menopausal women [Baber et al., 2016]. Since the introduction of intravaginal oestrogens, the traditional 25 microgram twice weekly dose of oestradiol vaginal tablets has been replaced by the ultra-low dose 10 microgram twice weekly vaginal tablet, to mitigate the risks of endometrial stimulation associated with the original, higher dose [Simon & Maamari, 2013]. This has unfortunately led to reduced efficacy and does not appear to be adequate for the control of overactive bladder symptoms in post-menopausal women, 50% of whom may suffer from genitourinary syndrome of the menopause if untreated. Fears regarding unopposed oestrogens, have led to the development of ultra-low dose vaginal oestrogen formulations. There are now a variety of preparations and concentrations (see **Table 11**) available. Their efficacy when compared to one another, is , undetermined.

However, the most recent Cochrane review, which included 30 trials with 6235 women, found only low-quality evidence that intra-vaginal oestrogenic preparations improve the symptoms of vaginal atrophy in postmenopausal women when compared to placebo, and confirmed earlier review conclusions that there was no difference between various types of formulation [Lethaby et al., 2016]

3. OTHER HORMONES

3.1. Selective Oestrogen receptor modulators (SERMS)

Selective oestrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both oestrogenic and anti-oestrogenic effects. Initially the best data available related to Raloxifene, as this was the only drug licensed for the treatment of postmenopausal osteoporosis. However, raloxifene has not been shown to have any effect at all on urinary incontinence [Vardy et al., 2003, Waetjen et al., 2004]. Studies evaluating the effect of Tamoxifen on urinary incontinence are limited, and although some have demonstrated an increase in urinary incontinence among breast cancer survivors taking Tamoxifen, none have identified a statistically significant relationship. [Vardy et al., 2003; Morales et al., 2004; Alfano et al., 2006].

More recently, Ospemifene, a third generation SERM, indicated for treatment of moderate-to-severe symptomatic VVA [Nappi et al., 2017] and dyspareunia [Bondi et al., 2016] in postmenopausal women in whom oestrogen therapy is contraindicated, has shown promising results regarding the management of OAB symptoms. A retrospective review of 46 women with VVA found a significant improvement in frequency, nocturia, urgency, and urgency incontinence after 12 weeks of Ospemifene treatment [Schiavi et al., 2017].

A study of 105 patients, aimed at assessing the effectiveness of Ospemifene in the improvement of sexual function in postmenopausal women with VVA and OAB symptoms, found a significant improvement in frequency, nocturia, urgency, and urgency incontinence [Schiavi et al., 2018]. There were also significant improvements in OAB questionnaire scores. These results have subsequently been replicated in a prospective cohort study of 25 women with VVA and OAB symptoms refractory to first-line pharmacologic treatment [Novara et al., 2020]. Additionally, ospemifene has been shown to be effective the treatment of the urgency component of mixed urinary incontinence following insertion of a mid-urethral sling [Schiavi et al.,2019].

3.2. Androgens

Preliminary studies of dihydroepiandrosterone (DHEA) and its sulphate (DHEAS), which are metabolised to oestradiol and testosterone in peripheral target tissues, have demonstrated promising results for the treatment of postmenopausal women with symptoms of vaginal atrophy. However, as there are no reported, clinical trials evaluating the effect of androgens, and, in particular, DHEA, on urinary incontinence in women, it remains to be seen whether this improvement in the VVA aspect of GSM symptoms, will be extrapolated to its lower urinary tract manifestations.

3.3. Progesterone and progestogens

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence have been reported to increase in the progestogenic phase of the menstrual cycle [Hextall et al., 2001]. In similar studies, progesterone has been shown to increase beta adrenergic activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progestin was given in addition to oestrogen [Hendrix et al., 2005].

Conclusions. Oestrogen has an important physiological effect on the female lower urinary tract and its deficiency is an aetiological factor in the pathogenesis of a number of conditions. However, the use of oestrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of systemic oestrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have only been based on self-reported symptoms of urinary leakage without any objective data. Despite this, all of these large randomised controlled trials show a worsening of pre-existing urinary incontinence, both stress and urgency and an increased new incidence of urinary incontinence with both oestrogen and oestrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine oestrogen and this may not be representative of all oestrogens taken by all routes of administration.

Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal oestrogen therapy there is currently no evidence that oestrogens with or without progestogens should be used in the treatment of urinary incontinence.

Although the SERM, Ospemifene, has demonstrated encouraging results regarding the treatment of OAB symptoms, there remains a paucity of high-quality evidence to support its routine use. Most studies concerning Ospemifene do not include improvement in the urogenital symptoms of GSM as their primary outcome. Currently there are no randomised controlled trials comparing either Ospemifene to vaginal oestrogen alone, or in combination with an antimuscarinic for the management of urinary symptoms. More rigorous clinical trials will be needed before SERMs/Ospemifene are included in the stepwise management of overactive bladder symptoms.

The International Menopause Society (IMS) produced recommendations in 2016 on

women's midlife health and menpause hormone therapy (MHT) to help guide healthcare professionals in optimising their management of women in menopause transition and beyond. They have given a Grade A recommendation to the use of local oestrogens

for urogenital symptoms and a Grade B recommendation for the long-term use of such treatment. They have also allocated a Grade B recommendation to the use of low dose local oestrogens in the management of recurrent lower urinary tract infection [Baber et al., 2016].

The British Menopause Society's (BMS) most recent consensus statement [Pitkin et al., 2018] corroborates these recommendations and goes further to support the use of local vaginal oestrogen on a long-term basis, for as long as it is needed. The BMS also quote evidence for the use of local vaginal oestrogens for the management of OAB, especially in cases of concomitant vaginal atrophy.

4. DESMOPRESSIN

The endogenous hormone vasopressin (also known as anti-diuretic hormone) has two main functions: it causes contraction of vascular smooth muscle and stimulates water reabsorption in the renal

medulla. These functions are mediated by two specific vasopressin receptors of which there are two major subtypes, namely the V_1 and V_2 receptors. The V_2 subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V_2 receptor can cause nephrogenic diabetes insipidus [Insel et al., 2007]. Accordingly, decreased vasopressin levels are believed to be important in the pathophysiology of polyuria, specifically nocturnal polyuria (NP), which can lead to symptoms such as nocturia [Matthiesen et al., 1996; Weiss et al., 2011a, Weiss and Everaerts. 2019]. Nocturia and NP was currently defined by the International Continence Society (ICS), nocturia as "The number of times urine is passed during the main sleep period. Having woken to pass urine for the first time, each urination must be followed by sleep or the intention to sleep. This should be quantified using a bladder diary," and nocturnal polyuria as "Passing large volumes of urine during the main sleep period. This should be quantified using a bladder diary" [Hashim et al., 2018]. Nocturia leads to decreased quality of life [Kupelian et al., 2011, Torimoto et al., 2021], and has been associated with both increased morbidity and mortality [Nakagawa et al., 2010; Kupelian et al., 2012; Pesonen et al., 2020]. While it remains largely unknown in which fraction of patients nocturia can indeed be explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist. While it remains largely unknown in what fraction of patients nocturia is explained by too little vasopressin, the presence of NP in the absence of identifiable medical conditions that can explain it (e.g., excessive fluid intake) is usually considered to indicate decreased vasopressin levels [Bosch and Weiss., 2011, Weiss et al., 2011b]. Based upon these considerations, vasopressin receptor agonists have been used to treat nocturia, both in children and in adults [Weiss and Everaerts, 2019].

Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for anti-diuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and intranasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration [Rittig et al., 1998]. An oral lyophilisate (MELT) formulation requiring no concomitant fluid intake is globally the most commonly used for reasons of pharmacokinetics and patient preference, although it has not been approved in many countries, including the United States [Neveus et al., 2020]. The MELT formulation was shown also to have better pharmacodynamic characteristics of than desmopressin tablets [De Guchtenaere et al., 2011]. Another newly approved formulation was AV002 (SER120), a novel, emulsified, microdose desmopressin nasal spray with rapid absorption, high bioavailability, limited duration of action, and low coefficient of variation [Andersson et al., 2019]. AV002 was shown to cause significant improvements over placebo for co-primary and secondary efficacy end points that corresponded with quality of life improvements and had an acceptable safety profile [Kaminetsky et al., 2019].

4.1. Demopressin in children

An excess urine production during sleep is a common finding in children with enuresis and disturbances in the circadian rhythm of arginine-vasopressin (AVP) is found in the majority of children with nocturnal polyuria. Children with enuresis and nocturnal polyuria lack the physiologic increase in AVP levels during sleep and treatment with the AVP analogue desmopressin can restore this rhythm and lead to dry nights [Kemperis, 2021]

The pediatric pharmacology of desmopressin in children with enuresis was recently reviewed by Gasthuys et al. [2020]. Among the various pharmaceutical formulations of desmopressin commercialized for this indication - nasal spray, nasal drops, oral tablet and oral lyophilizate, the lyophilizate is the preferred formulation]. A profound food effect on the oral bioavailability was demonstrated as well as different plasma concentration-time profiles (double absorption peak) of the desmopressin lyophilizate between adults and children. Regarding the safety of the different desmopressin formulations, the use of desmopressin was generally considered safe, but measures should be taken to prevent severe hyponatremia .Because of symptomatic hyponatremia with water intoxication which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin [Thumfart et al., 2005; Robson et al., 2007; Van de Walle et al., 2010], the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin.

The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener et al., 2002]. Previous guidelines for the evaluation and treatment of children with enuresis were recently updated by experts affiliated with the International Children's Continence Society (ICCS) [Neveus et al, 2020].

In the Cochrane Collaboration study the authors evaluated 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to their analysis, desmopressin was effective relative to placebo in reducing bed-wetting (e.g. a dose of 20 μg resulted in a reduction of 1.34 wets/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that desmopressin suppresses symptom enuresis but does not cure the underlying cause. The Cochrane Group have reviewed a total of 40 randomised or quasi-randomised controlled trials of 1780 children who were in enrolled receiving an active drug other than Desmopressin or a tricyclic. 31 different drugs or classes of drug were tested. For drugs versus placebo, when compared to placebo Indomethacin, Diazepam, Mestorelone and Atomoxetine appeared to reduce the number of children failing to have 14 consecutive dry nights. Althogh Indomethacin and Diclofenac were better than placebo during treatment, they were not as effective as Desmopressin and there was a higher chance of adverse effects [Desphande et a., 2012]. Additionally, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates [Alloussi et al., 2011]. The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone [Austin et al., 2008; Alloussi et al., 2009). A Cochrane Review showed that when imipramine combined with desmopressin was compared with imipramine monotherapy there was no different in outcomes. However, when imipramine plus desmopressin was compared with desmopressin monotherapy the combination was more effective with 15% not achieving 14 consecutive dry nights at the end of treatment for imipramine plus demospressin versus 40% for desmopressin monotherapy [Caldwell et al., 2016].

The guidelines of the working group of the ICCS recommended active therapy from the age of 6 years [Neveus et al., 2020]. In nonmonosymptomatic enuresis, basic advice regarding voiding and

drinking habits should be provided. In monosymptomatic enuresis, or if the above strategy did not make the child dry, the first-line treatment modalities are desmopressin or the enuresis alarm. If both these therapies fail alone or in combination, anticholinergic treatment is a possible next step. If the child is unresponsive to initial therapy, antidepressant treatment may be considered by the expert [Neveus et al., 2020].

4.2. Desmopressin in adults

Neurologic disorders. Several studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults including those with neurological disorders, e.g., multiple sclerosis [Eckford et al., 1994;1995; Haddad et al., 2020]. One study with single dose administration reported a reduction in nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with a small patient number (16-33 patients total per study) reported a significant reduction in nocturia [Hilton et al., 1983; Eckford et al., 1994; Valiquette et al., 1996]. Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 h after desmopressin administration rather than nocturia as their primary endpoint. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious [Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998]. While desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment due to asymptomatic or minimally symptomatic hyponatremia [Valiquette et al., 1996]. Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study, desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou et al., 2007].

Haddad et al [2020] systematically reviewed the literature about nocturia in neurological patients by electronic search of Cochrane and Medline databases. The studies were included if their participants had acquired neurological pathology among multiple sclerosis (MS), Parkinson's disease (PD), stroke, spinal cord injury (SCI). Among 132 included studies, nocturia prevalence ranged from 15% to 96% depending on the pathology and definition used. Haddad et al. [2020] concluded that nocturia is highly prevalent in patients with neurological disorders. Causalities and treatments are not different from the general population but are poorly studied in neurological patients.

Absence of neurologic disorders. Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. The recruited patient populations were based upon different criteria, including having at least two nocturia episodes per night or having nocturnal polyuria. Earlier studies mostly used a desmopressin dose of 20 µg given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (≤25 patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1-0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults [Mattiasson et al., 2002; Lose et al., 2003; van Kerrebroeck et al., 2007]. A total of 632 patients entered the dose-titration phase and 422 patients entering the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed-out following the dose-titration phase and in order to be randomized, it was a requirement that the patients returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2 or 0.4 mg) is effective in both men and women aged ≥ 18 years with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared to 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as ≥ 50% reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

Weiss and colleagues reported outcomes on a four week multi/centre randomised double-blind placebo-controlled trial to determine the efficacy of orally disintegrating sub-lingual desmopressin, i.e., "melt" formulation. The authors randomised patients to 10, 25, 50 and 100 micrograms. Approximately 90% of the subjects reported true nocturnal polyuria, 710 patients completed the study. A statistically significant difference in the number of nocturnal voids was seen for all patients with a100 micrograms and 50 micrograms. Women responded to 25 micrograms as well, however for men there was only a statistically significant difference with 100 micrograms. The proportion of patients with at least a 33% reduction in the number of nocturnal voids (primary outcome measure) increased with dosage for all patients but there was a stronger response seen in women at 25 micrograms. A total of 24 patients (3%) experienced hyponatremia which was a more likely occurrence in patients over the age of 65 years [Weiss et al., 2012].

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response [Lose et al., 2004]. An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects [Johnson et al., 2006].

Around 75% of community-dwelling men and women with nocturia (≥2 voids/night) have nocturnal polyuria (NP) [Rembratt et al., 2003; Swithinbank et al. 2004]. The key urological factors most relevant to nocturia are NP and OAB in women [Irwin et al., 2008], and NP and benign prostatic hyperplasia (BPH) in men. About 74% of women with OAB have nocturia and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP; 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or bladder outlet obstruction [Chang et al., 2006]. Therefore, desmopressin combination therapy with α_1- adrenergic blockers and/or anticholinergics should be considered for patients with treatment–resistant nocturia. Seventy-three percent of α_1- adrenergic blocker-resistant BPH patients experienced a ≥50% reduction in nocturnal voids with oral desmopressin [Rembratt et al., 2003; Yoong et al., 2005]. A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low dose (0.1 mg) oral desmopressin in elderly (≥ 65 years) patients reported that low dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH [Wang et al., 2011].

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, non-randomized pilot study of men believed to have BPH, desmopressin was reported to improve not only nocturia, but also to reduce

the overall international prostate symptom score (IPSS) [Chancellor et al., 1999]. An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence reported that intranasal administration of 40 μg desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in voids along with an improvement in quality of life (QoL) [Hashim et al., 2009]. While these data indicate that desmopressin may be effective in treating voiding dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations. Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL.

4.3. Desmopressin and hyponatremia.

One of the main clinically important side-effects of desmopressin is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al., 2003; 2006]. Based on a meta-analysis, the incidence is around 7.6% [Weatherall, 2004]. Increased age and female gender are well-known risk factors for the development of desmopressin-induced hyponatremia [Rembratt et al., 2006]. Bae et al. [2007] assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (greater than 3 voids nightly), who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration serum sodium should be assessed regularly, at least every 6 months.

There has been some research exploring gender differences in the antidiuretic response to desmopressin. Juul et al. [2011] found an increasing incidence of hyponatremia with increasing dose, and at the highest dose level of 100 micrograms decreases in serum sodium were approximately twofold greater in women over 50 yrs of age than in men. A new dose recommendation stratified by gender was suggested in the treatment of nocturia: for men, 50- to 100 micrograms melt was suggested to be an efficacious and safe dose, while for women a dose of 25 micrograms melt was recommended as efficacious with no observed incidences of hyponatremia. Weiss and colleagues investigated the efficacy and safety of 50 and 75 micrograms desmopressin orally disintegrating tablets in 385 men with nocturia. They showed that both doses increased the time to first void from baseline by approximately 40 minutes compared to placebo. The response to desmopressin was seen within a week of treatment and was sustained producing signficant increases in health-related quality of life and sleep quality compared to placebo. Only 2 subjects aged 74 and 79 years respectively developed hyponatremia [Weiss et al., 2013]. A similar study carried out in women explored the efficacy and safety of 25 micrograms of Desmopressin orally disintegrating tablets compared to placebo. 261 women with nocturia were randomised to either 25 micrograms of desmopressin or placebo. Desmopressin significantly reduced the mean number of nocturnal voids compared to placebo and increased the mean time to first nocturnal void by 49 minutes compared to placebo. Once again response was seen within the first week of treatment and sustained throughout the three-month trial. Desmopressin was well tolerated with only three transient decreases in serum sodium level [Sand et al., 2013].

Initiation of desmopressin is currently not indicated for patients aged ≥65 years. The mechanisms behind desmopressin-induced hyponatraemia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to recommended dosing, should be followed to minimize the risk of hyponatremia [Vande Walle et al., 2007].

Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. It is the only antidiuretic treatment indicated specifically for nocturia due to NP. The drug has been proven to be well-tolerated and effective by several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) for patients who have been appropriately evaluated and whose nocturia is related to NP whether or not this isaccompanied by BPH or OAB. For assessment, see Table 2.

COMMITTEE 10

SURGERY FOR MALE URINARY INCONTINENCE

Chairs

Averbeck, Marcio (Brazil)
Goldman, Howard (United States)

Members

Chung, Eric (Australia)
Collado Serra, Argimiro (Spain)
Comiter, Craig (United States)
Guralnick, Michael (United States)
Herschorn, Sender (Canada)
Singla, Ajay (United States)

COMMITTEE 10

SURGERY FOR MALE URINARY INCONTINENCE

I. INTRODUCTION AND METHODS **1186**
1. Methods and Materials 1186

II. TIMING OF SURGICAL INTERVENTION AND EVALUATION PRIOR TO SURGICAL THERAPY **1187**
1. Timing of Intervention 1187
2. Evaluation Prior to Surgical Therapy 1192
2.1. Diagnostic Objectives 1192
2.2. Diagnostic Methods 1192

III. PATHOPHYSIOLOGY AND RISK FACTORS **1194**
1. Male Urinary Sphincter 1195
2. Incontinence Related to Prostate Cancer Treatment 1195
2.1. Post-Prostatectomy (Radical) Incontinence (PPI) 1195
2.2. Risk Factors for PPI 1199
3. Incontinence After Surgery for BPH 1208
3.1. UDS Findings 1209
3.2. Risk Factors for Incontinence After BPH Surgery 1210

IV. POST PROSTATECTOMY SURGICAL OPTIONS **1216**
1. Male Slings 1216
1.1. Argus sling (Promedon, Cordoba, Argentina) 1216
1.2. Remeex Sling (Neomedic, Barcelona, Spain) 1218
1.3. AdVanceSsling (Boston Scientific Formerly American Medical Systems, MN, USA) 1219
1.4. Virtue Sling (Coloplast, Humlebaek, Denmark) 1220
1.5. I-STOP TOMS sling (CL Medical, France) 1221
1.6. ATOMS Sling (A.M.I. GmbH, Feldkirch, Austria) 1222
1.7. Predictors of MS Success 1223
1.8. Conclusion 1223
2. The Artificial Urinary Sphincter (AUS) 1223
2.1. Indications 1223
2.2. Contraindications 1224
2.3. Preoperative Evaluation 1224
2.4. Surgical Technique 1225
2.5. Outcomes 1225
2.6. Complications and Troubleshooting 1227
2.7. Other Devices 1232
2.8. Follow-up Protocol Of Patients Undergoing AUS Implant Surgery 1232
3. Male Slings vs. AUS 1233
3.1. Introduction 1233
3.2. Specific Patient Factors 1234
3.3. Sling vs. Sphincter Based on Non-RCT 1235
3.4. MASTER Trial 1235
3.5. Conclusion 1235
4. Periurethral Bulking Agents 1236
4.1. PUBA Classification 1236
4.2. Conclusion 1237
5. Adjustable Continence Therapy (Periurethral Balloons) 1237
6. Future Directions 1239
6.1. New Technologies Under Evaluation 1239

V. REFRACTORY DETRUSOR OVERACTIVITY/SPECIFIC SURGERY FOR OVERACTIVE BLADDER **1240**
1. OAB 1240
1.1. Prevalence 1240
1.2. Refractory OAB/UUI 1240
2. Neurogenic Voiding Dysfunction 1241
3. Diabetic Voiding Dysfunction 1241
4. Bladder Outlet Obstruction 1241
5. Urethral Stricture 1242
6. Urgency Urinary Incontinence Following Prostate Cancer Treatment 1242
7. Voiding Dysfunction After Treatment for Rectal Cancer 1242

VI. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE **1242**
1. Urethrocutaneous Fistula (UCF) 1243
1.1. Congenital Urethrocutaneous Fistula 1243
1.2. Acquired Urethrocutaneous Fistula 1243
1.3. Management of UCF 1243
2. Rectourethral Fistula (RUF) 1243
2.1. Congenital Rectourethral Fistula 1243
2.2. Acquired RUF 1244
2.3. Clinical Presentation of RUF 1246
2.4. Evaluation of Rectourethral Fistula 1247
2.5. Therapy for RUF 1247
2.6. Summary 1253

VII. SUMMARY OF RECOMMENDATIONS **1253**
1. Evaluation and Recommendations 1253
2. Incontinence Post-Prostatectomy for BPO and Post-Radical Prostatectomy for Prostate Cancer 1254
3. Incontinence Following External Beam Radiation for Prostate Cancer 1254
4. Incontinence Following Pelvic Trauma 1254
5. Refractory Urgency Incontinence and Detrusor Overactivity 1254
6. Urethrocutaneous Fistula and Rectouretral Fistual 1254
7. Management of AUS Complications 1255
8. New Technologies 1255
9. Future Research Directions 1255
10. Clinical Trial Recommendation 1255

REFERENCES **1256**
