Surgery for male incontinence is currently done primarily for those with leakage resulting from radical prostatectomy. However, some men who have had other treatments for prostate cancer, surgery for benign prostatic disease, who have significant overactive bladder (OAB), some following traumatic injury or those with a history of neurologic disease will have incontinence requiring some sort of surgery. Leakage related to OAB will be primarily covered in the Chapter on Surgery for OAB.

Urinary incontinence (UI) is a common complication after radical prostatectomy (RP) and has a negative effect on quality of life (QoL). Post-prostatectomy urinary incontinence (PPI), like any UI, may be caused by bladder dysfunction, sphincter dysfunction, or a combination of both. Several risk factors have been associated with PPI, including advanced age, obesity, comorbidity index, bladder dysfunction before surgery, prostate volume, pelvic floor dysfunctions and previous transurethral resection of the prostate.

RP for prostate cancer is performed far more frequently now than 25 years ago. Robot-assisted RP (RARP) has become the most frequently used approach for surgical management of localized prostate cancer in the United States, with 85% of all surgical cases performed via the robotic-assisted laparoscopic approach. According to an analysis of the Surveillance, Epidemiology and End RESULTS-Medicare dataset, which identified men who had open RP and minimally invasive RP (MIRP) for prostate cancer from 2003–2009, MIRP was associated with a higher risk of voiding dysfunction (hazard ratio [HR] 1.31, 95% confidence interval [CI] 1.20–1.43) and erectile dysfunction (ED) (HR 1.43, 95% CI 1.31–1.56), but a lower risk of bladder outlet obstruction (HR 0.86, 95% CI 0.75–0.97). However, as experience with the robotic approach has grown, the rate of adverse events has dropped significantly–particularly in high volume centers. In many centers, RARP is utilized for the overwhelming number of cases with excellent outcomes.

Approximately 5–25% of patients will experience incontinence that fails to improve with conservative management, and a substantial minority will ultimately undergo surgical treatment.[1] The incidence of PPI depends on the exact definition of UI, methods of data collection (surgeon vs. patient; complete vs. social continence) and the length of follow-up. The artificial urinary sphincter (AUS) has provided a satisfactory result in most cases, regardless of the degree of UI, with a positive impact on QoL. Sling procedures have emerged as an efficacious treatment in many men with mild to moderate stress UI (SUI). More recently, however, Abrams et al conducted a non-inferiority randomized clinical trial (RCT) to compare the male transobturator sling (N=190) vs. the AUS (N=190) among men with moderate to severe SUI, showing non-inferiority. At 12 months after randomisation, utilizing a very strict definition of continence, incontinence rates were 134/154 (87.0%) for male sling vs. 133/158 (84.2%) for AUS (*P*=0.003). Other minimally invasive options, such as bulking agents have not shown durable long-term results and its use has largely been abandoned. Periurethral balloons are a feasible minimally-invasive option for treatment bothersome PPI in selective reference centers. However, high revision and complication rates have been reported.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment is indicated following similar strategies applied in post-prostate cancer treatment incontinence, i.e., slings and AUS.

Incontinence following radiation therapy (XRT), cryosurgery, high-intensity focused ultrasound (HIFU), other pelvic operations, and trauma is a particularly challenging problem because of tissue damage inside and outside the lower urinary tract. In such instances, periurethral bulking, sling procedures, and inflatable periurethral balloons have generally proven inefficacious and worsening of incontinence may happen after such surgery. The use of anti-androgen therapy in men with prostate cancer may result in tissue atrophy, which can exacerbate radiation-related SUI. The AUS is the most successful surgical procedure in this setting, but is associated with a higher rate of complications compared to implantation following surgery in the absence of adjuvant cancer therapy. With tissue damage beyond the urinary sphincter, other surgical approaches may be necessary. Patients with unresolved problems from childhood and with associated incontinence from detrusor overactivity may benefit from a variety of complex reconstructive surgical procedures. Patients with primarily OAB symptoms who have failed conservative management may benefit from neurostimulation or botulinum toxin injection. Other complicated problems encountered include urethrocutaneous fistulae, and fistulae between the prostate, bladder neck, or urethra and rectum. Surgical reconstruction, in experienced hands, often in a staged manner, is usually successful. Nonetheless, these cases often have higher complication rates and a multi-disciplinary team approach may be useful (e.g., colorectal, plastic surgeons).

This Chapter is a literature review and summary of the recommendations presented during the 7th International Consultation on Incontinence (ICI) by the Committee on Surgical Treatment of UI in Men.

1. METHODS AND MATERIALS

The Committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Sixth Consultation for non-neurogenic male incontinence.[4] Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the Committee and included in the Chapter.

Incontinence was classified according to its etiology, i.e., either primarily sphincter, bladder related or fistulae (Table 1).

Specific recommendations are made based on published results and determined by the levels of evidence. Consensus of the Committee determined these clinical recommendations, which are found at the end of the Chapter. Recommendations for future research are also included.

TABLE 1. Classification of Surgically Correctable Problems

Sphincter Related	Post-prostatectomy for prostate cancer Post-prostatectomy for benign disease Post-TURP and radiation for prostate cancer Post-cystectomy and neobladder for bladder cancer Post-traumatic After prostato-membanous urethral reconstruction Pelvic floor trauma or dysfunction Unresolved pediatric urologic incontinence Exstrophy and epispadias Neurological (pelvic floor or sphincter) abnormality
Bladder Related	Refractory urgency incontinence Small fibrotic bladder
Fistulae	Prostatorectal (urethrorectal) Urethrocutaneous

II. TIMING OF SURGICAL INTERVENTION AND EVALUATION PRIOR TO SURGICAL THERAPY

1. TIMING OF INTERVENTION

Following RP, there is a consensus that progressive recovery of continence during the postoperative period can be expected.[5,,,,,,,] However, it is not established what duration of recovery time must be allowed to elapse to be confident of the long-term continence outcome. This duration is important, as it gives the patient a timepoint at which they can revise their expectations, and decide when to receive interventional treatment for persisting incontinence. Nonetheless, it is often recommended that patients wait a year after prostate surgery before considering incontinence surgery since improvement in SUI with conservative therapy is often most pronounced in the first year post-prostatectomy.[5,,] While there can be further improvement in incontinence beyond 1 year,[11,,] most patients will plateau by 1 year; although, in some cases, this may occur at 6 months.[20,]

Both the AUS Consensus Conference 2015 and the American Urological Associaion (AUA)/Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) 2019 Guidelines for incontinence after prostate treatment recommend surgery for incontinence as early as 6 months post-prostatectomy if the patient's incontinence is not improving.[16,18] These guidelines state that continence stability play an important factor in determining the timing of surgical intervention such that if a patient has severe bothersome symptoms without apparent improvement by 6 months post-prostatectomy, it is unlikely there will be significant improvement over time with conservative management and that it is reasonable to consider incontinence surgery at that stage. However, if minor improvement is seen, even at 12 months, the patient can be advised to consider delaying surgical intervention.

Following surgery for benign prostatic enlargement (BPE), some patients may experience incontinence that is typically transient. As can be seen in Table 2, transient incontinence has been reported after all forms of BPE sugery including TURP, PVP, HoLEP, ThuLEP and open prostatectomy. Up to 50% of PVP patients have been reported to experience transient incontinence postoperatively—typically urge urinary incontinence (UUI). Transient incontinence usually resolves by 6-12 months.[,,] Persistent incontinence post-TURP is often due to underlying sphincteric damage[22] and this will warrant surgical treatment. Given that transient incontinence after BPE surgery is not uncommon and typically resolves by 1 year postoperatively, it is reasonable to counsel men to wait a year before considering surgical therapy for SUI (similar to post-RP incontinence). The degree of urinary incontinence will play an important factor in the decision-making process for surgical intervention. While daily continence-pad requirement provides an objective measurement, various patient factors such as perceived wetness or hygiene practice may affect the number or size of incontinence pads. More recent studies have attempted to improve outcomes assessment with validated questionnaires, such as the domains of Expanded Prostate Cancer Index Composite [EPIC]) or items from the ICI Questionnaire (ICIQ). The person undertaking assessment is a clear-cut bias risk since there is the potential to influence behavior and reporting, or use of less stringent definitions of continence (for example, counting use of a single daily incontinence pad as "continent"). This needs to be discouraged, since patients regard any need for continence pad protection as detrimental to the overall QoL. A significant decrease in QoL is evident when comparing people with no pad requirement, compared with those using a security pad or a single pad. Hence, a strict definition of continence as 0 pads is advocated.

2. EVALUATION PRIOR TO SURGICAL THERAPY

2.1. Diagnostic Objectives

- To determine presence, type and severity of incontinence.
- To exclude risk factors for complications.
- To help with treatment selection.
- To establish prognostic factors for outcome.
- Evaluation for presence of symptoms that make it necessary to carry out the diagnostic study early to rule out other complications (urethral stricture, bladder neck contracture, etc.).

2.2. Diagnostic Methods

As with any medical condition, a history is obtained to identify the presence and type of incontinence, the inciting factors, the magnitude and degree of bother. Other lower urinary tract symptoms that may suggest the presence of other issues should also be elicited (see side note). One wants to clarify the underlying causative factor that led to the incontinence (prior surgery and/or XRT, trauma etc.) and also identify any prior treatments for the incontinence (e.g., conservative, medical, surgical therapy) as well as previous lower urinary tract surgery that could impact surgical approach and outcome (e.g., prior urethral surgery such as urethroplasty). Both desire for and acceptance of treatment need to be evaluated, considering patient goals and expectations of treatment and support systems (including caregivers).

The presence of any medical comorbidities should also be determined as these can impact the patient's suitability for additional surgery as well as the outcomes of surgery. Cardiopulmonary risk factors may preclude the patient from receiving anesthesia for surgery while the presence of poorly controlled diabetes may increase the risk for infection with a surgical implant. Along with the general importance of medication review, mechanistically certain drugs may alter sphincter function, notably the antidepressant duloxetine. Hormone therapy of prostate cancer may be relevant, since low serum testosterone level predisposes to artificial urinary sphincter cuff erosion.

2.2.1. Past Medical History

2.2.1.1. Symptoms

The terminology relating to symptoms, signs, urodynamic observations and therapy has been standardized by the International Continence Society.[1]

2.2.1.2. Previous Conservative, Medical and Surgical Treatment

Previous artificial sphincter surgery does not preclude successful outcome for redo surgery. Outcomes for secondary AUS reimplantation are comparable to those of primary AUS implantation and salvage of a good outcome is always probable, even following multiple prior revisions and cuff erosion. The data regarding prior sling surgery generally favors AUS over sling revision, with the exception of late sling failure with a persistently positive repositioning test or in cases where the sling is poorly located postoperatively based on our quantitative analysis of magnetic resonance imaging (MRI) parameters. The impact of prior urethral sling on artificial urinary sphincter outcomes has been reported. AUS placement after failed sling has a high success rate (80–90%) without an increase in the expected complication rate.[39] Patients who require an artificial urinary sphincter after an initial male sling seem to fare as well as those who undergo primary artificial urinary sphincter implantation. However, according Ziegelmann et al,[40] there could be a trend towards worse three-year device outcomes in patients with prior urethral sling, and suggested the need for longer-term studies to determine if slings pose an increased hazard for subsequent sphincter implant surgery.

2.2.1.3. Co-Morbidity

2.2.1.3.1. Cardiovascular Risk Factors

Risk factors such as hypertension, diabetes mellitus, coronary artery disease and smoking need to be evaluated. These represent a concern, given that retropubic radical prostatectomy decreases membranous urethral microcirculation; hence, additional surgical interventions with implants may entail more risk.

2.2.1.3.2. Presence and Severity of Symptoms Suggesting Neurological Disease

This may influence choice of intervention, since male slings may require some residual sphincter functionality.[1] All individuals need to be able to understand proposed management plans and to discuss, where appropriate, alternative treatment options. Use of the artificial sphincter requires adequate cognitive and dexterity function, so formal testing should be considered for individuals where there are concerns regarding memory or attention deficits, and depression screening.

2.2.2. Validated Questionnaires

The use of validated symptom questionnaires allows for a standardized method of grading symptoms to determine severity and degree of bother, as well as track changes/progress over time. This is useful in research studies but also in clinical practice. Questionnaires can be incontinence specific such as the ICIQ-SF that assesses the prevalence, frequency, and perceived triggers of urinary incontinence, and its impact on everyday life, or part of a larger questionnaire assessing symptoms from several systems after prostate cancer treatment such as the EPIC questionnaire. While good correlation between questionnaires and pad usage have be reported, combining symptom scores with pad testing (see below) may be best.

2.2.3. Physical Examination

As with any urologic patient, a focused physical exam is performed. Abdominal exam rarely identifies any significant unexpected findings but the presence of a palpable bladder should alert one to possible outlet obstruction and overflow incontinence. Scarring from previous surgeries should be noted, especially in the inguinal regions where one might place an AUS reservoir. Genital exam should identify any skin pathology that might complicate genital surgery (e.g., lichen sclerosis) as well possible increased risk for infection (e.g., hidradenitis). A hydrocele is typically easily identified and may influence site choice of an AUS pump.

A focused neurological exam is performed to rule out cognitive and/or functional deficits that may impact surgery selection. Dexterity is required to manipulate an AUS pump; a tremor or disfiguring arthritis may preclude this.

2.2.4. Cough Stress Test

A cough stress test (CST), typically done in the standing position is a good way to demonstrate SUI, but in addition, grade its severity.[1] The standing CST was shown to correlate highly with 24-hour pad weights and have predictive value with respect to the outcomes of transobturator slings.[53] A negative CST in the clinic should prompt a repeat CST either at the time of cystoscopy or urodynamic study (UDS).

2.2.5. Bladder Diary

The term frequency-volume chart is used to describe a chart that records the time of each micturition and the volume voided for at least 24 hours. The bladder diary may include fluid intake, incontinence episodes, pad usage, the degree of incontinence as well as a record of episodes of urgency and sensation and activities performed during or immediately preceding the involuntary loss of urine. Therefore, bladder diaries are most suited for the purpose of comprehensive evaluation of urinary incontinence.[35] A frequency-volume chart (FVC) or bladder diary (BD), if properly completed, can confirm all of the following information: daytime urinary frequency, nocturnal frequency/nocturia, urine production, maximum voided volume:, average voided volume, median functional bladder capacity, and the measurement of voided volumes allows for the identification of polyuria contributing to the symptoms.

Recommendations for diary duration vary considerably including 24 hours, 3 days or 7 days; this inconsistency is partially explained by differences among study populations, based on diagnosis, age, sex, and geography, and by differences in methods of analysis and in interpretation of the results. Excessive duration could reduce patient compliance, but too short a duration may produce unreliable measurements.

2.2.6. Pad Testing

An assessment of the magnitude of incontinence is important in determining how aggressive one should be in managing the incontinence and may impact choice of incontinence surgery. While an AUS is suitable for all degrees of incontinence, other therapies such as slings, appear to have greater success when the incontinence is less severe.[,,,]

Incontinence magnitude has been assessed via pad usage and pad weight testing. Pad usage is typically based on the patient's reporting of how many pads they use and will depend on actual incontinence severity as well as type/size of pads and the patient's tolerance for pad wetness (some patients will change a pad upon the slightest amount of urine leakage whereas others may allow their pads to be soaked before changing them).

On the other hand, pad weight testing eliminates these confounding issues and directly measures the amount of urine leakage and is thus considered a more objective measure of incontinence severity and the 24-hour pad weight test is considered the gold standard for measuring incontinence.

Pad usage has been shown to correlate poorly with 24-hour pad weights.[,] However, in the SUFU pad test study, using a more detailed standardized questionnaire, men were able to accurately describe the number, size and degree of wetness of their pads and these parameters correlated well with urine loss as measured by 24-hour pad testing.[62] Furthermore, a single QoL question that asked the extent to which urine loss affects quality of life was able to stratify men into distinct categories based on pad weights. However, there are no publications using the SUFU pad test questionnaire to help guide surgery selection in post-prostatectomy incontinence.

On the other hand, 24-hour pad weight testing may be a predictor of outcomes after male slings. Significantly lower efficacy with transobturator slings has been reported in several studies based on the preoperative 24-hour pad weight testing with the cut off typically around 400 g of leakage,[58,60] and possibly as low as 200 g.

2.2.7. Assessment of Voiding and Emptying

A history of voiding difficulty should alert the surgeon to possible bladder outlet obstruction (possible urethral stricture or bladder neck contracture) and/or a weak detrusor. An assessment of bladder emptying (post void residual) is warranted in most patients in this regard.[16] As well, an unintubated (free) uroflow may confirm if the flow rate is truly abnormal. Cystoscopy would then be warranted to assess for anatomic obstruction. While UDS provides the most definitive testing for outlet obstruction (pressure flow test), some have argued that a normal uroflow and low post-voiding residual (PVR) imply adequate bladder contractility and the absence of outlet obstruction and may suffice for the majority of patients.

In general, abdominal imaging is unnecessary in the evaluation of male incontinence with the exception of the aforementioned PVR that is usually accomplished via an ultrasound bladder scanner. In patients with incontinence following prior incontinence surgery (e.g., AUS, periurethral balloons [ProACT]), imaging may be warranted to assess for the presence of fluid in the system and can be accomplished by plain x-ray (if contrast was used), ultrasound (US) or computerized tomography (CT) scan.[,]

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of in-continence following artificial sphincter implantation when during the original procedure the hydraulic sys-tem was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons.

2.2.8. Urine Testing

As with any patient with lower urinary tract symptoms (LUTS), a urinalysis (with culture as indicated) is mandatory to rule out infection as well as the presence of microscopic hematuria.

2.2.9. Endoscopy

Cystoscopy is indicated in the presence of gross or microscopic hematuria to rule out urethral, bladder, or prostatic pathology as the cause. However, even in the absence of hematuria, both the AUS Consensus Conference of 2015 (Grade of recommendation D) and the recent AUA/SUFU Guidelines on incontinence after prostate treatment (Clinical principle) recommended cystoscopy prior to surgery for incontinence.[16,18]

Cystoscopy allows one to rule out the presence of urethral stricture/anastomotic contracture or other forms of obstruction (e.g., prostatic regrowth after TURP, necrotic tissue/stones after radiation, cryo or HIFU), as well as any bladder pathology (tumor, stones) that may require further treatment prior to incontinence surgery. In addition, one can assess the integrity of the external sphincter as this may have ramifications regarding surgical selection: it has been suggested that a patient who is unable to volitionally contract his external sphincter and/or in whom it is not possible to manually reposition the membranous urethra in a cephalad fashion via perineal pressure may not be a good candidate for a transobturator sling.[,] Furthermore, cystoscopy allows for direct filling of the bladder and performance of a CST to visualize SUI (this is important if a negative CST occurs in the clinic, possibly due to inadequate bladder volume). However, to date, no study has directly addressed the need for cystoscopy prior to incontinence surgery.

2.2.10. Urodynamics

As noted in the AUS Consensus Conference 2015 (Grade of Recommendation C)[16] and more recently the AUA/SUFU Guidelines 2019 (Conditional Recommendation, Evidence Level: Grade C),[18]

UDS may be performed to facilitate the diagnosis of incontinence and/or aid in patient counseling.

UDS may be used for the following reasons:

a) Determine the extent of SUI especially in patients with non-classic SUI or mixed symptoms.

In a study of 60 men with post-radical prostatectomy incontinence, intrinsic sphincter deficiency was demonstrated in 54 patients (90%). However, 27 patients (45%) patients were found to have underlying bladder dysfunction and in 16 cases (27%) incontinence was the result of bladder dysfunction only (rather than ISD).

The determination of Valsalva leak point pressure (VLPP) or cough leak point pressure (CLPP) could improve the assessment of underlying sphincteric function/weakness although there is poor correlation between VLPP and incontinence magnitude based on 24-hour pad test. On the other hand, VLPP was reported to have predictive value for transobturator slings: a VLPP of ≤100 cmH_2O had a HR for failure of 4 compared to a VLPP of >100 cmH_2O (95% CI 0.68–23.7).[61] Caution must be taken regarding the significance of a negative VLPP (no leak at all). When VLPP is measured with a urethral catheter in place, the catheter may create some degree of urethral obstruction resulting in a false reading. In fact, 18-35% of patients with SUI may have negative leak point pressure (LPP) testing with a urethral catheter in situ but demonstrate SUI when the catheter is removed.[,] Thus, it is recommended that the clinician repeat LPP testing without a urethral catheter in-situ.[75] Rectal transducer catheter is then used to determine the LPP during cough/Valsalva (termed abdominal LPP [ALPP]). Another method of assessing external sphincter function is the retrograde LPP [RLPP} which evaluates the ability of the sphincter complex to resist the retrograde leakage of fluid into the bladder. Unlike, the VLPP/ALPP, the RLPP was demonstrated to have good correlation with 24-hour pad testing and was able to differentiate between cases of mild/moderate (<400 g) and severe (≥400 g) incontinence. As such, it has the potential to be a substitute for pad weight testing and help with surgical selection. However, to date, no study has demonstrated the predictive value of RLPP with respect to surgical outcomes.

b) Identify detrusor storage dysfunction (detrusor overactivity [DO], bladder capacity, compliance).

One study found that DO was present in up to 3/4 of patients during UDS and decreased bladder compliance could be observed in up to 2/5 of patients after RP. Preoperative DO has been reported as an adverse predictive factor for successful outcomes for male slings.[79,] However, the data between preoperative DO and AUS outcomes is variable.[66,76,77,78,]

Bladder capacity on UDS (cystometric capacity) has also been reported to be a predictor of successful incontinence surgery. A smaller cystometric capacity (<400 mL and especially <250 mL) has been associated with a greater failure rate with transobturator slings (Advance, Virtue),[79,] adjustable transobturator slings (ATOMS) and adjustable balloons (ProACT). However, as with preop DO, preop cystometric capacity may not have an impact on outcomes of AUS.[82,,] Thus the presence DO and low cystometric capacity on UDS, while not necessarily contraindicating a specific type of surgery, may help in counseling patients regarding postoperative expectations.

Continence surgery performed in a poorly compliant bladder can be an issue if this results in higher bladder pressures and if there are significant urinary postvoid residuals.[82] However, some hypothesize that elevated storage pressures noted on UDS in severely incontinent patients may be the result of a chronically underdistended bladder (because of intrinsic sphincter deficiency [ISD]) being subjected to higher fill volumes than it is accustomed to[86] and many studies on AUS and slings have not identified low bladder compliance to be an adverse prognostic factor.[79,81,,] Nevertheless, the AUS Consensus Conference in 2015 acknowledged this concern noting the role for UDS and the need for close follow-up in patients at risk of low bladder compliance, such as those who have had pelvic radiation or suffer from neurogenic lower urinary tract dysfunction (Grade of recommendation C).[16]

In some patients with severe sphincteric incompetence, it is not possible to fill the bladder to a sufficient volume to fully assess its storage pressures as a steady state of filling and leaking may be reached. A Foley catheter balloon can be utilized to occlude the bladder neck to prevent urine leakage and allow for a better assessment of bladder storage pressures. Alternatively, a penile clamp can also be used to achieve the same result.

c) Assess bladder contractility and emptying (including outflow obstruction)

Anatomic urethral obstruction may be present in a significant number of patients after local treatment for prostate cancer (RP, radiation, cryosurgery, HIFU) as well as BPE surgery, and its presence can complicate management of incontinence. In general, this will take the form of urethral stricture that can be located anywhere from the urethral meatus to the bladder neck, but obstruction may also be due to necrotic tissue (radiation, cryosurgery, HIFU) and prostatic enlargement (in non-RP patients). Pressure-flow testing is the gold standard for diagnosing outlet obstruction in these patients. However, at least in the case of post-RP incontinence, it has been suggested that a normal non-invasive uroflow and complete bladder emptying may be indicative of the absence of significant outlet obstruction and obviate the need for more formal pressure-flow testing.[66] Adequate bladder contractility has been suggested to be needed in patients considering urethral slings because of concern that the sling may cause some degree of urethral obstruction, whereas this would be less of a concern in the setting of an AUS where the urethral compression is reduced during micturition. Impaired contractility was identified in about 47% of patients after RP although most recovered.[80] Despite this concern, it was shown that in patients undergoing a sling (especially a transobturator sling) there was no difference in postop Patient Global Impression of Improvement (PGI-I) scores or PVRs between those with normal preop contractility and those with decreased contractility (using BCI); similar findings were noted when comparing Valsalva voiders to non-Valsalva voiders. However, the use of BCI to assess contractility is questionable since the prostate is absent and BCI was defined in BPE patients. The maximum isometric detrusor pressure, determined via a mechanical stop test, has been recommended as a better surrogate for bladder contractility,[92] although there are no reports of using Piso to guide surgical selection.

III. PATHOPHYSIOLOGY AND RISK FACTORS

Urinary continence in the male is maintained by a complex interaction between the central/peripheral nervous system, bladder (detrusor) muscle, internal and external urinary sphincter musculature, pelvic ligaments/fasciae and pelvic floor musculature.

Incontinence in males, similar to that in females, can occur as a result of:

a) deficiency in the urethral sphincter mechanism (sphincteric incontinence)–typically resulting in SUI.
b) urine storage pressure elevations:

   i) DO/OAB – may result in UUI
   ii) low bladder compliance

c) a combination of a) and b) – mixed urinary incontinence (MUI)
d) urinary retention with overflow (i.e., an emptying dysfunction)
e) fistula

In general, damage to the urethral sphincter mechanism occurs because of some form of direct insult (e.g., surgery, trauma, radiation) to the sphincteric musculature or some neurologic insult affecting sphincteric innervation (neurologic disease, nerve trauma from surgery). Bladder storage pressure dysfunction comes in two forms: an DO and a bladder that stores urine at high pressure (LBC). Incontinence associated with DO occurs when the intravesical pressure overcomes the ability of the urinary sphincters to withstand the intravesical pressure. This may or may not result in the sensation of urgency with UUI. With LBC, there is often an activity related component to the incontinence that is akin to SUI, the difference being that with LBC, the intravesical storage pressure is elevated due to rigidity of the bladder wall whereas with genuine SUI, the intravesical storage pressure is actually low. Both forms of dysfunction may be associated with radical treatment of prostate cancer including surgery and XRT. However, they can also be present prior to therapy, often in relation to pre-existing benign prostatic hyperplasia (BPH), neuropathy or even aging itself. Urinary retention can result in incontinence via an overflow mechanism and as such isn't even a urinary storage issue (the bladder is overdistended with resultant "spillover" or overflow incontinence; alleviating the urinary retention resolves the incontinence). A fistula bypasses the urinary storage mechanisms, which may or may not be concomitantly affected. Bladder storage pressure related incontinence (OAB) will specifically be addressed in a separate chapter while rectourethral fistula is addressed later in this chapter. In this section, the focus will be on incontinence as a consequence of treatment (surgical/nonsurgical) of benign/malignant.

Most studies that report on the incidence of incontinence fail to differentiate the type/etiology of incontinence (e.g., sphincteric vs storage pressure related) and simply refer to the presence of incontinence in general. As such, the risk factors/pathophysiology of incontinence will be presented for the specific insult (e.g., prostatectomy for cancer/BPH, radiotherapy and other prostate cancer treatments, cystectomy with orthotopic neobladder, other pelvic surgery/trauma), and when possible, the different types of incontinence will be addressed.

1. MALE URINARY SPHINCTER

The male urethral sphincter has 2 independent components: an internal sphincter (smooth sphincter) composed of smooth muscle (the bladder neck is part of this) that is under autonomic control and an external (rhabdosphincter) sphincter composed of striated muscle that is under voluntary control. The smooth muscle of the internal sphincter, being able to maintain tone for long periods with minimal exertion, maintains continence during normal activity when there is little stress on the bladder outlet (passive continence).[1] As delineated by Strasser et al, the external (rhabdosphincter) sphincter (EUS) is a vertically oriented muscle extending from the bulb of the penis to the bladder neck (BN), separate from the levator ani. It is omega shaped spanning the anterior (between symphysis and urethra) and lateral aspects of the membranous urethra. Both ends of the omega shaped sphincter insert at the perineal body, and posterior to the membranous urethra (between urethra and perineal body), smooth muscle and connective tissue appear to predominate. Contraction of the rhabdosphincter pulls the urethra towards the perineal body thus compressing the membranous urethra against Denonvillier's fascia and rectourethralis muscle to achieve active continence.[95]

The rhabdosphincter is anatomically related to and physiologically assisted by the pelvic floor muscles (levator ani, bulbocavernosus) in the voluntary constriction of the urethra. As will be discussed, they may play an even more important role after prostatectomy.

There are multiple support structures of the membranous urethra and bladder neck (BN) that act to stabilize the position of the BN and EUS complex and anchor the membranous urethra to the pubic symphysis. Anteriorly: the pubourethral ligaments (pubovesical and puboprostatic); posteriorly: perineal body/central tendon, Denonvillier's fascia, rectourethralis muscle, levator ani muscle; and laterally: arcus tendinous/endopelvic fascia. Damage to these structures during radical prostatectomy is thought to be a contributor to post-prostatectomy incontinence and efforts to preserve/reconstruct these structures have resulted in improved continence rates, as will be discussed.[1]

The innervation of the EUS is very complex and still yet to be completely elucidated. There appears to be somatic and autonomic co-innervation: somatic via 1) pudendal nerve which has extrapelvic branch (via Alcock's canal) and in some patients, intrapelvic branches that travel through the levator ani muscle and enter EUS at 5 or 7 o'clock near the apex of the prostate; and 2) somatic branches of S2, 3, 4 that travel with the autonomic fibers of the pelvic plexus to innervate the EUS. Autonomic innervation has been identified via intrapelvic branches of the hypogastric and pelvic plexuses that have been observed at the posterolateral aspect of the prostate apex.[98] In fact, stimulation of the neurovascular bundles during radical prostatectomy has been shown to elicit significant increases in intra-urethral pressure. Communication between somatic and autonomic pathways exist, especially as one follows the fibers more proximally.[98]

2. INCONTINENCE RELATED TO PROSTATE CANCER TREATMENT

2.1. Post-Prostatectomy (Radical) Incontinence (PPI)

RP for prostate cancer involves surgical removal of the prostate and frequently seminal vesicles with anastomosis of the bladder to the membranous urethra. The bladder neck is transected proximally (the majority of the internal sphincter is lost) and the membranous urethra distally. Thus, both the internal and external urinary sphincters are at risk. The neurovascular supply and rhabdosphincter itself are intimately associated with the prostate and thus at risk for damage. The surgical steps associated with greatest risk for incontinence after radical prostatectomy include wide excision at the level of the seminal vesicles, the periprostatic dissection and dissection at the prostate apex where convergence of nerve fibers occurs and nerves are within millimeters of the dissection plane and suture bites.[98] In fact, Egawa et al demonstrated that the urethral sphincter innervation lies 0.3–1.3 cm away from the prostate apex.

These issues will predispose the patient to sphincteric/SUI. Since the majority of patients recover continence within 6–12 months, true direct sphincter damage is unlikely in these patients and it is more likely that trauma to nerves and support structures results in the temporary incontinence. The nerves innervating the sphincters are at risk for injury either directly (transection, cautery) or indirectly (retractor stretching). As reviewed, by Porena et al,[80] ISD represents the primary diagnosis in 55–100% of PPI patients.

Autonomic denervation of the membranous urethra after RP was demonstrated by Catarin et al who prospectively identified alterations in the pelvic and membranous urethral afferent and efferent innervation after nerve sparing RP by using several neurophysiological tests as well as a validated questionnaire. Sensory and motor pudendal innervation was unaffected after surgery, whereas autonomic afferent denervation of the membranous urethral mucosa was found in 77% of patients, including 92% of patients with urinary leakage (especially occasional leakage).

Surgery can also result in a bladder dysfunction that may be related to nerve injury as well (the pelvic plexus sits on the surface of the rectum). Bladder dysfunction as it relates to incontinence may take the form of OAB/DO and/or LBC. In their review of 10 prospective and 9 retrospective studies that included UDS after RP, Porena et al noted the following reported incidences: *de novo* DO in 2%-77% of patients, impaired bladder compliance in 8–39% of patients (*de novo* in about 47%, persistent in 26% after 8 months), and impaired detrusor contractility in 29–61% of patients (*de novo* in 47%, recovered in about 50% of patients). Most patients with DO had other associated UDS dysfunctions such as ISD and impaired contractility. Isolated DO was noted in up to 10% of patients.[1] Postoperative decentralization of the bladder, inflammation and/or infection, and geometric bladder wall alteration associated with preexisting hypoxemia with/without neuroplasticity have been posited as causes of detrusor dysfunction particularly when an isolated finding.[1]

An association between DO and SUI/ISD in PPI patients has been noted by many[75,,,] and might be related to activation of the urethrovesical reflex via C-fiber afferent effect: urine leaking across an incompetent sphincter into the proximal urethra triggers DO.[1,]

However, in many cases, the urodynamic demonstration of DO and low bladder compliance (LBC) when associated with ISD/SUI on post-RP cystometry may be an “artifact” of UDS. Some have suggested that because of ISD/SUI, there’s an inability to adequately store urine on a day to day basis resulting in the bladder dysfunction noted on UDS (DO or LBC): on UDS the bladder is getting filled at supraphysiologic rates to higher than normal volumes, which then triggers the apparent bladder dysfunction.[72,86,] Furthermore, it’s been reported that DO and bladder compliance are not adverse prognosticators and may improve after SUI surgery.[89,107] Whether this improvement is a direct effect of the SUI surgery preventing activation of the urethrovesical reflex or via the SUI surgery allowing for more urine storage/better bladder filling on a day to day basis is unclear.

Studies Reporting Continence Outcomes of Various Surgeries for Prostate Cancer are shown in table 3.

2.1.1. UDS Findings After RP

Urodynamic evaluation of patients, pre and post-RP, has yielded varying results regarding the types of storage dysfunctions that are present in the PPI patient. Giannantoni et al performed UDS before RRP and longitudinally postoperatively in 54 patients in whom 37 had 3-year follow-up and reported bladder and sphincter function changes in a significant number of patients after RRP including: ISD/SUI in 74% at 8 months with persistence at 36 months in 59%, DO in 70% at 8 months (although preoperatively present in 61%) and 56% at 36 months, and *de novo* decreased compliance in 32% of patients at 8 months with persistence at 36 months in 28%. Song et al, in a prospective study, similarly did UDS before RRP and serially postop up to 36 months and found reductions in maximum cystometric capacity (MCC), maximum detrusor pressure ($Pdet_{max}$) and maximum urethral closure pressure (MUCP) at 3 months, all of which remained relatively unchanged over time. At 3 years, the mean MCC changed from 393.0mL before RP to 322mL (P<0.001), the MUCP from 64 to 53cmH_2O (P=0.001), and $Pdet_{max}$ from 54 to 45cmH_2O (P=0.001). DO was present in 38% of patients before RP and it persisted in 74% of them at 3 years. However, only 24% of patients with DO at 3 years felt the symptoms were severe enough to warrant medication. Incontinence was noted in 46% and 18% of patients at 3 and 6 months after RP respectively, but all were continent by 3 years. Kadono et al did UDS before RARP (with or without nerve sparing [NS]), 3-4 days after catheter removal, and approximately 1 year postop in 84 patients. MUCP was noted to decrease immediately after catheter removal but at approximately 1 year postop, recovered to approximately 70–90% of preop values depending on nerve sparing: there was less of an early decline and a greater degree of improvement by 1 year with greater degree of NS. ALPP, cystometric capacity and bladder compliance also had a trend of early deterioration and late improvement to almost preop levels but there were no significant differences between degrees of nerve sparing. Ventimiglia et al used UDS and neurophysiologic testing (pudendal nerve somatosensory evoked potentials [SEP], perineal EMG) in 51 patients with incontinence at 8–24 months after RP. They found DO in 63% (isolated DO in 35%, DO + SUI in 28%), and SUI in 65% (isolated in 37%). Patients with isolated DO had intact perineal muscle and pudendal nerve function. The remaining patients had varying degrees of injury/dysfunction of the perineal musculature/pudendal nerve with associated SUI. The most severe group had sphincteric incontinence with very poor perineal muscle function and SEPs suggestive of more severe nerve injury (neurotmesis) and these patients were also noted to have decreased bladder compliance. They believe that the high rate of DO in PPI patients is due either to a high rate of pre-existing DO that was missed or due to a neuropathic mechanism related to trauma to the pelvic plexus during the surgery (i.e., bladder denervation). A more recent report by the same group had similar findings. Recently, MacKenzie et al evaluated 64 men with post-robotic assisted laparoscopic prostatectomy lower urinary tract symptoms

(RALP LUTS)/incontinence using the ICIQ on Male Lower Urinary Tract Symptoms Long Form (ICIQ-MLUTS) and UDS. There was a significant increase in total ICIQ-MLUTS and bother scores at 6, 12 and 18 months postop and postop UDS showed 81% had urodynamic stress incontinence (isolated SUI in 64%), 17% had SUI and DO, and 3% had isolated DO. Low bladder compliance (≤12.5 mL/cmH_2O) was present in 5%, outlet obstruction in 11%, detrusor underactivity (using the bladder contractility index) in 46%, while 16% had no urodynamic abnormalities identified.

Thus, while sphincter incontinence is the main storage dysfunction after RP (and the main indication for surgical management of incontinence in men), bladder dysfunction also occurs in a significant number of patients. Regardless of urodynamic findings after radical prostatectomy, i.e., phasic DO, incontinence following this surgery is overwhelmingly due to sphincteric insufficiency.

2.2. Risk Factors for PPI

Studies have shown that the incidence of incontinence after prostatectomy for cancer varies considerably depending on clinical and surgical factors as well as methods of assessment (including who is reporting, surgeon or patient) and the definition of urinary incontinence. Surgical approach/technique, surgeon experience as well as patient factors including age, obesity, anatomic issues (membranous urethral length, prior benign prostate surgery, prior XRT) have all been implicated as risk factors for PPI (see below). Incontinence has been defined via questionnaire responses regarding the presence or absence of incontinence and/or use of pads we well as formal pad testing. While it has been noted that a 0 pad per day definition of continence is more reliably associated with patient perception of continence, many studies reporting on incontinence after prostatectomy consider up to 1 pad per day, typically referred to as a safety pad to deal with minimal dribbling incontinence, as “social continence” and use this as their outcome measure. The use of patient reported outcomes via questionnaire is widely considered superior and more reliable compared to surgeon reported outcomes, and often yields significantly higher rates of reported PPI.

Various factors have been associated with the recovery/lack of recovery of urinary continence after RP. Broadly divided, there are surgical and patient factors:

2.2.1. Surgical Factors

2.2.1.1. Surgical Approach/Surgeon Experience

The literature regarding which approach to RP has the best continence outcomes is inconclusive. While several meta-analyses over the past 10 years have concluded that RARP is associated with better continence rates than open RP (RRP, radical perineal prostatectomy [RPP]) and standard laparoscopic approaches,[20,,] others have not shown a significant difference.[,,] In their often cited systematic review and meta-analysis, Ficarra et al analyzed 5 studies comparing RRP to RARP and noted better 12-month urinary continence recovery after RARP in comparison with RRP: the absolute risk of incontinence was 11.3% post RRP and 7.5% post RALP (a 3.8% absolute risk reduction) (OR: 1.53; *P*=0.03). Similarly, in 5 studies comparing RARP to LRP: the absolute risk of incontinence at 12 months after LRP was 9.6% vs 5% after RARP (a 4.6% absolute risk reduction) (OR: 2.39; *P*=0.006).[117]

A Cochrane Review was only able to analyze 2 randomized trials comparing RARP/LRP to open RRP using EPIC questionnaires, and assessed the quality of the evidence according to GRADE.[119] They concluded that urinary and sexual QoL-related outcomes appear similar between the various surgical approaches and the quality of the evidence was moderate.

In the LAPPRO trial, a multicenter, prospective trial (not randomized) comparing open RRP to RARP, Haglind et al,[114] using questionnaires to assess continence (<1 pad change/24 hour) reported no significant difference in 12 month postop incontinence (21.3% after RARP vs 20.2% after RRP). This lack of a statistically significant difference was maintained at 24 month follow-up (19% after RARP vs 16% after RRP; AOR 1.29, 95% CI 1.00–1.67; *P*=0.053). Coughlin et al[27] conducted a randomized study of open RRP vs RARP and found that urinary function scores (EPIC) did not differ significantly between the groups at 6 months, 12 months or 24 months postop.

Haese et al prospectively compared 10790 consecutive treated patients undergoing either RARP or RRP and found slightly better continence rates (0–1 pads) at 12 months after RARP compared to RRP (90.3% vs. 88.8%; *P*=0.01), but when stratified by age there were no significant differences.

Other recent studies have similarly found no significant difference between open RRP, laparoscopic radical prostatectomy (LRP) or RARP with respect to urinary function/bother (using EPIC questionnaires).[17,] As well, when RPP was compared to RRP by Martis et al, no differences in continence (1 hour pad test) were noted at 6 (74% vs 76%) or 24 months (96% vs 95%) postop between groups, while Jafri et al reported that RARP had greater overall urinary recovery (using EPIC questionnaire) compared to RPP at 6 months but there was no difference at or beyond 12 months.

Thus, whether or not the surgical approach matters with respect to postoperative continence is still unresolved. However, there is little question that the skills of the surgeon performing the surgery will impact the functional outcomes of RP. While not specific to the issue of postoperative incontinence, Vickers et al determined that for open RRP the learning curve for prostate cancer recurrence is steep and does not start to plateau until approximately 250 cases, presumably related to improved technique with more experience. For LRP, the learning curve is longer: the 5-year risk of cancer recurrence decreased from 17% to 16% to 9% for a patient treated by a surgeon with 10, 250, and 750 prior LRPs, respectively (risk difference between 10 and 750 procedures 8.0%, 95% CI 4.4-12.0). A study on RARP noted that postop urinary continence rates improved amongst several surgeons from ~60% early in the RARP learning curve to almost 90% after more than 400 procedures. In a single institution review, Hashimoto et al reported a learning curve of 100 cases with respect to 12 month post-RARP continence. On the other hand, others have found that with intensive structured modular training, fewer than 100 live cases are needed to optimize urinary continence after RARP. Recently, Nyberg et al confirmed the issue of surgeon experience in their analysis of the data from the LAPPRO trial. They found significant heterogeneity in incontinence (as well as ED and oncologic) outcomes among surgeons with differences in surgeon volume explaining 42% of the observed heterogeneity for incontinence (*P*=0.003).

2.2.1.2. Preservation/Reconstruction of Functional and Anatomical Support Structures

2.2.1.2.1. Nerve sparing

Many studies reporting on the incidence of PPI have found an association between nerve sparing and postop urinary continence.[110,,,]

This association between NS and postop continence may be relevant only with respect to early (first 6 months postop) continence. In a systematic review and meta-analysis of data from 13,749 participants in 27 studies, Reeves at al noted that NS (especially bilateral) appears to improve early postop continence rates up to 6 months but beyond that there is no difference compared to nonNS. The authors hypothesized that preservation of intrapelvic somatic nerves to the sphincter may help hasten recovery of continence. They also suggest that compensation by other continence mechanisms (e.g., pelvic floor muscles) may explain the lack of longer-term difference in incontinence between NS and nonNS. However, more recent studies have shown that NS may in fact be beneficial at 12 months postop. Kadono et al[110] evaluated predictive factors for postop continence in 111 patients who underwent RARP using UDS, MRI and 24-hour pad testing. On univariate and multivariate analyses, NS was the only variable that was predictive of postop continence (24-hour pad test <2 g). In 84 patients who underwent serial UDS postop, similar fluctuations in postop MUCP were noted between NS and non-NS patients (early decrease in MUCP with later partial recovery) but a higher degree of NS was associated with a lesser decrease in MUCP postop (3-4 days after catheter removal) and a higher MUCP at approximately 1 year. Kim et al, in a prospective study on 529 RARP patients, noted significantly greater return of continence at 12 months (pad free and no unwanted leakage) with bilateral NS (93%) compared to unilateral NS (78%) or non-NS (77%). Bilateral NS was independently associated with continence return 12 months postop (OR=3.671).[136] And in the CEASAR study, a prospective, population based, observational study of men diagnosed with localized prostate cancer in 2011 to 2012 comparing surgery to radiation, on multivariable analysis younger age, nonblack racial group and BilatNS (BNS) were associated with better urinary incontinence scores (EPIC) 3 years after surgery. However, this benefit of BNS on the urinary incontinence score was only significant in men with high baseline sexual function. On the other hand, Park et al,[134] in a retrospective review of 360 patients with preop erectile dysfunction undergoing NS or non-NS LRP or RARP, still found significantly higher urinary continence (0 pad usage) recovery rates at 3, 6, and 12 months in NS patients with the 12 month continence rates being 78% in the nnsRP group and 85% in the nsRP group, respectively (*P*=0.02). On multivariate analysis, age (HR 1.254; 95% CI, 1.002–1.478; *P*=0.026) and nerve-sparing status (HR 0.713; 95% CI, 0.548-0.929; *P*=0.012) were independently associated with recovery of urinary continence.

Considering that NS in patients with preop ED can still be associated with continence improvement after RP suggests the nerve function itself may not be the key but rather the careful apical dissection that accompanies NS RP. Hefermehl et al in a prospective study of patients having open RRP evaluated the effect of NS (using both surgeon defined NS based on operative report and postop international index of erectile dysfunction (IIEF)-defined NS [i.e., successful NS = postop IIEF >11]) on urinary continence using EPIC questionnaire. With a median follow-up of 48 months multivariate analysis for regaining continence demonstrated no significant difference between NS and NNS regardless of how NS was assessed (surgeon defined, IIEF) with 65% being continent at 3 years.[139] Furthermore Michl et al retrospectively analyzed 18427 men who underwent RP from 2002 to 2014 comparing patients having bilateral NS RP vs primary NNS RP, and those who ultimately had secondary resection of the neurovascular bundles(NVBs) for positive frozen-section results after an initial bilateral NS RP (secNNS – i.e., they had initial nerve sparing dissection). Continence rates (0–1 safety pad/day) at 12 months after surgery did not differ significantly between patients who had bilateral NS and those who had secNNS (i.e., resection of both NVBs after an initial NS technique). In contrast, secNNS had significantly higher continence rates after 12 months compared to primary NNS suggesting the careful dissection rather than actual preservation of NVB is the key to postop continence.

The benefit of NS and/or careful apical dissection may not just extend to ISD/SUI: there could also be a benefit with respect to OAB. Matsukawa et al,[106] in a prospective study on 230 RARP patients, using IPSS and OABSS to diagnose OAB and a 0 pad definition of continence, identified *de novo* OAB in 38% of patients at 3 months postop and a significantly greater rate of incontinence at 3 months in patients with *de novo* OAB (92% vs 20%). There was a significant difference in the nerve-sparing rate between the two groups (40% of OAB free patients vs 23% *de novo* OAB patients, *P*=0.01). Furthermore, postop MUCP and functional profile length were significantly lower in the *de novo* OAB group; postop MUCP was found to be the most significant risk factor for *de novo* OAB. A postop MUCP of 50 cmH2O was determined to be the optimal cut-off value for *de novo* OAB with a sensitivity of 81% and a specificity of 72%. On the other hand, Kadono et al[110] did not find an effect of nerve sparing on longer term bladder storage function based on UDS at 1 year.

It remains unclear whether actual nerve preservation and/or careful apical dissection preserves functional urethral length and a more competent distal sphincter mechanism results in the improvement in OAB. Regardless, nerve sparing with careful apical dissection appears to reduce both postoperative SUI and OAB.

2.2.1.2.2. Anterior/Posterior/Total Reconstruction

Reconstruction of the anterior and posterior support of the membranous urethra and urethrovesical anastomosis appears to hasten the recovery of continence after RALP.[99] Anterior suspension mimics the puboprostatic and pubovescial ligament function and alleviates downward prolapse of the bladder on anastomosis. In posterior reconstruction, the aim is to maximize urethral length (by preventing caudal retraction), maintain a more anatomic position that avoids anastomotic tension, and provide a posterior platform that buttresses the sphincter complex to facilitate contraction.[9] In meta-analysis of studies on RARP using posterior ± anterior reconstr, Ficarra et al[117] noted posterior musculofascial reconstruction with or without anterior reconstruction was associated with a small advantage in urinary continence recovery 1 month after RARP but not at 3 or 6 months.

In an updated review in 2016 (21 studies including 3 RCTs), Grasso et al[143] noted that posterior reconstruction improved early continence recovery rates up to 90 days after catheter removal and had significantly lower anastomotic leakage rates with no difference in positive surgical margins or complications (urinary retention, anastomotic stricture).

The combination of anterior and posterior reconstruction (total reconstruction) may provide the best continence outcomes.[99] In their meta-analysis of RARP studies, Ficcarra et al[117] noted that only total reconstruction (anterior + posterior) provided a significant advantage in urinary continence 3 months after RARP (odds ratio [OR]: 0.76; *P*=0.04), but not after 6 months.

On the other hand, Wu et al,[146] in a recent meta-analysis of 10 studies, found that total reconstruction was associated with significantly better urinary continence outcomes at all time points assessed from 1 week postop to 52 weeks postop (at 52 weeks, OR 4.10, 95% CI 1.80–9.38, *P*< 0.001) without increasing the complication rate over the standard approach.

In a randomized trial comparing the standard posterior reconstruction in RARP to a more total reconstruction that includes anterior, posterior and lateral (bladder to arcus tendinous) fixation (ARVUS), using a 0 pad/day definition of continence, Student et al[148] reported statistically significantly more patients being continent at 6 (75% vs. 44%, [*P*=0.013]) and 12 months (87% vs. 61%, *P*=0.04) with the total reconstruction and with a quicker return of continence. On the other hand, Kováčik et al, in a partially randomized controlled study did not find any benefit to total reconstruction with respect to postop urinary continence (0–1 pads) using the ARVUS technique whereas nerve sparing had a significant positive association.

There may be a benefit of total reconstruction in open RRP. Ficarra et al[147] reported significantly fewer incontinent patients at all time intervals up to 3 months after catheter removal in a cohort of patients who had urethral fixation during RRP (basically a form of total reconstruction) compared to standard anastomosis–90% vs 63% continent at 12 weeks, *P*=0.001). Reconstruction was an independent predictor of continence recovery at all assessed times with odds ratios of 4–7.7.

2.2.1.2.3. Retzius Sparing/Fascial Preservation (Lateral)

Retzius sparing RARP (RS-RARP) is a newer posterior approach to RARP (via the pouch of Douglas) that preserves the endopelvic fascia, arcus tendineus, neurovascular bundle, deep dorsal vein plexus, and puboprostatic ligaments thought to be involved in the maintenance of urinary continence.[,] Several recent systematic reviews and meta-analyses (generally of the same studies), including a Cochrane review, have found that RS-RARP is associated with a faster and greater rate of continence recovery (0–1 safety pad) over conventional RARP.[,,,] However, they have yielded somewhat conflicting results with respect to longer term continence rates (12 months) with some finding better 12-month continence rates with the RS approach,[152,154] while others found no difference.[153,155] As well, there is some concern regarding a higher risk for positive surgical margins with the RS approach although there does not appear to be any difference in complications.[152,153,155]

2.2.1.2.4. BN Sparing/Reconstruction

As noted earlier, the bladder neck is a part of the internal sphincter (smooth muscle) mechanism thought to be involved in passive continence (maintenance of continence during normal activity). Prostatectomy separates the prostate from the bladder neck and often results in significant damage to the bladder neck rendering it nonfunctional. Sparing the bladder neck is thought to help preserve some of the internal sphincter complex and this appears to hasten the return of continence and lower the rate of PPI. Ma et al in a systematic review and meta-analysis (13 studies) noted that BN preservation improved early and late urinary continence rates (6 mo, OR = 1.66; 95% CI, 1.21–2.27; *P*=0.001; >12 mo, OR = 3.99; 95% CI, 1.94–8.21; *P*=0.0002). In a long term (mean followup ~4 years) update from a randomized trial on BN preservation, Nyarangi-Dix et al reported significantly higher continence rates (*P*=0.004), less pad-use (*P*<0.001), reduced frequency (*P*=0.023) and amount (*P*=0.009) of urine loss, and higher QoL outcomes (*P*=0.012) after BN preservation. BN preservation was the only independent predictor of urinary continence (OR=8.1, *P*=0.008). The type of RP (RARP vs RRP) did not affect the results and BN sparing did not appear to compromise oncologic outcomes.

2.2.1.2.5. Fibrosis

It has been suggested that fibrosis of the urethra in the region of the urethrovesical anastomsosis/external sphincter may be associated with worse continence. Anastomotic stricture (AS) occurs in approximately one-quarter of patients after RRP.[103,] Eastham et al noted that postop AS was a significant negative predictor of postop continence after RRP. Park et al reported that fewer patients with anastomotic stricture became totally continent (62% vs. 92%) and fewer were able to be pad free (54% vs. 88%) at 1 year after RRP. Sacco et al[5] evaluated 985 men who had RRP and found that anastomotic stricture was a significant prognosticator of postoperative incontinence (RR 2.42 (1.66–3.53, *P*<0.001). Desautel et al noted 67% of patients with sphincteric PPI had evidence of urethral fibrosis on cysto. Tuygun et al, using pelvic MRI to identify periurethral/urethral fibrosis after TURP, open simple prostatectomy and RRP and found that 100% of patients with postop incontinence had fibrosis whereas only 29% of patients who were continent had fibrosis (*P*<0.001). Furthermore, the most severe fibrosis was seen in the RRP patients (*P*<0.001). However, there was no relation between the severity of the fibrosis and the magnitude of incontinence or cystoscopic findings. Similarly, Paparel et al, comparing, preop to postop MRIs looking at urethral length and fibrosis, observed that patients with a high grade of periurethral fibrosis postop tended to have worse postoperative continence although this wasn't statistically significant. However, the decrease in membranous urethral length postop was significantly associated with postop continence. They postulated that periurethral fibrosis may impede continence recovery by altering the elasticity of the external sphincter.

2.2.1.2.6. Postoperative Membranous Urethral Length

The length of the membranous urethra (MUL) postop has been reported to be an important variable with respect to postoperative continence. Cameron et al, reported that on postop MRI the MUL was 31-35% shorter in incontinent men compared to continent men after RP (open, RARP -no difference). Kadono et al reported that the residual length of the urethral stump was a significant predictor of urinary incontinence after RARP (24-hour pad test) and leaving the urethral stump as long as possible at the transection between the urethra and the prostate may have a positive impact on urinary incontinence. Haga et al, using VCUG to assess MUL in 60 consecutive patients after RARP, reported that postoperative MUL was significantly associated with urinary continence in the early postoperative period (OR 1.94; 95% CI, 1.22-3.12; *P*<0.005) and using ROC analysis determined an optimal cutoff value of 17mm which had an AUC of 0.76, sensitivity of 0.76 and specificity of 0.4. A postoperative MUL > 17mm was significantly associated with early acquisition of urinary continence (*P*=0.006, log-rank test). Neurovascular bundle preservation was associated with a longer MUL. Similarly, Cho et al, using pericatheter urethrography to measure MUL, found that a shorter MUL was an independent predictor of delayed continence (0 or 0–1 pads) recovery after RP (open or RARP).

Consistent with these findings regarding postop MUL, Kahokehr et al, using MRI before and after transobturator (TO) sling for postprostatectomy incontinence, noted that compared to continent RP patients (controls), preop sling patients had a significantly shorter urethral length (from the urethrovesical anastomosis to penile bulb, i.e., MUL) at rest (1.92cm controls vs. 1.27cm pre-TO Sling, *P*=0.0018) and at Valsalva (2.13cm controls vs. 1.72cm pre-TOS, *P*=0.0371) but after sling placement these differences were no longer significant (i.e., the urethral length increased after the retrourethral sling). This is consistent with the importance of MUL for postop continence and might explain part of the mechanism of action of the retrourethral sling.

2.2.2. Patient Factors

2.2.2.1. Age

Older age appears to be associated with worse continence outcomes after RP. Mohamad et al, in a population-based analysis of

over 16,000 patients undergoing radical prostatectomy in Austria between 1992–2003 (95% of all RPs in the country), found that increasing age was associated with an increased risk of future AUS implant. Only 0.5% of patients in the 45–49-year-old group had subsequent AUS whereas 2.5% in the 70-74 year old group did (i.e., a 5-fold increase). Shikanov et al reviewed their results in over 1,400 robotic RPs and using UCLA-PCI questionnaire (continence defined 0 pads), reported the predicted probabilities (95% CI) of continence at age 65, 70 and 75 years were 0.66 (0.63, 0.69), 0.63 (0.57, 0.68) and 0.59 (0.52, 0.66), respectively. Older age was an independent predictor of postop incontinence on multivariate analysis, granted only 5% of their patients were 70 or older. Nilsson et al, in a series of 1,411 patients who underwent open or robotic RP between 2002–2006 found that age at surgery predicts in an exponential manner long-term urinary incontinence (defined as ≥ 2ppd based on questionnaire). They noted an estimated relative increase of 6% per year. Incontinence was prevalent in 19% of the oldest patients compared to 6% in the youngest (prevalence ratio of 2.4 [95% CI, 1.5-8.1]).

More recent studies have similarly reported the negative influence of older age.[133,135,] Mandel et al,[133] in a retrospective review of 5,902 patients undergoing open or robotic RP, found the 12-month continence rate (≤1 safety pad/day) was 91% overall with 1-year continence rates for age groups < 65, ≥ 65 and < 70, ≥ 70 and < 75, and ≥ 75 years of 93.2%, 90.8%, 86.0%, and 86.5%, respectively. Older age was a significant adverse factor for postop continence on univariate and multivariate analyses. Nerve sparing, BMI and pT category were also significant predictors on multivariate analyses. Lee et al,[135] in a retrospective review, compared patients older than 70 years to patients younger than 70 years undergoing RP (open or RARP). Using a ≤ 1 security pad/day definition of continence and with a median follow-up of 58 months, 60.9% and 88.6% of patients aged ≤ 70 years and 52.6% and 81.5% of those aged > 70 years recovered urinary continence within 3 and 12 months after surgery, respectively (*P*<0.001; between both groups). Nerve sparing and membranous urethral length were found to be predictors of continence recovery.

Older age could contribute to PPI via pre-existing LUTS (e.g., BPH) and/or age-related changes in bladder, urethra, and pelvic floor anatomy/function. Strasser et al[96] identified an age-related reduction in striated muscle cells of the male rhabdosphincter, with an increase in smooth muscle fibers and connective tissue, that was postulated to contribute to the apparent increase in PPI in men over 70. Tai et al, using MRI with 3 D reconstruction to compare post prostatectomy patients with ED and urinary incontinence to healthy young males and older controls, found there was age related atrophy in the puborectalis and ischiocavernosus muscles and postulated that this may predispose older patients to UI and ED following RP.

Older age is also associated with a greater incidence of bladder dysfunction such as DO which itself can be a cause of incontinence. This may be secondary to benign prostatic obstruction and subsequently resolve after prostatectomy (for BPH or prostate cancer) but it may also be independent of any obstruction (or there may not be obstruction present) and persist after prostatectomy.[176] The presence of pre-RP DO was shown in a recent meta-analysis to be negative predictor of postop continence.

On the other hand, some studies have not shown age to be an issue. Labanaris et al reviewed 2000 patients undergoing RARP and compared patients 75 years or older to the overall cohort and failed to show a significant difference in 12-month continence rates (no pads and/or no leakage): 87% in ≥75 yearr vs. 93% in the whole cohort (*P*<0.05). However, the clinical significance of the study is limited by the small number (45) of elderly patients.[133] Kumar et al retrospectively analyzed 3362 patients undergoing RARP stratifying them into groups based on various possible adverse features one of which was age ≥ 70 years and compared them to patients without risk factors (age < 70 years). Using a 0 pad and no leakage (based on EPIC questionnaire) definition of continence, they found no significant difference in 12-month continence rates between groups. However, patients without risk factors achieved continence faster. Recently, Nyarangi-Dix et al, in a retrospective analysis of 350 high risk prostate cancer patients undergoing RARP, found no significant difference on multivariable analyses in urinary continence (0 pads) recovery rates at 12, 24, and 36 months after surgery between men aged <70 years and ≥ 70 years.

2.2.2.2. Obesity, diabetes and metabolic syndrome

Many studies have found that obesity (typically defined as BMI >30), adversely affects continence outcomes after RP. In a meta-analysis of four studies comprising six trials with 2,890 participants, Wei et al found that obesity increased UI risk at 12 months in patients who underwent RARP (OR 2.43, 95% CI 1.21, 4.88, *P*=0.01). Similarly, Xu et al, in a meta-analysis of 4 studies (1 overlap with Wei et al[181]) that compared 735 obese patients with 2,662 nonobese patients, reported that obese patients had significantly higher probabilities of incontinence at 1 year (OR: 1.41; 95% CI, 1.13-1.77, *P*=0.003).

In a retrospective review of RP patients (open and lap), Wolin et al noted that obese patients, especially when physically inactive, were significantly more likely to have incontinence than non-obese patients. At 58 weeks postop, 31% of obese versus 18% of non-obese patients were incontinent (*P*=0.05). When considering obesity and physical activity together, at 58 weeks postop, non-obese men who were active were 26% less likely to be incontinent than men who were obese and inactive (RR 0.74, 95% CI 0.52-1.06). Furthermore, being active appeared to offset the negative consequences of obesity: obese and active men had the same prevalence of incontinence (25%) as nonobese inactive men (24%). In a multicenter review of open RRP, LRP and RARP patients (N=470) from Italy, using waist circumference (WC) to assess obesity (WC ≥ 102cm), Gacci et al noted a significant positive correlation between WC and postprostatectomy incontinence severity: the risk of needing at least two pads per day was 2.5 times greater in obese men than non-obese men (adjusted OR = 2.435, 95% CI 0.321-7.668, *P*=0.007).

On the other hand, some have not found a negative effect of obesity on PPI. Hsu et al noted no significant association between body weight and postop continence in 1024 men who had open RRP, Kumar et al[179] found no statistically significant difference in 1-year postop (RARP) incontinence rates between patients with obesity (BMI ≥ 35) and those without (although it took longer to achieve continence in obese patients), and Kadono et al[110] reported that BMI was not an independent predictor of 1 year post-RARP incontinence.

Diabetes and metabolic syndrome may be associated with OAB/DO in its early stages and thus may also be a contributors to urinary incontinence in both prostate cancer and BPH surgery (please refer to sections 3.3.2.2.2. and 3.3.2.2.3.).

2.2.2.3. Prostate Size

There have been conflicting reports as to whether or not prostate size impacts post-RP continence. Boczko et al noted that 6-month post-extraperitoneal RARP continence rate (no leakage and 0 pads)

was significantly lower in men with prostate size < 75g compared to >75g (97% vs 84%, *P*<0.05). They noted that larger prostate size resulted in less maneuverable space and a higher rate of urinary complications (postop retention, UTI); although, there was no difference in positive surgical margins. Konety et al, using the patients with preop prostate volume measurements in the CaPSURE database, noted lower 6- and 12-month continence rates (based on the UCLA-PCI) after RP if prostate size was greater than 50cc. However, the rates equalized at 24 months. They postulated that men with larger prostates may have subclinical bladder dysfunction related to the prostatic enlargement that then becomes more manifest after RP.

On the other hand, Foley et al did not find a difference in post-RRP incontinence in patients with prostate volume greater than 75g or less than 75g using self reported questionnaires (ICSmale). Similarly, both Pettus et al and Kadono et al[110] did not find prostate volume to influence post-RP continence outcomes.

2.2.2.4. Preop LUTS/OAB/DO/LUTD

As noted elsewhere, men undergoing prostate cancer treatment not uncommonly have LUTS. The ProtecT Study, a randomized trial of active surveillance vs RP vs radiotherapy published their baseline patient characteristics and noted that while LUTS were fairly common (e.g., nocturia in 22%), overall urinary function was good (EPIC score 95.1) and bother due to LUTS was low. Interestingly, 30% of men had some degree of incontinence; although, fewer than 1% were using pads or reported incontinence as a big problem. Followup data has not been published yet.

Preoperative urinary continence status was noted to be a significant predictor of postop urinary continence on multivariate analysis by Wei et al in a prospective study of RP patients. They noted that 12% of their patients had incontinence preoperatively; although, they did not specify what type of incontinence was present. More recently, Kurimura et al, using the 1-hour pad test, similarly found that the presence of preoperative incontinence resulted in postop incontinence being present for a longer duration after RARP compared to patients who were continent preop (*P*=0.042). They found a significant correlation between the result of the preoperative 1-hour pad test and the OABSS (R=0.32, *P*<0.01) suggesting that it may have been UUI in these patients preoperatively and this potentially was provoked by the activities of the one-hour pad test.

Preop LUTS may also impact post-RP functional outcomes. Choi et al reported that patients with severe preop LUTS (using AUASS) had higher post RARP urinary bother scores (EPIC) compared to those with milder preop LUTS. Similarly, Yamada et al reported that preop OAB was a negative predictor of return of continence at 12 months after RARP. More recently, Collette et al, using patient reported outcome measures with a median follow-up of 36 months after RARP, found the severity of preop LUTS (based on IPSS) was an independent predictor of PPI (≥ 1 ppd) (OR 0.56, *P*=0.004).

The presence of DO on preop UDS may increase the risk for incontinence post-RP. Comparing preop UDS to that at 2 years postop, Dubbelman et al noted preop DO was present in significantly more patients who had persistent incontinence at 6 months postop compared to those who regained continence (34% vs 5%, *P*=0.015). A systematic review and meta-analysis by Kim et al,[177] incorporating 9 studies with 419 participants, determined that PPI was more likely to occur in patients with preoperative DO [pooled OR 2.30; 95 % CI 1.39-3.82], as compared to patients who were DO negative. However, they were unable to correlate preoperative DO with subtypes of PPI (SUI vs UUI) due to study limitations.

On the other hand, RP can improve preop LUTS and DO.[111] Gordon et al compared men with severe preop LUTS (using AUASS) to those with mild to moderate LUTS undergoing RARP and noted that in men with severe preop LUTS, long term AUASS improved by 70% with 59% improving to the mild category. However, significantly fewer preop severe LUTS patients were continent (0 pads) postop (71% vs 89% (*P*=0.002).

2.2.2.4.1. Neurogenic Lower Urinary Tract Dysfunction

There is very little data on patients with significant neurologic disease undergoing RP. Given that NGB can be associated with significant bladder and sphincter dysfunction (see elsewhere) the expectation is that patients might be more prone to PPI. In a review of 20 Parkinson's disease (PD) patients who underwent RP, Routh et al reported that *de novo* incontinence occurred in 20% at 1 year, was mild (none needing >2 pads/day) and all had another known risk factor for PPI including (prior XRT, TURP, non-nerve sparing technique). None of the 15% with preop incontinence regained continence after RP but there was no worsening of the UI. They felt that even in PD patients, it is reasonable to consider RP for CAP.

2.2.2.5. Preoperative Membranous Urethral Length

As noted earlier, the postoperative MUL has been associated with post-RP continence. Not surprisingly, the preoperative MUL has also been positively associated with post-RP continence. In a recent systematic review and meta-analysis, Mungovan et al determined that based on 4 studies (1,738 patients) reporting hazard ratios, every extra mm of preop MUL was associated with a faster return to continence (hazard ratio: 1.05; 95% CI: 1.02-1.08, *P*<0.001). Similarly, in 11 studies (6,993 patients) that reported odds ratios for the return to continence at one or more postoperative time points, MUL had a significant positive effect on continence recovery at 3 (OR: 1.08, 95% CI: 1.03-1.14, *P*=0.004), 6 (OR: 1.12, 95% CI: 1.09-1.15, *P*<0.0001), and 12 months (OR: 1.12, 95% CI: 1.03-1.22, *P*=0.006) following surgery. Every extra millimeter of MUL was associated with significantly greater odds for return to continence (OR: 1.09, 95% CI: 1.05-1.15, *P*<0.001) such that for every extra 10mm of MUL, the odds of continence recovery is increased by between 63% and 205% (OR: 2.37, 95% CI: 1.63–4.05).[202]

More recently Kim et al, in a prospective study on 529 patients undergoing RARP, reported significantly higher continence rates at 12 months in patients with a preoperative MUL ≥ 11.7mm (92% vs 80%).[136] This is consistent with the findings of Coakley et al in RRP patients: 89% of patients with a preop MUL >12mm had an 89% rate of continence at 12 months postop compared to 77% of patients with an MUL of ≤ 12mm.

2.2.2.6. Pelvic Floor Muscle Function

The status of a patient's pelvic floor muscle (PFM)/sphincter prior to RP may predict UI/incontinence after RP. Majoros et al compared preop and postop (2 months) UDS in 63 RRP patients and reported that patients who were continent postop had significantly higher preoperative maximal voluntary sphincter contraction pressure (125 vs. 96.5 cmH_2O, *P*<0.0001) and those who were immediately continent following catheter removal had higher preop and postop MUCP and no preop LUTS compared to those who had delayed return of continence. Dubbelman et al similarly found higher median preop and postop MUCP in RP patients who regained continence after 6 months compared to men with persistent incontinence with a preop MUCP cut off of 53 cmH_2O.

Preoperative PFM status has been evaluated with MRI. Song et al correlated levator ani muscle thickness on preop MRI (as a gauge of their integrity) with early (3 months) post RP continence but not

longer term (6 months). Interestingly, they noted that preop incontinence was present in 16% and UUI in 13%. They concluded that patients with better developed pelvic floor muscles, especially in relation to the size of the prostate, can be expected to achieve earlier recovery of continence after radical prostatectomy. Similarly, in a recent study it was observed that significantly more continent (based on ICIQ < 6) than incontinent post RARP patients had, on preop MRI assessing perfusion quality of pelvic muscle structures, a higher perfusion ratio (comparing perfusion of levator ani complex to surrounding pelvic muscle structures). Furthermore, there was a negative correlation between perfusion ratio and ICIQ score (higher perfusion ratio negatively correlated with ICIQ score) which is consistent with patients who have better preoperative pelvic muscle function tending to have better postop continence. As well, a systematic review and meta-analysis on the effect of preop pelvic floor therapy on postop urinary continence after RP reported that preop pelvic floor exercises improved early postop (3 months) continence rates.

The importance of good pelvic floor muscle function was recently demonstrated by Stafford et al who, using transperineal ultrasound, compared various measures of pelvic floor muscle function (e.g., contraction of the striated urethral sphincter, puborectalis, bulbocavernosus muscles, displacement of urethrovesical junction/bladder neck) during voluntary muscle contractions and coughs between post-prostatectomy patients with and without incontinence (based on ICS-male SF) and a continent control group. They found that post-prostatectomy continent patients can voluntarily activate their pelvic floor muscles at least as well if not better than continent controls, especially during a cough, whereas PPI patients were not. The recently published AUA SUFU guidelines on incontinence after prostate treatment recommends pelvic floor physiotherapy postoperatively, and also that it should be considered preoperatively with the goal of improving pelvic floor strength.[18]

2.2.2.7. Stage of Disease

As noted in ICI 6, stage of disease has not been correlated with postop urinary incontinence. Stage of disease might affect surgical technique (e.g., less likely to do nerve sparing in higher clinical stage patients) and that could impact postop incontinence rates but this is more a reflection on technique rather than stage of disease. Loeb et al reported in their series of high risk or locally advanced prostate cancer patients undergoing RRP that 92% of patients were continent (dry and 0 pads) postop. They were able to perform at least some degree of nerve sparing in about 85% of patients despite the adverse cancer factors and this might have contributed to their results. More recently, Kumar et al[179] reported on RARP patients with various adverse risk factors including a cohort with prostate size greater than 80g and compared these groups to a group without risk factors and did not find any significant difference in the 1-year postop continence outcomes although those without adverse risk factors achieved continence sooner.

2.2.2.8. Prior BPH Surgery (e.g., TURP, HoLEP)

There is conflicting data regarding prior BPH surgery as a risk factor for PPI.

2.2.2.8.1. BPH Surgery Is a Risk Factor

In a recent systematic review and pooled analysis (12 studies) of patients undergoing RARP or LRP, Veccia et al compared patients with a history of bladder outlet surgery to those without. They found that a history of bladder outlet surgery was associated with lower continence recovery at 12 months (OR 1.61, 95% CI 1.14-2.27, *P*=0.007). But patients with a history of bladder outlet surgery tended to be older, have more complications and were less likely to have nerve sparing performed. In a retrospective review of over 18,000 patients undergoing RP, including 470 with prior TURP, using propensity score matching, Pompe et al reported that TURP patients had a higher risk for urinary incontinence (> 0-1 safety pad/24 hour) at 3 months (OR: 1.47; 95% CI 1.01-2.12, *P*=0.04) and 12 months postop (OR: 2.06; 95% CI 1.23-3.42, *P*=0.006).

2.2.2.8.2. BPH surgery is not a risk factor

Palisaar et al compared open RRP patients with a history of TURP to those without and found similar 1 year continence (0 pads) rates (81% vs 82%). Su et al, in a retrospective review of 2693 patients who had RARP, compared those with prior TURP to those without and found no significant difference in urinary continence (0 ppd), social continence (1 ppd) and overall AUASS between the groups at 12 months postop.

Suardi et al compared various types of pre-RRP bladder outlet surgeries (HoLEP, TURP, open prostatectomy) using the ICIQ-SF to assess post-NSRRP incontinence and found no significant difference between groups: 6-month postop continence rates were 93%, 93% and 80% for HoLEP, TURP and open prostatectomy, respectively (*P*>0.05). There was no difference in ICIQ-SF scores between groups at most recent followup (mean follow-up 24 months). More recently, Kretschmer et al noted that on multivariable analysis, prior HoLEP did not have an adverse impact on urinary continence (0 pad use) at 1 year post RARP or open RP (OR 0.87, 95% CI 0.74–1.01, *P*=0.07), whereas Abedali et al, comparing prior HoLEP to no prior HoLEP, found no statistically significant difference in social continence (0–1 pads/day) at a median of ≤ 6 months post-RARP (59% vs. 81% *P*=0.156) although the HoLEP group had fewer patients who had complete continence (pad free + leak free): 22% vs 74% *P*<0.001, and the time to achieve continence took longer (24 months vs. 13 months, *P*=0.007).

While not commonly performed, RPP may be preferred over open RP in patients with a history of BPH surgery. Imperatore et al retrospectively compared patients with a history of BPH surgery who underwent RPP vs RRP and noted that significantly more RPP patients achieved complete continence at 3, 6, and 12 months compared to RRP. However, the timing of RPP relative to TURP may be important. Elder et al reported that if RPP was performed between 4 weeks and 4 months after TURP, there was a 50% incidence of incontinence whereas when performed less than 4 weeks or more than 4 months after TURP, no patient experienced post RPP incontinence. They recommended waiting at least 4 months after TURP before performing RPP.

2.2.2.9. Prior XRT – Salvage RP

Patients with a history of XRT for prostate cancer already experience some risk for urinary incontinence (see section **3.2.2.2.10**). When they then undergo RP for persistent/recurrent disease, there are the added risks for incontinence that are associated with RP. Rosoff et al in their review of the literature on salvage RP (SRP) between 1980 and 2012 reported postop urinary incontinence rates ranged from 36 to 81%. In a systematic review of publications between 1980 and 2011, Chade et al noted continence (0 pads) rates of 21–90% for open RP, 67–78% for lap RP, and 33–80% for RARP, and that overall complications appeared less frequent in the more recent publications. More contemporary series also show that while there is still a significant incidence of incontinence after SRP, it does seem less than previously reported. Mohler et al, in a multicenter prospective study, reported on patients undergoing open SRP at a median of 64 months after XRT: 45% of evaluable patients had urinary incontinence (≥3 pads/day) prior to SRP with 88% reporting urinary incontinence at 6 months, 85% at 12

months and 63% at 24 months after SRP. Given their definition of incontinence, their results may actually underestimate the true incidence of incontinence. Gontero et al retrospectively reviewed results from 18 institutions comparing 186 open to 209 robotic SRPs. They noted fewer anastomotic strictures with robotic SRP (8% vs 17%, *P*<0.01) and better continence preservation (0 pads): at 6 and 12 months more patients in the robotic SRP group were continent (26% vs 22%, *P*=0.0234 and 32% vs 23%, *P*=0.0432, respectively). On multivariable analysis, robotic SRP was an independent predictor of continence preservation (OR 0.411, 95% CI 0.232-0.727, *P*=0.022). Salvage RP has also been performed after focal therapy (FT) for prostate cancer including HIFU. In a retrospective review, Herrera-Caceres et al found that after a mean follow-up of about 4 years, 91% of patients were continent after salvage RP for FT. However, the remainder had moderate (>1 pad/day) to severe incontinence (needed AUS). De Groote et al retrospectively reported that 83% of patients were either completely or socially continent (0-2 pads) more than 2 years after salvage RARP (post HIFU, EBXRT, brachytherapy, cryo). They noted better continence rates after prior FT versus whole gland treatments (88% vs. 72%); although, not statistically significant.

2.2.2.10. Radiation Therapy (Without Surgery) and Incontinence

XRT can affect the lower urinary tract via changes in the structure and function of the detrusor and the urinary sphincter. It can be administered via external beam or directly into the prostate tissue via seed implant (brachytherapy). It can be used as primary or adjuvant/salvage therapy after RP. When used after RP (adjuvant/salvage XRT), one is already dealing with the potential lower urinary tract effects (especially sphincter deficiency) of the surgery which may then be compounded by the effects of the XRT.

Radiation causes edema initially followed by gradual degeneration and fibrosis (related to ischemia from radiation-induced vascular damage) in the primary target tissue (i.e., prostate cancer) and surrounding tissues (bladder/urethra/ureter). As such, similar to after prostatectomy, both sphincteric and detrusor related (DO/OAB, low compliance) incontinence may occur. UPP showing inflexible parts of the external sphincter has been identified in some patients over time after XRT and it has been suggested this is related to fibrosis. Shortening of the membranous urethral length (a risk factor for post-RP incontinence) as well as alterations in urethral and pelvic muscle signal intensity on MRI have been reported after various froms of XRT. OAB after XRT may be due to BOO (bladder neck stenosis, urethral stricture), bladder stones (dystrophic calcification of prostate) or mucosal inflammation.

Older series of external beam radiotherapy (EBXRT) have shown a generally low rate of post-treatment incontinence. Lawton et al reported an ~8% risk of long-term urinary complications after EBXRT, proportional to dose. Perez et al noted incontinence in <1% of patients after XRT. Shipley et al in their review of multi-institutional and single institutional studies similarly noted that UI as a direct result of EBXRT is rare (<1%). Budäus et al in their review of the literature between 1999–2010 reported that long-term total UI and other severe urinary symptoms (RTOG grade > 2) are rare; although, early storage symptoms are common. Recently, Hoffman et al examined functional outcomes (using EPIC) of patients undergoing active surveillance, nerve sparing RP, EBXRT or low dose rate brachytherapy and found that at all time points up to 5 years, EBXT patients had incontinence domain scores that were not significantly different than active surveillance patients. RP patients had the worst incontinence scores (compared to other modalities) throughout the 5 years, whereas LDR brachytherapy patients had worse incontinence scores compared to active surveillance patients at 6 months but not beyond.

Radiotherapy for prostate cancer has evolved to become more focused to deliver more accurate dosing to the prostate and minimize effects on surrounding tissues. EBXRT has progressed to more intensive/higher dose treatments that are able to be more focused to the target organ. A systematic review and meta-analysis by Ávila et al[121] noted that for various types of EBXRT there is a small worsening of UI after treatment without statistically significant differences among the five modalities (proton therapy, stereotactic body radiotherapy, intensity modulated radiotherapy, EBXRT, and 3-Dimensional [3D] conformal radiotherapy). Evans et al similarly showed no significant difference in incontinence after IMRT, SBRT or brachytherapy in a multi-institutional pooled cohort analysis of patient-reported QoL [EPIC-26] pre and post XRT.

Recently Pan et al, using outcomes of patients undergoing SBRT who completed EPIC 26, were able to create models via machine learning that could predict urinary toxicity (irritation/obstruction, incontinence). At 12 months, 41.2%, 27.3%, and 56.5% of patients experienced a clinically significant decline in urinary irritation, UI, and bowel function, respectively. Bladder dose-volume metrics (e.g., the bladder volume and radiation dose received by the bladder) strongly predicted patient-reported urinary irritative and incontinence symptoms (area under the curves [AUCs] of 0.79 and 0.87, respectively) at 12 months.

The importance of adequate follow-up with respect to outcomes after XRT was highlighted by Pinkawa et al. They surveyed patients using EPIC questionnaire up to 12 years after 3D conformal EBXRT. The rate of UI (need for pads) increased over time (8% of patients pre-XRT vs. 15% of patients 10 years post-XRT, *P*=0.01). As well, there was worsening of urinary bother scores compared to baseline over time and a higher radiation dose was associated with increased urinary problems.

2.2.2.10.1. Urodynamic Studies

There is limited literature on the issue of post-XRT UDS and much of it relates to salvage XRT after RP. In a prospective study, Choo et al evaluated 15 patients, pre- and 18 months post-EBXRT, for prostate cancer using symptom questionnaires (IPSS, QoL) and UDS. They found no statistically significant change in self-assessed urological symptoms at 18 months post-RT compared to pre-RT baseline. On UDS, only the volume at first sensation and cystometric capacity were significantly different (lower) at 18 months. There were no significant differences between pre-XRT and 18-month post-XRT with respect to: DO, low bladder compliance, outlet obstruction, urinary urgency or urgency urinary incontinence. However, the small sample size and follow-up limited to 18 months makes significant conclusions, particularly regarding long term issues, impossible. To this point, Ervandian et al[229] assessed urodynamic parameters and Danish Prostatic Symptom Scores (DAN-PSS) in 16 patients (none with SUI on UDS) who had salvage XRT after RP (median time from SRT to UDS was 7.7 years – range 5.8-10 years). They found that cystometic capacity, bladder compliance (low compliance was <30-40mL/cmH_2O), and bladder function were affected: 11/16 had decreased MCC (<350mL), 10/16 had low compliance, 7/16 had DO. Based on questionnaire, over a 6-year period after XRT there was an increase in the prevalence of incontinence. The authors noted that longer term follow-up (of which there currently is very limited UDS data) is needed to fully comprehend the effects of XRT with respect to fibrosis and its effect on bladder function.

In a recent publication, Hoffman et al[236] compared men with a history of XRT to those without who were undergoing AUS or sling surgery for SUI (due to prostatectomy, XRT or both). They noted that more men with a history of XRT had DO on UDS (70% vs. 38%, *P*<0.0001) and had a lower maximum cystometric capacity (255 vs. 307mL, *P*=0.01). They were also more likely to use OAB meds preop. After AUS, radiated patients were mo re likely to use OAB meds (44% vs. 25%, *P*=0.01) and more likely to require third line OAB therapy (9% vs. 1%, *P*=0.01).

2.2.2.11. Adjuvant/Salvage XRT

There is conflicting data as to whether adjuvant/salvage XRT after RP increases the risk for incontinence. A Cochrane Review in 2011 found 3 randomized controlled trials comparing RP + XRT to RP alone, involving 1815 men; although, the information about continence was reported only in a subset of 100 men treated at a single institution, representing 5.5% of the men studied. UI was not increased at 5 years (RD 0.06; 95% CI -0.02 to 0.15; *P*=0.15) or 10 years (RD 0.04; 95% CI -0.00 to 0.08; *P*=0.07) for men who received adjuvant radiation. On the other hand, Suardi et al analyzed RP patients with adverse pathologic features at (positive margins, pT3) and compared patients who did (153 patients) and did not (208 patients) have adjuvant XRT to look at the impact of XRT on continence (defined as 0 pads). They found that adjuvant XRT patients were less likely to recover continence at 1 and 3 years than non-XRT patients (51% and 59% vs. 81% and 87%, *P*<0.001). Even when controlling for age, non-organ confined disease and nerve sparing, adjuvant XRT was an independent predictor of worse continence recovery (HR: 0.57; *P*=0.001) resulting in a 1.6-fold higher risk of incontinence. Van Dessel et al retrospectively reported on 244 patients who had salvage XRT (3D-CRT or IMRT) for biochemically recurrent prostate cancer after RP to assess the effect on urinary continence (score of 0 on Common Terminology Criteria for Adverse Events [CTCAE]). 70% of their patients were continent prior to SRT. *De novo* incontinence (grade ≥ 1) was reported in the acute (within 90 days of XRT) and late (>90 days after XRT) phases in 6.1% and 17.6% of patients, respectively. Worsening of preop incontinence or persistence of acute *de novo* incontinence beyond 90 days occurred in 9.8% of patients.

The timing of post-RP XRT, adjuvant (soon after RP) or salvage (delayed after RP) has inconsistently been reported to influence functional outcomes. Adam et al, in a questionnaire based observational study reported that while patients after RP + XRT had a 4% higher overall incontinence rate (87%) and a higher rate (4%) of severe incontinence (>3 pads) compared to matched RP-only patients (91% continent, 2% severe), the timing of RT after RP had no influence on continence at 3 year followup. Nyarangi-Dix et al, using the ICIQ-SF questionnaire in a survey, similarly found worse continence over time after post-RP XRT (only 22% of the men who were continent at the time of XRT remained continent afterwards) and the timing of XRT (adjuvant vs. early salvage vs salvage) did not make a difference with respect to incontinence or its effect on quality of life. Baumgarten et al, in a post hoc analysis of RTOG 9601 trial cohort, similarly found that the timing of XRT after RP (≤ 2.1 yrs vs. > 2.1 years) did not seem to predict urinary adverse events. Huelster et al, in the CESAR trial, evaluated functional outcomes up to 60 months after RP alone, RP + adjuvant XRT (median 7 months after RP) and RP + salvage XRT (median 29 months after RP) and found that both adjuvant and salvage XRT patients had worse urinary (incontinence, storage symptoms) domain scores (EPIC) than patients who had RP alone and the timing (adjuvant vs. salvage) did not appear to make a difference (although delayed XRT occurring 24 months after RP had better sexual function than earlier XRT).

On the other hand, Jenkins et al reported that at 2 years post sEBXRT, there was a significant worsening of EPIC scores in the urinary function, bother and incontinence subscales with the most severe being incontinence (worsened by more than 10 points from 66.49–56.14, *P*=0.0003). When they compared early sEBXRT (1 year or less after RP) to late (>1 year after RP), the urinary domain summary score was worse in the late group (i.e., sEBXRT more than 1 year after RP fared worse than those treated sooner).

Interestingly, Parker et al, in the RADICALS-RT trial, a randomized trial comparing adjuvant XRT (>90% within 6 months post-RP) to early salvage XRT (at prostate-specific antigen biochemical progression; 1/3 of patients received sXRT (within 8 years of randomization) at time of analysis), reported that adjuvant XRT did not have any oncologic benefit compared to early salvage XRT, but did increase the risk of urinary and bowel morbidity at 1 year; although, not beyond (granted the data is immature).

While adjuvant/salvage XRT appears to be a risk factor for incontinence, the dose of XRT may or may not affect continence. In a multicenter randomized trial of patients with biochemical recurrence having SRT grouped by radiation dose (64Gy vs. 70Gy) Ghadjar et al found no difference between groups in the incidence of de novo incontinence or in the improvement in post-RP incontinence at 3 months (32% of population had post-RP incontinence prior to SRT and continence recovery was achieved 3 months after SRT by 44% vs. 41% with 64 vs. 70 Gy, respectively [*P*=0.8]).

On the other hand, Bresolin et al, in a prospective study using ICIQ-SF, recently noted a possible independent detrimental effect of both fractionation and higher XRT doses on the risk of severe urinary incontinence following both aXRT and sXRT. Importantly, baseline PPI prior to XRT was the strongest predictor of mid term (2 years) post-RP patient-reported continence recovery, regardless of subsequent aXRT or sXRT.

2.2.2.12. BPH Surgery Prior to XRT

Pre XRT BPH surgery appears to be a risk factor for incontinence after XRT. In a systematic review of the literature up until 2011, Ishiyama et al reported higher incontinence rates in XRT patients with a history of TURP. Odrazka et al found on multivariate analysis, prostatectomy for BPH (TURP, open) carried out before EBXRT (including IMRT), significantly increased the risk of Grade 2 or higher GU toxicity (risk ratio 1.88). The 5-year actuarial likelihood of Grade 2-3 urinary incontinence was 23%, compared to 9% for those without prostate surgery (*P*=0.01).

2.2.2.12.1. Brachytherapy

Brachytherapy (BT) is another form of guided XRT in which radioactive seeds are implanted into the prostate and has generally been tolerated by patients with mild GU toxicity. In their literature review from 1999–2010, Budäus et al[235] noted that after BT the predominant acute toxicity is radiation urethritis that tends to improve in the majority over the course of a year. Morgan et al compared low dose rate (LDR) BT to high dose rate (HDR) BT using AUASS and noted that while there was a deterioration in the short term (≤2 months), by >30 months, for each group there was no significant difference compared to baseline AUA score. On the other hand, Hathout et al found that HDR BT patients had better EPIC urinary irritative scores on repeated measures at 1, 3, 6 and 12 months compared to LDR BT patients although there was no significant difference in the urinary incontinence scores between groups at any time point. However, over time the effects may worsen. Stone et al followed patients after BT using AUASS and noted that for patients with minimal baseline symptoms the 10- and 15-year estimates for

freedom from worse symptoms were 72.9% and 39.1%, respectively. They identified risk factors for worsening LUTS over time: EBRT boost (HR 1.45, *P*=0.004), biologic equivalent RT dose >200 Gy2 (HR 1.25, *P*=0.024), hypertension (HR 1.37, *P*=0.006), and alcohol use (HR 1.46, *P*=0.001). Boettcher et al compared changes in LUTS (questionnaire based including ICSmale) up to 36 months after radical prostatectomy and BT. They reported that after adjusting for age and pretreatment symptoms, more BT patients complain of OAB symptoms (urgency) at 36 months (30% vs. 11%, *P*<0.025). Repeated measurements showed that the OAB symptoms were highly fluctuating and that in patients treated with BT compared to RP, the severity of symptoms as well as variability of symptoms was significantly higher. They also noted that the presence of LUTS before BT was significantly associated with higher rates of OAB after BT.

Incontinence can occur after BT and ICI 6 noted an overall rate of post-BT incontinence of 0-45%. Both sphincteric incontinence (SUI) and OAB issues may develop after BT. Blaivas et al studied men with persisting LUTS for at least 6 months after BT for CAP using IPSS, 24-hour voiding diary, VUDS and cystoscopy and they compared them to a previous study on men with LUTS without CAP. They reported that UDS showed: DO in 47% vs. 85%, decreased compliance in 9% vs. 25% and urethral obstruction in 69% vs. 73% of nonCAP patients with LUTS vs. BT patients, respectively. While not significantly different with respect to urethral obstruction incidence, after BT more patients had urethral strictures and adherent stones. Leapman et al reviewed a prospective database of 2461 men who underwent BT with or without EBXRT (2 months after the implant, 3D conformal therapy or IMRT) who had > 2 year follow-up (median 6 years). They reported an overall rate of UI (need for a pad for involuntary leakage) of 4.4% at a median of 1.8 years (IR 5 months-4.4 years), but there was a gradual deterioration in urinary continence beyond 5 years. Of patients reporting UI, 28% had SUI whereas 72% had UUI. Two-thirds (2/3) of incontinent patients used 1 pad per day whereas 11% were using at least 3 pads per day. The 2-, 5- and 10-year freedom from incontinence rates were 99%, 97% and 93%, respectively. Schlussel et al in a retrospective analysis of 902 patients reported UUI in 9% of patients after BT and SUI in 8%; the numbers were even higher in patients who had BT + EBXRT (UUI in 22%, SUI in 11%).

Probably the most important risk factor with respect to incontinence after BT is surgery for prostatic obstruction/BOO. This is typically done for urinary retention issues that can occur in 1-14% after BT. Ragde et al noted that incontinence after BT and TURP was nearly always preceded by various degrees of superficial urethral necrosis, visualized as areas of shaggy, mucoid concretions mixed with calcifications adherent to the distal walls of the resected prostate cavity. Because the distance between the sphincter muscle and urethral wall after TURP could be significantly decreased, necrosis and accompanied inflammation of the urethral wall could thus affect the function of sphincter muscle. Leapman et al,[259] when comparing patients who had TURP to those who did not, found that post-BT men without TURP had a 3% rate of UI whereas men who had TURP after BT monotherapy had 26% rate of UI and those with TURP after BT + EBXRT had 38% rate of UI (*P*<0.001). On multivariate analysis, UI was associated with combination EBRT (HR = 3.87), higher baseline IPSS scores (HR = 1.62), and posttreatment TURP (HR = 2.72). Post-implantation TURP was the single factor that was significantly associated with the development of SUI (HR 4.01, 95% CI 1.98-8.15), whereas combination EBRT, baseline IPSS ≥7, and post-implantation TURP were significantly associated with UUI.[259] The timing of TURP after BT may have an impact on UI. Kollmeier et al reported that the rate of post-TURP UI was 8% in patients who had TURP 2 years or less after BT compared to 36% in patients undergoing TURP more than 2 years after BT (*P*=0.04). They found no significant correlations between radiation dose, preimplant prostate volume or hormonal therapy with regard to this UI risk.

BPH surgery prior to BT may or may not increase the risk for UI. Leapman et al[259] reported that TURP prior to BT monotherapy had a 3% rate of UI while TURP prior to BT + EBXRT had a 21% rate of UI (*P*<0.01). After excluding patients having post-implantation TURP, they noted that TURP prior to BT was significantly associated with the development of UI. Peigne et al reported 16% of patients had *de novo* UI at 1 year, but only 4% persistent mild symptoms at 3 years in patients having channel greenlight PVP at least 6 weeks prior to BT, while Salembier et al reported UI (≥ 1 pad) in 2% of patients who had TURP at least 3 months prior to BT (median follow-up 49 months).

The need for more than one TURP may further increase the risk for incontinence. Mock et al reported a 25% incidence of UI in BT patients who had subsequent TURP whereas 3% had UI with BT only (OR 10.4, 95% CI 6-18, *P*<0.001). They noted that if >1 TURP was needed, 53% of patients experienced UI compared to 19% who only had 1 TURP (OR 4.9, 95% CI 1.5-16, *P*=0.006).

2.2.2.13. Cryosurgical Ablation of the Prostate

Cryosurgical ablation of the prostate (CSAP) uses multiple freeze-thaw cycles via transrectal ultrasound guided, perineally implanted probes to treat prostate cancer. Thermocouples are placed to maintain warmer temperatures in at risk structures (e.g., external sphincter, neurovascular bundles, Denonvillier's fascia/rectal wall) to minimize UI, ED and rectal injury/fistula. A urethral warming catheter is also used to protect the urethra from cold induced sloughing.

CSAP can be used for both whole gland treatment as well as more FT for CAP (primary or salvage therapy after XRT). A Cochrane review by Shelley et al in 2007 noted a relatively high incidence of side effects after whole grand CSAP: Impotence (47–100%), incontinence (1.3–19%), urethral sloughing (3.9–85%), fistula (0–2%), bladder-neck obstruction (2–55%), stricture (2.2–17%) and pain (0.4–3.1%). This was based on older CSAP techniques that have been modified/improved over the years (thermocouplers, urethral warming catheters). A review of the cryo-online data (COLD) registry noted a 4.8% rate of post-CSAP UI with a pad use rate of 2.9% at 12 months. A prospective case series noted incontinence (≥ 1 pad) in 5.6%, urinary tract obstruction in 1.9%, urethral sloughing in 5.6%, hematuria in 1.9%, perineal pain in 11.1%, rectourethral fistula in 0.9%, and erectile dysfunction in 98.1%. More recently, in a prospective study comparing whole gland CSAP to HIFU + TURP, Liu et al reported a 24 month UI rate (≥ 1 pad) of 1.6% (vs 2.5% for HIFU+ TURP, *P*=0.5).

When used as primary therapy for higher stage CAP, a 2.6% rate of *de novo* UI, 6% rate of urinary retention and 1.1% rate of rectourethral fistulization after CSAP was reported using the COLD registry.

However, the type of incontinence present after CSAP is not specified in these reports. On the other hand, Kimura et al reported that 9.5% of their patients had temporary incontinence after CSAP and 2.7% had prolonged mild stress incontinence. The presumed mechanism would be cold induced damage/necrosis of the tissues of the internal and external urinary sphincters resulting in SUI. They also noted that after CSAP there was an initial deterioration in IPSS and bother scores but these recovered at 12 and 18 months, respectively.

CSAP more recently been used in a focal fashion to treat unilateral CAP and seems to have fewer complications. A systematic review of focal CSAP reported low rates of incontinence between 0-3.6%. A recent publication from a multicenter registry reported UI (any pad use) occurred in 6% at 3 months and 0% by 6 months after focal CSAP.

CSAP has also been used as salvage therapy after XRT failure and appears to be associated with an increased risk for incontinence. In an older publication, Cespedes et al reviewed 143 patients who had salvage CSAP after prior XRT with a median follow-up of 27 months. They noted that UI occurred in 42% of patients, but resolved in 47% such that the long-term incontinence rate was 28%. In Pisters et al's review of the COLD registry they identified 137 patients who were continent prior to salvage CSAP and noted that at 12 months, 5.8% experienced incontinence without needing pads and 4.4% were using absorbent pads. A recent systematic review/meta-analysis of salvage CSAP case series reported an incontinence rate of 12-15%.

Generally, patients who undergo CSAP for prostate cancer are older and have more comorbidities than those undergoing RP.[270,] Given the previously discussed age related changes in the lower urinary tract that may predispose the elderly to incontinence following ablative/destructive procedures, the relatively low rates of incontinence that have been reported more recently after CSAP attests to the technical improvements over time.[278] Another possible risk factor for post-CSAP incontinence is TURP (either pre or post CSAP). TURP prior to CSAP has been considered a relative contraindication because of a significant risk for urethral slough due to poor coaptation around the urethral warming device.[270] This increases the risk for incontinence after CSAP, (7.6% of patients reported by Benoit et al). Some patients can also experience bladder outlet obstruction after CSAP. This can be due to the presence of necrotic tissue slough or urethral stricture. Roberts et al,[279] using SEER/Medicare data, reported that by 12 months post CSAP, 29% of patients underwent various procedures to deal with lower urinary tract obstruction. Ingrosso et al,[278] in their recent meta-analysis of salvage CSAP series, reported a urinary obstruction/retention rate of 5% (95% CI 2–9%; I2 = 86%). While TURP will alleviate the obstruction/retention issues, it carries a risk for incontinence. This is particularly problematic in the context of salvage CSAP after XRT. In Cespedes et al[276] series (using older cryo techniques), 60% of patients needing TURP after salvage CSAP developed UI.

2.2.2.14. HIFU

HIFU is a minimally invasive modality to treat CAP that uses high intensity ultrasound to selectively destroy prostate tissue (cancer) via coagulative necrosis. Despite its focused nature, it can also be associated with functional lower urinary tract complications. Three systematic reviews/meta-analyses reported similar findings with respect to adverse effects of HIFU. Warmuth et al reported bladder neck/urethral stenosis/stricture in 2–17%, prolonged urinary retention in 3–14%, urinary tract infection in 2–58%, UI in 2–34% and rectourethral fistula in 0–3%. Cordeiro et al reported urinary retention in <1-20%, urinary tract infections in 1.8-47.9%, UI in <1-34.3%, and rectourethral fistula in <2% of patients. Recently, He et al reported in their meta-analysis a UI rate of 10% (95% CI 0.06–0.14, *P*<0.00001), urinary obstruction rate of 15% (95% CI 0.10–0.20, *P*<0.00001), urinary retention rate of 11% (95% CI 0.07–0.16, *P*<0.00001) and urinary infection rate of 7% (95% CI 0.03–0.12, *P*<0.00001).

Mearini et al did UDS pre and 3-6 months post HIFU in 30 consecutive patients. Incontinence was defined as >1 pad/day and type of incontinence (UUI vs SUI) was assessed via voiding diary. At baseline, one-fifth of patients had urgency and UUI on voiding diary while on UDS DO was detected in 53% of all patients; impaired or poor bladder compliance in 30% and BOO in 23%; 1 patient had SUI. At 3–6-month follow-up, there was no difference in LUTS (IPSS) and no patient reported *de novo* SUI. However, 27% and 17% of patients had UUI at 3 and 6 months, respectively (*P*=0.341), with a significant increase in *de novo* UUI at 3 months compared with baseline (*P*=0.04). On follow-up UDS at 3 months, *de novo* DO was detected in 10% and 40% of patients had impaired bladder compliance (<20 mL/cmH_2O) compared to 30% pre-HIFU. Postoperative urethral sloughing may be etiologic in the early postoperative urinary storage symptoms after HIFU and with time this seems to improve.[285,] By 6 months, only 26% of patients showed impaired bladder contractility (BC) and 53% had DO (similar to pre-HIFU). SUI was detected urodynamically in 7% at 3 months and 3% at 6 months. Bladder capacity was unchanged. BOO was found in 10% of patients at 3 months and 3% of patients at 6 months.[285]

More recently, partial gland/hemiablation HIFU has been performed and may have less adverse effects than whole gland HIFU because of the sparing of more tissue. In their recent meta-analysis, He et al[284] reported a post-hemiablation HIFU UI rate of 2% (95% CI 0.01–0.03, *P*=0.004), urinary obstruction rate of 2% (95% CI 0.00–0.034, *P*=0.01), urinary retention rate of 9% (95% CI 0.00–0.12, *P*<0.00001), and urinary infection rate of 11% (95% CI 0.05–0.17, *P*=0.00007). HIFU hemiablation was compared to RALP by Albisinni et al in a matched pair analysis and was noted to be associated with better and faster recovery of continence (0 pads), with 82% not needing pads at 1 month postop whereas only 40% of RALP patients had 0 pad usage at 1 month (*P*<0.001). However, 13% of HIFU patients ultimately needed treatment of the contralateral side.

HIFU has also been used as salvage therapy after XRT and not surprisingly appears to have a higher rate of UI than primary HIFU. In their meta-analysis of sHIFU studies, Ingrosso et al[278] reported a UI rate of 28% (95% CI 19–38%). This rate was greater than that for sEBXRT, sBT or sCSAP. Furthermore, sHIFU had the worst rate of urinary obstruction (26%, 95% CI 15–39%). In a retrospective comparison of salvage HIFU to SRP (most were open RP), Devos et al noted that while there were no significant differences in estimated 5-year survival, sHIFU had a lower rate of complications and incontinence – at 12 months after treatment, 22.2% of sHIFU vs. 56.0% of sRP patients were using pads (*P*=0.0104).

3. INCONTINENCE AFTER SURGERY FOR BPH

Surgery for benign prostatic obstruction (BPO) may take the form of resection, vaporization or enucleation procedures. All of these can be done endoscopically with monopolar/bipolar electrocautery/plasma energy or laser energy (KTP/Greenlight, Diode, Holmium, Thulium) whereas enucleation procedures may also be performed via an open/laparoscopic approach (simple prostatectomy). Endoscopic approaches are the more commonly performed procedures and at least in the US, there has been a decrease in the use of simple prostatectomy over time.

Incontinence following BPH surgery may occur secondary to bladder and/or sphincter dysfunction (similar to post-RP) and may be transient or persistent. Sphincteric incontinence after BPH surgery is due to damage to/weakness of the external urethral sphincter coupled with the deliberate destruction of the internal sphincter/

bladder neck. The nature of benign prostatectomy is such that the bladder neck is deliberately destroyed and thus postop continence relies on the function of the more distal sphincter mechanism (at and below the level of the verumonatum). This region may be at risk with endoscopic procedures, particularly at the 12:00 position. Bladder dysfunction associated with post-BPH surgery incontinence has been postulated to have several causes: Irritation from healing of the prostatic fossa, thermal injury to the prostate capsule (especially with HoLEP), associated UTI and pre-existing DO/OAB have all been implicated in bladder dysfunction associated with BPH surgery.

Pre-existing DO/OAB may be secondary to BPO that causes elevated bladder pressure resulting in partial denervation of the detrusor leading to postjunctional denervation supersensitivity and DO. As well, it might be mediated via aberrant C fiber activity, abnormal sensory stimuli/altered prostatic urethral anatomy related to BPH, altered adrenoceptor function, neurotransmitter imbalance, neuroplasticity, or an actual myogenic deficit.[176] For further information on OAB, including neuromodulation techniques and botulinum toxin, please refer to chapter 11 (Surgery for Urinary Incontinence in Women) and 12 (Neurogenic Patients), respectively.Some patients may experience temporary incontinence after BPH surgery that improves with time postop, typically by 3-6 months (transient urinary incontinence [TUI]) and this may be sphincteric and/or bladder related (i.e., SUI, UUI, MUI). In their literature review of complications of TURP, Rassweiler et al[22] noted that early post-op incontinence is typically urge related and occurs in up to 30-40% of patients. Early postop UUI is often associated with irritative symptoms secondary to fossa healing, associated UTI or pre-existing DO caused by long-standing BPH. This will often improve. Persistent late incontinence may be iatrogenic stress incontinence and is rare (<0.5%).[22] Transient SUI and UUI are more common after HoLEP than TURP, but by 12 months they are comparable. In their review of the HoLEP literature, Shah et al[291] noted a rate of TUI between 1–44% with persistent UI in 0–2.4%. Enucleation procedures may be associated with a greater incidence of transient post-op incontinence than resection/vaporization procedures, possibly related to the more aggressive apical dissection. There is more complete removal of the adenoma and when this is done close to the external sphincter temporary damage to the continence mechanisms may occur. The retrograde dissection at the prostatic apex, particularly with transurethral enucleation procedures may stretch the inner longitudinal layer of the internal sphincter (lissosphincter) at the level of the prostate apex resulting in damage to the urethral sphincter and resultant transient incontinence. Hirasawa reported a 14% rate of incontinence at 3 months after transurethral bipolar enucleation of the prostate and they contrasted that to the rate of TUI after open simple prostatectomy of 5.6–9.4% reported by others.[,] They noted that open prostatectomy is done in an antegrade fashion (from bladder neck to prostate apex) and therefore does not stretch the inner layer of the sphincter at the prostatic apex.[297] Consistent with this is the report by Endo et al who modified the traditional retrograde approach to enucleation of HoLEP (apex to BN) to an antegrade approach (BN to apex) and saw a reduction in postop TUI from 25% to 3%. They believe the antegrade technique allows the apical gland to be removed from the sphincter without causing damage.

TUI associated with HoLEP resolves in 95–98% of patients by 6-12 months post-HoLEP (similar to TURP and PVP) and persistent incontinence after HoLEP generally occurs in about 5% or less beyond 1 year out to 10 years of follow-up.[22,,,,,]

3.1. UDS Findings

The limited number of studies that have used UDS to evaluate patients with post-BPH surgery incontinence, present mixed findings. Goluboff et al evaluated incontinence after TURP (N=31) and RRP (N=25) with UDS at a mean of 37 months post-op. They identified the cause of incontinence in TURP patients to be DO alone in 77%, SUI alone in 3% and mixed DO + SUI in 19% whereas for RRP patients 40% had DO alone, 8% had SUI alone and 52% had mixed. Thus, DO was the most common UDS findings after TURP occurring in 97% of incontinent patients in this study. Older age (>75 years) and the presence of neurological disease were more prevalent in the post-TURP patients with DO. On the other hand, Winters et al in a similar study of incontinent patients at least 1 year (mean 6.4 years) post-TURP (N=27) or post RP (N=65) found that sphincteric incontinence was the most common finding occurring in 93% of post TURP patients (44% had isolated SUI, 48% had SUI + DO) and 99% of post RP patients. More TURP patients than RP patients had DO (57% vs 29%, *P*=0.019) but isolated DO was present in only 7% of post-TURP patients. Not surprisingly, the TURP patients were significantly older (74 years vs 68 years, *P*=0.03). Theodorou et al also identified mixed findings after BPH surgery in their review of 56 patients with incontinence noting that while 41% had isolated DO or SUI, 43% had mixed incontinence and/or associated pathology (e.g., BOO) making them more “complex” cases. More recently, Bruschini et al[290] compared symptoms and UDS findings in incontinent patients after TURP (N=81), open simple prostatectomy (N=44) and RRP (N=21) at a mean of 21 months post-op. The symptom of SUI was noted in 43%, 73% and 52% of TURP, open prostatectomy (OP) and RRP patients respectively, whereas UUI was noted in 16%, 2% and 2% and total incontinence in 40%, 25% and 47%, respectively. On UDS, SUI was detected in 67%, 80% and 86% of TURP, OP and RRP patients, bladder dysfunction (DO and/or decreased compliance) in 59%, 57% and 57% patients (isolated DO in 16%, 14% and 10% of patients [*P*=0.848]), mixed incontinence (SUI + DO) in 10%, 21% and 14% and isolated decreased compliance (<12.5 mL/cmH_2O) resulting in incontinence in 14%, 5% and 0% patients, respectively. On logistic regression, there were no significant differences in the UDS findings between the different surgical approaches. However, age was a significant predictor of bladder dysfunction (DO and/or decreased compliance).

Studies reporting postop UDS that document DO and SUI are less common after laser BPH surgery and tend to include patients who aren’t incontinent. UDS was performed pre and postop after Greenlight PVP in 45 men with UD proven BOO by Hamann et al. They reported the incidence of DO dropped from 22% preoperatively to 11% after 3 months and to 9% after 12 months. *De novo* DO was found in 4% at 3 months and this reduced to 2% by 12 months. SUI did not occur in any patient. Nomura et al compared PVP to TURP in a prospective study using UDS and found similar improvements in outcome variables between the procedures within 12 months. Pre and post OP DO was present in 49% and 27% (*de novo* in 8%) of PVP patients and 53% and 29% (*de novo* in 8%) TURP patients, respectively. Transient SUI was noted in 1.3% after PVP and 2% after TURP (1 patient each group) and resolved by 6 months.

Naspro et al, in their review of the literature from 2006–2008, reported on the types of postop incontinence (not based on UDS) and noted rates after Greenlight PVP (with 6-60 month follow-up) of: UUI in 0-26% and SUI in 0-3%. For HoLEP they noted (with followup > 2 years): SUI in 0.6-3.2% and UUI in 0-28%.

3.2. Risk Factors for Incontinence After BPH Surgery

Similar to RP, both surgical and patient factors have been reported to be possible risk factors for incontinence after BPH surgery.

3.2.1. Surgical Factors

3.2.1.1. Surgical Approach

Broadly, surgical management of BPH can be classified into 3 categories based on their mechanism prostate tissue removal: resection procedures (e.g., M-TURP, B-TURP, ThuRP), vaporization procedures (PVP) and enucleation procedures (HoLEP, ThuLEP, DiLEP, TUEB, simple prostatectomy). All are reasonable options for small to large prostates (<90cc) but for very large prostates enucleation procedures are generally favored.[,] A meta-analysis of 31 publications involving 26 RCTs with a total of 3283 patients compared enucleation procedures (HoLEP, ThuLEP, PKEP, DiLEP [diode laser]) to resection procedures (m-TURP, b-TURP).[292] Efficacy was not different between groups with respect to IPSS and Qmax at 24 months postop (although, at 12 months better results were noted in the enucleation group). While resection procedures took less operative time, enucleation procedures had a shorter hospital stay. There were no significant differences in postop UUI or SUI between enucleation and resection groups although UUI did occur more frequently in PKEP compared to B-TURP groups.

In addition to the different mechanisms of prostate tissue removal, there are different energy sources that can be used: monopolar/bioplary electrocautery (TURP), plasma, laser (KTP, Holmium, Thulium). A recent systematic review/meta-analysis of 27 studies (4382 patients) compared lasers (HoLEP, thuLRP/ThuLEP, DiLEP) to bipolar technology (resection or enucleation) and determined that there were no significant differences between lasers and bipolar technology in the maximum flow rate (Qmax) and international prostate symptom score (IPSS) at a minimum of 3 months after treatment or in complications, including urethral stricture, urinary incontinence, urinary tract infection, re-catheterization and blood transfusion. In a systematic review and meta analysis of 69 randomized trials of different transurethral procedures for BPO, Cornu et al did not find a difference in efficacy or postop incontinence rates between monopolar and bipolar TURP, although B-TURP had fewer perioperative complications. A recent Cochrane review of 59 randomized trials (8924 participants) similarly found no difference in the risk of postop incontinence between M-TURP and B-TURP, although B-TURP slightly reduced TUR syndrome and blood transfusions.

Other meta-analyses have similarly shown no difference in incontinence between PVP vs TURP [Zhou et al did a meta-analysis of 4 randomized trials involving 559 patients comparing PVP to TURP and found no difference in the postop incontinence rates] and ThuLRP vs TURP [Jiang et al did a meta-analysis of 6 studies comparing ThuLRP to TURP and found that while ThuLRP was associated with less transfusion and shorter catheterization time, it had a longer surgical time. However there was no difference in postop UI (UUI, SUI)].

Open simple prostatectomy was historically the gold standard for large BPH but its use has been supplanted by the various endoscopic/energy modalities. The 2010 AUA guidelines for the management of benign prostatic hyperplasia in their review of publications on open prostatectomy from the early 2000s, noted that incontinence was reported at rates between 0.5% and 8% (confirmed).

More recently, Ugwumba et al reported on their results using open prostatectomy (transvesical) in the developing world and noted transient UI in 11%. In a randomized trial comparing TURP, TUVP, BPEP (bipolar enucleation) and OP, Geavlete et al found no difference in incontinence at 1-12 months between groups.

Simple prostatectomy can also be performed laparoscopically and by 2012, about 5% of simple prostatectomies were done in a minimally invasive fashion.[289] Using an extraperitoneal laparoscopic approach in 51 patients in which the prostatic urethra is preserved, Xing et al had a 0% rate of postop incontinence following simple prostatectomy as well as preservation of erectile function and antegrade ejaculation. When they compared LSP to bipolar TURP in a randomized trial, they noted transient incontinence (resolved in 1 month) in 2.8% of LSP vs 9.3% of b-TURP patients.

Table 2 shows results of various publications on BPH surgery with respect to postop incontinence.

3.2.1.2. Surgeon Experience

Surgeon experience influences operative time and complications including capsular perforation, urethral stricture and potentially incontinence ratres (especially for enucleation procedures).

Yang et al reported the learning curve of DiLEP was 20 cases. Shah et al noted that the HoLEP learning curve takes about 50 cases. Shigemura et al found that increasing surgical experience significantly contributed to surgical time, enucleation time and postop incontinence after holmium laser enucleation. They identified a learning curve of at least 20 cases. This is consistent with Kobayashi et al who noted enucleation time >100 min to be associated with postop UI).

3.2.2. Patient Factors

3.2.2.1. Age

Multiple studies over the years have identified increasing age to be an independent risk factor for incontinence following BPH surgery. Bae et al[302] noted that age was an independent predictor of postop UUI in patients undergoing PVP, while Hirasawa et al[297] and Xu et al noted age to be an independent predictor of transient urinary incontinence after endoscopic enucleation (bipolar, PK). Several studies have shown increasing patient age to be a significant predictive factor for TUI after HoLEP.[,]

Aging might be a factor because of an increased incidence of bladder dysfunction (e.g., DO) that is associated with increasing age.[290] Bruschini et al[290] calculated that each additional year of age increases the likelihood of bladder dysfunction by 5% and bladder dysfunction was 2.3 times more likely in patients older than 70 years (P=0.017).

Aging is also associated with decreasing external sphincter muscle function as demonstrated by Strasser et al[96] and thus might even be a contributor to post-BPH surgery SUI. Nam et al showed that advanced age and longer operative time were significant risk factors for TUI after HoLEP.[330] They suggest that compression, stretching, and tearing by the resectoscope during the operation coupled with the reduced sphincter muscle (atrophy) that occurs with aging may be the reason why age appears to be a risk factor for incontinence.[330]

3.2.2.2. Obesity/Metabolic Syndrome

Obesity and MetS appears to be associated with benign prostatic enlargement. Gacci et al in a systematic review and meta-analysis found that patients with MetS had significantly higher total prostate volume when compared with those without MetS (+1.8 mL,

95% CI 0.74-2.87; *P*<0.001) although no differences in IPSS. On meta-regression analysis differences in total prostate volume were significantly higher in older (adjusted R=0.09; *P*=0.02) and obese patients (adjusted R=0.26; *P*<0.005). Obesity was also noted to be associated with increasing LUTS (using IPSS) over time in a prospective study by Mondul et al. They found that the risk of LUTS and LUTS progression increased with increasing body mass index (≥35kg/m^2), waist circumference (>42 inches) and weight gain since age 21 years (≥50 lbs).

In addition to obesity/MetS having an impact on LUTS, it also appears to affect LUTS outcomes (storage symptoms) after BPH surgery. Sener et al prospectively compared men with and without MetS undergoing TURP using IPSS and uroflowmetry and found that patients with MetS had significantly higher postop IPSS and lower Qmax than non-MetS patients. Furthermore, while both groups of patients had significant improvement in QoL after TURP, the effect was greater in the non-MetS group. Obesity had a significant negative correlation with postop QoL (OR 7.286, *P*=0.043). Likewise, Gacci et al assessed LUTS using IPSS in a multicenter prospective study on men undergoing TURP or simple open prostatectomy (OP). They found that a waist circumference (WC) >102 cm was associated with a higher risk of an incomplete recovery of both total IPSS and storage IPSS. Furthermore, despite a similar resolution of obstruction, obese patients achieved only a 50% improvement in storage LUTS whereas nonobese patients had complete resolution. Elevated BMI was significantly associated with UI at 3 months (OR per SD = 1.23 [1.09-1.38], *P*>0.001) and at 6 months (OR per SD = 1.25 [1.03-1.5], *P*=0.02) after HoLEP in a retrospective study of 2346 patients.[331]

3.2.2.3. Comorbidities: DM, Neuropathy

Patients with neurologic issues are more prone to bladder and sphincter dysfunction and thus may be at greater risk for urinary storage problems after BPH surgery. Parkinson's disease has historically been a concern with respect to post-TURP incontinence. Staskin et al noted an increased rate of post-TURP incontinence (17% preop, 28% postop) and identified an association between normal voluntary sphincter control and postop urinary continence. Patients with preoperatively poor voluntary sphincter control were more likely to experience postop incontinence than patients with normal preop sphincter control (83% vs 4%). *De novo* incontinence developed in 20% and it was UUI. However, more recently Roth et al called into question this finding because of the possibility that many of those patients may have had multisystem atrophy which is more severe than Parkinson's. They reviewed 23 patients with Parkinson's disease who had TURP for BPO and of 10 with preop UUI, 8 had improvement or resolution post TURP. Furthermore, no patient developed *de novo* UI after TURP at a median followup of 3 years. They argued that Parkinson's is not a contraindication to TURP provided that BPO is proven. However, their patients were predominantly stage 2 Parkinson's (none >3) and thus were on the milder spectrum of disease.

Diabetes may be associated with OAB/DO in its early stages and thus may be a contributor to these issues after BPH surgery. However, Elmansy et al reported that the presence of diabetes mellitus was also a statistically significant predictor of post-HoLEP SUI and posited that the pathophysiology might related to the effect of DM on the nerve supply to the external sphincter. Diabetes was the main predictor of UI at 6 months post-HoLEP in a retrospective review of 2346 patients.[331]

3.2.2.4. Preop LUTS/Bladder Dysfunction

Abrams et al identified DO in 60% of patients prior to prostatectomy that decreased to 25% postoperatively. Machino et al noted in 62 patients undergoing TURP for symptomatic BPH that preoperative DO associated with BOO is more likely to resolve after TURP (73%) than preoperative DO without BOO (40%) and patients with preoperative DO without BOO have significantly worse symptomatic and overall outcomes after TURP. De Nunzio et al[294] followed 101 patients with urodynamic BOO who underwent watchful waiting, medical management (alfuzosin/finasteride) or surgery (TUIP, TURP) with repeat UDS at a mean of 2 years. They found DO at baseline in 52% overall and 40% at followup. The watchful waiting and medical management groups as well as the TUIP group showed no significant change in prevalence of DO on followup UDS whereas in the TURP group prevalence of DO decreased from 68% at baseline preop, to 31% at follow postop (*P*=0.02). This would be consistent with DO resolving after improvement in BOO caused by the BPH.

However, DO is not always associated with BOO and may be a consequence of aging itself. In a study on UDS in healthy elderly males, Andersen et al identified DO in 53% on UDS and a lack of correlation between BOO and DO. Gormley et al evaluated elderly males (mean age 80 years) with pre- and post-TURP UDS. All had DO preoperatively and it persisted postop in in 92%. They suggested that in the elderly, DO is age related and not necessarily due to BOO. Antunes et al noted that in 46 BPO patients undergoing TURP, older age was more common in patients with preop DO (65 vs 61 yr, *P*=0.041) as well as those with persistent DO postop (69 vs 63 yrs, *P*=0.043). Consistent with all of this is the fact that DO may recur after several years after prostatectomy despite sustained reduction in BOO (noted in 40-64%).[94]

It is possible that there is a sensory neural issue at play. Chalfin and Bradley were able to abolish urodynamic DO in patients with BOO by administering a prostate nerve block (that does not alter BOO). This suggests a possible abnormal afferent effect from the prostate (possibly secondary to the BOO), may be responsible for DO. Rather than via reduction of BOO with surgery, it is possible surgery causes a "deafferentation" of the afferent neurones responsible for initiating the involuntary detrusor contractions characteristic of detrusor overactivity and causing symptoms of overactive bladder.[176] This theory is consistent with why TURP can be effective in improving LUTS in patients without actual urodynamic obstruction. De Nunzio et al[294] noted that TUIP and TURP significantly reduced BOO, but detrusor overactivity was permanently reversed, with fewer *de novo* cases in the TURP group. The finding could be explained by TURP resulting in greater destruction of the prostatic urothelium and submucosa compared to TUIP.[176] Consistent with this is the finding in the CLAasP trial, that compared conservative therapy to standard TURP and a side-fire laser (vaporization) treatment of BOO, that laser was as effective as TURP in reducing preoperative overactive bladder symptoms and urodynamic detrusor overactivity, despite being a significantly poorer procedure at reducing BOO. Furthermore, Van Melick et al, in a randomized trial comparing TURP, contact laser prostatectomy and electrovaporization, noted a 50% resolution of preop DO on 6 month postop UDS in all groups.

However, OAB/DO may be an adverse risk factor for post-BPH surgery outcomes, especially when not associated with BOO. Dybowski et al evaluated 76 patients who had PVP for UDS proven BOO using IPSS and noted that while the incidence of moderate or severe storage LUTS decreased over time, the presence of preop urgency was predictive on multivariate analysis of persistent storage symptoms 6 months postop (OR 5.7, 95% CI, 1.41-23.16;

P=0.014). Seki et al also found that greater preop storage symptom score (IPSS) and presence of preop DO were negative predictive factors for QOL improvement after TURP. Kim et al compared patients with high preop storage symptoms (IPSS storage score ≥8) to those without (IPSS storage score <8) who underwent TURP and found that at 12 month follow-up, those with high preop storage symptoms were more likely to have persistent symptoms and significantly worse QoL. Bae et al[302] noted that preop OAB issues predisposed patients to transient postop *de novo* UUI after Greenlight PVP. They reported that *de novo* UUI occurred commonly early in the early postop period (43% of patients at 1 week) but improved over time such that by 1 year 0 patients had it. On multivariate regression, they identified older age, higher symptom scores (including higher total OABSS), small volume at first desire to void and smaller cystometric capacity on preop UDS were independent predictors of *de novo* UUI. Machino et al[341] reported less favorable efficacy after TURP in patients with preoperative DO without BOO. They noted more persistent DO postoperatively in patients without preop BOO (60%) than in those with BOO (27%). Choi et al, on multivariate analysis, identified worse initial storage symptoms (OR=8.32), impaired detrusor contractility (OR=2.96), small bladder capacity (OR=4.31) and age (OR=1.05) were significantly associated with persistent (at 6 months) storage symptoms (IPSS storage score >7) after TURP. Zhao et al identified that the pattern of DO may play a role in persistent OAB symptoms after TURP. Preoperative terminal DO (as opposed to phasic DO) was associated with worse postop OAB symptoms (including UUI).

3.2.2.5. Prostate Size

Xu et al[328] and Hirasawa et al[297] reported prostate volume to be an independent predictor of transient urinary incontinence after endoscopic enucleation of the prostate (PK, bipolar). In addition to prostate volume (>81g) being an independent predictor of post-HoLEP TUI (SUI), Elmansy et al[339] found that a postop PSA reduction of >84% was a significant associated factor. Recently, Das et al reported that prostate volume >100g was associated with an increased risk for TUI after HoLEP and on multivariate analysis, resected prostate weight was predictive of any SUI. Hirasawa et al[297] explain that with increasing prostate volume, there will be a larger prostatic fossa following enucleation (they did transurethral bipolar enucleation) and this may cause urine trapping and leakage with stress maneuvers in the short-term. Furthermore, they postulate that the longer surgical time associated with larger prostates results in a longer period of stretch induced injury of the internal sphincter at the prostatic apex.

3.2.2.6. Preop Sphincter Function

Baseline MUCP was identified as an independent predictor of *de novo* TUI after HoLEP.[301] Furthermore, preoperative pelvic floor muscle function may help hasten the resolution of TUI. A recent randomized trial found that a regimen of preoperative pelvic floor muscle exercises (in addition to postop PFME) significantly reduced the post-HoLEP UI (any pad usage) rate at 3 months from 26% to 3%, (*P*=0.01) compared to just postop PFME although by 6 months postop there was no difference.

3.2.2.7. Prior XRT

XRT for prostate cancer before BPH surgery appears to be a risk factor for UI and is addressed in XRT section. Please see Table 2.

3.2.3. Incontinence After Orthotopic Neobladder

Urinary diversion after radical cystoprostatectomy for bladder cancer may take the form of an orthotopic neobladder (ONB) constructed from intestine (small or large). Various techniques for neobladder construction have been described and in general detubularization of the bowel and reconfiguration into a spherical pouch has been the main principle. Urinary continence after neobladder creation depends on both an intact urethral sphincter as well as a reservoir of adequate capacity and low storage pressure.

As with radical prostatectomy, radical cystoprostatectomy transects the urethra distal to the prostate and is thus similarly prone to sphincteric deficiency postoperatively akin to post-prostatectomy. In addition, depending on the bowel segment used and how it is configured, elevated storage pressures are possible, and this could impair urinary continence. Unlike after prostatectomy where in theory the guarding reflex is still intact (reflex sphincter contraction as the bladder fills, particularly overnight), after cystoprostatectomy and neobladder formation, the guarding reflex no longer exists since the bladder is made from bowel. This has ramifications particularly with respect to nocturnal continence.

ICI 6 noted daytime continence after ONB to range between 85-100% and nighttime continence between 51-100%. However, continence may deteriorate with time. Madersbacher et al published longer term results (> 5 years) of the Studer ONB using a continence definition of complete dryness or loss of no more than a few drops of urine once or twice a month on patient completed questionnaire, as well as frequency volume charts. They reported that daytime continence plateaued at 12 months with 92% being continent but there was a deterioration at >5 years: after 5 and 10 years 82% and 80%, respectively used 0-1 pads during the day. Nocturnal continence was not as good and similarly deteriorated over time: it peaked at approximately 85% at 3 years, but at 5 years, 31% were incontinent at night and at 10 years 45% had nocturnal incontinence. However, the magnitude of incontinence in most patients was no more than a few drops. Ahmadi et al, in a prospective randomized trial of T pouch neobladder vs Studer neobladder, used BCI questionnaire as well as reported pad usage at ≥12 month follow up (mean 4.5 yrs). They noted that 40% of patients had daily urinary leakage and 17% reported no control/frequent dribbling during the day. 55% of patients noted nighttime urinary leakage, 53% reported no control/frequent dribbling at night. 78% of patients used pads: 47% of patients used at least 1 pad during the day with 23% of patients using diapers. 72% of patients used nocturnal pads with 39% wearing diapers at night. However, overall, 47% of patients noted minimal wetness to their pads day and night and around 80% of patients noted no/minimal bother by incontinence and no/minimal limitation with daily activity. More recently Kretschmer et al,[217] using questionnaires and pad testing (continence equals 0-1 safety pad and ≤10g of urine loss), with a median followup of 61 months after ileal ONB, reported continence rates of 54.3% and 36.3% during the day and night respectively. Median daytime pad use was 1 pad (range 0 to 9) with median daily urine loss (pad weight testing) of 8 g (range 0 to 2400). Median nocturnal pad use was 1 pad (range 0 to 7) with median nocturnal urine loss of 28.5g (range 0 to 1220).

The etiology of ONB incontinence, similar to post-prostatectomy can be sphincter related (ISD) and/or reservoir related (hyperactivity). Koraitim et al did UDS in men after ONB (tubularized ileocecal, detubularized sigmoid detubularized ileum) and noted: MUCP showed statistically significant correlation with daytime continence whereas nocturnal continence was significantly positively correlated with MUCP and negatively correlated with maximum reservoir contraction amplitude and baseline pressure at mid and max capacity. MUCP, maximum reservoir contraction amplitude and baseline pressure at capacity were significant predictors of continence on multivariate analysis. Keszthelyi et al studied 28 patients with incontinence after ileal ONB (mean follow-up 43 months) and compared those with daytime and nighttime incontinence (total incon-

tinence) to those with nighttime incontinence only (partial incontinence). They noted significantly higher urethral resting pressures and maximum voluntary sphincter contractions in the partially incontinent patients. Furthermore, totally incontinent patients were more likely to have neobladder hyperactivity with higher pressure and longer duration contractions, and lower neobladder compliance and capacity. Thus, they had a mixed picture of sphincteric and reservoir dysfunction.

Given that intestinal contractility is mediated via the parasympathetic cholinergic system (similar to the bladder), it is not surprising that medical treatment of pouch hyperactivity (anticholinergic medication) has been shown to improve neobladder storage (including nocturnal enuresis) presumably via anticholinergic suppression of the neobladder motility. Both El-Bahnasawy et al and Zahran et al demonstrated improvement in ONB incontinence using anticholinergic OAB medication in randomized crossover studies. Furthermore, the medication was shown to significantly increase the neobladder volume (at first desire, at normal desire and at the maximum enterocystometric capacity) on UDS and decrease neobladder hyperactivity (frequency and amplitude).[361]

Decreased urethral sensitivity after radical cystectomy has also been suggested to play a role in neobladder incontinence. Hugonnet et al demonstrated that the sensory threshold in the membranous urethra is lower in incontinent patients and it was suggested that this may impair the conscious or unconscious sensation of urine leakage in the membranous urethra that would otherwise result in a reflex or voluntary contraction/increased tone of the external urethral sphincter. The higher nighttime incontinence rate that has been reported after ONB has been attributed to several factors including the absence of the guarding reflex, decreased rhabdosphincter tone and increased diuresis at night.[357] In fact in a recent study, nocturnal polyuria was found in 58% of ONB patients at a median of 3 years postoperative.

Incomplete emptying of an ONB in males has been reported on average to be about 5% but up to 43% of patients may end up catheterizing for residuals of >100mL.[365] Depending on the degree of retention, the ONB capacity may be reached in short time intervals and coupled with weakness of the urethral sphincter may result in incontinence.[365] This may especially be the case with respect to nocturnal incontinence in that the residual urine will cause the ONB to reach volumes at which pouch contractions occur (typically after 50% of actual ONB capacity) earlier during sleep and this coupled with lower urethral pressure during sleep (in part related to loss of the guarding reflex) results in NE.[365]

As with RP, both surgical and patient related risk factors for incontinence after ONB have been identified.

3.2.3.1. Surgical Factors

3.2.3.1.1. Bowel Segment (and Length)

Both small bowel (ileum) and large bowel (sigmoid) may be used to create an ONB. However, there may be an advantage to ileum. In a meta-analysis of 12 cohort studies comparing ileal ONB to sigmoid ONB, Tao et al noted that both daytime and nighttime continence rates were significantly better in IN group than in SN group: incidences of daytime continence in patients with ileal and sigmoid ONB were 74.1-97% and 66.7-90% respectively (RR=0.87, 95% CI: 0.81-0.94) and nighttime continence were 57.1-90% and 23.8-65.2% respectively (RR=0.73, 95% CI: 0.60-0.90) although SN patients were more likely to have spontaneous voiding. Furthermore, when looking at UDS results, ileal neobladders had larger capacity (WMD=-84.93, 95% CI: -160.36 to -9.50), lower pressure at capacity (WMD=11.18, 95% CI: 4.29-18.06), and better compliance (WMD=-25.55, 95% CI: -32.45 to -18.64) although post-void residual volume was also larger (WMD=-23.48, 95% CI: -36.75 to -10.21). On the other hand, El-Helaly et al recently compared sigmoid ONB to ileal ONB and found no significant differences in the continence status and spontaneous voiding between both groups. Sigmoid ONB patients had higher nocturnal voiding frequency. MUCP was significantly higher in ileal neobladder patients.

Given that adequate ONB capacity is considered essential for urinary continence, one might speculate that using a longer bowel segment to construct the ONB would be associated with better continence. However, this is not necessarily the case. Yadav et al used a modified W shaped ileal ONB made from only 25cm of ileum and reported good or satisfactory daytime (up to 1 pad per day) and nighttime (up to 1 pad per night) continence in 100% and 93.8% respectively at a mean follow-up of 27 months. All but one patient had good ONB compliance on UDS by 1 year and the mean capacity was 588mL at 3 years. Nesrallah et al, in their comparative study of 40cm small J-pouch and 60cm larger spherical pouch, found that large initial volume does not result in better continence rates at 12 months and instead predisposed to urinary retention (0% vs 19%) due to neobladder atony and progressive emptying failure.

3.2.3.1.2. Detubularization

Of major importance to ONB continence is a low-pressure reservoir of adequate volume. Detubularization of the bowel helps to achieve this.[367] By preventing transmission of myogenic activity from the intestinal longitudinal smooth muscle to the inner circular muscle, detubularization limits the intestinal contraction and intraluminal pressure elevation.[356] The pressures within tubularized neobladders are 1.8 times those of detubularized spherical reservoirs. Given that nocturnal continence depends on low internal reservoir pressure, it is no surprise that Koraitim et al[359] reported better nocturnal continence rates in ONB with detubularized compared to non-detubularized bowel.

3.2.3.1.3. Nerve Sparing

Similar to RP, nerve sparing may help post-ONB continence. Turner et al reported that daytime continence rate was significantly higher in men with attempted nerve sparing (94%) versus no nerve sparing (83%) cystectomy technique (*P*=0.003). Furrer et al reviewed 180 ONB patients with >10 year follow-up, reporting that 89% were continent during the day and 69% at night and on multivariable analysis, any degree of attempted NS was significantly associated with daytime continence (odds ratio [OR] 2.08, 95% CI 1.05-4.11; *P*=0.04) and night-time continence (OR 2.51, 95% CI 1.08-5.85; *P*=0.03). On the other hand, el-Bahnasawy et al compared NS to non-NS cystectomy + ONB in preoperatively potent patients younger than 65 using standardized questionnaires to assess daytime and nighttime continence (complete dryness without need for pads) as well as UDS. They found no difference between groups in daytime or nighttime continence. However, they did find that the NS group had significantly longer functional urethral length although there was no significant difference in maximum urethral pressures between groups. Interestingly, there was no difference between postoperatively potent and impotent patients in the NS group with respect to continence or UPP measurements which suggests meticulous apical dissection, rather than actual nerve preservation may be the key to postop continence (similar to what has been reported after prostatectomy).

3.2.3.1.4. Open vs. Intracorporeal

Palleschi et al evaluated 30 pure laparoscopic ONB (40cm ileum, U shape) patients with UDS at 180 days postop. They reported that 80% of patients were continent during the day and 64% at night. On UDS, the mean maximal capacity was 287mL and while all had residual peristaltic activity, 30% of patients had reservoir contractions exceeding 35cmH_2O and overall, 67% of these (20% overall) experienced incontinence with these contractions. 5/30 (17%) of patients had demonstrable SUI at neobladder capacity on UDS with a VLPP ranging between 44 to 82cmH_2O. 20% of patients needed CIC for PVR>100mL. Satkunasivam et al retrospectively compared open ONB to robotic intracorporeal ONB using BCI and SF-36 questionnaires and found comparable BCI scores for urinary function and bother between groups. Rates of 24-hour pad use were comparable between iONB and open ONB groups (pad-free 17% vs. 19%; ≤2 pads 84% vs. 79%). However, pad size and daytime wetness were worse in the iONB group. This might be explained by the significantly shorter follow-up in the iONB group (9.4 months vs 62 months) that may not have allowed enough time for spontaneous improvement in the iONB group.

3.2.3.2. Patient Factors

3.2.3.2.1. Age

Similar to RP, several studies have reported that increasing age may be associated with neobladder incontinence.[357,358] This might be in part due to age related decline in sphincter function, although a negative correlation between reservoir capacity and age has also been reported.[357]

3.2.3.2.2. DM

Ahmadi et al[358] noted that after ONB older patients and those with DM scored significantly poorer with respect to urinary function on the BCI questionnaire, although there was no correlation with pad usage. Kessler et al reported a lower nighttime continence rate in patients with DM which remained significantly different from that of patients without diabetes even 2 years after surgery. Furthermore, the patients with DM took longer to achieve daytime continence. It is possible that diabetic neuropathy affects autonomic nerve fibers supplying the urogenital diaphragm/sphincter or intrapelvic afferent fibers from the membranous urethra, which can lead to decreased urethral closure pressure or decreased voluntary sphincter contraction.[378]

3.2.3.2.3. BMI

Palleschi et al[375] noted that patients with a higher BMI and lower mean cystometric capacity were more likely to experience SUI after lap ONB. They suggested that the higher BMI results in less bladder expandability and more pressure on the pelvic floor.

3.2.3.2.4. Prior Prostate Surgery

De Arruda et al, using a >1 pad per day definition of incontinence, reported a 13% incidence of incontinence after ileal ONB with median follow-up of 53 months. Previous prostate surgery appeared to be associated with a greater incidence of ONB incontinence (33% vs 7%, OR=6.5, *P*=0.023).

3.2.4. Incontinence After Pelvic Fracture/Urethral Injury/ Posterior Urethroplasty/Pelvic Extirpative Surgery

Urinary incontinence after pelvic fracture/urethral injury and/or its management is uncommon, but does occur. In a systematic review/meta-analysis of the different forms of initial PFUDD management (primary realignment [PR], early endoscopic realignment [EER], initial suprapubic catheterization with delayed urethroplasty [SCDU]), Light et al reported that UI affected 8.5% of PR patients, 5.8% of EER patients, and 8.2% of SCDU patients. They noted no statistically significant difference in the rate of UI between PR and SCDU (fixed effects model; OR: 0.94; 95% CI: 0.49–1.79; *P*=0.86) or EER and SCDU (fixed effects model; OR: 1.10; 95% CI: 0.48–2.53; *P*=0.82).

Owing to the tethering of the posterior urethra to the pubic arch by the puboprostatic ligaments proximally and perineal membrane distally, this region is vulnerable to injury when there is a pelvic fracture. The proximal tethering is thought to be tighter and thus urethral disruption, if it occurs, tends to occur more distally; in fact most commonly just distal to the external sphincter at the level of the bulbomembranous junction.[17] It has commonly been thought that either the initial trauma itself or posterior urethroplasty may result in damage to the rhabdosphincter resulting in continence depending on the BN and supramontanal urethra (i.e., proximal part of the internal sphincter/lissosphincter).[17] Given this, the presence of an incompetent BN is considered a risk factor for incontinence after posterior urethroplasty. BN incompetence related to PFUDD is present in approximately 4.5% of patients. The mechanism typically involves direct injury to the BN by the sharp edge of the fractured and displaced pubic bone and typically there are fractures of both superior and inferior pubic rami on same side.[384] Boys younger than 15 years old may be at greatest risk because their small prostates provide less protection from pubic bone fragments.[384] However, while an open bladder neck on preoperative cystography can be an indicator of increased risk for postoperative incontinence (especially with a longer open bladder neck), most patients who are found to have an open BN do not experience postoperative incontinence. This may be related to varying severity of the BN injury as well as the possibility that the rhabdosphincter function may actually be preserved to some degree (probably due to the urethral disruption occurring more distally at the bulbomembranous junction). In fact, several studies have confirmed the presence of rhabdosphincter function after posterior urethroplasty.[17] Furthermore, some patients have intact support of the posterior urethra by the levator ani complex (despite the trauma and surgery) and therefore can have a pelvic muscle contribution to urinary continence.[388]

Similar to a BN injury at the time of pelvic fracture being a risk for incontinence, a history of BPH surgery such as TURP is a risk factor for incontinence after posterior urethroplasty. Given that TURP destroys the internal sphincter/lissosphincter, there is reliance on the external sphincter for continence. If posterior urethroplasty is needed for a proximal bulbar/bulbomembranous urethral stricture, the external sphincter will be at risk for damage and consequently sphincteric incontinence.[17] Because of this concern, it has been suggested that one avoid anastomotic urethroplasty that involves urethral transection and instead use substitution urethroplasty with grafting (typically buccal mucosa).[390] A recent multicenter retrospective study of posterior urethroplasty in continent patients with a history of BPH surgery used a ventral onlay of buccal mucosa, avoiding urethral transection, and reported a stricture free success rate of 84% and incontinence (defined as a subjective incontinence or use of pads reported by the patients) in 4%. The authors felt that by avoiding urethral transection and injury to dorsal urethral tissues, they were able to preserve external sphincter function bulbar urethral blood supply. On the other hand, anastomotic posterior urethroplasty has been reported successful with relatively low risk for incontinence in patients with a history of BPH surgery. Favre et al reported on their results of anastomotic posterior urethroplasty in 77 patients with a history of BPH surgery and noted 6 (7.8%) with UI: 4 had moderate UI (defined as <4 pads/day) while 2 were severe. Interestingly, the majority of patients with UI had a history of open prostatectomy. Gómez et al recently identified a connective

tissue plane between the membranous urethra and external sphincter muscle that allowed them to mobilize the external sphincter muscle off the membranous urethra to the level of the prostate via a dorsal, bulbar artery sparing approach in order to perform anastomotic urethroplasty. With a mean follow-up of 53 months, they reported that 90% of their patients were free of stricture recurrence and 85% were continent (0-1 pad).

The corollary to this is that BPH surgery in patients with a history of PFUDD/posterior urethroplasty may similarly place patients at risk for incontinence. While there is limited data on this issue, recently a modified TURP technique involving conservative resection of the median lobe (or one of the lateral lobes if no median lobe was present) with avoidance of resection of the circular fibers at the bladder neck was reported to maintain continence in 5 patients.

3.2.4.1. Pelvic Extirpative Surgery

Radical non-urologic pelvic surgery (e.g., for rectal cancer) may affect genito-urinary function. This is typically attributed to anatomical changes within the pelvis or autonomic nerve injury leading to an impairment of the parasympathetic innervation to the detrusor muscle or the sympathetic innervation to the bladder neck, trigone, and urethra. Damage may result from ischemic injury, nerve stretching, thermal damage, local inflammatory effects, and ligation of sacral splanchnic plexus or hypogastric nerve. When parasympathetic nerves are damaged the bladder may become non-contractile (detrusor hypoactivity) and this may result in urinary retention with overflow incontinence. Sympathetic denervation may result in reduced closure/resistance of the bladder neck/internal sphincter that may contribute to SUI. In addition, damage to the pudendal nerve or its branches may compromise the striated external sphincter and similarly contribute to SUI.[397] In many publications, the issue of bladder dysfunction after colorectal surgery refers to incomplete bladder emptying/urinary retention and this has been noted in 30-60% of patients after APR or LAR.[395] Most cases are short lived. In a non-systematic review, Panteleimonitis et al reported that urological function tends to deteriorate in the early postop period but recovers with time (6-12 months) irrespective of surgical modality (open, lap/robotic). In a systematic review of 89 studies from 2005–2015, Dulskas et al reported that sexual function is more commonly affected after rectal surgery than urinary function with urinary dysfunction (mainly urinary retention) occurring in approximately one-third of patients after rectal cancer surgery. They noted that the main cause of the dysfunctions is damage to the pelvic nerves that can occur during rectal mobilization from adjacent structures as well as indirect injury via traction. The preservation of autonomic nerves has been associated with a reduction in the incidence of postoperative urinary dysfunction.[395] Surgical experience/learning curve (*P*=0.019), male gender (*P*=0.006) and T stage (T1-2 vs T3-4) independently impacted identification of pelvic nerves intraoperatively and thus impacted postoperative function.

There is conflicting data as to whether or not lap/robotic surgery result in better nerve preservation and urinary functional outcomes compared to open surgery.[395,399]

3.2.4.1.1. Climacturia

Climacturia is incontinence that occurs with orgasm and was first reported in 1996 by Koeman et al. It has been most commonly associated with radical prostatectomy; although, it has also been reported after cystoprostatectomy with neobladder. In a recent literature review of orgasmic dysfunction after radical pelvic surgery (RP, cystoprostatectomy with neobladder, colorectal surgery), Haney et al noted that climacturia has been reported after RP in 20-93% whereas after cystoprostatectomy the rate is 6-45% and it has not been quantified after colorectal surgery. Clavell-Hernanez et al, in their review similarly noted a wide range in post-RP prevalence of climacturia but most data suggested 30%. Climacturia is a separate entity from SUI and UUI and it often bothers patients with up to 48% of patients with climacturia experiencing significant bother from it. Mitchell et al evaluated 1459 men who underwent open RP and using UCLA-PCI questionnaire noted that 44% of patients reported bother from sexual incontinence (not specified if this was orgasm associated) at 3 months postop and this decreased to 36% at 24 months. While bother from incontinence during sexual activity and from SUI were strongly associated at all times (~ 50% of patients with bothersome sexual incontinence also had bothersome day to day incontinence), 10% of sexually incontinent patients had no daytime incontinence at all. Similarly, Nilsson et al assessed postop climacturia using a questionnaire in 691 sexually active men post RP (open or RARP) and found that 39% had climacturia but 86% of these patients were otherwise continent. Furthermore, 28% of patients who had daytime incontinence, did not have climacturia. Prior TURP (RR 1.4 [95% C.I. 1.0–2.0]), self-assessed loss of penile length (RR 1.4 (95% C.I. 1.1–1.7) and postop erectile dysfunction (RR 1.3 [95% C.I. 1.1–1.6]) were risk factors for climacturia. Choi et al similarly reported that postop penile length loss was a predictor of climacturia as was orgasm associated pain.

Surgical approach (open RRP vs RALP) does not appear to matter with respect to the incidence of climacturia, but RALP is associated with a greater and faster recovery from climacturia over time (8.5% vs 5% at 24 months, 48% vs 15% at 84 months, *P*<0.01).

The pathophysiology of sexual incontinence is very similar between men and women and is influenced by injury to the pelvic and pudendal nerves, pelvic floor and external sphincter incompetence, and detrusor overactivity. It has been suggested that removal of the internal sphincter (ie BN) during RP combined with external sphincter relaxation that normally occurs with ejaculation might be responsible for climacturia.[401] However, arguing against this being the sole mechanism is the fact that climacturia is not as common as one would expect after RP (since the BN/internal sphincter is affected on all RPs) and furthermore, while a history of TURP (which involves resection of the bladder neck) has been implicated as a risk factor for climacturia after RP, there is a paucity of data reporting climacturia after TURP alone.

Damage to the external sphincter and support structure of the membranous urethra during RP has also been a suggested etiologic factor,[407] but the aforementioned lack of a consistent association with daytime SUI suggests other issues are relevant. Pudendal nerve/neurovascular bundle injury (direct or stretch) could also play a role in compromising sphincter function and a stretch injury could be consistent with the fact that climacturia can improve over time.[409] The fact that climacturia has also been reported with XRT suggests another process beyond surgical anatomic disruption may play a role: O'Neil et al reported climacturia in 28.3% of sexually active patients after RP alone, 5.2% after XRT alone and 28.6% after RP+XRT, while Jimbo et al[411] recently reported climacturia in 39% of patients after RP alone, 14% after XRT alone, and 52% after RP + XRT.

A study by Manassero et al reported urodynamic findings in patients with climacturia. They noted that of 84 patients who underwent BN sparing RP and were potent and continent at least 1 year postop, 24/84 (29%) experienced climacturia (at least 3 episodes of urinary leakage at moment of orgasm). Compared to 5 non-climacturic controls, climacturic patients had significantly lower functional urethral length on UDS (20 vs 35mm, *P*=0.02) and daytime con-

tinence recovery for them took significantly longer (mean 21 vs 0 weeks, *P*=0.02). While MUCP was lower in the climacturic group, it and other VUDS variables (presence of DO, Qmax, VLPP, fluoro appearance of vesicourethral junction), as well as pad testing and symptom scores were not significantly different between groups. They concluded that residual sphincter function, related to functional urethral length, may be enough for daytime continence in climacturic patients, but not for continence at orgasm. The fact that slings have successfully alleviated climacturia is consistent with a sphincteric mechanism.[409]

IV. POST PROSTATECTOMY SURGICAL OPTIONS

1. MALE SLINGS

In recent years, the synthetic male slings (MS) have gained significant popularity because of their relatively low cost, less invasive nature, as a relatively simple procedure and since patient can void normally without the need to manipulate a pump. The ideal candidate should have a mild to moderate degree of SUI with an adequate residual sphincter function and can generate a strong detrusor contraction to overcome the fixed resistance of the sling to void.

Although Berry was first to describe MS surgery, it was Kaufman who popularised one of the earlier external bulbar urethral compressive devices to treat male SUI. Nonetheless, this urinary device had poor success and high complication rates and was subsequently abandoned. Around a decade later, Schaeffer described a bulbourethral sling with Dacron bolsters placed under the urethra and suspended to the anterior rectus fascia by sutures with mixed outcomes where a third of patients required revision surgery. Poor outcomes were reported in patients who had radiation. By the early 2000s, several bulbourethral composite slings were designed and marketed with limited commercial success. John described a retropubic bulbourethral composite suspension using a porcine dermal graft secured to the bulbospongiosus muscle and a separate 1cm wide polypropylene sling that had a reported 69% cure rate but this device was associated with high intraoperative bladder perforation rate. Xu et al reported the use of a suburethral polyester patch plus a narrow polypropylene tape with around 85% successful outcome, while Wadie et al showed that revision surgery was necessary for 25% of patients who received polypropylene bulbourethral sling suspended by nylon sutures and fixed to rectus sheath.

Bone anchor sling fixation became popular in 2000 and the bone-anchored male sling (BAMS) obviated the need for any suprapubic incision for suture passage and fixation. In 2001, Madjar et al described this technique with a synthetic or cadaveric fascial sling and 86% of the 14 patients were “cured” wearing none or 1 pad at 12 months follow-up. Comiter reported a 76% cure and 14% “substantially improved” rate in 21 men with post-prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months. Follow-up study by the author showed that 65% of patients remained pad free and 15% required 1 pad per day at a median of 48 months follow-up. In a study comparing various materials for the MS (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis), Onur et al reported 41% of patients (46 men) were dry and 35% reported a 50% reduction in the number of pads after a mean follow-up of 17 months (6–26). The InVance male sling (American Medical Systems, MN, USA) was marketed for a short time in the early 2000s with a reasonable success rate (around 50% patients were dry, 25% improved and 25% failure rate).[409] However, the morbidity related to bone screws such as pubic bone osteitis and bone-anchor dislodgement, coupled with the emergence of more effective alternatives decreased the popularity of these BAMS resulting in discontinuation from the commercial market.

The modern MS can be divided into adjustable or non-adjustable types and repositioned under the bulbar urethra either through a retropubic or transobturator (TO) approach. Commercially available adjustable MS include Argus (Promedon, Cordoba, Argentina), ReMeex (Neomedic, Barcelona, Spain) and ATOMS (AMI, Feldkirch, Austria) while the current non-adjustable MS are I-STOP TOMS (CL Medical, France), AdVance (Boston Scientific, Minnetonka, USA) and Virtue (Coloplast, Minneapolis, USA) slings. The adjustable MS has a theoretical advantage over non-adjustable MS because the sling can be revised easily to provide further urethral compression in the event of persistent and/or recurrent urinary incontinence without the need for another MS or salvage AUS surgery. Over the years, the TO sling technique has largely replaced retropubic placement of MS as the preferred approach for sling placement due to the low intraoperative risk of bladder injury. It is thought that newer generation of modern MS not only provides direct compression of the bulbar urethra, but it also allows for proximal urethral relocation by realigning the mobile sphincter complex to provide further urethral sphincter complex coaptation.[45]

More recently, there has been increasing interest in the role of MS surgery to treat climacturia following radical prostatectomy.[409] This condition is often underdiagnosed and undertreated.[409] The role of “mini-sling” sling in treating climacturia has gained some interest recently. The use of Mini-Jupette graft was popularised by Andrianne. Yafi et al reported that Andrianne mini-jupette is a feasible surgical adjunct to inflatable penile prosthesis placement in subsets of patients with post-RP climacturia and/or minimal incontinence with subjectively improvement noted in 92.8% and 85.7%, respectively at a mean follow-up of 5.1 months. In a different approach using a modified Virtue mesh, Valenzuela et al[414] showed that climacturia resolved in 28 of 30 (93%), and SUI improved in 23 of 27 (85%). The mean (SD) number of pads per day for those patients with SUI decreased significantly from 1.4 (1.1) before surgery to 0.4 (0.6) after surgery *P*=0.02). However, 1 patient required sling removal for urethral erosion after prolonged postoperative catheterization.

There are very few studies comparing the nonadjustable vs the adjustable MS procedures. Whereas the adjustability does not appear to increase the overall efficacy of the continence surgery, it does, by definition, also increase the need for surgical revision/tightening to ensure on-going urinary continence. Furthermore, it does not appear that mechanical adjustability improves continence compared to a fixed male sling placed with proper tension and/or adequate fixation. Chung et al reported that more men chose adjustable over non-adjustable MS when given the options despite no significant difference observed in the clinical outcomes and similar patient satisfaction rate.

1.1. Argus sling (Promedon, Cordoba, Argentina)

1.1.1. Manufacturer and Commercial Data

The Argus male sling was first released by Promedon as a retropubic MS in 2004 before the TO version known as Argus-T was introduced several years later.

1.1.2. Device

The Argus suburethral sling consists of a silicone foam pad for compression of the bulbar urethra, two silicone columns of multiple conical elements and silicone washers that allow for regulation of the desired tension on the bulbar urethra (Figure 1 and 2).

1.1.3. Surgical Techniques

The original Argus sling arms are implanted in a retropubic approach while the newer Argus-T arms allow for a TO sling placement (Figure 3).

The Argus sling is usually tensioned to a recommended maximum intra-operative retrograde leak point pressure of 45 cmH_2O, and in the event of persistent or recurrent SUI, the sling can be tightened through a small non-invasive incision and the silicone washers can be readjusted over the silicone arms to provide further urethral compression (Figure 4).[436]

1.1.4. Clinical Outcomes

Romano et al reported that 31 out of 47 patients (66%) were dry at 3-year follow-up with 6 patients improved to 1 pad per day and 10 patients had failures (2 or more pads per day). Of the 10 patients who failed, nine had their sling removed; six because of erosion and three were related to infection.[437] In 2011, three other studies analysed short-term outcomes of the Argus male sling showed similar device explantation rates around 16% (37 of 225 patients across three studies), with the majority due to erosion (19 out of 37 devices) followed by infection (11 out of 37 devices). The continence rates varied considerably depending on the exact definition but 17–79% of patients were reported dry at follow-up and most of the complications were transient and minor (Clavien grade 1/2). A larger multicentre series published by Siracusano et al[439] found that the success rate decreased with worsening baseline incontinence from 95% in mild incontinence, 78% in moderate incontinence and 70% in severe incontinence, with up to a third of patients required at least one adjustment surgery. More recently, Cotugno showed that readjusting of the tension of the sleeve is not uncommon where 5 patients required a 3 months adjustment and 4 needed 2 adjustments to improve stress incontinence.

Longer-term data by Casteleijn reported that after 5 years of follow-up, 53.3% of patients were completely dry, 71.5% reported an improvement greater than 90% and 79.6% reports an improvement greater than 50%, while the patient's satisfaction rate remained high (70 ± 21 vs.16 ± 9, $P<0.001$) and similarly, the patient's quality of life (85 ± 20 vs. 88 ± 13, $P=0.1$).

A more recent comparative study between retropubic and transobturator Argus sling showed better continence rates (33.3% vs 11.8%, $P=0.114$) with superior functional outcomes and decreased explantation rates after Argus classic compared to Argus-T. Figure 5 shows cutaneous erosion of the Argus sling.

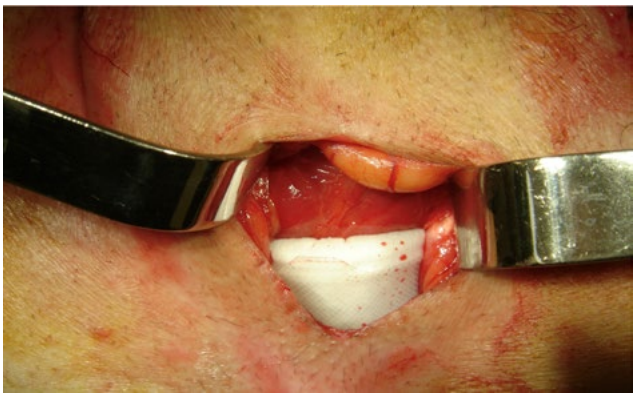

Figure 3. Argus silicone foam pad in place. Courtesy of Dr. Luís Gustavo Morato de Toledo

Figure 5. Cutaneous erosion of the Argus arm silicone tip. Courtesy of Dr. Luís Gustavo Morato de Toledo

Comparing inguinal-perineal incision to single-perineal incision for the Argus-T, Cornel et al showed greater infective complications in the inguinal approach compared to the single incision approach, and four patients required device explantation (three inguinal vs one single incision). Comparing Argus to Advance MS, Chung et al[435] found that 25 out of the 44 patients preferred adjustable Argus MS over the non-adjustable AdVance MS despite 6 out of 25 patients required revision surgery to tighten the Argus MS, and 23 out of 25 Argus patients were socially continent vs. 16 out of 19 with AdVance sling at 2 years postoperatively with similar improvements in quality-of-life domains. In a smaller study, Lima et al showed a slightly superior outcome for Argus-T compared to AdVance MS but this was at the expense of an increased rate of explantation of Argus-T in four patients (3 erosion, 1 pain) compared to none from the Advance group. In a different study, Lim et al demonstrated relatively high success rate (one safety pad or less per day) of 85% for Argus compared to 73% in the AUS group at 2-year follow-up. Salvage surgery with AUS following failed Argus sling appears to be relatively straight forward.[445]

A recent retrospective analysis from a large cohort study by Husch with the following patient distribution of 294 (62.6%) patients received a fixed MS (109 AdVance and 185 AdvanceXP) and 176 (37.4%) had an adjustable MS (127 Argus classic or Argus-T and 49 ATOMS), persistent or recurrent incontinence occurred in 17 (5.8%) patients with fixed and 16 (9.1%) patients with adjustable MS. While there were no differences in ICIQ-SF or PGI-I detected between adjustable and fixed slings, significantly more intraoperative complications occurred in adjustable slings (P<0.001, 0.3% vs. 10.2%).

1.2. Remeex Sling (Neomedic, Barcelona, Spain)

1.2.1. Manufacturer and Commercial Data

The Remeex sling which stands for Readjustable Mechanical External device was introduced by Neomedic around 2004 and is another adjustable MS inserted under the bulbar urethra.

1.2.2. Device

The Remeex system involves a 1.5 × 3 cm polypropylene suburethral sling connected to a mechanical regulator via traction threads (figure 6A and 6B).

The mechanical regulator is a subcutaneous permanent implant (known as varitensor) and allows for adjustment of suburethral pressure from outside the body using an external manipulator.[447]

1.2.3. Surgical Techniques

The Remeex sling is inserted via a retropubic approach and a transverse suprapubic incision, for the passage of a modified Stamey needle. The two monofilament traction threads are then drawn through the passage created with the needle until the polypropylene sling mesh is in full contact with the bulbocavernous muscle without pressure. The threads are attached to the varitensor device which is implanted subcutaneously over the abdominal rectum fascia 2 cm above the pubis. The morning after the surgery, the sling is tensioned appropriately with the external manipulator (Figure 7).[447]

1.2.4. Clinical Outcomes

There are only a few studies thathave reported clinical outcomes for this device. In a prospective multicenter Phase II trial of the Remeex adjustable sling, Sousa-Escandon et al[448] reported a continence rate of 64.7% with an additional 19.6% of patients reporting improvement over baseline, but 90% of patients requiring at least 2 adjustments. More recent but smaller studies have also shown

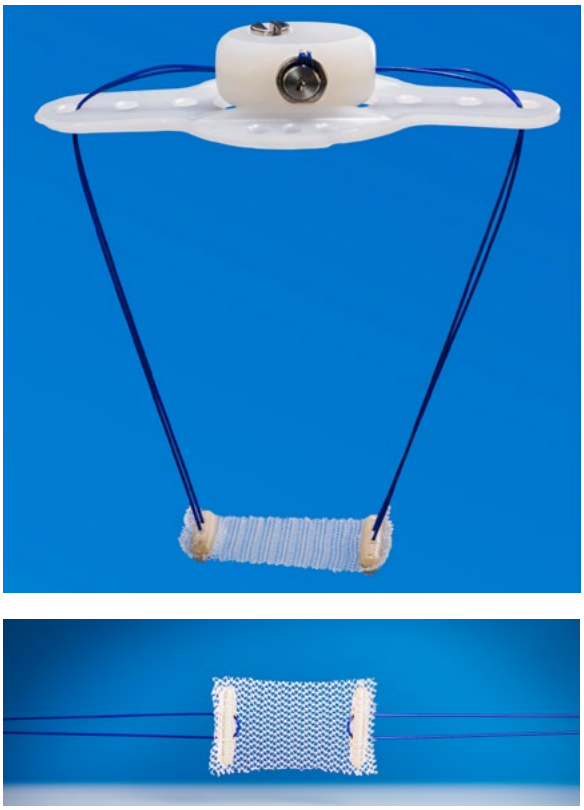

Figure 6A and 6B: Reemex system

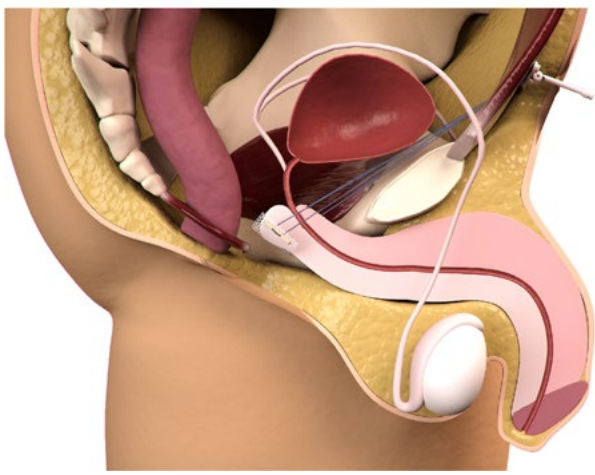

Figure 7. Illustration showing the Reemex system in place

similar outcomes.[447,448] Navalon Verdejo et al found that 3 of 5 men were dry but 4 of 5 patients experienced recurrent SUI, which was resolved after surgical re-adjustment via the varitensor, while Jimenez Parra et al reported 42% of the patients were dry and 33% reported improvement at an average of 18.6 months postoperatively. However, complications such as bladder perforation occurred intraoperatively in 29%, sling explantation was required in 21%, urinary retention occurred in 36%, and sling readjustment was necessary for 83% of patients.

1.3. AdVanceSsling (Boston Scientific Formerly American Medical Systems, MN, USA)

1.3.1. Manufacturer and Commercial Data

The AdVance MS is a non-adjustable male sling which was introduced by American Medical Systems around 2006. The AdVance XP is a second-generation TO sling released in 2010 and it incorporates several new features such as tensioning fibres, chevron anchors to limit sling slippage and altered trochars to aid placement in larger patients.

1.3.2. Device

This male sling is made of polypropylene material with 2 (outside-in) arms for TO surgical placement.

1.3.3. Surgical Techniques

The placement of the AdVance involves a midline perineal incision with dissection continued to expose the underlying bulbospongiosus muscle, which is then opened. The corpus spongiosum is mobilized from the perineal body by dividing the central tendon allowing anterior and cranial relocation of the bulb by around 2 to 3 cm when the sling is appropriately tensioned. The trochars are passed in an out-to-in fashion through the obturator foramen from a point, just below the adductor longus tendon to a point as high as possible in the triangle formed by the inferior pubic ramus and urethra. Following appropriate sling tensioning, the bulbar urethra is relocated proximally, by a distance of 2 to 3 cm, into the higher-pressure pelvic outlet, functioning as a "backstop" during straining Membranous urethral rather than bulbar urethral placement of the sling was introduced with the TO sling to relocate the urethra in a more proximal direction. This approach relies more on the rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than on direct compression of the urethral lumen. The sling arms can then be pulled back to the groin wounds; the central portion of the mesh is secured to the bulb, and the sling then tensioned before wound closure under direct cystoscopy examination. Figure 8 (A, B and C) demonstrate the Advance Male Sling mechanism of action, as proposed by Rehder et al.

1.3.4. Clinical Outcomes

The original publication on AdVance sling by Rehder and Gozzi in 2007 reported an increase in retrograde leak point pressures >60 cmH_20 following appropriate tensioning of the sling along with a mean 14mm increase in membranous urethral length based on cadaveric placement and a small clinical series of 20 men. Over the past few years, there have been several case series reporting greater than 2-year follow-up. Success rates are generally between 50 and 80%, with cure/dry rates averaging 50%.[450] While an early report from the Cleveland Clinic showed a diminished efficacy over time, with patient-determined success rate decreasing from 87.3% to 62.5% with the average daily pad use more than doubling over 2 years postoperatively,[451] others have shown reasonably sustained efficacy over time.

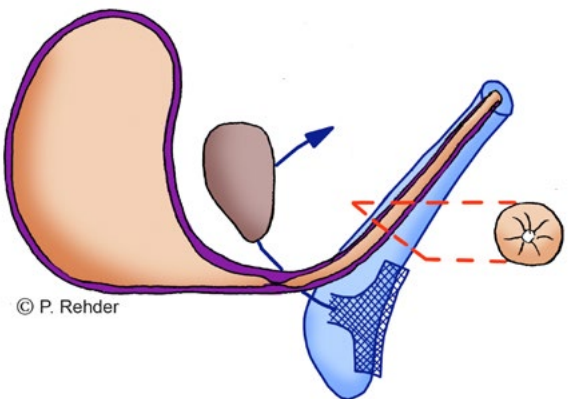

Figure 8B This figure demonstrates the relative position of the middle portion of the sling on the urethral bulb. Note the short distance of urethral sphincter closure. When scoped a half open sphincter is seen endoscopically. Courtesy of Dr. Peter Rehder

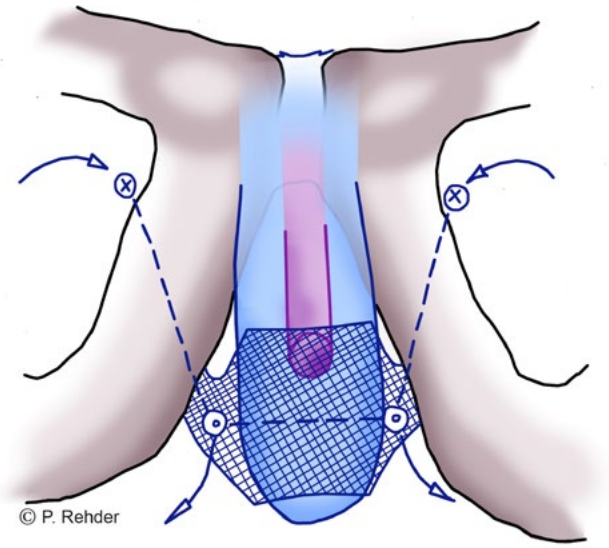

Figure 8A The arrows indicate the outside-in transobturator trocar placement. Note the retroluminal (subluminal) trocar exit site. When the sling is finally tensioned, the middle portion of the sling will double-fold in a position below the distal membranous urethra. There is no direct obstruction of the urethral lumen. Courtesy of Dr. Peter Rehder

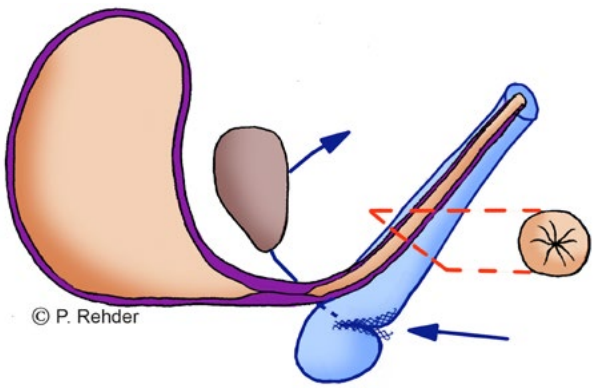

Figure 8C After tensioning of the sling, the middle portion double-folds, and in the process indenting the urethral bulb. This functional suspension, supports the distal aspect of the membranous (sphincteric) urethra. During physical activity this suburethral suspension enables better sphincter function and closure. The endoscopic view confirms better sphincter closure, and an increase in retrograde leak-point pressure. Courtesy of Dr. Peter Rehder

Over the past decade, the AdVance has become the most implanted male sling device with the largest body of literature supporting its use. In a multicentre European series, Rehder et al[456] reported results with 53.8% cure rate (dry) and 23.1% improved (using 1–2 pads with 50% reduction in pad use from baseline) at 12 months which was maintained at 3-year-follow-up with cure and improved rates of 53% and 23.8%, respectively. Using a similar definition of success (dry and 50% reduction in pad use), Zuckerman et al were not able to show similar durability of efficacy with success rates declining from 74% at 12 months to 63% at 2 years and 62% at final follow-up (mean 36 months). This finding was replicated by Li et al[455] where a progressive decrease in efficacy from the initial follow-up to 2 years with mean pad use rising from 0.8 to 1.7/day and the number of patients using two or fewer pads/day falling from 87 to 62.5%.

In another multi-centre study, Mascle et al reported 39.4% (of 66 patients) achieved continence, with an additional 40.5% improved at an average of 3 years follow-up study. Interestingly, success related strongly to the degree of preoperative leakage, with 94%, 74% and 56% achieving surgical success with mild (1 pad per day), moderate (2-3 pads per day) and severe (>3 pads per day) leakage. In another report, Serra et al found similar efficacy around 80% success rate depending on the degree of incontinence, with 86% success was achieved in those with < 100 g/d leakage, vs only 40% success in those with > 400 g/d leakage. Kowalik et al also showed a 60% cure rate and 13% improvement rate in 30 patients with median 39 months follow-up, with the finding that higher pad weight (in this report > 200 g/d) predicted surgical failure. The risk of poor durability of success with AdVance placement has been reported as particularly high in those patients with a history of radiotherapy or storage dysfunction on urodynamics with a recent series reporting a return to baseline levels of incontinence at 3 years of follow-up.[81]

Published data from the MASTER trial[6] with randomisation of 134/154 (87.0%) for male sling versus 133/158 (84.3%) for AUS showing non-inferiority (difference 3.6% [95% CI -11.6 to 4.6, PNI=0.003]), with incontinence symptoms (ICIQ-UI SF) reduced from scores of 16.1 and 16.4 at baseline to 8.7 and 7.5 for male sling and AUS, respectively (mean difference 1.4 [95% CI 0.2-2.6], *P*=0.02). Furthermore, all secondary and post-hoc analyses were in favour of artificial urinary sphincter versus TO male sling.

With the newer AdVance XP device, Bauer et al reported 66% of patients cured (no pads) and 23.4% improved at 36 months study period. Direct comparison of mid-term results between AdVance and AdVance XP has been reported by three authors[,] showed no significant differences in outcomes were seen although, in one study.[464] There was a higher rate of urinary retention observed with AdVance XP. Marzi reported that even after external beam radiation therapy, Advance XP male sling can be effective with 12 patients (21.4%) using 1 safety pad and 15 (26.8%) wearing no pad, without a significant increase in failures and complications when compared to those without previous radiation therapy. A recent long-term report on Advance XP by Mumm found that at 60-month follow up in 59 patients, there were 57.6% cured and 25.4% improved continence rate.

Reported adverse events are generally mild with transient urinary retention and groin pain being the most frequently encountered. The need for explantation is exceedingly low. In patients with a failed AdVance sling, the implantation of a second AdVance sling has demonstrated relatively good and safe outcomes with more than a third of patient requiring no pad and only 10% (3 of 29 patients) considered as treatment failures. Failure of AdVance sling can also be salvaged with AUS or prostate adjustable continence therapy.[43] However, patients with a failed primary sling who underwent a secondary sling procedure were up to 6 times more likely to have persistent incontinence compared to those who underwent salvage AUS placement. Similarly, men who suffer from recurrent UI secondary to cuff compression atrophy can be made continent by the placement of an MS without an AUS revision surgery. The advantages of using AdVance to salvage recurrent SUI in AUS patients include a lower risk of postoperative infection due to non-violation of AUS pseudo-capsule and avoiding the need to rely upon the use of the AUS to maintain continence.

1.4. Virtue Sling (Coloplast, Humlebaek, Denmark)

1.4.1. Manufacturer and Commercial Data

The Virtue quadratic “adjustable” sling manufactured by Coloplast was introduced in 2009.

1.4.2. Device

This quadratic ventral elevation urethral sling consists of monofilament polypropylene mesh that measures 5.5 cm x 7 cm with four mesh arms, 2 (inside-out) TO arms and 2 (outside-in) prepubic arm. This sling was designed to provide both urethral relocation and prepubic compression.

1.4.3. Surgical Techniques

The surgical technique is similar to other TO sling surgeries. With the patient in lithotomy position a vertical perineal incision is made, dissection then proceeds to the bulbospongiousus which is retracted superiorly to allow division of the perineal body attachments and permit mobilisation. Then, the J-hook passer is used to pass through the TO space, and the TO sling arms are passed through the TO space with an inside-out technique. This is repeated on the opposite side. Next, requires the prepubic sling arms to be passed, so two small suprapubic stab incisions are made, two fingerbreadths lateral to the midline. Then, the J-hook passer is moved through the prepubic space to the perineal surgical area just lateral of the urethra. The sling is then attached and pulled through the prepubic space with the J-hook and repeated on the opposite side. The sling is then tensioned via the TO arms, then prepubic arms by using the retrograde leak point pressure, with a target pressure of 60 cmH_2O.

Figure 9 (A, B and C) illustrates the surgical steps for implantation of the Virtue Male Sling.

Following a lower than anticipated success rate, the surgical technique on Virtue sling placement was updated in the early 2010s with proposed tensioning of the TO arm laterally to elevate the bulbous urethra and the prepubic arms superiorly similarly to compress the bulbous urethra. Additional fixation sutures are placed onto the prepubic mesh arms to the underlying pubic bone to provide further distal urethral compression, similar to InVance sling mechanism of action.[472] The retrograde leak point pressure system is completed intraoperatively at 60 cm water pressure closure to visualise compression of the urethra as the prepubic arms are tensioned and fixated with a nonabsorbable suture.[470] The TO sling arms can be re-routed back into the perineal wound to be fixed to their opposite side to secure the mesh in place.

1.4.4. Clinical Outcomes

Comiter published the first Virtue MS study in 2012[470] followed by a larger multicentre trial in 2014[473] which compares the original sling fixation as described above and the modified technique where the prepubic and TO sling arms were fixed to their opposite side. Around 42% of the original fixation group achieved either objective

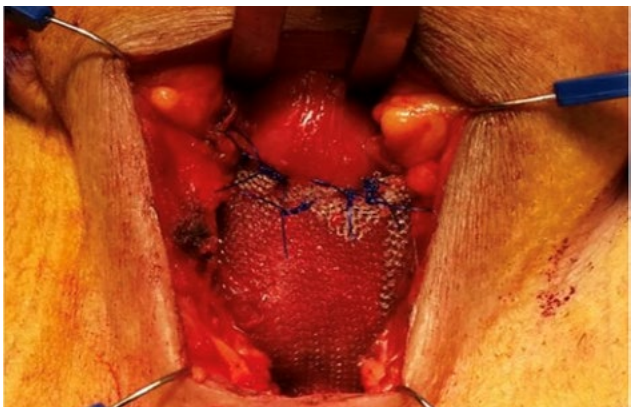

Figure 9 (A, B and C). Virtue Male sling – surgical technique

or subjective success (defined has reduction > 50% pad weight or "much" or "very much" better on the Patient Global Impression of Improvement respectively) compared to 70.9% subjective and 79.2% objective success rates in the group undergoing the additional fixation steps. Neither group developed any complications greater than Clavien grade 1 in the 12-month follow-up period.[473] Smaller studies with longer-term clinical outcomes[456,457] showed similar continence rate between 30 to 40% with relatively high failure rates requiring subsequent continence surgery. Cystoscopy-guided sling tensioning gave significantly worse continence outcome compared to sling tensioning based on retrograde leak point testing (39% vs 70%). Prior radiation therapy was strongly related to treatment failure while patient age and severity of incontinence were not significant factors. This was confirmed in a retrospective study by Abdullah et al with clinical success at 83% in 35 men. A history of radiotherapy, low bladder compliance, and severe incontinence were associated with negative result. More recently, Ferro reported significant improvement in 24-hour pad test (128.6 vs. 2.5g), number of pads per day (2 vs. 0) and ICIQ-SF score (14.3 vs. 0.9) and outcomes remained stable at 36 months, in 29 patients, most of whom had mild to moderate incontinence.

In terms of revision or salvage surgery, imbricating non-absorbable sutures can be placed into the dense fibrous mesh and tied down onto the bulbospongiosus muscle, with further tensioning based on retrograde leak point pressure of 60 cm water pressure.[472] The potential adverse events include wound infection, perineal pain and urinary retention. At the time of this review, there is no reported pubic bone osteitis in the literature.

1.5. I-STOP TOMS sling (CL Medical, France)

1.5.1. Manufacturer and Commercial Data

The I-STOP TOMS sling was developed by CL Medical in 2009.

1.5.2. Device

The I-STOP TOMS is a monofilament polypropylene 4-arms sling (2 arms on each side) measuring 4.5 cm × 1.4 cm, with a 2.8-cm central part placed over the urethra. This device was developed from the female I-STOP TO sling. Grise et al described it initially as a two-arm sling, but subsequently, the larger four-arm was released. It was proposed that the larger surface area, in addition to the fact that the sling was designed to be placed more distally, over the bulbar and post-bulbar urethra, which has bulbospongiosus coverage, would reduce the risk of erosion.[478]

1.5.3. Surgical Techniques

It is placed via a TO approach in the lithotomy position with a vertical perineal incision.[478] The perineal aponeurosis and superficial fascia are then incised, no muscle dissection is undertaken and the central tendon is not divided. The sling allows for either an outside-in or inside-out approach with the helical needle used along with blunt dissection to guide the passage through the TO space for the passage of the two arms on each side. Once in position, the sling is tensioned symmetrically after being sutured to the bulbospongiosus muscle.[479]

1.5.4. Clinical Outcomes

An early publication by Grise et al[478] based on ISTOP-TOMS (2 arms) reported that 30% of patients were dry with 32% using one pad per day with the global improvement of quality-of-life scores at 12 months follow-up.[479] In a later study, Grise et al[479] showed that patients after the ISTOP TOMS (4 arms) have higher continence outcomes with 59% dry and 20% using one pad per day at 12-month follow-up. Similar outcomes were also reported in other studies. A longer-term follow-up study by Ej-Jennane et al showed lower dry rates of 47% and 17% on total continence and one pad per day use respectively, with no report of any significant complications. Similarly, Malval et al demonstrated 40% dry rate with 77% of patients using one pad or less per day at 1 year; these figures decreased to 15% and 22% respectively at 5 years post-insertion. Furthermore, 18 patients required further surgical procedures for recurrence of incontinence, with the majority opting for AUS (12 out of 18 patients). Apart from device failure, the only other reported complication was persistent pain in one patient that lasted for more than 2 years.

1.6. ATOMS Sling (A.M.I. GmbH, Feldkirch, Austria)

1.6.1. Manufacturer and Commercial Data

The adjustable TO male system (ATOMS) sling was developed and marketed by Agency for Medical Innovations, an Austrian company that manufactures medical technology, in 2010.

1.6.2. Device

The ATOMS system is composed of a TO-placed mesh tape with an adjustable soft inflatable silicone cushion, connected to a refillable port. Adjustments are made via inflation of the silicone cushion rather than by manipulation of the sling arms. Three models have been released with different port arrangements. The original design utilised an inguinal port and the current design utilizes a scrotal port.

1.6.3. Surgical Techniques

The surgical technique involves a single perineal incision. The tunneller is placed outside in. The ATOMS device is secured in place by two mesh arms of polypropylene, which are drawn on either side through the obturator foramina and then back to the central cushion component of the implant (figure 10).

The arms are then attached to the cushion, creating a firm, 4 points fixation point. The implant is connected by a silicone tube to a silicone covered titanium port, which is placed in the scrotum; this allows for adjustment of the system's pressure postoperatively by altering the filling volume of the cushion. The suburethral substitute sphincter cushion is left in deflated state postoperative and normal saline can be injected into the port to inflate the cushion appropriately, often initially at 4 to 6 weeks post-implantation and adjusted every 6 weeks until the pressure is optimal.[484]

This is an adjustable sling that has similar components and aims to replicate a similar principle to that of the AUS, but with two major differences. It does not create a circular compression of the urethra, and secondly, it is designed for postoperative adjustment. Similar to the AUS, it is implanted in the region of the bulbar urethra, however, the bulbospongiosus is left intact as an additional protective layer between the implant and the urethra. Figure 11 shows a cross-sectional image of Atoms sling.

1.6.4. Clinical Outcomes

In one of the early studies, Seweryn et al reported that 60.5% of patients were using one pad or less per day following ATOMS insertion. Hoda et al[484] showed that 63% of their 99 patients were dry at 18-month follow-up with an additional 29% of patients reporting improvement in continence. The mean adjustments per patient were 3.8 and 4 patients had device removal due to inguinal port infection.[484] Krause et al reported a lower success rate with 38.9% achieved "social continence" and 11 (30.6%) patients underwent device removal, the majority due to infection. More recent publications with longer-term outcomes[,] have confirmed similar findings. In one of the largest studies to date, Muhlstadt et al[487] found an overall 50% of men were dry, and 32% reported improvement in continence by at least 50% with an average device adjustment rate of 3.4 ± 2.1 per person at follow-up of more than 3 years. Interestingly, similar continence and quality of life outcomes were reported but there were significantly higher complications requiring explantation in the inguinal port group compared to the scrotal port option with late infection or erosion occurred in 30 out of 37 cases (24 out of 30 from the inguinal port group alone). The pre-connected scrotal port had the lowest complication rate overall. While Friedl et al showed similar continence rates with 64% of men being dry and 26% improved, there was a 20% (56 devices) explantation rate. The majority of the removals were described as being due to titanium intolerance (41%, 23 patients), device leakage (21%, 12 devices) at the port or cushion, and infection (21%; 6 early and 6 late device infection), with device failure, reported in 8 devices.

More recently, a systematic review and meta-analysis comparing ATOMS and Pro-ACT device[7] reported a higher continence (68 vs. 55%, *P*=0.01) and improvement (91 vs. 80%, *P*=0.007) rates for ATOMS than ProACT device based on a combined data from 41 observation studies. Furthermore, the satisfaction rate was higher for ATOMS (87 vs. 56%, *P*=0.002) and explantation rate was higher for ProACT (5 vs. 24%, *P*<0.0001); although, significant heterogeneity was evidenced due to variable factors such as incontinence severity baseline, difficulties in common reporting of complications, different number of adjustments and time of follow-up and the absence of proper randomised studies.

1.7. Predictors of MS Success

The literature evaluating the efficacy of MS in patients with mild to moderate SUI is marked by heterogeneous study population, variable definitions of incontinence prior to treatment and characterizations of "cure" or "improvement" following treatment, inconsistent use of validated and non-validated outcome measures and relatively short follow-up study, as well as lack of direct comparisons among devices, making it difficult to accurately evaluate currently available MS devices. Nonetheless, in a carefully selected group of men who received MS for mild to moderate post-prostatectomy SUI following failed conservative measures, published literature shows that a majority of patients achieved cure or at least 50% improvement in social continence (as defined as at least a 50% improvement in pad weight or pad use).

There is an increasing volume of evidence in the literature pertaining to patient factors that predispose to sling surgery failure. The presence of prior urethral stricture, pelvic radiation, or prior incontinence surgery can compromise sling efficacy. These factors are associated with poorer MS outcome, probably due to urethral fibrosis, inadequate urethral coaptation and lack of proximal bulbar urethral relocation.[435,495] The presence of a more complex prior history and neurological disease can result in poorer clinical outcomes. Critical success factors for MS are good mobility of the urinary sphincter region and a good residual sphincter function.[45,429] Radiotherapy, PUBA, prior TURP, failed stem cell therapy, previous AUS placement and urethral fibrosis are all compromising factors.[429,494]

Urodynamic predictors of surgical failure include the presence of a short functional urethral length, a low maximal urethral closure pressure and abdominal leak point pressure,[61] and a negative repositioning test.[70] Preoperative incontinence severity as measured by the degree of leakage also appears to adversely influence sling outcomes. Several studies support a strong correlation between those with more severe preoperative incontinence and poorer continence outcomes.[58]

In terms of MS composition, the use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material. Furthermore, failure to adhere to strict surgical principles such as poor suture fixation of the TO sling and failure to adequately tunnel TO sling arms could contribute to an inferior outcome.[473] Similarly, for the quadratic sling, improper fixation of the arms can result in a substantially lower success rate compared to sling with properly fixated prepubic and TO sling components.[473]

1.8. Conclusion

In men with mild to moderate degrees of SUI, or for patients demanding a less invasive procedure or non-mechanical device, the MS has established itself as an effective viable alternative to the AUS. When given a choice of surgery, patients have been reported to overwhelmingly choose the MS over an AUS.[59] Although high-level comparative evidence is lacking, it is generally accepted that MS shows good efficacy in mild to moderate incontinence that may be comparable to an AUS but MS represents a less favourable alternative to AUS placement in men with severe incontinence, previous radiotherapy or urethral stricture surgery. The MASTER trial is a UK multi-center randomized, non-inferiority trial comparing male sling surgery to AUS in men with any degree of SUI who are suitable for surgery may provide higher-level evidence relating to the comparative effectiveness of MS surgery. Published data showed that both surgical options result in fewer symptoms and high satisfaction, despite most men not being completely dry.[6] Secondary outcomes measures were in favour of AUS in terms of operative and postoperative details, patient-reported measures and adverse events.[6]

In the intermediate-term, the MS appears to be a reasonable option. At present, there is no conclusive evidence to suggest that one type of male sling is better than another, and there is no evidence that adjustability of the male sling offers an additional benefit over other types of sling.[435] We recommend that going forward a standard set of outcomes measures be decided upon and utilized so that future studies can be more readily compared. While the ideal MS is probably yet to be developed, continued scientific advances in slings design, mesh technology and more refined surgical techniques will improve continence rate and deliver better safety records. As clinical data mature from each of the sling designs, adequate preoperative counselling and the ability to select the optimal MS for a particular patient will hopefully improve. Strict patient selection and counselling, selection of MS with proven clinical records, and safe surgical practice are paramount to ensure high continence rate, good patient satisfaction and low postoperative complications.

(Level of evidence 3; Grade of recommendation B).

2. THE ARTIFICIAL URINARY SPHINCTER (AUS)

The first description of an AUS dates back to 1947. The modern AUS was designed by F.B. Scott, W.E. Bradley and G.W. Timm in 1974. Their original model has undergone numerous modifications, ultimately resulting in the current AMS 800 (Boston Scientific, Marlborough, MA) released in 1983 (See Figures 12 and 13).

For more than three decades, the AUS was the most popular surgical treatment for post RP incontinence due to intrinsic sphincter insufficiency, with more than 200,000 devices implanted worldwide, only recently surpassed in popularity by the male sling. The current model consists of three components: a narrow backed urethral cuff, a pressure regulating balloon (PRB), and a scrotal pump. The three components must be connected through their tubing with the help of connectors. The components are prepared free of any air bubbles and connected tightly. Since 2009, the only major change to the AUS has been the addition of a 3.5 cm cuff option.

The PRB is filled with 22-23 mL of saline or contrast and transmits pressure to the occlusive cuff. It is available in six pressure ranges from 41 to 100 cmH_2O. The most commonly used pressure is 61-70 cmH_2O. The goal of this pressure regulation is to occlude the urethra by increasing the resting urethral pressure.

The control unit or pump consists of two parts. The lower part is a bulb which transfers the fluid out of the urethral cuff to the PRB to allow micturition. The upper part contains the resistor valves and deactivation button which allows the cuff to be placed into a locked open position.

2.1. Indications

The AUS remains the most reliably effective surgical treatment for all degrees of stress urinary incontinence due to sphincter insufficiency in men resulting from various etiologies, which may include prostate cancer surgery, surgery for benign enlargement of prostate, pelvic XRT, neurological disease, trauma or congenital anomalies. Prior to 1985, a significant proportion (17–50%) of AUS devices were placed for neurological disease. However, since 1985, with increasing number of radical prostatectomies, post-prostatectomy

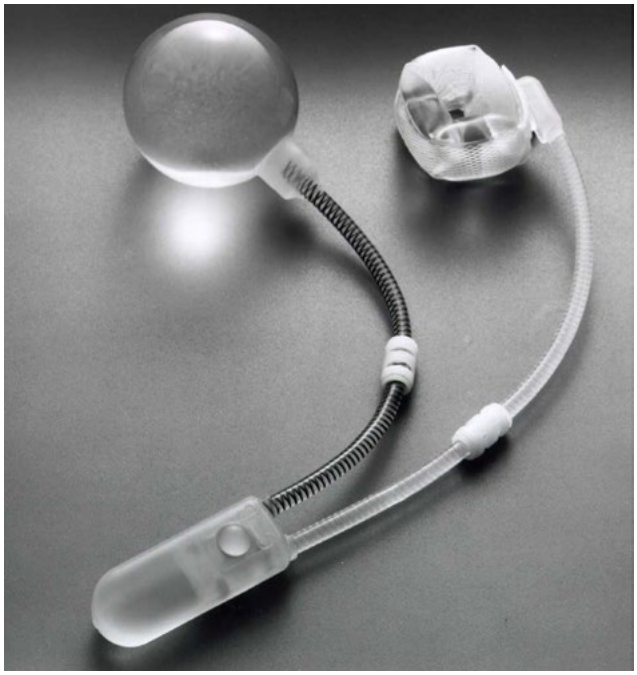

Figure 12. AMS 800. The urethral cuff is available in various sizes ranging from 3.5 to 11 cm. The narrow- backed cuff was introduced in 1987 [504,505] to improve transmission of cuff pressure to underlying tissue and to decrease the incidence of cuff erosion.[506] The cuff was later coated with InhibiZone (rifampicin and minocycline coating) in 2008 aiming to reduce the infection rates. However, a decrease in infection rates with the InhibiZone coating has not been demonstrated. [507, 508, 509]

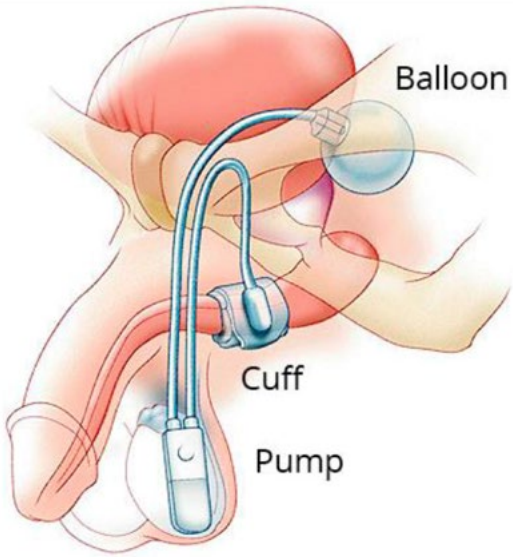

Figure 13. Artificial urethral sphincter

incontinence (PPI) has been the most common indication, representing 39%-69% of AUS placed through 2005.[513,] Indications for spinal cord disease are more common in the pediatric population with myelodysplasia.

In the era of robotic-assisted radical prostatectomy, the 12-month incidence of urinary incontinence rate varies between 4% and 31%. However, only a portion of these patients (4–6%) will have enough bother to pursue AUS placement.[,] Currently, approximately 11500 AUS are placed annually worldwide. In 2005, only 13% of US urologists performed AUS surgery, with only 4% considered high volume surgeons performing at least 20 AUS implantations per year.[513] Traditionally, active conservative management with pelvic floor muscle exercises for at least 12 months following prostate cancer treatment has been suggested in men with bothersome SUI. However, per the new American Urologic Association guidelines, patients with severe symptoms that have not improved with conservative treatment can be offered an AUS as early as six months postoperatively.[16]

The recent development and widespread adaptation of alternative surgical approaches such as the various male slings (described elsewhere) have given patients alternative surgical options. Ultimately, choice of AUS will be based upon patient dexterity, patient preference, severity of incontinence, previous incontinence surgery, history of pelvic radiation and expectations from surgery. Kumar et al[59] reported that most patients chose a male sling over an AUS and when advised to undergo a specific continence surgery, when given a choice 92% chose a sling.

2.2. Contraindications

The ability of the patient to understand and manipulate the device is of paramount importance. Patients who are unable to comprehend or lack sufficient dexterity to manipulate the scrotal pump should not be offered implantion of an AUS. Advanced age is not a contraindication to AUS placement. A recent analysis by Ziegelmann et al demonstrated that while patients over 80 years of age were more likely to experience device erosion or infection compared to men under 60, overall device failure rates were noted to be acceptably low in properly selected octogenarians. Patients with poor bladder compliance, low bladder capacity or high grade vesicoureteral reflux may be at increased risk for upper tract deterioration after AUS placement as the device increases bladder outlet resistance that would otherwise be low and protect the upper tracts.[16,82] While not necessarily a contraindication to or predictive of adverse outcomes after AUS implant,[86,88] it has been recommended that patients receive appropriate treatment for their detrusor storage pressures prior to AUS implant and be followed closely postoperatively[16,82]

2.3. Preoperative Evaluation

The evaluation should start with a detailed history and physical examination, with attention paid to duration and severity of incontinence, detailing stress versus urge symptoms, any previous surgical or non-surgical treatments, history of pelvic radiation, change/improvement in continence over time, ability to interrupt urinary stream, other associated urological disease including bladder neck or anastomotic stricture, urothelial malignancy and urinary stone disease. All patients should have urinalysis to rule out urinary tract infection, measurement of post void residual urine volume to assess for incomplete bladder emptying, and cystoscopy (or other urinary contrast studies, such as video-urodynamics) to rule out anastamotic disease (Figure 14). Further testing with multichannel urodynamic studies may be indicated in patients with suspicion of altered compliance (history of radiation, underlying neurological disease or severe voiding dysfunction)[18] or to rule out low volume detrusor overactivity in patients with mixed incontinence.

2.4. Surgical Technique

Preoperative prophylactic intravenous broad-spectrum antibiotics covering both gram negative and gram positive organisms should be administered preferably 60 minutes before skin incision. For a perineal approach, the patient is positioned in dorsal lithotomy position for bulbar urethral cuff placement. In transcrotal AUS placement, the patient is placed in frog-leg position. While traditional dictum required a five to ten-minutes surgical scrub with chlorhexidine or povidone-iodine, contemporary literature showed the use of alcohol-containing chlorhexidine or povidone-iodine preparation is effective and avoids the need for preoperative surgical scrub.

Figure 14: Videourodynamics showing an open bladder neck in a male patient that underwent radical prostatectomy (RP) and and external beam radiation therapy (EBRT)

However, another study showed that chlorhexidine scrub is more effective and is associated with lower device infection rate than a povidone-iodine preparation. The anus is isolated by covering with a sterile drape or towel to prevent any fecal contamination during surgery. A "no-touch" technique using Loban™ may be considered for draping the area. A size 14 or 16 Fr Foley catheter is inserted in the bladder to facilitate urethral palpation during urethral dissection.

The recommended initial approach for a single cuff initial device placement is via midline perineal incision (Figure 15).[18]

A lone star retractor with skin hooks is helpful for adequate exposure. The bulbo-spongiosus muscle is exposed and divided sharply or with electrocautery. The proximal bulbar urethra is dissected circumferentially off the overlying corporal bodies and a 2cm window is created on the dorsal aspect of the urethra. This should accommodate the measuring tape, which is used to measure urethral circumference, and an appropriately sized cuff is selected; the urethral catheter may or may not be left *in situ* for this measurement.

Bladder neck cuff placement is not required in patients with incontinence after prostate surgery or radiation. This surgical approach is reserved in salvage female stress incontinence cases or those with neurogenic bladders.

The pressure regulating balloon reservoir (PRB) is typically placed in the space of Retzius either in the midline or to one side, via a second incision. However, a high sub-muscular location (under the rectus) has been espoused as it avoids the scarring in the space of Retzius and/or inguinal regions related to prior surgery (RRP, inguinal hernia repair) while yielding comparable functional outcomes in comparison to traditional placement within the space of Retzius. The PRB is filled with 22-23mL of fluid, some of which will fill the cuff once connected. The fluid can be isotonic saline or a contrast mixture, the latter having the advantage of being radio-opaque and thus easily identified on plain x-ray, while the former can still be imaged via ultrasound.[67]

The pump is placed in the anterior scrotum on the side of the patient's dominant hand in an effort to avoid difficulty with pump manipulation. This is achieved by passing a long Kelly clamp subcutaneously from the abdominal wound and transferring the pump into scrotum. The cuff tubing is transferred into the abdominal wound with a needle passer in the reverse direction. The quick connector system is recommended to complete connections between the three components. At the end of the procedure, the device is left deactivated for a period of four to six weeks to allow for any scrotal swelling to decrease and minimize the risk of cuff erosion that can occur with immediate activation.

Another surgical approach has been described using an upper transverse scrotal incision for placement all of 3 components through the same incision. It also allows simultaneous placement of a penile prosthesis through the same incision. While this approach has the benefit of fewer incisions, a few reports have revealed that surgical outcomes are less favorable compared with the perineal approach. The perineal approach allows more proximal cuff placement than does the transcrotal approach, which permits the cuff to be placed on the area of the urethra with a thicker spongiosum. A multicenter retrospective study by Henry et al in 158 patients reported that patients undergoing perineal approach had higher completely dry rates as compared to trans-scrotal approach (44% vs 28%, $P<0.03$) and had much higher rates of social continence. The cuff sizes were also typically larger in the perineally placed AUS patients. Thus, the perineal approach appears to control stress incontinence better than trans-scrotal approach, and is therefore the recommended technique for initial AUS placement when penile prosthesis is not concomitantly planned.

2.5. Outcomes

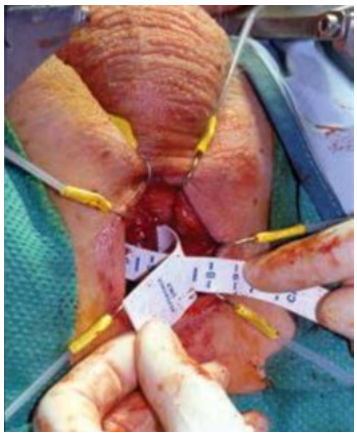
The AUS has the longest track record of success for the surgical treatment of PPI and appears to be efficacious regardless of the degree of leakage. There are more than 400 articles that have been published reporting outcomes of the AUS. As most are retrospective small series, it remains difficult to compare outcomes among reports. This is due to the fact that, in the literature, there are many different methods for reporting the degree of incontinence and numerous criteria to define success. Despite variation in definition and length of follow up, the current literature consistently demonstrates high long-term success rates and patient satisfaction for primary AUS implantation[37,88,...]

The success rates for AUS as defined by social continence of 0-1 pad ranges from 59% to 90%.[88,528,529] While actual pad free rates are somewhat low (10% to 72%), there are, nevertheless high satisfaction rates (87% to 90%).

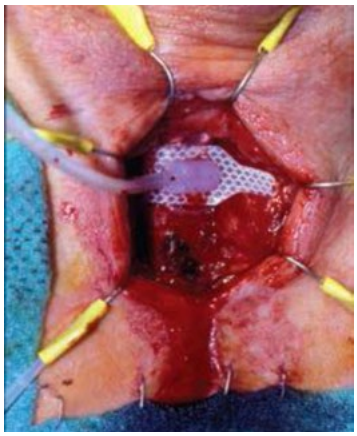
In a systematic review of 623 patients from 12 series, social continence (0-1 pad) was reported at 79% (range 61–100%) with follow-up ranging from 6 months to 192 months. The dry rates varied widely between 4% and 86%. In this pooled analysis, overall, re-intervention rates were 26% (range 14.8–44.8%), with 5-year device survival ranging from 59% to 79%.[37,88,528,529,530,531,533]

FIGURE 15. Artificial sphincter technique

A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to expose the bulbar urethra.



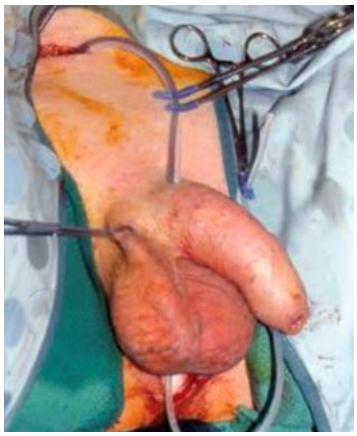
B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size.



C. The belt-like cuff is positioned around the urethra.

D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir.

E.



F.

G.

H. Connectors are placed to join the tubes from the cuff and reservoir to the corresponding tubes from the pump in the RLQ incision.

A number of studies reported 10-year device survival rates ranging from 28% to 64%.[527,529,,] In Webster et al's report of 554 implantations over a 10-year period, 21.4% required at least one revision surgery, while 78.6% did not. Of the119 patients who required re-operation, 76.5% required no further treatment, while 23.5% required another re-operation for either mechanical or non-mechanical failure.[536] Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence rates were comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day.

In a retrospective series reported by Singla, in 79 patients with 10-year follow-up, 62% required no revision while 12% required one revision and another 12% underwent 2 revisions.

Data regarding outcomes beyond 10 years is sparse. In a few series, 15-year device survival rate was 15% and 41%.[527,534] Leon et al[527] reported on 57 patients who underwent AUS with median follow up of 15 years, AUS survival rates without revision were 59%, 28%, 15%, and 5% at 5, 10, 15 and 20 years respectively. No patient was lost to follow up in this series. In another large series of 1082 patients who underwent primary AUS implantation at the Mayo Clinic, the 5-, 10-, and 15-year device survival rates were 74%, 57% and 41%.[534] High patient satisfaction (94%) was also reported.[534,]

It is important to note that patients undergoing AUS should be properly counseled regarding outcome and provided with realistic goals. Patient expectation is not the same as Surgeon expectation and are not equivalent to surgical outcomes. They should be advised to expect to wear a thin social pad as 100% dryness may not be guaranteed.

2.6. Complications and Troubleshooting

Despite excellent continence outcomes and high patient satisfaction reported in the literature, AUS implantation is nevertheless associated with potential risks. The complication rates are generally low; however, the need for revision remains high. As experience with AUS has grown and the total number of cases performed at high volume centers (>20 cases in a year) has increased, the overall revision rate has decreased.[513] What follows are general recommendations for managing some of these complications as there are no detailed descriptions available in the literature dealing exclusively with their management.

The complications may be divided into early versus late.

2.6.1. Early complications

Early complications in post-operative period include: urinary retention, scrotal hematoma, hematuria, inability to activate the device, device infection and urethral erosion.

The most common immediate post-operative complication is urinary retention: This may occur in up to 31% of cases as reported by Linder et al, and is generally due to urethral edema, improper cuff sizing, urethral erosion or inadvertent device activation. It is usually transient in nature and resolving without surgical intervention and may be more common with a 3.5 cm cuff and/or transcorporal cuff placement. With early postop retention, one needs to make sure the AUS pump is in fact in the open deactivated state. When in doubt, the device should be deactivated again and no fluid should be left in the pump. If retention persists, the patient may be instructed on self catheterization or have a catheter left indwelling for 48-72 hours. Generally, a small size catheter should be used (12 Fr or less). If retention persists, then suprapubic tube diversion should be considered. In patients with ongoing retention despite suprapubic catheter drainage, office cystoscopy should be performed. Persistent retention usually results from an error in cuff sizing (cuff too small) or a urethral erosion. In these situations, patients should undergo immediate surgical exploration. Prolonged urinary retention has been reported to be associated with adverse overall device survival and significantly high rates of infection/erosion.[539]

Scrotal hematoma can be managed conservatively with rest, ice packs, scrotal support and prophylactic oral antibiotics. Patients should be observed for signs of infection. The presence of scrotal and perineal wound swelling along with cellulitis should alert the surgeon to the possibility of infection or urethral erosion leading to urinary extravasation. This may be secondary to unrecognized intra-operative urethral injury or error in cuff sizing. A tight urethral cuff may cause urethral wall ischemia. Urethral erosions occurring early in post-operative period (within first 2-3 months), are likely due to an unrecognized urethral injury.

2.6.1.1. Unable to Activate AUS

After an initial period of postoperative deactivation, one may occasionally be unable to activate the AUS. If this occurs, first try compressing the deactivation button and/or entire surface of the pump forcibly for a longer period of time. If unsuccessful, squeezing the narrow sides of the upper portion of the pump should be tried. If again unsuccessful, press hard with a Q-tip on the back side of upper portion of the pump. In refractory cases, patients should undergo open exploration to assess for fluid loss or for air lock.

2.6.2. Late Complications

2.6.2.1. Urethral Erosion

Late erosions present at a median time of 19.8 months at a rate of 5–10%.[528] Late erosions may be related to constant cuff compression that may cause tissue atrophy/ischemia and eventual erosion. The incidence of erosion and/or infection varies widely between 0% to 24.6%.[529,,,,,,,,,] Most recent large series report an incidence less than 8%.[73,528,533,535,,,,,] In a retrospective series reported by Singla,[537] erosion/infection occurred in 8.9% at a mean duration of 1.9 ± 1.1 months (range 0–3 months) after implantation. Lai et al reported that patients undergoing a "secondary" implant, following a prior explant for erosion or infection had a four-fold higher rate of erosion as compared to "primary or virgin" cases.[545] Other risk factors for erosion include urethral catheterization or blind manipulation with an activated sphincter. It is of paramount importance to educate patients to inform healthcare providers regarding the presence of an implant and the need for deactivation prior to any urethral manipulation.

Erosion is suspected in patients with a history of new onset incontinence, hematuria or retention. It is confirmed by office cystoscopy demonstrating exposed cuff material within the urethral lumen (Figure 16).

If confirmed the entire device should be removed. In some cases of sterile asymptomatic erosion, only the cuff may be removed while the tubing is plugged with an available steel button. A new cuff is replaced at a later date and connected to existing tubing with a connector. A urethral catheter is left in place for a few weeks to allow healing. A retrograde urethrogram may be performed to rule out extravasation before removing the catheter. A period of three months wait is recommended before re-implantation of a new AUS particularly if erosion is associated with infection. There are no clear guidelines regarding removal of entire device versus only the cuff in sterile late erosions. However, a recent AUS consensus panel

noted that the decision to remove the cuff alone or the entire device mainly depends on time since original AUS implantation.[16] Erosions occurring many years after surgery may require removal of the entire device, as a new balloon reservoir and scrotal pump are generally recommended if they are more than two years old.

The necessity of surgical repair of the urethra (urethroplasty) versus allowing the erosion to heal spontaneously over a catheter is debatable and left to the discretion of the surgeon at the time of explantation. A recent study in 26 patients by Rozanski et al found that the incidence of urethral stricture formation was significantly lower when patients underwent an in-situ urethroplasty with re-approximation of urethral edges (38%), compared to patients treated with Foley catheter alone (85%) with a mean follow-up of 24 months (range 8–69). This facilitates healing and expedites time to re-implantation. Urethral repair in these patients added an additional 8 minutes to the total operating time. Those patients treated with in situ urethroplasty had a much higher rate of undergoing secondary AUS implantation (54% vs 15%) compared to those with cuff erosion treated with Foley catheter only. In another retrospective study by Chertack et al, 75 patients with AUS erosion were treated with either Foley placement or urethroplasty. With a mean follow-up of 13 months, they concluded that Foley catheter drainage alone may be suboptimal management for a large erosion. There was no difference in probability of re-implantation between primary urethral anastomosis, catheter-only placement, or abbreviated urethroplasty (63% vs 69%, 63% vs 33% respectively).[559]

2.6.2.2. Infection

As with any prosthetic implant, infection can be a significant concern and requires early recognition and prompt action. Infection usually presents with scrotal edema, cellulitis and induration/skin fixation at the pump site (Figures 17 and 18).

The incidence of implant infection is generally low. The rate of infection in most series is reported as between 1% and 8%.[541,552] The rates at high volume centers are less than 2%6.[37] Not all series report erosion and infection separately. Gram positive organisms such as *Staphylococcus aureus* and *Staphylococcus Epidermidis* and *Enterococcus* account for majority of infections, while Gram negative bacilli such as *Escherichia Coli* and *Pseudomonas aer*uginosa infections account for 26% of infections.[533]

In cases of overt infection, the standard of care is removal of the entire device. A subsequent device may be re-implanted at least three months later to allow the infection to clear and inflammation to subside. It is preferably implanted at a different location along the urethra.[18] Good results have been reported in these patients undergoing repeat implantation. It has been demonstrated in a single small series, that a salvage technique with immediate re-implantation of a new device, after the removal of infected, but not eroded AUS is possible, with a reported success rate of 87%. Coating of the device with Inhibizone (minocycline and rifampicin) did not result in reduced infection rates but did increase costs.

2.6.2.3. Urethral Atrophy and/or Inadequate Compression

Urethral atrophy is the most common sequela following AUS implantation, and is unavoidable as aresult of constant urethral compression leading to ischemia. The urethra loses tissue bulk over time and the original cuff may become relatively loose and provide suboptimal urethral coaptation resulting in recurrent incontinence. The incidence of urethral atrophy requiring revision varies from 3% to 9.3%.[528,537,542,546,547,548,549]

Urethral atrophy typically presents as new onset stress incontinence following a prolonged period of surgical success. Such "sub-cuff atrophy" typically presents many years after the primary AUS implantation. Diagnosis is confirmed by office cystoscopy demonstrating inadequate urethral wall coaptation. Fluid leak should be ruled out by pelvic ultrasound (to confirm a full reservoir) or plain xray (in patients whose device was filled with contrast). Several options exist to manage recurrent incontinence, including downsizing the cuff, increasing reservoir pressure, placement of a tandem cuff to increase the area of urethral resistance, transcorporal cuff placement or interposition of a biologic graft as a urethral wrap.[69,,,] The most common and easiest approach is downsizing the cuff size, while the latter 2 options provide additional bulk of tissue to the urethra.[536] The use of a 3.5 cm cuff in smaller urethras may lessen the incidence of sub-cuff atrophy as cause for surgical revision.

However, there are some who question the entity of urethral atrophy and instead have noted constriction of the sub-cuff urethra by the pseudocapsule, that can be released via incision of the pseudocapsule resulting in increased urethral circumference.[,] This would allow for replacement of the original sized components with satisfactory outcomes. There is limited data on performing this.

2.6.2.4. Mechanical Failure

As with any prosthetic implant, mechanical failure can be expected with AUS and is typically a late complication. It is believed to be due to wear-and-tear of the tubing or components of the device. This includes loss of fluid from the system, malfunction in the pump, leak in the reservoir or tear and/or kink in the tubing. Introduction of "kink-free" tubing has virtually eliminated this last tubing problem although tubing break next to the pump can occur over time if the device is not situated properly within the subdartos pouch. The current implant design of the AMS 800 has significantly lowered the device failure rates secondary to mechanical issues. The incidence varies widely and ranges from 0%[547]to 52.5%. In a study with long follow-up ranging from 10–15 years,[569] the authors reported the cuff being the most vulnerable component of the system (22 cuff failures in 18 patients), most of them occurring in first 2-3 years following implantation, followed by pump failure (6 times in 4 patients). Blockage only happened once in 61 patients.

In a 13-year review by Lai H,[528] mechanical failure occurred at an average of 68.1 months following implantation.

Malfunction can be identified on physical exam with improper device cycling and lack of coaptation during office cystoscopy. The loss of fluid should be ruled out first with a quick office pelvic ultrasound to check the amount of fluid in the pressure regulating balloon. The bladder ultrasound is readily available in urology clinics.[67] Plain abdominal x-ray can be utilized if contrast was used to fill the reservoir.[69] There is limited data on the management of this sort of failure available in the literature. There are no guidelines or recommendations regarding management in cases of malfunction. Some suggest replacing the individual component only if the device has been in place less than 5 years. On the other hand, others recommend replacing the entire device in all cases regardless of duration of implanted device due to minimal added surgical risk.[67,,]

Unusual mechanical complications may occur which included displacement of the locking tab into the cycling portion of the cuff preventing fluid transmission into the cuff or even a persistently open locking tab.

Figure 19 illustrates the case of a young spina bifida patient in whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Comparing the second KUB to the original one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is sus-pected20 (e.g., following abdominoperineal resection of the rectum). CT or MRI may be useful as well particularly in cases where there is concern that components of the AUS have shifted or herniated (Figure 20 A and B).

2.6.2.5. Complications in the Long-Term

More recently, Schillebeeckx C et al presented their 30-year experience with AUS implants in a tertiary referral center during the ICS 2021. All patients who underwent artificial urinary sphincter implant for non-neurogenic stress urinary incontinence between June 1989 and January 2020 were included in this single-centre retrospective consecutive series. All implants were AMS 800® (Boston Scientific) and performed by two experienced surgeons. A total of 263 patients were included in this retrospective series with a mean follow-up of 61 months. The median patient age was 69 years. 86.7% of the patients became incontinent due to radical prostatectomy. Twenty-two early postoperative complications were registered (5 retentions, 12 scrotal hematomas, 1 infection, 2 wound problems and 2 hematuria cases). A total of 294 sphincters were implanted; 249 patients received one implant, 40 patients received a second implant and 5 patients underwent a third AUS implant. Of these implants, 71 (24%) were explanted. Explants were mainly due to urethral erosions (51%) and infection (39%). Explant-free survival

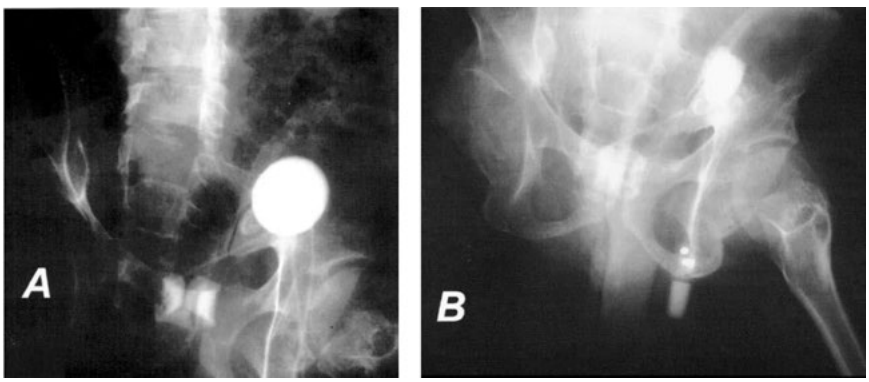

Figure 19. Young spina bifida patient who had a bladder neck artificial sphincter implanted. After more than 10 years, he become incontinent. Early abdominal plain film, A, shows a full reservoir. After leakage started abdominal plain film, B, demonstrates loss of fluid from the reservoir.

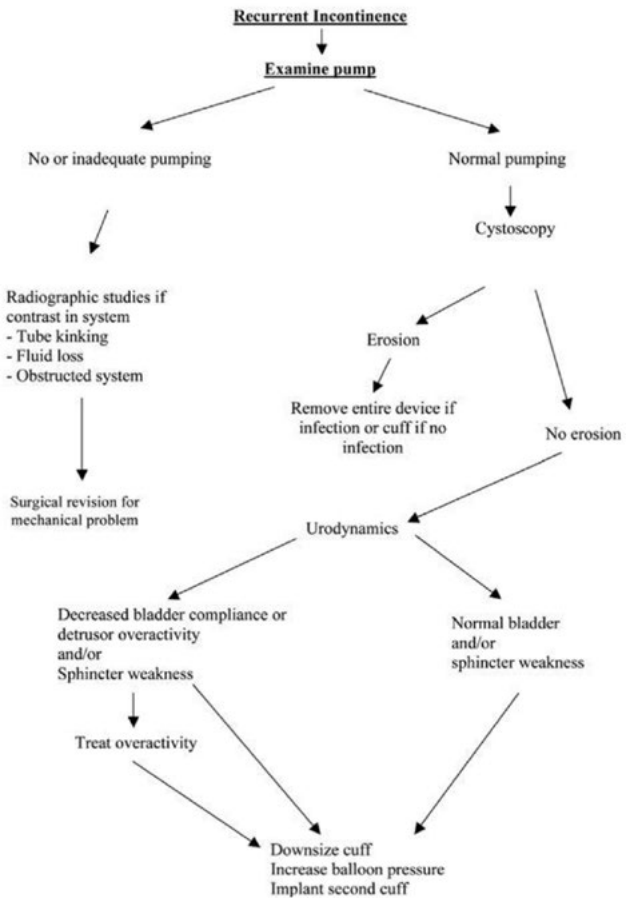

Figure 21 shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

after 5 years was 75.3% (CI 68.8% - 80.7%) with a median time to explant of 16.2 years (CI 12.2 – 28.1). A total of 73 patients (24.8%) underwent revision or maintenance surgery. Overall revision-free implant survival was 62.1% (CI: 55.0%-68.4%) after 5 years with a median revision-free implant survival rate of 10.8 years. Previous pelvic irradiation, a history of stricture disease and previous artificial urinary sphincter implants were independent risk factors for decreased implant survival. Overall social continence rate (i.e. needing no more than 1 pad/day) after 5 years was 60.3% (CI: 53.2% - 66.7%) and after 10 years social continence rate decreased to 37.9% (CI: 30.1% - 45.6). Prior radiation therapy, anticoagulation therapy, previous AUS implant and other previous anti-incontinence surgery were associated with a higher incontinence risk.

2.6.2.6. Alteration in Bladder Function

Patients undergoing AUS can develop *de novo* OAB. Lai and Boone reported the need for anticholinergics medication in 23% of patients for OAB symptoms. More reports of bladder dysfunction are available in the pediatric neurogenic population. These include decrease in bladder compliance, development of high detrusor pressures resulting in hydronephrosis and even renal failure.[543,,,,,] Changes in detrusor pressure with upper tract dilation were reported in up to 57% of patients with bladder dysfunction.

Ideal candidates for AUS implantation are patients with adequate bladder capacity and normal vesicalcompliance. It has been reported that even those with “unfavorable” urodynamic parameters may have a good outcome after AUS implantation.[82] It is recommended to re-train small capacity bladders for several weeks prior to implantation and to treat such patients with anticholinergic medications as necessary.

2.6.2.7. Role of Tandem Cuff

In an effort to improve efficacy and continence, some authors have proposed using two cuffs in a tandem fashion. This is based on a concept of increasing resistance over a greater surface area. While placing a tandem cuff, it is recommended to leave 1-2 cm of normal urethral tissue between the two cuffs to avoid a long segment of possible urethral ischemia. The 2 cuffs are connected using a Y connector. It is estimated that approximately 15% of total AUS are placed as tandem cuffs.[559] Brito et al was the first to describe successful tandem cuff placement with success reported at 95%. Multiple reports recommend it as a primary procedure in totally or se-

verely incontinent patients,[580,] or as a salvage procedure by adding a second cuff following a failed previous single cuff.[580,581,] Despite initial enthusiasm and favorable outcomes following tandem cuff, subsequent reports with longer follow-up demonstrated a higher rate of complications. O'Connor et al[556] reported their experience in 28 patients who underwent double cuff placement, noting that with longer follow up there was no difference in continence compared to 28 men who underwent single cuff placement.

2.6.2.8. Role of Transcorporal Cuff Placement

Guralnick et al[564] first reported the transcorporal cuff technique in an attempt to improve continence in patients with recurrent incontinence due to urethral atrophy, urethral erosion, inadequate urethral coaptation, small urethral circumference (less than 3.5 cm), or multiple previous revisions to prevent future erosions. The urethra itself is not circumferentially mobilized but instead incisions are made into the tunica albuginea of the overlying corporal bodies and a tunnel created dorsal to the urethra, between these tunical incisions. This provides added dorsal bulk to the urethra and helps to avoid an inadvertent dorsal urethrotomy and further devascularization of the dorsal urethral tissue that could lead to cuff erosion. Initial success was reported in 84% of patients. In a prospective series, dry or socially continent rates were reported to be 76% at a median follow-up of 20 months.[583]. Many authors believe that transcorporal cuff placement affects erectile function and patients should be cautioned regarding this concern. Despite this concern, a small series report that a majority of patients (5/6, 83%), maintained their erectile function even after transcorporal cuff placement.

Despite conflicting reports, violation of the tunica albuginea is widely considered a contraindication in patients who have normal erectile function and/or desire a penile prosthesis for their erectile dysfunction.

Alternatively, in this complex patient population, a circumferential urethral wrap using biologic graft may be interposed between the urethra and the cuff as a salvage procedure. The graft materials used are either cadaveric dermis (personal experience, unpublished data) or small intestinal sub-mucosa (SIS). In a small retrospective study by Trost and Elliott[565] in eight patients with mean follow-up of 12 months, 38% (3/8) patients were dry requiring no pads, three patients had AUS explantation for erosion and infection and two patients developed recurrent incontinence.

2.6.2.9. Special Populations

2.6.2.9.1. AUS Following Sling Placement

For patients with persistent or recurrent stress incontinence after male urethral sling placement, AUS implantation as a secondary procedure is utilized.[42,43,] It is believed that the resultant fibrosis from sling limits the urethral compression and/or urethral mobility needed for sling efficacy.[163,] This will decrease overall sling efficacy with time and even a second sling will not be effective. Following sling surgery, recurrence of incontinence ranges from 20% to 35%. The outcomes of primary AUS placement are comparable to those performed after prior failed sling placement. An AUS may be placed following bone anchored sling, transobturator sling or quadratic sling. Usually a transobturator sling is not seen during AUS placement and may be left in place. If a sling is encountered, it may simply be incised to expose the urethra. AUS outcomes following sling placement are high, with success rates reported between 79–83% without increase in the complication rates.[42,469] Few reports suggested a repeat urethral sling surgery after a prior failed sling with reasonable success.[467] In another study in 28 patients undergoing AUS after a failed urethral sling, similar high success rates were reported when compared to a control group without prior urethral sling surgery.[43] Similarly, in a comparative analysis of patients with SUI after a failed urethral sling, patients undergoing repeat transobturator urethral sling placement were six times more likely to have persistent incontinence than those who underwent AUS.[468] Unfortunately, these reports are small series, retrospective in nature and with a short follow-up. Due to lack of long-term outcomes, it is strongly advised to offer AUS placement following failure of male urethral sling.

2.6.2.9.2. Pelvic Radiation and AUS

It is believed that post-XRT patients constitute a group of high risk patients with a substantially increased risk of complications. Radiation is associated with endarteritis and chronic vascular changes that may lead to decreased blood flow making urethral tissue vulnerable to higher complications.[16] Several series have found higher rates of urethral erosion and atrophy necessitating higher rates of revisions in patients with prior history of radiation.[228,512,537,] A recent report showed that the relative risk of erosion is significantly higher in those who underwent radiotherapy compared to those who did not – RR 4.05, 95% CI 1.1-15.3 – and this risk is not diminished despite the improvement in radiation techniques. There are conflicting reports in the literature regarding increased complication rates and lower continence rates. Some series contradict these reports and show comparable complication rates and continence rates with or without a history of radiation.[,] In a recent meta-analysis of 15 series, including 1886 patients, men with history of radiation in addition to prostatectomy had higher rates of AUS revisions than those treated with surgery alone.[228] Most of the studies included in this meta-analysis were small retrospective series, but when analyzing the four largest series, the relative risk of revision was not significantly different between those with and without prior radiotherapy.[228] Because of the concerns in these compromised urethras, some surgeons recommend using a lower pressure regulating reservoir (51-60 cm of water) and a longer period of deactivation time (6 weeks) instead of standard pressure of 61-70 cmH_2O and 4 weeks of deactivation.[537,]

Despite these conflicting reports, it should be noted that patients with history of radiation should not be excluded from receiving an AUS implant. These patients should be counseled accordingly and given realistic expectations of a lower continence rate and increased need for revision.

Regarding timing of the AUS insertion in patients who may need salvage radiation, there are scarce evidences in the literature, which preclude definitive conclusions. DeLay et al assessed 306 men, 292 (95.4%) received radiation before AUS placement (group 1) and 14 (4.6%) received radiation after AUS placement (group 2). Median follow-up was 30 months after AUS placement. Group 1 had 32 of 292 (11.0%) patients suffer from erosion, compared with 0 of 14 (0.0%) patients in group 2 (P=0.191). None of the patients in group 2 had infection or mechanical failure. The number of patients who received revision in group 1 was 91 of 292 (31.2%) and in group 2 was 2 of 14 (14.3%) (P=0.180). The number of pads used per day in group 1 before and after AUS placement was 5.24 ± 3.12 and 1.13 ± 1.31, respectively (P<0.001). In group 2, the number of pads used per day before and after AUS placement was 6.09 ± 1.97 and 1.53 ± 0.99, respectively (P<0.001). There was no significant difference in the average number of postoperative pads used per day between group 1 and group 2 (P=0.907). It is noteworthy that there were zero erosions in the group that had AUS first, then radiation. Nevertheless, the "N" was too small to achieve significance. Thus, future research is still needed.

2.6.2.9.3. AUS Implantations Following Radical Cystectomy

A significant proportion of patients will suffer from SUI following radical cystectomy with neobladder reconstruction. Only a few studies exist in the literature evaluating clinical outcomes in patients with orthotopic neobladders who have undergone an AUS. In one of the largest series reported, 72% (21/29) of patients noted an improvement in incontinence at a mean follow up of 40 months. However, 60% of patients underwent a revision or explantation due to device erosion, infection, device malfunction or recurrent SUI at a mean of 28 months after initial implant. It should be noted that a significant minority of these patients (28%) received adjuvant or salvage pelvic radiation. In comparison, these outcomes are inferior to outcomes in PPI.

2.6.2.9.4. AUS in Neurogenic Population

In a series of 30 males with spina bifida, Spiess et al found that the mean lifetime of AUS was4.7 years with no statistically significant difference in device survival of those inserted at the bladder neck versus the bulbar urethra (4.6 and 4.9 years, respectively). Significant decline in device survival was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point.[596] In a series of adolescents with neurogenic voiding dysfunction implanted with a bladder neck cuff over an 11-year period, with an average follow up of 5.5 years, Lopez Pereira and colleagues reported 20% mechanical failure rate with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, necessitating augmentation cystoplasty to improve bladder function although urinary continence was achieved in 91.4% of patients.

2.7. Other Devices

For futher information on technologies under development, please see Section 4.6 Future Directions.

2.7.1. Zephyr Surgical Implant (ZSI 375)

The ZSI 375 (Zephyr Surgical Implants, Geneva, Switzerland) is a more recently developed device. It is a one-piece device and pre-connected. It has no reservoir, but has an adjustable urethral cuff which is connected to a chamber which hosts the pump and a pressure regulating tank. It obviates the need for any abdominal incision, thereby reducingd operative time. In comparison to AUS 800, the smaller device should also have a lower overall cost.

Since its introduction, there have been a few reports confirming the safety and efficacy of the device. Staerman et al reported a retrospective study in 36 patients with moderate to severe incontinence following radical prostatectomy, TURP or bladder replacement. The median follow-up was 15.4 (6–28) months. Complications were noted in 4 patients requiring removal for erosion/infection. Social continence (0-1 pad) was achieved in 73% at 6 months after activation.

Another series with a longer follow-up of 4 years was reported by Ostrowski et al in 50 patients. In their series, the majority of patients suffered from severe incontinence. The median follow-up was 21.04 (1–50) months. Complications leading to revision or device removal occurred in 24%. These included erosion and/or mechanical failure. Social continence was achieved in 58% and 30% of patients improved significantly.

More recently, Ostrowski et al reported a large multicenter study in 10 European centers. A total of 109 patients with severe urinary incontinence underwent ZSI 375 device implant. The average follow-up was 43 (24–78) months. Complications leading to device removal were noted in 11% urethral erosions in 8.25% and mechanical failure in 2.75%. Total continence was observed in 19.27% and social continence was reported in 65.14%. Another 8.25% of patients noticed significant improvement. The authors concluded that the ZSI 375 is highly effective in treating severe incontinence with acceptable low complication rates. The ability to adjust the internal pressure via in-situ trans-scrotal applicator in an office setting makes this device an attractive option for men with severe incontinence.

2.7.2. VICTO and VICTOplus AUS

A new AUS called VICTO hase been recently introduced into Europe and South America. Manufacturers have introduced two configurations of this new AUS called the VICTO and VICTO plus. This device comes pre-connected with minimally invasive adjustments required. VICTO is a single unit pre-connected adjustable device with an occluding cuff (OC). The filling procedure is performed by inserting the needle into the port and filling the system with 13 mL of saline solution. In theVICTO plus the initial filling is 20 mL.

The pressure regulating balloon is placed intraperitoneally and with the VICTO plus, the stress balloon is be placed under the fascia. After passing the cuff through a subcutaneous channel from the abdominal incision to the perineum, the cuff is placed around the urethra. Finally, the pump is placed in the scrotum.

Four different cuff sizes are currently available (3.7, 4.0, 4.5, 5.0 cm).

Only one center reported outcomes of 51 patients (VICTO N=22, VICTO plus N=29) with a mean follow-up of 14.1 months. The pad per day usage improved from 6.2 (±3.3) to 1.4 (±1) and the continence rate (max. 1 pad per day) was 58.8%. There were on average 1.7 (median=2) adjustments needed and in two patients cuff revisions were required to achieve continence. An overall high patient satisfaction of 86.4% was reported. No erosions or device explants were reported by the authors.

2.8. Follow-up Protocol Of Patients Undergoing AUS Implant Surgery

No standardized recommendations are available in the literature regarding post-operative follow-up of patients after AUS implant surgery. Recommendations are based on expert opinion own protocol.

1. Peri-operative intravenous broad spectrum antibiotics are given to provide coverage for both gram positives, specifically *Staphylococcus Epidermidis*, and gram negative bacilli like *E.Coli.*
2. At the conclusion of the surgery, the device is deactivated and the Foley catheter may be left in place to drainage.
3. Patient is either discharged same day or may be kept overnight in hospital under observation and is discharged following morning based on surgeon's preference.
4. Foley catheter is removed in the recovery room or the following morning and a voiding trial is given to ensure complete voiding or leaking by the patient. A post void residual is checked with bed side bladder ultrasound before discharging patient.
5. The AUS device is kept deactivated for 4–6 weeks following surgery. Patients with a history of radiation are kept deactivated for a longer period, usually 6 weeks and 4 weeks for patients without history of radiation. Patients should avoid strenuous activity during this time.
6. Patients are seen in the clinic for the AUS activation by the surgeon and taught how to squeeze the pump for urination. Nocturnal deactivation of the device should be considered in high-risk patients (e.g., prior radiation or urethral erosion) and those who are comfortable deactivating the device themselves.

Figure 22. Victo artificial sphincter Courtesy of Dr. Luis Seabra Rios.

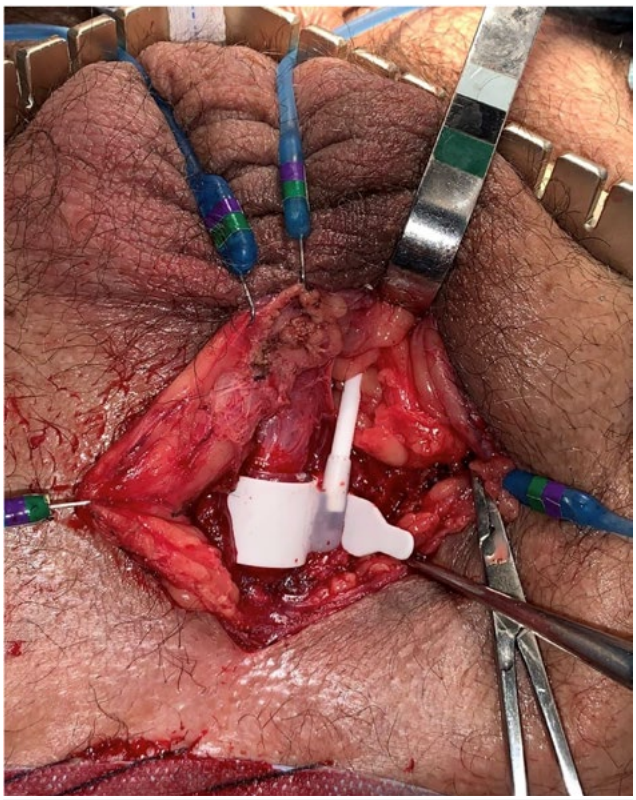

Figure 23. Victo cuff implanted around the bulbar urethra. Courtesy of Dr. Luis Seabra Rios.

7. Patients are reviewed around 3 to 6 months after activation to ensure proper functioning of the device and to assess continence status.
8. Patients are instructed to contact the physician in case of hematuria, pain, redness, new onset of incontinence or any difficulty manipulating the device.
9. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time alteration in bladder function may compromise the upper tracts and overall renal function in the neurogenic patients. As such these patients should be monitored with periodic assessment of renal function/renal imaging.
10. If changes are observed or patients complain of worsening incontinence, urodynamic evaluation may be necessary to rule out detrusor overactivity or poor bladder compliance.
11. Office cystoscopy may be required in patients with a history of new onset of hematuria or difficulty in emptying the bladder to rule out cuff erosion.

3. MALE SLINGS VS. AUS

3.1. Introduction

Post-prostatectomy incontinence is multifactorial. Adequate sphincter function depends on the ability of the urothelium and urethral wall to properly coapt and seal, functional smooth and striated muscle, and sufficient support of the membranous urethra and the pelvic floor. As these factors can change over time, before embarking on surgery, one must be sure that the patient´s symptoms are stable, that conservative treatment has been fully undertaken, and that bladder function is assessed. Careful clinical history and evaluation is mandatory, since the pathophysiology of "post prostatectomy incontinence" may include **stress urinary incontinence**, **urgency incontinence**, **nocturnal enuresis**, i**nsensible urinary incontinence** and p**ostural urinary incontinence**.[35] The key to a successful treatment is to determine the presence/absence and impact of each type.

It is difficult to compare surgical techniques that are based on differing mechanisms of action: the **compressive nature of annular systems** around the urethra (artificial urinary sphincter);[533,600] **non annular compression of the bulbous urethra** of a compressive sling (quadratic and adjustable slings)[484] or **urethral re-positioning** (transobturator retroluminal sling).[453] Choice of surgical procedure depends on the patient's degree of incontinence, history of prior incontinence procedure or prior XRT, bladder function, and the goals of treatment. This shared decision-making between patient and surgeon is based on the principle that treatment poses risks and confers benefits for the patient. Shared decision-making is a process in which providers and patients work together to make decisions about tests, interventions, and care plans. The physician provides the clinical evidence and the patient is free to express his preferences and values. The surgeon should honor the patient's preferences for treatment goals and consider those preferences when giving a treatment recommendation, including long-term continence and long-term complications when we compare sling (loss of continence, perineal pain) with AUS (risk of erosion, mechanical failure, and loss of compression in urethra). In the case of adjustable systems (e.g., ATOMS™, Argus™, Reemex®), the need for any postoperative adjustments should be explained to the patient. Furthermore, AUS is a mechanical device requiring pump manipulation with the potential for mechanical breakdown, and it has been reported that some patients prefer to avoid the mechanical nature of an AUS and choose a sling even when their surgeon recommends an AUS over a sling.[59] Shared decision-making produces better

health outcomes by decreasing anxiety, promoting faster recovery, and improving compliance.[,,,]

In the patient who has failed conservative management, the two main choices for surgery to restore urinary continence are the artificial urinary sphincter (AUS) and the male sling. There are few comparative studies of the artificial sphincter and the various male slings, and only one prospective randomized trial comparing the devices. However, there are several recent cohort studies comparing outcomes of the AUS with those of specific male slings in certain patient populations. While no one device is preferred in all patients in all clinical situations, there are some recommendations made in the literature regarding the preferred treatment in certain patient populations depending on prior radiation, prior incontinence surgery, prior treatment of urethral stricture,[31,] degree of urinary incontinence, and degree of residual sphincter function.

While it can be difficult to measure bladder contractility in these patients, detrusor hypocontracility is a relative contraindication to a potential obstructive sling. However, most series have not included men with known detrusor hypocontracilty in their cohort. In the setting of detrusor underactivity in the group with moderate incontinence, AUS is preferred, as it is cycled to an open (nonobstructed) state during voiding (a potential advandage of the AUS is the ability to open the cuff to allow valsalva voiding.). On the other hand, the compressive sling is designed to prevent leakage with straining and may therefore interfere with voiding in those patients unable to produce an adequate bladder contraction. In the patient with detrusor underactivity who does not want implantation of a mechanical device, a non-compressive sling such as the transobturator male sling, is an option. Han et el,[93] in their retrospective review, show that patients with post-prostatectomy urinary incontinence with urodynamic findings suggesting impaired contractility or Valsalva voiding can be safely treated with sling surgery if they have normal preoperative emptying. Thus, in the man with a poorly contracting detrusor, the transobturator sling may be preferred versus a compressive sling, given its non-compressive mechanism of action.

3.2. Specific Patient Factors

3.2.1. Degree of Incontinence

Success for sling surgery appears to relate to the severity of leakage (by pad weight). The success rate in men who leak more than 200g per day were lower than those with milder leakage, and in those with 400g per day incontinence, failure rate was 80% higher than in those with less than 200g per day on pad weight. Averaged out, for each 1g increase in 24-hour pad weight, success rate declines by 0.4%.[60,498,] Similar data was shown for the bone-anchored sling, where the AUS was recommended over sling implantation for those with greater than 450g per day urine loss.[585] Whereas the international trial of the quadratic sling with fixation (a modification of the initial technique with the attachement of the retropubic arms over the pubic rami) showed equal efficacy for those with mild (up to 100g per day), moderate (100–400g per day) and severe (more than 400g per day) leakage, a more recent report indeed demonstrated higher failure rates with greater degree of incontinence.[476]

In the MASTER RCT (Sling vs AUS),[6] 24-hour pad test baseline was 256g (range: 89–545) in the sling group and 267g (range: 130–554) in the AUS group. While non-inferiority was reported for the primary endpoint (any self-reported urinary incontinence at 12 months after randomisation), subgroup analysis of the primary outcome suggest that the male sling is indeed less efficacious tan the artificial sphincter for men with greater incontinence at baseline (pad weight >250g); although, the difference does not reach statistical significance.

3.2.2. Prior Radiation

Adequate urethral compliance is necessary to allow sufficient urethral compression with a non-circumferential sling implantation. Similarly, prior radiation has been shown to limit the mobility of the bulbar urethra, often preventing adequate proximal urethral relocation. Moreover, it has been described the damaging effects of XRT on the structure and function of the pelvic floor muscles of patients with cancer in the pelvic area.

Debates exist whether men with urinary incontinence post-prostatectomy should receive continence surgery prior to XRT, or to wait post-radiation to ensure tissue fibrosis has settled.

It is not surprising, therefore that a history of radiotherapy correlates with a higher rate of sling failure.[419,500,611] Radiation was the most significant predictive factor for sling failure for both the Northwestern pubourethral sling[419] and for the bone-anchored sling.[500] Torrey et al[492] reported that only 29% were improved (none were cured) with the transobturator sling in men with a history of XRT, versus a 90% cure/improved rate in those without prior radiation. Bauer et al[611] showed similar findings, with TO sling success of 80% in non-radiated men compared to only 50% in those with prior radiation.

3.2.3. Prior AUS

Similarly, prior AUS implantation and explantation can result in a fibrotic and poorly compressible urethra that fares poorly with a non-circumferential sling placement.[425,] On the other hand, reimplantation of the AUS is associated with a high success rate. In a comparative study of men undergoing salvage sling placement versus AUS re-implantation after prior AUS surgery, AUS patients were three times more likely to achieve adequate continence than were sling patients.[586]

3.2.4. Prior Sling

The data regarding prior sling surgery generally favors AUS over sling revision, with the exception of late sling failure with a persistently positive repositioning test. It is well-established, that following sling surgery, recurrence of incontinence occurs in a significant minority of patients (20–35%). There is a growing body of literature regarding the choice of repeat sling surgery versus AUS following sling failure. The history of prior sling failure does not adversely affect the success of AUS implantation, which can be implanted via a standard perineal approach distal to the membranous urethra and proximal bulb, unencumbered by the *in situ* sling. The efficacy of a repeat sling depends on the time to sling failure, and the degree of residual sphincteric function. With early sling failure (less than 6 months postoperatively), the efficacy of repeat sling surgery was lower (20% cure, 20% improved) than men with late sling failure (greater than 6 months postoperatively). Late failure patients realized a 63% cure and 13% improvement rate 1 year post sling revision.[38] Similarly, in the cohort reported by Soljanik et al,[467] 46% of patients were cured at 6 months following repeat sling surgery. However, only men with a positive repositioning test were offered repeat sling implantation. Singla's group, who did not discriminate based on the repositioning test, found a low success rate with repeat sling, noting a 55% failure rate, which was seven times higher than the likelihood to fail with AUS implantation.[468]

Recently, a pelvic MRI has been proposed to correlate the postoperative position of the sling and the success of the surgery. MRI can show proper positioning of the sling (successful surgery) based on our quantitative analysis of MRI parameters. A strong relationship was found between proper positioning of the sling (a complete sling indentation on the urethral bulb profile and a small sling backward distance, defined as the distance between the prolongation of a line through the major axis of the pubis) and the continence outcome. According to these data, only in cases where the sling is poorly lo-

cated postoperatively would a second mesh surgery be indicated.[39] Given the high success rate of salvage AUS, and the relatively high failure rate for repeat sling (with the exception of late failure and positive repositioning test), AUS is the procedure of choice in men who have failed primary sling.

Approximately 13% of men who undergo male sling surgery will ultimately have AUS implantation. AUS placement after failed sling has a high success rate (80–90%) without an increase in the expected complication rate.[422,423,424,425,426] The TO sling may be left *in situ* while the AUS is placed distal to the sling in the normal bulbar urethral location, whereas the quadratic sling must be divided to allow access to the bulbar urethra for AUS cuff placement. The sling is readily identified via a perineal incision, and is easily dissected off the underlying bulbospongiosus muscle, which should be left intact over the urethra during quadratic sling placement.

3.2.5. Pre-Existing Comorbidities

In patients with comorbidities or a history of previous incontinence surgeries, these should be evaluated to decide between a sling or an AUS. It is, however, difficult to draw conclusions due to bladder neck contractures or urethral strictures treated and previous surgery are usually exclusion criteria for all published studies (i.e,. patients were excluded if they had had previous male sling or AUS surgery in RCT MASTER study).[6] AUS implantation seems to be a viable, safe and effective therapeutic strategy for incontinence treatment despite previous buccal mucosa graft urethroplasty (BMGU) beforehand.[609] Although, AUS implantation in patients with former urethroplasty can provide satisfying results, compared to patients without the previous urethroplasty, the higher risk of cuff erosion and AUS explantation has to be addressed during preoperative consultation.[31] Related sling surgery, anastomotic stricture treated has not been demonstrated as a risk factor for successful after 49 months median follow-up sling surgery.

Endoscopic surgery after the placement of an AUS should be considered, mainly in patients with previous nonmuscle Invasive bladder cancer (AUS might be difficult if need to undertake TURBT). *De novo* detrusor overactivity must also be considered; although, it is feasible treatment with botulinum toxin injection with flexible cystoscopy in men with AUS.

3.3. Sling vs. Sphincter Based on Non-RCT

In a retrospective review of 124 patients with mild to moderate PPI (≤ 5 pads per day), 76 of whom underwent TO sling surgery vs 48 who underwent AUS placement, Hoy et al showed relative equivalence in surgical outcome. Specifically, there was no statistical difference in continence (88.2% vs 87.5%), satisfaction (93% vs 92%) or complication rate (19.7% vs 16.7%). However, those complications associated with the AUS were more severe than those following sling surgery.[618] In a comparison of men with mild-moderate PPI receiving AUS (N=20) or adjustable TO sling (N=20), Lim et al[445] reported no statistically significant difference in efficacy (72.7% vs 85% success). However, there was a greater rate of pain reported in the adjustable sling group (30% vs 7.7%), and sling explantation was required three times more often in the sling group.

3.4. MASTER Trial

More recently, the MASTER trial was a prospective noninferiority randomized trial assessing of the transobturator male sling versus the AUS.[6] The primary outcome measure was based on patient reported urinary incontinence at 12 months. Based on the strictest definition of “any leakage”, 87% and 84% of men had some degree of incontinence postoperatively in the sling and AUS groups, respectively (confirming non-inferiority of sling vs AUS). When a less strict definition of incontinence was used (“small amount” and “less than once a week”), 66% and 65% of men in the sling versus AUS group were incontinent (again confirming non-inferiority). Preoperative and postoperative pad use was not statistically different between the groups. Satisfaction via ICIQ questionnaire was higher in the AUS group than the sling group (90.6 vs 72.2%). Despite the primary outcome showing that the TO sling is not inferior to an AUS (with urinary incontinence being greatly reduced after surgery in both groups), there were differences in secondary outcome measures at 12 months postoperatively including incontinence symptoms (using ICIQ-SF), self-reported amount of urine leakage, self-reported pad use, and the impact of incontinence on everyday life, with greater improvements in the AUS group. Furthermore, at 12 months after surgery, significantly more sling patients needed additional incontinence surgery (7.2% vs 1.2%) and the overwhelming majority of sling failures ended up having an AUS placed.

Adverse events were generally rare, with the male sling group having a higher rate of catheter problems which is not surprising considering catheterization is almost never indicated after AUS placement with deactivation. As device-related complications do not always occur in the first 12 months (the data currently published are at 12 months of follow-up), and longer-term data acquisition has been advised for all surgical devices, the authors will continue with a 5-year follow-up of the established MASTER trial cohort.

This well-run clinical trial did not show a statistically significant difference in continence or pad use at 1 year. However, it must be taken into account the baseline characteristics of the patients. The median of the 24-hour pad test result was 256g in the sling group and 267g in the AUS group and the range was 89–545 in the sling group ant 130-554g in the AUS group. Although, all the subgroup analyses forest plot (primary outcome) show a large amount of uncertainty around the effect sizes, baseline pad weight subgroup study suggest that the male sling is inferior to the sphincter for men with greater incontinence at baseline (pad weight >250g). This corresponds to it has been previously published that success for sling surgery appears to relate to the severity of leakage.[60,498,611] Furthermore, the strict definition of incontinence and the omission of postoperative pad-weights makes it difficult to compare the outcomes of this trial with those of the non-randomized cohort studies that typify the majority of the literature regarding surgery for PPI. Regarding the preoperative status, a 20% of sling group patients and 20.5% of AUS group patients had received radiotherapy for prostatic disease. As mentioned previously history of radiotherapy correlates with a higher rate of sling failure and therefore this data should also be evaluated. The subgroup analyses also suggest that the male sling may perform better than the AUS for men with pure SUI at baseline

3.5. Conclusion

The Committee’s conclusions should be evaluated accepting that there is no strict consensus in the degree of incontinence (with classification of pad weight and category of incontinence). In men who have not been radiated and have not had prior incontinence surgery, factors such as degree of leakage, proximal urethral mobility, and detrusor contractility can help determine the preferred surgical approach.

The Committee’s recommendation in those with mild to moderate leakage (with 24-hour pad test below 400g per 24 hours) and a positive repositioning test or adequate urethral mobility on video urodynamics, a retroluminal (transobturator) or compressive (quadratic or adjustable) sling is a reasonable approach, with lower complication rates compared to AUS placement and without an adverse effect on future AUS placement. Nevertheless, data from the recent RCT MASTER study show no evidence of difference between male sling and AUS.

With leakage > 400g per day (moderate to severe), AUS is the recommended option, due to a general demonstration of superior efficacy than the male sling in non-comparative studies and in the MASTER subgroup analyses suggest that the male sling is inferior to the sphincter for men with greater incontinence at baseline (pad weight >250g). The recently published MASTER trial does not support this finding of AUS superiority in those with higher preoperative pad weights due to the range in both groups was below (the range was less than 554g in both groups,89–545g in SLING group and 130–554g in AUS group).

In the patient who will not or cannot have an AUS, a compressive sling is also a reasonable alternative as long as he has urodynamically demonstrable normal bladder contractility and understands the higher risk of sling failure.

The Committee's recommedations in patients with persistent mild to moderate SUI following prior sling, AUS implantation is the treatment of choice for persistent PPI because it can provide the circumferential urethral compression necessary for adequate coaptation even in the setting of diminished urethral compliance. Even though the mechanism of action is quite similar in both AUS (AMS-800® and Zephyr®), nowadays the track record of AMS 800® is much longer.

It has the largest body of literature reporting long-term success and this success and high patient satisfaction seem to outweigh the need for periodic revisions in some patients with AUS. Intermediate-term data with the male sling demonstrates that the sling is equally efficacious with a lower rate of severe complications in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility.

The Committee's propose there exist a need for further study (multi-institutional) to evaluate the grey zones (i.e., leakage > 400g per day, prior radiotherapy, pre-existing comorbidities, bladder, hypocontracility) due to clinicians need to adequately counsel patient and have back-up plan if intended clinical outcome is suboptimal.

4. PERIURETHRAL BULKING AGENTS

Periurethral bulking agents (PUBA) offer men with stress urinary incontinence (SUI) a minimally invasive surgical option to restore urinary continence by increasing the urethral resistance to urinary flow and augmenting urethral coaptation at the level of the bladder neck and/or distal sphincter. In contrast to male urethral sling which is predominantly utilized in the setting of post-prostatectomy, PUBA has been used in post TURP and neurogenic SUI patients, some with relative success rate. PUBA has received considerable attention for the treatment of SUI in women; however, their role in male SUI is more uncertain with the optimal agent, patient selection, and technique(s) still yet to be defined. Published literature shows suboptimal clinical outcomes compared to other surgical continence options, with the need for multiple periurethral injections and the risks of subsequent deterioration and/or migration of bulking particles over time.

4.1. PUBA Classification

PUBA can be divided into two major classes: those made from solid microparticles in an absorbable liquid or gel carrier (particulate agents) and those comprising a homogenous gel (non-particulates) that resists absorption. The two types of bulking agent achieve their effect of urethral coaptation in slightly different manners. In the case of the particulate bulking agents, they induce a foreign-body reaction around the particles resulting in fibrosis formation. Current and previously marketed particulate bulking agents includes Macroplastique® polydimethylsiloxane (Uroplasty Ltd, Reading, Berkshire, UK), Durasphere® carbon-coated zirconium oxide (Carbon Medical Technologies, Saint Paul, Minnesota, USA), Coaptite® calcium hydroxyapatite (Boston Scientific, Marlborough, Massachusetts, USA) and Tegress® and Opsys® polyacrylate/polyalcohol copolymer (Promedon, Córdoba, Argentina). With the exception of calcium hydroxyapatite, these particles are non-degradable with each agent achieving its long-term bulking effect through reactive changes around the persisting particles while the carrier volume is lost. Non-particulate PUBA are Bulkamid® polyacrylamide hydrogel (Contura Ltd, London, UK), Contigen® glutaraldehyde cross-linked bovine collagen (CR Bard, Covington, USA) and Deflux® dextranomer hyaluronic acid (Q-Med, Uppsala, Sweden).

Contigen has served as the standard by which all other injectables are compared for the treatment of SUI. Contigen was FDA approved as a urethral bulking agent in 1993 but its production was discontinued in 2011. There are a significant number of studies published on the role of Contigen as PUBA with reported clinical "success rates" around 36–69% in post-prostatectomy incontinence, with 4-20% of patients reporting no pad use postoperatively.[,,,,] In these studies, multiple injections were required to achieve subjective improvement in the continence rate. There was no reported advantage between retrograde and antegrade periurethral injection techniques.[627] The presence of extensive bladder neck scar or urethral stricture formation, previous radiation, and severe SUI and low abdominal leak point pressure (ALPP) adversely effect the success postoperatively.[624,627] Comparing treatment outcome in those with SUI following transurethral prostatectomy as opposed to radical prostatectomy, it was shown that the presence of residual prostatic tissue was associated with more favourable continence postoperatively. The use of PUBA did not appear to adversely affect the outcomes including complication rate of subsequent artificial sphincter implantation or bone-anchored male sling surgery. Some of its major drawback include biodegradability, need for retreatment, allergic reaction and the unknown long-term risk of urethral complications as well as the possibility of distant migration.

Macroplastique® is a minimally invasive silicone macroparticulate agent with global clinical literature describing its use over 20 years. In one of the early studies, Bugel et al reported an initial success rate of around 71% at 3 months but this improvement decreased to 26% at 12 months follow up. A similar observation was confirmed by a recent study that showed 43% success at 3 months following Macroplastique® injection, which declined to 32% at 6 months; lower ALPP and a history of radiation correlated with treatment failure. In a larger prospective study, Kylmala et al demonstrated that 2 injections were more ideal with short-term continence achieved of 12%, 20%, 18%, and 10% following 1, 2, 3, and 4 injections respectively. A quantitative meta-analysis review of Macroplastique supports its use as an effective, durable, and safe treatment option for female SUI, with some patients requiring reinjection. In a randomized trial of the artificial urinary sphincter (AUS) vs Macroplastique® injection in patients with minimal SUI, Imamoglu et al[57] demonstrated no significant difference in success with AUS vs Macroplastique® in the short-term. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. As one would expect, due to the poor efficacy of PUBAs, their use for treating male SUI had decreased dramatically over the past decade, from 80% of cases in 2004 to 60% in 2010, and less than 40% cases in 2013.[615]

Newer PUBAs have been reported in several small series publications with suboptimal clinical outcomes. Hurtado et al showed that

not only was the failure rate high, but the complication rate was also unacceptable, as 10 out of 17 patients suffered complications, such as erosion of injected material, which was reported in 41.1% of patients. Tregress has been voluntarily removed from the market due to safety concerns. Clinical utility of Opsys which is manufactured by the same company, has also shown poor outcomes with only one patient with success, one with improvement, and eight with failures after 1 month of follow-up study. Subsequently, one patient was treated with an artificial urinary sphincter and two patients with a male sling. Carbon-coated zirconium beads have been similarly reported to be inefficacious, with one recent study reporting that none of the patients achieved subjective or objective cure. Similarly, Deflux use as PUBA has been shown to be poor with a high failure rate.

Common PUBA-related complications include urinary retention, UTI, dysuria, and hematuria.[620] Postoperative retention is the most common complaint (3–17%) with most study protocols requiring satisfactory voiding as the condition for discharge. No intervention was needed in most cases, however, a few patients required temporary catheterisation. Uncommon complications such as periurethral pseudocyst and urethrovaginal fistula have been reported in women.

While it is generally accepted that PUBA works best in carefully selected men with mild-to-moderate SUI, PUBA injections may be as effective as AUS or male sling.[630] Several factors have been cited as preoperative indicators towards treatment success. A VLPP value of 60cmH_2O or higher was more likely to have a better response to PUBA.[625] There is a strong correlation among previous radiation therapy, concomitant detrusor overactivity, or bladder neck contracture with treatment failure.[620] Furthermore, previous intraoperative complications, such as excessive blood loss, scarring from multiple anastomotic incisions, and difficult prostatectomies are associated with worse clinical outcome.[623] Comparing PUBA use in post-prostatectomy vs. TURP-related SUI, more favourable outcomes were reported in the TURP group.[57] Nonetheless, there is a lack of standardized protocols and surgical techniques in the literature. The volume of injection, injection site, and even the procedure approach (antegrade vs retrograde injection) differ among published studies.[620]

There has been considerable interest in the use of novel agents such as autologous muscle cells, stem cells, and fibroblasts recently. Numerous pre-clinical studies have demonstrated the therapeutic utility of stem cells in various animal models of mechanical, nerve, or sphincteric injury, with improvement observed in terms of leak point pressure, myoskeletal dedifferentiation and urethral muscle contractility. Several clinical studies have now demonstrated the short-term safety and efficacy of stem cell therapy in treating SUI.[,] Current research has leaned towards the use of adipose-derived stem cells and muscle-derived stem cells, as they are easier to harvest with higher yield compared to autologous bone marrow-derived stem cells.[637] In a landmark publication, Mitterberger et al[645] demonstrated a 67% continence rate at an average of 1-year follow-up following transurethral ultrasound-guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies. Another study from the same group also demonstrated that men with post-prostatectomy incontinence achieved a 52% dry rate with the injection of adult autologous stem cells, which appeared superior to a similar cohort of men treated with collagen injection.[646] However, this study was subsequently retracted and was investigated by the country governmental agency for scientific data irregularities.

In another large study, Gerullis et al demonstrated that muscle-derived stem cells can achieve complete continence in 12% and improvement in 42% of 222 men at 1-year post-injection. Nonetheless the levels of stem cells viability and engraftments following periurethral injections remain uncertain at this stage with studies showing that the concomitant administration of other bioactive factors such as poly-lactic-coglycolic acid (PLGA), various growth factors (e.g., nerve growth factor, brain-derived neuropathic factor) or calcium concentration microdomains, may improve the clinical outcomes such as urinary leak point pressure, muscle mass density, and concentration of neuronal density compared to delivery of stem cells alone. While the current evidence is accruing to suggest that stem cells may be a viable alternative for PUBA, issues relating to long-term safety, efficacy, and quality of stem cell therapy remain a potential concern and pose considerable bioethical challenges before widespread clinical application.

4.2. Conclusion

PUBAs remain the most minimally invasive surgical treatment option for male SUI despite the heterogeneous study populations. In addition to its simple administration technique, injectable therapies offer men with SUI who are not able to tolerate or refuse more invasive continence surgery such as male sling. Bulking agents should be differentiated into two classes based on their mode of action and whilst few head-to-head data exist, differential safety profiles are emerging. A higher success rate is observed in patients with a higher abdominal leak point pressure, absence of scarring or stricture, and no radiation history. There are no demonstrable differences in clinical outcome with respect to a transurethral vs retrograde injection method, and similarly, no differences were seen between proximal urethral or bladder neck injection site. However, patients should be counselled regarding the modest success rates with very low cure rates and these clinical effects will deteriorate over time. The use of PUBA for the treatment of male SUI should only be utilized when other more effective treatments are contraindicated or have been rejected by patients.

(Level of evidence 3; Grade of recommendation C)

5. ADJUSTABLE CONTINENCE THERAPY (PERIURETHRAL BALLOONS)

The adjustable balloon procedure (ProACT, Uromedica, Plymouth, MN), which is performed under general or spinal anesthesia through a perineal incision and guided with fluoroscopy and urethroscopy, relies on passive compression of the urethra by two adjustable balloons located on either side of the membranous urethra.

Adjustable balloons appear to be a feasible procedure in the short to medium term for patients with mild to moderate leakage and no prior radiation. However, the potential benefits should be weighed against the need for multiple sessions of refilling the balloons, and the reported rate of peri- and post-operative complications.

Reuvers et al evaluated changes of the urethral pressure profile (UPP) after implantation of ProACT in men with PPI. Maximum urethral closure pressure (MUCP) increased significantly from median 58.0 to 79.0 cmH_2O in the successfully treated group (P=0.001). Within the subgroup of unsuccessfully treated patients, MUCP did not change significantly (P=0.715). The change in MUCP was statistically significantly different between the successful and unsuccessful group (P=0.034). The authors concluded that increased

static urethral pressure contributes to the working mechanism of the ProACT device to achieve continence.

Larson et al carried out a systematic review to assess the efficacy, safety profile and rates of adverse events associated with the implantation of adjustable balloon devices in the treatment for male stress urinary incontinence (SUI). In total, 19 studies were included with a total of 1264 patients. ProACT implantation resulted in an incontinence QOL improvement of 30.8 points from baseline. At baseline, patients on average were using 4.0 pads per day (PPD) (95% C: 2.6-5.4), which was reduced to an average of 1.1 PPD (95% CI: 0.5-1.7) after ProACT implantation. The number of patients that were considered “dry” was 60.2% (95% CI: 54.2%-65.9%) and the number of patients who were found to be either “dry” or improved greater than 50% was 81.9% (95% CI: 74%-87.8%). Across the analyzed patient populations, the average number of adjustments was 3.2, with mean reported final balloon volume of 3.1mL. A total of 18 studies had adverse event data available for analysis. The most common intraoperative complication during ProACT implantation was bladder or urethral perforation. The meta-analysis estimate for intraoperative perforation of the bladder or urethra was 5.3% (95% CI: 3.4%- 8%). Estimates for infection and urinary retention were 2.2% (95% CI: 1.1%-4.3%) and 1.5% (95% CI: 0.7%-3.4%), respectively. The estimated overall revision rate for all causes was 22.2% (95% CI: 15.2%-31.2%) with a mean follow-up of 3.6 years (range 12–118 months). The pooled estimate of either urethral or bladder erosions causing explant was 3.8%. The pooled estimate of migrations resolved by explant was 6.5%. The mean follow-up time was 3.6 years, with only one study having a mean follow-up greater than 5 years; although, many papers included patients with longer follow-up. More long-term data is needed to better determine long-term efficacy results of the therapy. Heterogeneity among included patient cohorts was a major issue. The median follow-up ranges, the number of patients per study, surgical technique, and management of complications varied greatly across the studies.

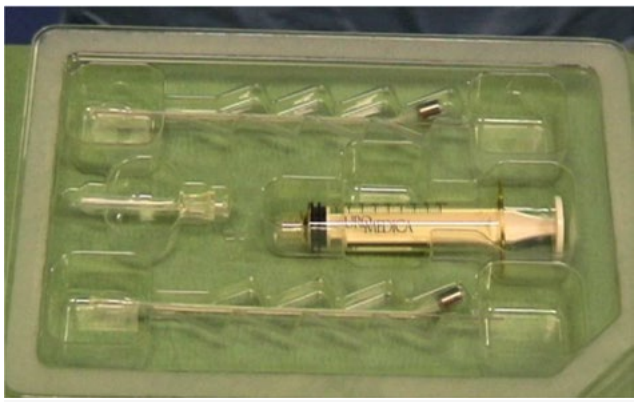

Figure 24. Adjustable Continence Therapy (Periurethral Balloons) surgical kit. Courtesy of Dr. Emmanuel Chartier-Kastler

Angulo et al[7] have also systematically reviewed the literature to compare ProACT to Adjustable Transobturator Male System (ATOMS) with respect to efficacy and safety. Combined data of 41 observational studies with 3059 patients showed that from an efficacy standpoint, there were lower dry and improvement rates for ProACT compared to ATOMS (55% vs 68%, *P*=0.01; 80% vs 91%, *P*=0.007, respectively). The decrease in mean pad usage and pad weights were significantly lower with ProAct compared to ATOMS (-2.5 vs -4 PPD, *P*=0.005; -211.4 vs -425.7 g, *P*<0.001, respectively. Furthermore, patient satisfaction was significantly higher for ATOMS (87 vs. 56%; *P*=0.002). The complication rate for ProACT was also higher, but not statistically significant (17 vs. 26%; *P*=0.07); although, the explant rate was significantly higher with ProACT (24% vs 5%, *P*<0.001). While the mean follow-up was lower for ATOMS than ProACT (20.8 vs. 30.6 months; *P*=0.02), the rate of working devices favored ATOMS at 1-year (92 vs. 76%; *P*<0.0001), 2-years (85 vs. 61%; *P*=0.0008) and 3-years (81 vs. 58%; *P*=0.0001). Significant heterogeneity was seen among the studies, thought mainly due to variable incontinence severity baseline. Other issues identified were differing criteria for reporting of complications, different number of adjustments and time of follow-up and absence of randomized studies.

Of interest while these two reviews note similar efficacy outcomes the complications rates listed are somewhat different. **Periurethral balloons are a feasible minimally-invasive option for treatment of bothersome PPI. However, high complication rates have been reported (Level of evidence 3-4; grade of recommendation C). Heterogeneous data suggest that periurethral balloons were less effective than an adjustable TO sling (LE 3, GR C).**

Figure 25 (A and B). Adjustable Continence Therapy (Periurethral Balloons) surgical technique. Courtesy of Dr. Emmanuel Chartier-Kastler.

Most studies focused on ProACT for post-radical prostatectomy urinary incontinence. However, one recent publication assessed the use of ProACT for incontinence after TURP. Adjustable continence balloons were implanted in 29 patients with post-TURP SUI between 2007 and 2018. Continent status was defined as no pad or one security pad. Preoperative urinary incontinence was mild in 7 (24%), moderate in 12 (41%), and severe in 10 (35%) patients. The median follow-up duration was 21 (IQR, 11–43) months. Within 30 days postoperatively, a Clavien-Dindo grade less than or equal to II complication occurred in 24% of the patients. Reintervention rate was 24%. Six and 12 months after implantation, the International Prostate Symptom Score (IPSS) quality-of-life item improved significantly from 5 (IQR, 5-6) preoperatively to 3 (IQR, 1-4.5) and 1 (IQR, 0-3), respectively. At last visit (median 21 months after implantation), the outcome on continence had improved in 76% of the patients, including, 45% dry patients. After a median follow-up of 28 months (IQR, 13-63; N=23), all but one patient reported improvement on the PGI-I scale. In detail, 10 patients reported "very much better" condition compared with before the implantation, 10 patients "much better," two patients "a little better," and one patient "no change." Daily pad use decreased from three (IQR, 2-5) to one (IQR, 0-2) pads/day (P<0.001).

Due to the paucity of data, no definitive recommendation can be made on ProACT for SUI after surgical treatment of benign prostatic obstruction.

6. FUTURE DIRECTIONS

6.1. New Technologies Under Evaluation

6.1.1. Introduction

Despite the advances in the surgical treatment of PPI, both slings and AUS present limitations in terms of continence rates and complications. With greater than 100,000 prostatectomies performed per year with a 9–20% risk of incontinence, treatment of PPI is a common clinical issue treated by urologists.[2,] This context makes room for the development of new technologies and minimally invasive treatments.

6.1.2. AMS 800 Innovations

While the AUS has not been modified or updated significantly for more than two decades, Boston Scientific and other manufacturers are working on new AUS concepts. Current research and development are focused on changes in the activation and regulation mechanism. In the future, the manual pump may be discarded in favor of a Bluetooth controlled automatic filling/emptying mechanism.

Newer engineering developments in electronics and remote-control focus on innovative activation mechanisms, which are designed to meet the needs of individual patients. For instance, if a patient needs more pressure for a specific activity as in heavy lifting or straining, the electronic actuator could be programmed to meet that need.[658] Furthermore, these electronic actuator may increase the longevity of device with the possibility of "deactivation" during the nighttime to reduce urethral atrophy from constant cuff compression. These developments are closely related to the advances in lithium battery technology with batteries rated to last up to 16 years,

Using these concepts, Biardeau et al[16] proposed different options for an electronic control system for the AMS 800 AUS. Possible working mechanisms for remote-controlled electronic artificial urinary sphincters would include:

a) "Closed" state: the cuff is inflated, and the pump is unpowered; the pressure is equilibrated between the pressure-regulating balloon and the cuff, allowing to maintain a constant predetermined occlusion closure pressure (OCP) as long as necessary;
b) Cuff deflation: as soon as a Bluetooth connection is established, the microcontroller activates the pump; the fluid is then transferred from the cuff to the balloon;
c) "Open state": the cuff is deflated, and the pump is unpowered.
d) Cuff inflation: as soon as decided via the control interface, the fluid progressively flows back to the cuff in 2–3 min thanks to the hydraulic resistor, returning to a "closed" status.

Many of these modifications, which are currently being researched by the companies, remain in development and are proprietary.

6.1.3. ZSI 375 (Zephyr Surgical Implants)

Over the past several years, the Zephyr artificial sphincter device (Zephyr ZSI 375; Zephyr Surgical Implants, Geneva, Switzerland) has been investigated and results have been recently reported. Like an AMS 800 AUS, the ZSI 375 is a hydraulic device with a fluid filled cuff that wraps around the urethra and a pump mechanism to deflate the cuff for voiding. Unlike an AMS 800, the ZSI 375 is a one-piece device with the cuff being connected by a tube to a pump and pressure regulating tank. The cuff is adjustable with a strap that can be set to different levels of tightness (like a belt) and the amount of fluid in the system can be adjusted postoperatively as needed via an injection port transcrotally. There is no abdominal reservoir. Unlike the AMS 800, the ZSI 375 allows for readjustment of cuff tightness in the case of postop urethral atrophy. However, there are only a limited number of peer reviewed publications.

Staerman et al[598] evaluated 36 patients who underwent a ZSI 375 device placement. The median (range) follow-up was 15.4 (6–28) months. Social continence (0 or 1 pad per day) was achieved in 28/36 patients (78%) at 3 months and 26/36 patients (73%) at 6 months after device activation. No patient experienced bladder overactivity, chronic urinary retention, or any other adverse effect after device activation. Complications leading to device removal arose in four patients (one case of erosion, three cases of infection).

Kretschmer et al conducted a multicenter study to assess ZSI 375 efficacy and safety in men with stress urinary incontinence. Thirteen patients underwent implantation of a ZSI375 artificial urinary sphincter device between 2010 and 2012 in three international continence referral centers. Median follow-up was 13.5 months. Mean daily pad usage decreased from 5.8 ± 1.5 to 2.4 ± 2.1 (P=0.066). One patient (7.7 %) did not use any pads. Social continence (0-1 pads) was achieved in only 15.4 % of the patients. In this period, four device defects (30.8 %) were observed, and were the main cause for device explantation, followed by device infection (15.4 %), non-resolving pain (7.7 %), and urethral erosion (7.7%). Overall explantation rate was 61.5 %. Mean time-to-explantation was 279 ± 308 days. There was no significant influence of previous irradiation or previous invasive incontinence therapy (P=0.587 and P=0.685, respectively).

Llorens and Pottek reported medium-term results and reported on 106 patients with a mean age of 72 years and followed up for 24 months. They found a 91.8% success rate with 83.6% of patients dry. There were 4 infections, 19 erosions, and a total of 24 patients required explantation. There were three mechanical malfunctions caused by intraoperative sphincter cuff damage.

Ostrowski et al reported on fifty patients followed for a median of 21.04 months. There were 12 explantations (9 erosions, 3 mechan-

ical malfunctions, and 0 infections). Outcomes were 0–1 pad per day 29/50 (58%), and there was improvement to 50% of preoperative pads per day 15/50 (30%) and failure in 6/50 (12%).

More recently, in a multicenter, retrospective review of 109 patients with "severe" incontinence (≥4 pads per day) and mean follow-up of 43 months, Ostrowski et al[600] reported daily pad usage decreased significantly to 0.84 pads per day with 19% achieving total continence, 65% social continence (0–1 pads per day), 8% improved (<less than 2 pads per day and 50% fewer pads than at baseline) and 7% failures (≥4 pads per day). Complications were noted in 12 (11%) patients with cuff erosion in 9 (8%) and mechanical failure (fluid leak) needing surgical revision in 3 (3%). There were no device infections.

This device is currently available in selected Western countries (not in USA) and is not promoted in Asia or Africa. While long-term data on clinical efficacy and safety are lacking, but the data available show some promise for the Zephyr ZSI 375.[658]

6.1.4. ContiClassic aus (Rigicon, USA)

The ContiClassic AUS (Rigicon, USA) is a new non-adjustable AUS similar to the AMS 800 in terms of design and mechanism of action. However, it has 2 potential advantages over the current AMS 800 namely a more diverse occlusive cuff sizes (increments of 0.25cm) and a hydrophilic coating on all external surfaces of the device allowing for individualized use of antibiotic and subsequent drug elution into the implant spaces. As this product is new, the data on clinical outcomes is accruing.

6.1.5. BR-SL-AS-904 Device

Another new design of the classic hydraulic AUS model BR-SL-AS-904 was recently reported from Brazil. Like the VICTO+, this modified AUS has a pressure transmission system with a reservoir placed in the abdominal cavity with connection with the inflatable urethral cuff. Any increase in pressure on this reservoir is transmitted through the hydraulic system to the urethral cuff, allowing increased pressure and preserved continence during stress-related increases in abdominal pressure. The authors have reported on 15 patients followed up for >1 year. Pad weight test had a mean change from 75.72 to 23.50g. ICQF - SF score also showed a decrease, ranging from 16.71 to 7.33. There were no infections; although, 27.2% of the devices were removed for mechanical complications with a 4% urethral erosion rate. Again, longer-term data is missing and further multicentre trials will be required to evaluate its clinical outcomes.

6.1.6. Stem Cells

Periurethral bulking using permanent injectable material has generally proven inefficacious for treating male ISD, due to non-incorporation of the injectate into functional tissue. In an effort to create a more functional urethral bulking, the use of stem cells has been studied and reported on in females with SUI. Currently, two studies looking at stem cells for male stress urinary incontinence are listed on clinical trials.org as enrolling patients. One evaluating the use of autologous adipose derived regenerative cells is run through Nagoya University and the other utilizing autologous muscle derived stem cells is run through Cook Myosite. While the use of stem cells to treat male SUI is very attractive, data collection and evaluation are still in progress and its use outside of a clinical trial cannot be recommended. Furthermore, the exact mechanisms of action and longer-term safety data are largely unknown.

V. REFRACTORY DETRUSOR OVERACTIVITY/SPECIFIC SURGERY FOR OVERACTIVE BLADDER

1. OAB

1.1. Prevalence

Overactive bladder (OAB) is a symptom complex characterized by urinary urgency, usually accompanied by increasd daytime frequency and/or nocturia with urinary incontinence (OAB wet) or with (OAB dray) in the absence of urinary tract infection or other detectable disease.[35] Quality of life is adversely affected in 65% of patients with OAB. According to the 2001 study by Milsom's group, which is a population-based study out of the United Kingdom, Sweden, Spain, Italy, Germany and France of 16776 randomly selected women and men, the overall prevalence of OAB symptoms was 16.6%. In men the prevalence was 15.6% versus 17.4% in women. Most storage symptoms were similarly prevalent regardless of gender, but urgency urinary incontinence (UUI) was more common in women than men. The 2003 National Overactive Bladder Evaluation study focused on men and women in the United States, reporting that 16% of men and 16.9% of women suffered OAB. Regardless of age, women experienced UUI at higher rates than men. Interestingly, whereas higher BMI was associated with a higher prevalence of UUI in women, no such association was found in men. The 2006 EPIC study regarding lower urinary tract symptoms and OAB surveyed 19,165 adult men and women in the United Kingdom, Canada, Germany, Italy, and Sweden by telephone. Prevalence rates of 12.8% in women and 10.8% in men were reported. Women were nearly three times more likely to have incontinence (13.1% vs 5.4%), but with respect to UUI, prevalence was similar regardless of gender. The 2011 EpiLUTS (Epidemiology of Lower Urinary Tract Symptoms) study surveying men and women from the United States, Sweden, and United Kingdom reported that 15.8% of men and 32.6% of women complained of OAB symptoms "often", with women having a higher rate of UUI. The 2018 LURN (Symptoms of Lower Urinary Tract Dysfunction Research Network) found that the prevalence of incontinence in men seeking urologic care was 51%, with post-void dribbling reported by 41% and UUI by 29%. SUI occurred in 3–4%. The inclusion of men who were already seeking urologic care, and the inclusion of post-void dribbling under the umbrella of "incontinence" skews this survey toward a higher rate of incontinence compared to previous reports. Initial management of OAB involves behavioral therapy, pelvic floor physiotherapy and/or medications (See chapter on surgical management of OAB).

1.2. Refractory OAB/UUI

In men with OAB/UUI who do not respond or do not tolerate pharmacotherapy, further treatment with peripheral tibial stimulation, chemodenervation with botulinum toxin and sacral neuromodulation should be considered (See chapter on surgical management of OAB). The possibility of occult neurogenic voiding dysfunction or undiagnosed bladder outlet obstruction (BOO) must be considered in patients with refractory OAB. Refractory OAB is the term used for patients who have failed a trial of symptom-appropriate behavioral therapy of sufficient length to evaluate potential efficacy and for those who have failed a trial of at least one anti-muscarinic medication administered for 4 to 8 weeks. Failure of an anti-muscarinic medication may include lack of efficacy and/or inability to tolerate adverse drug effects. For further information on OAB, including neuromodulation techniques and botulinum toxin, please refer to

chapter 11 (Surgery for Urinary Incontinence in Women) and 12 (Neurogenic Patients), respectively.

2. NEUROGENIC VOIDING DYSFUNCTION

Neurogenic bladder results from a variety of congenital or acquired conditions that can adversely affect the central or peripheral nervous system. Storage and voiding dysfunctions typically vary with the level of the neurological lesion. In general, UUI is more likely with a suprasacral lesion than with a sacral lesion, due to augmentation of the purinergic signaling pathway. Unlike in the bladders in neurologically intact men, where cholinergic innervation predominates, there is an increase in purinergic innervation in the setting of suprasacral neurologic insult. This abnormal elevation of P2X2 receptor density, characteristic of suprasacral spinal cord injuries, may inhibit the parasympathetic release of acetylcholine.

Neurologic disease affecting the areas of the brain associated with bladder control can cause UUI in the absence of other neurologic dysfunction. It has been generally established that the periaqueductal gray and pontine micturition center regulate voiding control in the brainstem, after receiving coordinated suprapontine signaling from the thalamus, insula, and frontal lobes.[1] The subcortical circuit consists of the hippocampal and paralimbic regions, permitting initiation of voiding when the brain judges that it is safe to void. The neurologically intact man can postpone voiding until he deems it appropriate. This inhibition may be lost in the setting of neurologic dysfunction of any of these brain or pontine regions. Part of this inhibition relies on bladder sensory information (including urgency) being properly registered in the midcingulate circuit from the periaqueductal gray to the supplementary motor area and dorsal anterior cingulate cortex. After registering urgency, pelvic floor and urethral sphincteric tone can be autonomically increased. Dysregulation of this suppression of the bladder can result in UUI.

Men with lumbar disc disease may suffer from UUI. However, unlike those with idiopathic OAB, these men will typically have lower back pain. More than half of such men will complain of storage and voiding symptoms, with nearly 50% demonstrating urodynamic abnormalities. While the most common finding is detrusor underactivity, DO may also be observed. As UUI is often a symptom manifesting from a combined abnormality of bladder activity and pelvic floor weakness, it is not surprising that perineal floor muscle innervation is often abnormal in the setting of lumbar disc disease. While chronic nerve damage typically results in bladder insensitivity and detrusor atrophy, early nerve root stretching can initially cause neurogenic DO. Detrusor overactivity with UUI can result from irritation of the sacral roots, especially with walking. Approximately half the time, the UUI resolves with lumbar disc surgery.

3. DIABETIC VOIDING DYSFUNCTION

Diabetes can also cause OAB symptoms with UUI. There appears to be a progression from DO as a cause for OAB in earlier and milder cases of diabetes mellitus, progressing to diabetic cystopathy over time, manifesting as impaired contractility and inefficient bladder emptying as a cause for bothersome urinary symptoms including overflow and urgency incontinence. Kebapci et al showed that in a group of 27 men with diabetes mellitus, urodynamic demonstration of bladder dysfunction was present in nearly 75%. Diabetic cystopathy was most common (50%) followed by an equal prevalence (25%) of BOO and DO. Diabetic cystopathy was most common in older men (> 64 years old), those with longer duration of disease (> 9 years), and with HbA1C > 7.9%. Elevated post void residual urine > 100 ml was associated with more severe disease, namely in men with autonomic neuropathy (delayed gastric emptying and cardiac conduction abnormalities) and with retinopathy and microalbuminuria.[679] In another study of 57 men, Majima, et al confirmed that more mild and early disease was characterized by DO with preserved contractility, while impaired contractility was most prevalent in men with diabetic retinopathy and nephropathy.

4. BLADDER OUTLET OBSTRUCTION

Although the prevalence of OAB symptoms in men and women is generally comparable, in men the symptoms are often attributed to bladder outlet obstruction (BOO), while in the absence of high-grade pelvic organ prolapse or prior suburethral sling, bothersome storage symptoms are rarely attributed to BOO in women. This difficulty differentiating between UUI due to detrusor overactivity (DO) with or without BOO related to benign prostatic enlargement (BPE) based on symptoms alone can lead to a diagnostic dilemma. As a significant minority of men with storage symptoms indeed do not suffer from prostatic obstruction, misdiagnosis can result in delayed and inefficient treatment, exacerbating the negative impact on quality of life caused by UUI in men. In the absence of a weak urinary stream, hesitancy, straining, and incomplete emptying, clinically relevant BOO is unlikely, yet only a minority of men with OAB symptoms are treated with detrusor-directed therapy.[11]

Men with BPO often suffer from mixed voiding and storage symptoms. Half of men with BPO complain of bothersome storage symptoms including UUI,[11] and in a significant minority (approximately 20-40%), the incontinence will persist following de-obstructive surgery.[340,343]

The use of detrusor-directed therapy in men with bothersome storage symptoms induced by BPH carries the theoretical risk of precipitating urinary retention. And with the risk of cognitive impairment in older patients taking anticholinergic medication, medical treatment has generally focused on alpha blockers with or without 5-alpha reductase inhibitors. Kaplan et al reported that the beta-three agonist mirabegron was both efficacious and safe when taken as add-on therapy in men with overactive bladder symptoms receiving tamsulosin for LUTS due to BPH. Statistically significant improvements were noted in urinary frequency, urgency and urgency urinary incontinence in men taking mirabegron plus tamsulosin versus those taking placebo plus tamsulosin. There was only 1 instance of retention requiring catheterization in the treatment group while taking the medication, and minimal change in average post void residual urine.[688] A meta-analysis of the use of mirabegron for the treatment of bothersome storage symptoms in men with BPH demonstrated the mirabegron was effective in treating overactive bladder induced by BPH in men receiving tamsulosin therapy. The number of micturitions per day decreased, urgency episodes decreased and total OAB symptoms score decreased significantly, with a clinically irrelevant increase in post-void residual urine volume of 12.02 mL (95% CI: 6.02018.04, P<0.0001).

While there are no patient-specific or urodynamic findings that can predict resolution or persistence of UUI with certainty, there are

several risk factors that are associated with a higher prevalence or persistent or de novo UUI following de-obstructive surgery: advanced age, pre-operative bladder capacity <250 mL, and DO.[344] Those patients with higher amplitude and with more frequent (repetitive) uninhibited bladder contractions were at particularly high risk of persistent postoperative UUI. Reitz et al recently showed that a novel ice water test during urodynamics can more accurately predict the persistence of storage symptoms following prostate resection. Specifically, the majority with a positive response (DO in response to bladder filling with cold water) and a minority of those with a negative response had persistent storage symptoms.[691] Interestingly, new onset urgency and incontinence is more common following laser vaporization of the prostate than after transurethral electrocautery resection, but also more likely to resolve over time. *De novo* UUI was recently reported to occur in >40%, resolving in approximately half by one month, and in all patients by 6 months following photovaporization.[302] Patients with bladder outlet obstruction should be considered for either medical or surgical therapy to decrease the obstruction.

5. URETHRAL STRICTURE

Similar to men with prostatic obstruction, those with urethral stricture disease are also susceptible to bothersome storage symptoms. Urgency or incontinence after stricture surgery may represent persistent or recurrent stricture, unrecognized prostatic obstruction, or bladder dysfunction. In a large multicenter study of over 400 men with anterior urethral stricture, 58% of men had urgency and 31% had UI preoperatively, which decreased to 40% for urgency and 12% for UI (each $P<0.01$) post stricture repair. Overall, 37% experienced improvement in urgency and 74% in UI. *De novo* symptoms were rare, with only 9% and 5% developing urgency and UI postoperatively. Risk factors for symptoms persistence were older age and stricture recurrence. In McCammon's series, nearly 90% of men had resolution of urgency and incontinence following successful stricture repair. Herschorn et al reported similar results in his review of 439 men, of whom one-third had UUI preoperatively, with only 12% complaining of persistent UUI postoperatively, and 5% developing de novo leakage. In general, those with the most severe symptoms preoperatively had the greatest improvement. For those with postoperative UUI, evaluation should include assessment of urethral patency via uroflowmetry, measurement of post void residual urine volume, retrograde urethroscopy, and cystoscopy. In the absence of a stricture, treatment should follow the OAB guidelines. Failure to improve should prompt urodynamic evaluation to rule out proximal (prostatic) obstruction, dysfunctional voiding, or DO. [Incidence and management of lower urinary tract symptoms after urethral stricture repair.[693]

6. URGENCY URINARY INCONTINENCE FOLLOWING PROSTATE CANCER TREATMENT

Following prostate cancer treatment, SUI is much more prevalent than is UUI. With respect to prostate extirpation, the most common cause of incontinence is intrinsic sphincter deficiency. However, a minority of patients will develop new onset UUI. In a recent large cohort, 29% of men developed de novo storage symptoms following radical prostatectomy, and 6% had frank UUI. The main risk factor for urgency leakage was radiation (either adjuvant or salvage) secondary to radiation-induced bladder changes.

Urinary incontinence is rare after brachytherapy for prostate cancer. Between 4% and 5% of men will have new onset leakage, with UUI occurring in 3.2% and stress incontinence in 1.2%.[259] Stress incontinence is much more prevalent in men who undergo transurethral resection of the prostate following brachytherapy, occurring in 18 to 70 % of such individuals.[263,266,] The data relates to urinary incontinence following more movel prostate cancer therapy such as proton beam or nanoknife technology is accruing and at this stage, there is very limited published data in this emerging field.

7. VOIDING DYSFUNCTION AFTER TREATMENT FOR RECTAL CANCER

Both the disease itself and the treatment for colorectal cancer can also cause urinary incontinence. In a large German case-control study of 3249 individuals with rectal cancer, the majority of whom were male, 16.7% reported UI, compared to only 5.3% of men without cancer (HR 3.59, 95% CI 2.91-4.44). Karlsson et al prospectively followed more than 1000 patients with rectal cancer. At baseline, 14% of women and 8% of men reported urinary incontinence, which doubled at 1 year to 29% of women and 14% of men.[699]

Following XRT for rectal cancer, temporary urinary dysfunction is much more common in men than in women, but typically resolves over several months. Following abdominal perineal resection, nerve damage is a common and typically unavoidable complication. During rectal extirpation, the parasympathetic nerve supply is vulnerable during deep dissection of the lateral planes, while sympathetic nerves may be injured during presacral and ventrolateral dissection of the mesorectum. Following surgery, anastomotic leak can lead to an inflammatory response causing pelvic nerve damage. While urinary leakage following rectal cancer treatment can be due to overflow or sphincteric insufficiency, UUI is typically due to DO following sympathetic nerve damage.

VI. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE

A urethrocutaneous fistula (UCF) is a connection between the urethra and skin. The fistulous opening is typically located on the penis, scrotum or perineum. A rectourethral fistula (RUF) connects the lower urinary tract and the distal rectum. Both types of fistulae can be either congenital or acquired, with the latter being much more common. Most acquired fistulae are iatrogenic in nature, and can lead to significant deterioration in quality of life including urinary incontinence if the fistula is suprasphincteric or associated with underlying sphincteric deficiency or *de novo* overactive bladder. Both conditions require a high index of suspicion for diagnosis, and can be readily identified with proper radiographic and endoscopic evaluation. Whether congenital or acquired, spontaneous closure is atypical, and most instances of UCF and RUF will require surgical repair.

It is important to recognize the varying causative factors, as the diverse etiologies (such as surgical versus radiation induced fistula) lend themselves to different surgical approaches to achieve satisfactory treatment outcome. More than three dozen distinct surgical techniques have been described in the literature, ranging from transanal to transabdominal, and from endoscopy to laparoscopy to open surgery. To date, there are no randomized studies, and

there is a lack of consensus regarding the "best" surgical approach. While the type of reparative surgery chosen is often related to the surgeon's familiarity with a specific procedure, the wide variety of approaches are characterized by different pros and cons, and should be considered in relation to the diverse etiology of UCF and RUF formation. For further information, please refer to chapter 13.

1. URETHROCUTANEOUS FISTULA (UCF)

1.1. Congenital Urethrocutaneous Fistula

Congenital anterior UCF is rare, with less than 65 reported cases in the literature. While a distinct embryological error causing UCF has not been characterized, these fistulae are thought to result from abnormal infolding of the urethral groove or from congenital urethral plate defects.

1.2. Acquired Urethrocutaneous Fistula

UCF is more typically an acquired rather than a congenital condition. With the increased utilization of gender confirmation surgery, urethrocutaneous fistula following phalloplasty or metoidioplasty is becoming more and more common. Retained vaginal remnant can lead to a urethral diverticulum, which, if untreated, can ultimately fistulize. Rarely UCF can occur following prostate cancer treatment, with an incidence of up to 0.4% after radical perineal prostatectomy, but as high as 10.7% following open perineal prostate cryosurgery. There have been case reports of UCF related to invasive fungal infection, genital tuberculosis, self-instrumentation of the urethra, urethral stones, circumferential penile strangulation by a broken condom, and even following circumcision, and penile fracture surgery gone awry.

By far, the most frequent cause of acquired UCF is related to urethroplasty and hypospadias repair. Risk factors include the length of urethral defect/location of the hypospadiac meatus, patient age, prior urethral surgery, and utilization of a single-layer closure during precedent surgery. With more proximal hypospadias, the risk of postoperative UCF formation is 1.3–1.5 times higher than with distal hypospadias repair.

Age is also a risk factor, with adolescent and adult patients having a higher risk of fistula formation postoperatively than younger boys.[739,740] This is most likely related to more frequent erections in adolescents and adults versus young children. More recently, Sheng's group reported that in their large cohort of Tanner 4 and 5 adolescents, age did not matter, nor did degree of chordee, but prior surgery and a longer defect length did indeed predispose to post-operative fistula.[741] A recent meta-analysis demonstrated that for distal hypospadias repair, the Mathieu repair had a lower risk for urethral stricture than did the tubularized incised plate repair, but the fistula rate was 13% in both groups. With repeat hypospadias repair, the fistula rate has been reported to be three times higher (18.6%) than with primary surgery (5.1%). Moreover, the incidence is substantially lower with a double-layer coverage (0.6%) compared to 5.1% with single-layer coverage only.

1.3. Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography or voiding cystourethrogram (Figure 26), urethroscopy, fistulography, urethral ultrasound, or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess.

Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure. In addition, based on a recent meta-analysis by Fahmy et al, it appears that the use of a tunica vaginalis flap rather than a dartos flap has a higher success rate, with the former having a recurrent fistula rate of only 5.1% versus 12.2% in the latter.[745]

2. RECTOURETHRAL FISTULA (RUF)

A rectourethral fistula is a connection between the lower urinary tract and the distal rectum. Rectourethral fistulae are typically grouped according to etiology: congenital, traumatic, neoplastic, inflammatory and iatrogenic. This condition can be devastating, resulting frequently in fecaluria, urinary incontinence, recurrent urinary tract infections, and pain. Congenital RUF is typically related to imperforate anus. Acquired RUF can form from penetrating trauma, but is more commonly iatrogenic.

2.1. Congenital Rectourethral Fistula

Endo et al described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from 1976 to 1995 were analysed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be catego-

Figure 26. Voiding cystourethrogram after incision

rized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down´s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights.[752]

With respect to surgical outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) compared to that of posterior sagittal anorectoplasty (PSARP), Rintala et al reported that in boys with high anorectal anomalies, PSARP was superior to SP-SAP pull-through in terms of long-term bowel function and fecal continence. More recently, the German network for congenital uro-rectal malformations evaluated postoperative urological complications in 267 patients with anorectal malformations (recto-urethral fistula in 21 cases). According to type of operation, the highest number of postoperative urologic problems was reported after abdominosacroperineal pull-through.

2.2. Acquired RUF

While there are multiple causes for acquired RUF (See Table 4), the most common causes are penetrating trauma and iatrogenic.

2.2.1. Penetrating Trauma

With penetrating colorectal or genitourinary trauma, depending on the nature of the injury, RUF can form in 0–18% of instances.[,,,,] The risk of fistulization increases as the degree of rectal wall involvement surpasses 25%, and such substantial rectal wall involvement is characteristic of the majority of colorectal injuries suffered during wartime.

A high level of suspicion is necessary to diagnose concomitant genitourinary (GU) and rectal injuries. While hematuria is generally seen in patients with bladder or urethral injuries (sensitivity > 93%),[758] rectal injury can be occult, with only 25% of cases manifesting blood per rectum. Gunshot wounds to the GU or gastrointestinal (GI) tracts are generally associated with a high rate of multiple organ injuries. With gunshots to the urinary tract, up to 60% of patients have intestinal injuries and up to 34% have rectal injuries.[757,] In trauma victims presenting with a small bowel, colonic or rectal penetrating trauma, nearly half have an associated bladder injury.[757] Meticulous evaluation is often necessary to diagnose an acquired traumatic RUF. In the stable patient, a triple-contrast CT (oral, intravenous and rectal contrast) is generally 100% sensitive and 96% specific in diagnosing concomitant GI and GU injuries, which is substantially higher than direct proctoscopy. In the case of a missed injury, RUF occurrence is typically heralded by the symptoms of pneumaturia, urine per rectum, or recurrent/persistent urinary tract infection.

TABLE 4. Etiology of Acquired RUF

External Traumatic	Iatrogenic
• Penetrating trauma (gun, bladed weapon) • Polytrauma (complex pelvic fracture with pelvic visceral injuries)	• Lesions associated with prostate cancer treatment (surgery, radiotherapy, cryotherapy, HIFU, etc.) • Lesions associated with rectal cancer treatment (surgery, radiotherapy) • Other: ◦ Prostate-related: TURP, biopsy, infection ◦ Bowel-related: inflammatory bowel disease, anorectal pathology, etc.

2.2.2. Iatrogenic RUF

RUF can relate to complications of surgery (of the prostate or rectum), radiation or other ablative energy applications to the rectum or prostate (Figure 27).

While more commonly associated with treatment of malignant disease, RUF can be an uncommon result of therapy for benign disease. RUF can occur following cautery injury during TURP, and presents with urinary leakage per rectum, pneumaturia, fecaluria, and unexplained diarrhea.[,] (Figure 28).

Following Holmium laser enucleation, RUF is believed to occur due to delayed thermal or infectious reaction. Even more rarely, RUF can result from infectious or inflammatory processes.[,,]

RUF can occur following repeated prostate biopsy,[703,] and rarely secondary to severe invasive infections, such as pseudomonas prostatitis or Fournier's gangrene with aggressive debridement of necrotic tissue.[,]

RUF can also form when the large bowel is affected by inflammatory bowel disease, with several reports of RUF in patients with Crohn's disease.[,,] There have even been reports of fistula formation following sclerotherapy for hemorrhoids, as well as following transurethral resection of the prostate for benign prostatic obstruction.[765,766]

Whereas in prostate surgery, there is intentional incision (and anastomosis) of the bladder and urethra, and accidental injury to the rectum, RUF can also complicate transanal endorectal pull-through, with intentional incision and anastomosis of the rectum and accidental injury of the urethra. The largest series of such iatrogenic RUFs was reported in 7 patients who had surgery for Hirschsprung disease.

Iatrogenic RUF can occur most commonly from complications secondary to rectal or prostate cancer treatment. The incidence of acquired RUF has increased over the past 20 years, primarily due to the increased utilization of multimodal therapy for the treatment of high-risk prostate cancer. The use of high dose radiation combined with surgery and other ablative techniques correlates with a dramatic change in RUF etiology, from primarily surgical to largely related to nonsurgical causes. Up until 1997, in 315 reported cases of RUF, only 3.8% were due to radiation.[,,,,] In contrast, in more contemporary series, approximately 50% occur following radiation or ablative therapy for prostate cancer.[750,,,,,,,,,,,,,]

2.2.3. Treatment for Rectal Cancer

In addition to radiation for prostate cancer, there are reports of RUF occurring as a complication of radiotherapy for rectal cancer.

2.2.4. Treatment for Prostate Cancer

The vast majority of acquired RUF arise from complications secondary to treatment for adenocarcinoma of the prostate. With the increasing utilization of multimodal therapy for high risk and recurrent prostate cancer, the occurrence of RUF is increasing, with a current incidence of 0.5–12% following multimodal prostate cancer treatment.[703,,] With respect to radical retropubic prostatectomy (RRP), the incidence of RUF is higher following salvage treatment than with primary surgery. The incidence of rectal injury is generally 1–2% in primary surgery,[,,,] but is double that rate with RRP after prior radiation or ablative therapy, or previous rectal surgery or transurethral resection of the prostate.[783,799,,,,,,,] The higher rate of rectal injury coupled with the ischemic changes and reduced tissue elasticity following these aforementioned treatments increases surgical failure rates for repair of recognized rectal injury, thereby increasing

the risk of RUF formation. In cases of an unrecognized rectal injury during salvage surgery in the radiated patient, a resultant fistula is highly unlikely to resolve spontaneously.[797,798,,]

Local therapy for T1-T2 non metastatic prostate cancer is associated with a greater than 90% ten-year disease specific survival.[210] Thus, potential toxicity and quality of life following treatment are principal considerations in selecting therapy. However, for the treatment of more advanced cancer, there has been an increase in the use of higher risk multimodal and salvage therapies over the past two decades. As a result of the utilization of these higher risk therapies, the incidence and complexity of fistulas has increased substantially.[801,] Unfortunately, the use of a hydrogel injection system to inject synthetic polyethylene glycol hydrogel between the prostate and rectum prior to radiotherapy, which is designed to reduce the risk of rectal toxicity from radiation, can actually cause RUF if improperly injected.

Figure 27. Cystogram demonstrates a rectourethral fistula that occurred after a laparoscopic radical prostatectomy.

Additional risk factors for postoperative RUF include locally advanced cancer, whereby adherence of the prostate to the rectum and the need for a wider surgical margin likely contributes to rectal injury, as well as prior ablative therapy, rectal surgery, or a history of bacterial prostatitis or transurethral resection of the prostate.[783,787,799,805,809,811,812,,] Interestingly, in the series reported by Thomas et al, diabetes, previous bladder surgery, and use of hormonal ablation were *not* risk factors predisposing to RUF formation.

In 1972, Smith and Veenema reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only four fistulas developed in this group. Roberts et al published a series of 11,452 men who underwent open (RRP) or laparoscopic (LRP) radical prostatectomy. Rectal injury occurred in 18 men—12 in the RRP group (0.12%) and six in the LRP group (0.47%). When recognized intraoperatively and primarily repaired, rectourethral fistula was prevented in 87.5% of men. Primary repair performed with vascularized tissue interposition prevented rectourethral fistula development. In men with unrecognized rectal injury, the rectourethral fistula tended to persist and eventually required delayed surgical repair.[821] Thomas et al[819] reported that rectourethral fistulas developed in 13 of 2,447 patients (0.53%) after RP.

Noldus et al reported 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino summarized the incidence of rectal injury during RRP in 3834 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4 %.[823]

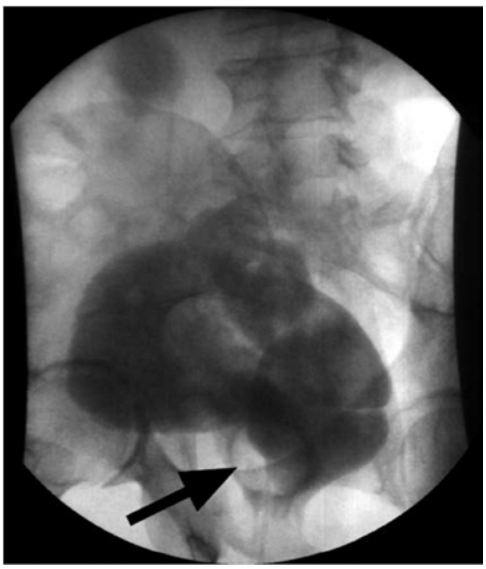

Figure 28. A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder.

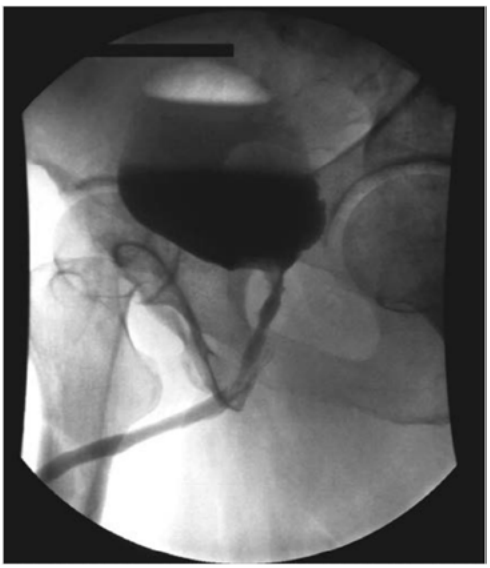

Figure 28. B. Retrograde urethrogram after transperineal closure of RUF.

With external beam XRT, brachytherapy, cryotherapy, and combination therapy, the risk of RUF is substantially higher than with RRP, generally ranging from 0.1-6%.

2.2.4.1. Salvage Radical Prostatectomy

RUF can result from unrecognized (or recognized but insufficiently repaired) injury during RRP. While the rate of rectal injury is quite low for patients undergoing primary RRP, generally in the range of 0-4%, it has been reported as high as 9% in patients undergoing prostate extirpation following radiation treatment, although there may be improvement in the complication rate more recently. Gotto et al[835] assessed data of 3,458 consecutive patients who underwent open radical prostatectomy and 98 who underwent open salvage radical prostatectomy from January 1999 to June 2007. The catheter was routinely left indwelling for 3 weeks after SP to allow healing of irradiated tissue. Postoperative cystography was done more often in patients with SP (36% vs 2%, *P*<0.001). The salvage group had a higher adjusted probability of medical and surgical complications, including urinary tract infection, bladder neck contracture, urinary retention, urinary fistula, abscess and rectal injury. There was a significant association between rectal injury and subsequent urinary fistula after SP but not after RP. In the SP group fistula developed in 2 of 9 men with (22%) vs. 2 of 89 without (2%) rectal injury (*P*=0.041). In the RP group fistula developed in 0 of 21 men with (0%) with vs 2 of 3,435 without (0.06%) rectal injury. There was also a significant association between persistent urine leak beyond 48 hours after surgery and subsequent fistula in the SP and RP groups. In the SP group fistula developed in 2 of 5 cases with (40%) vs. 2 of 93 without (2%) persistent leak (*P*=0.012). In the RP group fistula developed in 2 of 79 cases with (2%) vs. 0 of 3,379 without (0%) persistent leak (*P*<0.001).[835]

The potential for cure with salvage RP must be balanced against the risks of substantial potential toxicities. These risks are greater in the salvage RP setting than in the de novo setting because of radiation changes in the operative field that may cause fibrosis, merging of tissue planes used for dissection, and poorer wound healing.

2.2.4.2. Primary XRT

With primary XRT, RUF is a rare event, occurring at a rate of 0-0.6%. **[**Following primary brachytherapy, RUF is slightly more common than with external beam radiotherapy, ranging from 0.3-3% of cases, but is generally less than 1% in most series.[750,797,825,] However, with combined external beam radiotherapy and brachytherapy, the rate of RUF is substantially higher, generally around 3%.[785,810,]

2.2.4.3. Salvage XRT

It appears that with salvage brachytherapy–that is interstitial radiation treatment in the setting of disease recurrence following external beam radiotherapy, RUF incidence is approximately four times higher, up to 12% in one series. Chrouser et al[797] identified a total of 51 patients with a history of external beam radiation for prostate cancer that subsequently had a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

2.2.4.4. Cryotherapy

With *primary* cryotherapy, RUF is reported to occur at a rate of 0.5-2%.[831,] With *salvage* cryotherapy, the incidence is slightly higher, with recent reports showing RUF rates ranging from just less than 1% to as high as 3.3%.[277,800,] Badalament et al managed one patient (0.4%) with a urethrorectal fistula after cryoablation therapy for prostate cancer. Zippe reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF.[842] Porter et al[724] found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow-up was 33.5 months and RUF occurred in 1%.[851] A more recent series showed a substantially lower rate of fistulization decreased to 0.55% with improvements in patient selection and technical improvements.

Aminsharifi et al[852] recently noted a learning curve with reduced RUF from 1.2% to 0.55% over the last several years, suggesting better patient selection and technical improvement. Gleason score ≥ 7, and preoperative urinary incontinence were the key demographic, clinical, and pathologic features associated with RUF formation in this study.[852]

2.2.4.5. High Intensity Focused Ultrasound

High intensity focused ultrasound (HIFU) as primary treatment for prostate cancer is associated with a relatively low risk of RUF of 0.1%. Focal HIFU also has a low risk of <1%.

HIFU has recently gained popularity as a salvage treatment for disease recurrence following primary radiotherapy.[854] HIFU is associated with the highest rate of RUF among all the commonly used ablative treatments. Fistula rates are wide-ranging, reported to occur in 0-16% of cases.

In one older series of salvage HIFU following external beam radiation, RUF developed in 6% of patients. HIFU following combined external beam and interstitial radiation had a very high fistulization rate in one small series, with three of five patients (60%) developing a post treatment RUF.[824] There has also been a recent report of RUF associated with HIFU as a salvage technique for local disease recurrence after RRP in the non-radiated patient. Montorsi et al reported a RUF after transrectal prostatic hyperthermia (43°C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month.

2.3. Clinical Presentation of RUF

After radical prostatectomy, RUF manifests during the peri-operative period, with one large series reporting a mean of 14 days (range 7–49 days) from RRP until RUF diagnosis.[819] In contrast, following radiation or ablative therapy, RUF typically occurs much later. On average, fistulization becomes evident 4 months post-therapy. In one report, RUF occurred as late as 14 years after the last radiation treatment.[810,]

Whereas surgically-induced RUFs typically are small, often located in the bladder neck/trigonal region and generally can be closed primarily, radiation/ablation induced fistula are larger (>2 cm), tend to involve the prostatic urethra, and are fibrotic, therefore often requiring a combination of onlay grafting and interposition muscle flap for closure. Lacarriere et al noted that the use of radiotherapy had a major negative impact on the prognosis of the RUF patient. Multimodal therapy for high risk prostate cancer with radiation and ablative energy across the rectal wall induces microvascular injury

with resultant mucosal injury and ischemia. This in turn can lead to ulcerations, perforations and fistulization. The anterior rectal wall is less likely to heal well given the fibrotic, and generally fixed tissue that is characteristic following radiation.[797] Thus, these radiation and ablative therapy-induced fistulas tend to be associated with a larger rectal wall defect, and they are not uncommonly associated with urethral or rectal stricture and concomitant urinary or fecal incontinence.[807]

2.4. Evaluation of Rectourethral Fistula

RUF is often suspected based on the patient's history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Other common symptoms may include hematuria, recurrent uti (often with fever), and lower abdominal pain.[819,,] On digital rectal examination, the fistula can often be palpated on the anterior rectal wall. Direct vision with proctoscopy, and methodical cystourethroscopy is recommended as well. Retrograde urethrogram and voiding cystourethrogram can definitively make the diagnosis of RUF, as the radiopaque contrast agent placed into the bladder usually appears in the rectum on X-ray following voiding.[764] Radiographic imaging is useful for definitive diagnosis, as well as determining the size and location of the RUF, but direct visualization with cystourethroscopy and anoscopy/proctoscopy is important to rule out local cancer recurrence and to assess vascularity and the viability of the surrounding tissue. Sa et al evaluated the value of three-dimensional spiral computed tomography/cysto-urethrography (CTCUG) in diagnosing posterior urethral strictures associated with RUF. The accuracy in determining the RUF was higher with CTCUG (93%) than with conventional urethrography (71%).[868]

Rectal ulcers are extremely common before frank RUF development, and fistulization may be hastened or induced by biopsy.[810] Shakespeare et al reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1455 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. Marguet et al[810] described 6 cases of RUF in patients treated with BT plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. *Thus, with the poor wound healing known to be associated with ablative and XRT, rectal biopsy for post-radiation proctitis or ulcers should be discouraged*.[815] While concern for colorectal carcinoma in patients with persistent bleeding and ulceration after radiation treatment is typically the indication for biopsy, it is the biopsy itself that may actually cause the RUF. The increased risk in rectal carcinoma following pelvic radiation does not manifest until 5–15 years later.[870,] Therefore, biopsy for radiation proctitis should be discouraged.

As there is a high rate of associated urethral and anal sphincter dysfunction, it is vital to assess for stricture and for continence. Cystourethroscopy can identify bladder neck contracture or urethral stricture. Assessment of sphincteric integrity is important for proper preoperative counselling, as repair of RUF will not restore continence in the setting of sphincteric insufficiency. Similarly, bladder compliance should also be evaluated in the radiated patient prior to surgical repair.

2.5. Therapy for RUF

2.5.1. Initial Management

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Conservative therapy may involve urinary and or fecal diversion.

Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others.[819] Gibbons stressed the need for a diverting colostomy for 3-4 months. In the multi-institutional series of 201 RUFs from Harris et al,[750] 35% of non-energy treated and 16.4% of the energy-treated patients did not have a bowel diversion.

Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

2.5.2. Surgical Approaches

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (e.g., omentum, gracilis muscle, or scrotal flap) have been described. Surgical approaches include transabdominal, transvesical, transperineal, or posterior (transanal or transsphincteric).

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Hechenbleikner et al[815] searched MEDLINE (PubMed, Ovid) and the Cochrane Library by using the term RUF. All studies were retrospective. Of the 569 records identified, 26 articles were included. Four hundred sixteen patients were identified, including 169 (40%) who had previous pelvic irradiation and/or ablation. Most patients (90%) underwent 1 of 4 categories of repair: transanal (5.9%), transabdominal (12.5%), transsphincteric (15.7%), and transperineal (65.9%). Tissue interposition flaps, predominantly gracilis muscle, were used in 72% of repairs. The fistula was successfully closed in 87.5%. Overall permanent fecal and/or urinary diversion rates were 10.6% and 8.3%. Most high-volume centers (>25 patients) performed transperineal repairs with tissue flaps in 100% of cases.

Rivera et al staged RUF as: stage I, low (less than 4 cm from anal verge and nonirradiated); stage II, high (more than 4 cm from anal verge and nonirradiated); stage III, small (less than 2 cm irradiated fistula); stage IV, large (more than 2 cm irradiated fistula); and stage V, large (ischial decubitus fistula). Diverting colostomy was performed for stages III to V 6 weeks before definitive therapy.

Some of the patients in addition to the RUF will also have urethral strictures that have to be managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions.[829]

In 2018, Martini et al from Italy, published a novel classification of RUF following prostate cancer treatment that was used to guide management. This classification is broken down by stage and grade. The stage is mainly based on the size of the fistula (< or > 1.5 cm) and on involvement of the urethral sphincter; the grade and definition of complexity depend primarily on the etiology and surrounding tissue condition. Lastly, they recommended assigning recurrent fistulae into the grade complexity. The precise RUF size can be estimated by calculating the greatest diameters at computed tomography-urography, cystography, or by digital rectal examination (e.g., >1.5 cm when the tip of a finger passes easily through the opening). This fistula size subdivision relies on the fact that fistula smaller than 1.5 cm rarely causes evident fecaluria or sepsis and therefore unlikely requires fecal diversion before definite surgery. Grade 0 fistula are secondary “only” to surgical trauma, grade 1 category includes RUFs after radiation, grade 2 - men after salvage therapies such as salvage RP and prostate ablation following non-surgical management of localized PCa. According to this classification, stage 1 G0 fistulas can be treated with a minimally invasive approach with no tissue flap interposition and no fecal diversion.[881]

More recently Mishra et al published a meta-analysis of 7 studies with 490 patients in order to validate the Martini staging system. They found that receiving radiation/ablation increased the risk of permanent bowel diversion by 11.1 fold, eventual fistula recurrence by 9.1 fold, and post-op urinary incontinence by 2.6 fold. Similarly, compared to a Grade 0 fistula, a Grade I fistula increased the risk of permanent bowel diversion by 9.1 fold, fistula recurrence by 20 fold, and post-op UI by 2.7 fold. Since there were some valuable variables that were not captured by the staging system, they recommended development of a more comprehensive system.

The surgical approaches including the numbers of reported patients are listed in Table 5.[749,751,764,811,812,820,822,874,875,879,,,,,,,,,,,,,,,,,,,,,,,,,,,,,]

2.5.2.1. Perineal Approach

In 1926, Young[886] dissected the rectum away from sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis,[887] in 1947, described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al[888] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al[769] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in Figure 28.

Vanni et al[872] reported results in 74 patients using anterior transperineal approach with a muscle interposition flap (usually gracilis), and selective use of a buccal mucosal graft urethral patch onlay. At a mean follow-up of 20 months 100% of nonradiated rectourethral fistulas were closed with 1 procedure while 84% of radiated/ablation rectourethral fistulas were closed in a single stage. 31% of the patients with radiation/ablation RUFs required permanent fecal diversion.

Samplaski et al[811] reported transperineal repair with gracilis muscle interposition in 13 patients with complex RUFs of varying etiologies. One patient developed recurrence. They demonstrated low morbidity with high success rates regarding fistula repair.

Voelzke et al812 divided the fistula cohort of 23 patients into 2 groups, including postoperative and energy ablative fistulas, respectively. They recommended rectal sphincter preserving transperineal repair as a successful surgical method to repair postoperative and energy ablative rectourethral fistulas. An interposition muscle flap should be considered in the setting of energy ablative rectourethral fistulas to increase successful outcomes.

In the largest series to date, Harris et al[750] reported results in 201 patients after prostate cancer treatment in a multi-institutional retrospective study. All had a transperineal repair with or without concomitant transabdominal approach. In the energy ablation group (104 men) 84% had bowel diversions compared to 65% in the post-prostatectomy group (97 men). An interposition flap or graft (muscle or omentum) was placed in >90%. The ultimate success of repair

in the ablation and prostatectomy groups was 87% and 99% with overall success of 92%.

Pratap et al[891] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF. All patients had successful RUF closure on cystourethrography. Pfalzgraf et al[904] assessed fistula recurrence rate and health-related quality of life (HRQL) after repair in a retrospective study of 17 patients treated for RUF after RP between 1993 and 2008. Fistula closure was abdominal in 10 patients, perineal in five and combined abdominal and perineal in two, some with tissue interposition. Perineal or abdominal fistula repair yields excellent success rates and high patient satisfaction.

Selph et al[892] confirmed that patients who require placement of an AUS after a perineal RUF repair seem to fare just as well as patients who undergo primary AUS implantation with no increased rate of complications postoperatively.

2.5.2.2. Posterior Sagital Approach

Kraske in 1885 described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccygectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumor-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson[893] used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

2.5.2.3. Posterior (Parascrococcygeal) Transsphincteric Approach

In 1969, Kilpatrick and Mason[895] updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated transabdominal or transperineal approaches to RUF (Figure 29).

It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum.[885] After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization.

After closure of the prostatic urethra, it is recommended that the full-thickness rectal wall flaps are close in a “vest over pants” technique (Figure 30). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles. Fengler and Abcarian[885] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al[751] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al[896] in the management of a case of the urethroprostato-rectal fistula after a gunshot wound.

Stephenson and Middleton[894] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transsphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin[907] reported preliminary experience with the transsphincteric, transanal surgical approach to correct acquired urethrorectal fistula in five men. Mean patient age was 56.6 years (range 37–72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1. The time from the diagnosis of urethrorectal fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethrorectal fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al[897] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn’s disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn’s disease and in another with ulcerative rectocolitis.

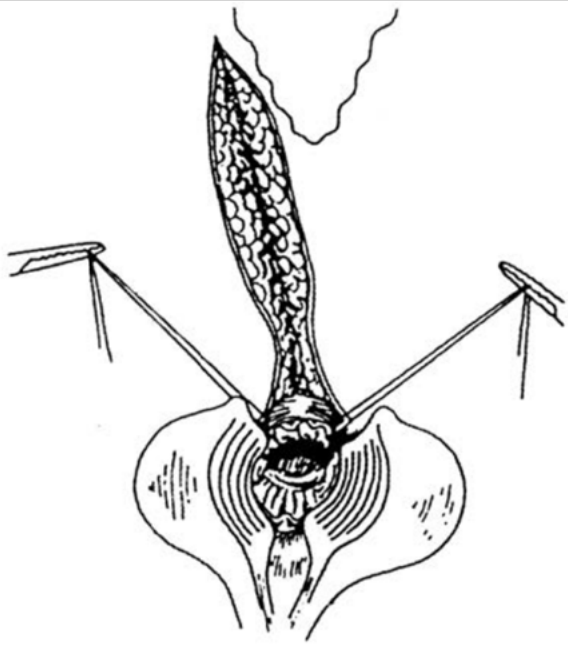

Figure 29. York-Mason approach to a rectourethral fistula via a parasacrococcygeal (transsphincteric) incision. Sutures are used to mark the sphincters. The speculum has been placed at the bottom of the incision and the anterior rectal wall is visible.

Erickson et al[875] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the exaggerated lithotomy position. In a modified prone

position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure.

Lorente et al[898] reported early successful closure in 10 patients with

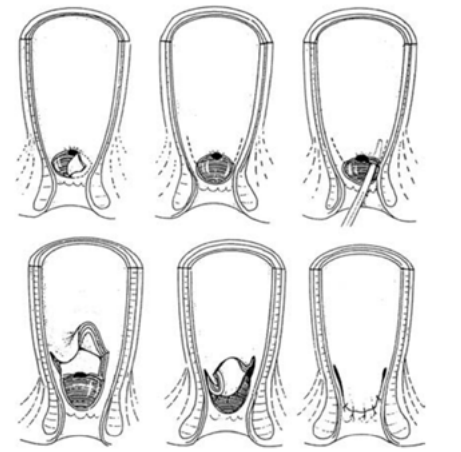

Figure 30. Rectourethral fistula repair. Full thickness rectal wall is mobilized to close in a "vest over pants" technique to close the fistula

the posterior transsphincteric York-Mason technique, with good recovery of urinary and fecal continence. Pera et al[899] reported on 5 patients successfully treated after RP with the York Mason technique. They reported minor morbidity and no impairment of continence.

Rouanne et al[900] reported 10 male patients with RUF due to radical prostatectomy who underwent York Mason repair between 1998 and 2009. All patients initially received both a urinary and a bowel diversion as the first step of the treatment. The second step consisted of a modification of the York Mason technique in which the approach began with a parasacrococcygeal incision extending from the coccyx to the anal verge. The mean time from surgery to York Mason repair was 15 (range, 4–42) months. All repairs were successful.

Kyrklund et al[901] aimed to define the long-term bowel functional outcomes following PSARP (posterior sagittal anorectoplasty) for RUF. They used validated Bowel Function Score (BFS) questionnaires mailed out to patients. Approximately one third of 34 respondents reported voluntary bowel movements (VBMs) and complete continence and 24% were reliant on anterograde continence enema (ACE) washouts, and 1 patient had a colostomy. Their results suggest that in the long-term, functional symptoms remain highly prevalent among patients treated for RUF with PSARP. However, the majority can be expected to achieve social continence.

Forest et al[902] retrospectively analyzed the data of 17 patients treated surgically for RUF with the York Mason technique between 2000 and 2012. All patients had a bowel diversion before surgery. They observed four recurrences of RUF (23.5%).

Van der Doelen et al reported on 28 patients who underwent 33 York-Mason procedures with concomitant graciloplasty in 4 primary and 2 secondary repairs. Success rates were 89% in and 50% in nonirradiated (18 men) and irradiated (10 men) respectively. Graciloplasty increased success rate in irradiated cases. No fecal incontinence was seen

Alam et al[903] from India prospectively reviewed the records of all the patients who developed RUF. A total of 18 patients were included and in all cases faecal and urinary diversion were done preoperatively. In 8 patients repair of fistula was done through the perineal approach where excision of the fistulous tract with anastomotic urethroplasty and repair of rectal wound was performed. Out of these 8 patients tunica vaginalis flap was applied in 3 and dartos pedicle flap in 5 cases; in the remaining 6 patients transrectal York-Mason repair was done. No patient developed urinary or faecal incontinence. Transrectal York-Mason repair is easier to do with less morbidity and complication while perineal approach with graft interposition may be done in cases where anastomotic urethroplasty is needed along with fistula repair.

2.5.2.4. Transanal Approach

Parks and Motson[906] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal (Figure 30 and Figure 31).

They modified the transanal technique by denuding the rectal mucosa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers´ fascia proximal to the fistula for four centimeters. Tiptaft et al[884] also used a special anal ring retractor for this surgery (Figure 32)

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al[822] reported 23 patients (3.9%) with rectal injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seven fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al[764] treated 30 men with RUF caused by war wounds. He used the method of posterior transsphincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in 'spontaneous' RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

Joshi et al[908] successfully used a rectal advancement flap in five patients with RUF.

Keller et al[874] introduced an algorithm-based treatment approach for RUF. Selective fecal diversion is possible, and the majority of patients who require definitive intervention can be treated with a transanal or transperineal (endorectal, dartos, or gracilis) approach. Only six patients (20%) required permanent urinary diversion or drainage catheters, but long-term urinary dysfunction is frequent. Healing rate was 90% and recurrence rate 0%.

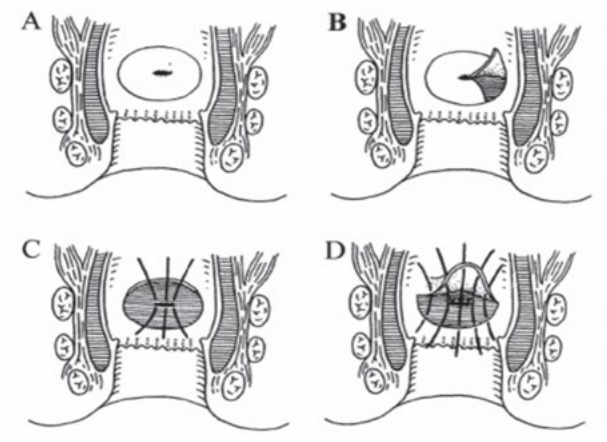

Figure 31. A. Elliptical incision of rectal mucosa around the fistula. B. Denudation of the rectal mucosa. C. Fistula closed with absorbable suture. D. Rectal mucosal flap sutured with absorbable suture.

2.5.2.5. Anterior Transsphincteric, Transanal Surgical Approach (ASTRA)

In 1973, Gecelter[909] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The anal sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by ASTRA.

2.5.2.6. Endoscopic Approaches

Wilbert et al[911] reported two patients with RUF who were repaired endoscopically transanally. The patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum. The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al[912] used cyanoacrylic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administrated endoscopically through an open-end 6F ureteral catheter. The fistulas were successfully treated. Quinlan et al presented the case of an iatrogenic fistula in a 71-year-old man

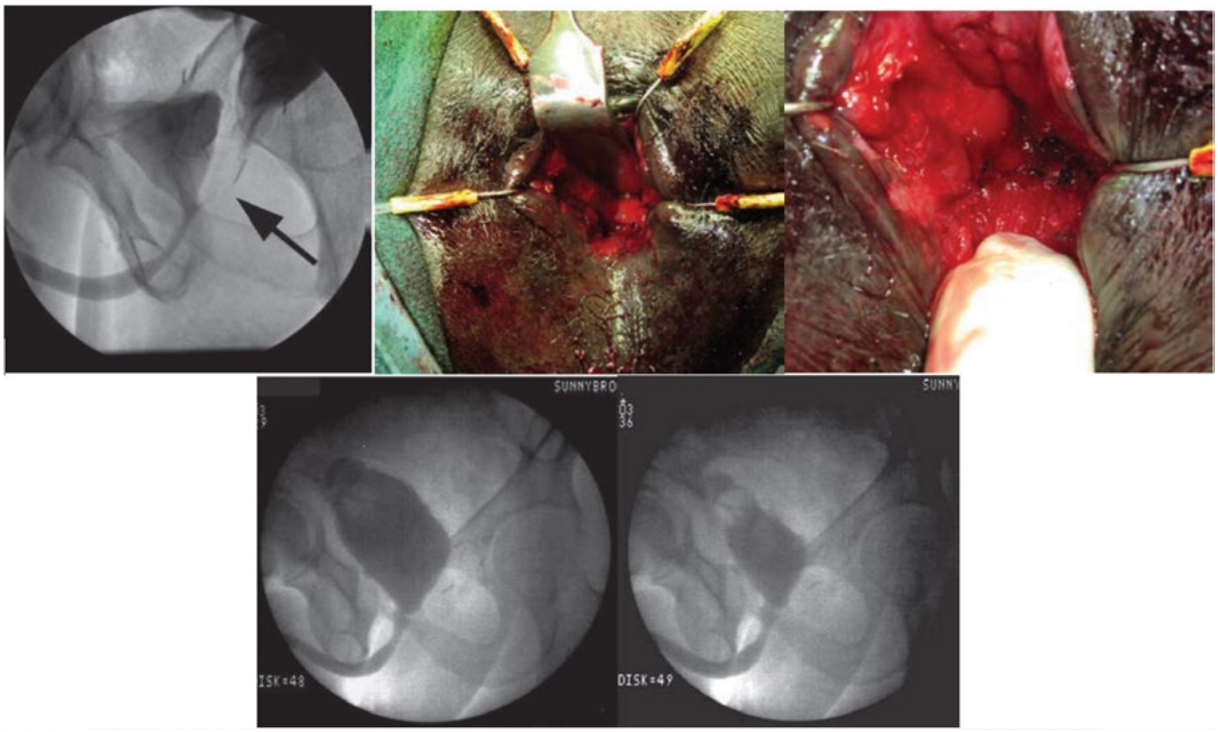

Figure 32. A. Retrograde urethrogram of a 55-year-old man who underwent a radical prostatectomy. He complained of fecaluria and urine per rectum. This shows urethral contrast in the rectum through a rectourethral fistula (Black arrow). B. Intraoperative photograph of transanal rectourethral fistula repair. The anus is held open by the ring retractor to permit direct access to the fistula. C. Intraoperative view of the rectal mucosal sutures in the rectourethral fistula repair. D. Retrograde urethrogram 3 months after transanal rectourethral fistula repair. There is no contrast entering the rectum from the urethra. The patient's suprapubic tube was removed and his colostomy was reversed

treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM): the RUF occurred after laparoscopic radical prostatectomy. Pigalarga et al[913] described a case of successful repair of iatrogenic RUF through a multidisciplinary approach consisting of cystoscopy, urethral stent placement, colonoscopy, and transanal endoscopic microsurgery assisted rectal advancement flap.

2.5.2.7. Other Modifications

Youssef et al[889] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous dartos flap procedure. The RUF resulted from crush pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphyseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous dartos flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous dartos flap may fulfill the principles for successful repair of RUF. Varma et al also concluded that dartos muscle interposition is a straightforward technique that can result in successful fistula repair, but should not be used in immune-compromised patients or after XRT.

Felipetto et al[772] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond. Verriello et al used fibrin sealant (Quixil) to inject it into the fistula tract and a rectal mucosal flap was used to close the internal opening. The fistula healed in a few weeks, and the patient remained symptom free after 1 year of follow-up. Chirica et al reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex rectourinary fistulas after radical prostatectomy or following anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7. Lesser et al reported a case of radiation and salvage cryoablation induced RUF after treatment of prostate cancer which was successfully repaired with a combined endorectal advancement flap with an Alloderm graft.

Muhlmann et al compared techniques of rectal mucosal advancement flaps (RMAF) and fistula plugs (FP) used to manage complex anal fistulas. The results of treatment of complex anal fistulas are disappointing. The choice of operation of either a RMAF or a FP did not alter the poor healing rates of about one third of patients in each group.

Gonzalez-Contreras et al treated the RUF after radical prostatectomy with interposition of the gracilis muscle. Eight weeks after surgery and with colostomy closed, no evidence of recurrence was detected.

Chen et al gained a high success rate in the treatment of complex rectovaginal fistulas and RUF by the technique of the gracilis muscle transposition and postoperative salvage wound irrigation-suction.

Yo et al also treated the recurrent RUF in a man after anoplasty for anorectal malformation during early infancy.They used a gracilis muscle flap approximately 30 cm long which was harvested from the left thigh, brought into the deepest part between the separated rectum and urethra through a subcutaneous tunnel and afixed there.

Iwamoto et al introduced a successful novel operative technique of a RUF with a pedicled vastus lateralis musculofascial flap. A first attempt failed to close the fistula utilizing the transanal rectal flap advancement technique.

Solomon et al described a new perineal approach using the medial aspect of the puborectalis muscles as a double-breasted rotational interposition flap to repair the RUF.

Ganio et al achieved the closure of the RUF in all 11 patients by the repair of using a bulbocavernosus muscle graft.

Lee et al presented a novel minimally invasive procedure: robotic-assisted laparoscopic segmental resection with rectoanal anastomosis for the management of difficult RUFs.

2.6. Summary

A review of recent literature shows an increasing number of papers describing UCF or RCFtreatment. The vast majority of available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a paucity of valid epidemiologic data about the incidence of UCF and RUF. The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and then undiversion).

Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF, and the management of these difficult conditions should remain in the hands of experts working in tertiary referral centres. Furthermore, with increasing use of energy ablation as well as salvage surgery for prostate cancer the resultant complex fistulae frequently require a multimodal approach. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients. Regardless of complexity, rectourethral fistulas have an initial closure rate approaching 90% when the transperineal approach is used. Permanent fecal and/or urinary diversion may be a last resort in patients with damaged fecal and urinary systems, especially associated with energy treatment for cancer.

All reports are still only retrospective case series **(Level of evidence 3; grade of recommendation C).**

VII. SUMMARY OF RECOMMENDATIONS

1. EVALUATION AND RECOMMENDATIONS

- Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (Level of evidence 1-2: grade of recommendation A).

- A voiding diary is helpful to assess urinary frequency functional capacity and total urine output (Level of evidence 1-2: grade of recommendation B).
- Pad tests may be useful in certain circumstances, and pad use is a reasonable surrogate to a formal pad test (Level of evidence 1-2: grade of recommendation B).
- Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria or poor urinary concentrating ability (in the absence of diuretics) is documented.
- Additional testing with cystoscopy and appropriate imaging of the urinary tract may be helpful in guiding therapy—this depends to a large degree on the type of incontinence and presumed etiology (Level of evidence 2-3: grade of recommendation B).
- Prior to surgical intervention for stress urinary incontinence, cystourethroscopy should be performed to assess for urethral and bladder pathology that may affect outcomes of surgery. Residual external sphincter function can also be assessed (Committee Opinion).
- The committee felt that multichannel urodynamics may be useful prior to invasive treatment for incontinence—this depends to a large degree on the type of incontinence and presumed etiology. (Level of evidence 3: grade of recommendation C).

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

- After a period of conservative management, which may be from 6 to 12 months the following should be considered (Level of evidence 3-4; grade of recommendation C):
- The artificial sphincter is the preferred treatment for properly selected men who have moderate to severe stress incontinence after radical prostatectomy as the AUS has the longest record of safety and efficacy. The AUS has been reported extensively for men with moderate to severe incontinence. This recommendation relates exclusively to the AMS 800 as newer devices do not have a similar evidence base or experience (Level of evidence 2-3; grade of recommendation A)
- Male slings are an acceptable surgical approach with several-year follow-up data supporting their safety and efficacy in men with mild to moderate degrees of PPI. They are associated with a low rate of urinary retention, infection, urethral erosion, and urethral atrophy. Adjustable slings appear to have similar efficacy rates compared to nonadjustable slings, but have a higher reoperation rate, typically for readjustment. (Level of evidence 3; grade of recommendation C)
- The Master trial showed that if surgery is needed, both AUS and sling result in improved leakage and high satisfaction, despite most men not being completely dry. However, most other published results indicate that men with moderate to severe incontinence undergoing implantation of an artificial urinary sphincter have better outcomes than those who undergo sling placement. (Level of evidence 2; grade of recommendation A). In the Master trial male slings had more overall complications, AUS complications were generally more significant when they did occur.
- Injectable agents, even with repeated application, have a low success rate and should only be used when more effective treatments are not possible. (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have also been reported, but have a higher complication rate than do the AUS and male sling. (Level of evidence 3; grade of recommendation D [no recommendation possible])

3. INCONTINENCE FOLLOWING EXTERNAL BEAM RADIATION FOR PROSTATE CANCER

- The artificial sphincter is most widely used, but radiation may be a risk factor for an increase in complications. (Level of evidence 3; grade of recommendation B).
- Slings generally have a lower success rate in radiated patients compared to those who have not had radiation. (Level of evidence 3; grade of recommendation C).
- Adjustable balloons have not been successful in the setting of radiation. (Level of evidence 3; grade of recommendation D).

4. INCONTINENCE FOLLOWING PELVIC TRAUMA

- The artificial sphincter is the most widely reported treatment for stress incontinence (Level of evidence 3; grade of recommendation C).

5. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

- BTx-A bladder injection is a minimally invasive treatment with a high level of efficacy (Level of evidence 1-2; grade of recommendation B). Reported outcomes in male patients are limited compared to reports in female patients.
- Neuromodulation is a treatment option with a high level of efficacy, but reported outcomes in male patients are limited compared to reports in female patients. (Level of evidence 3; grade of recommendation C).
- Augmentation cystoplasty may also be indicated in select patients and is associated with a high level of success in improving urine storage but may be associated with troublesome complications. (Level of evidence 3; grade of recommendation C).
- Urinary diversion is an option for males with severe, complicated problems who fail all other less invasive options. (Level of evidence 3; grade of recommendation C).

6. URETHROCUTANEOUS FISTULA AND RECTOURETRAL FISTUAL

(Level of evidence 3; grade of recommendation C)

- Etiologic factors causing acquired urethrocutaneous or rectourethral fistulae are demonstrated by clinical, endoscopic and imaging studies.
- Similar diagnostic maneuvers are applied to rectourethral fistulae.
- In cases that do not close spontaneously with or without temporary urinary and/or fecal diversion, surgical reconstruction may be carried out.
- Surgical reconstruction may be applied in the majority of cases.
- Most repairs are now carried out after urinary and fecal diversion.
- Various techniques are available for closure and can be done in collaboration with colorectal surgeons.

7. MANAGEMENT OF AUS COMPLICATIONS

(Level of evidence 3; grade of recommendation C).

- Incontinence may result from alteration in bladder function, urethral atrophy, cuff erosion or mechanical malfunction of the device.
- Reported therapeutic options for recurrent urinary incontinence due to urethral atrophy include: change of the pressure regulating balloon for a newer one or one generating a higher pressure; repositioning of the cuff proximally or distally; downsizing the cuff (most common approach); increasing the amount of fluid in the system; transcorporal cuff, and second-cuff implantation.
- Infection and/or erosion of components usually require surgical removal of all or part of the prosthesis (standard of care).
- Compared to primary urethral repair techniques, a Foley catheter placement alone may represent suboptimal management following severe cuff erosions due to increased risk of urethral complications. (Level of evidence 3, grade of recommendation C)
- A treatment algorithm is presented to aid in management and in follow-up of patients.

8. NEW TECHNOLOGIES

- Tissue engineering has not been widely reported in males apart from isolated reports of preliminary studies.
- A number of new artificial sphincter devices and slings are being evaluated. Currently, the number of patients implanted and studies with reported outcomes are relatively limited.

9. FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices (including integration of electronic components to the artificial urinary sphincter), neuromodulation devices and stem-cell based treatments should continue to be evaluated.
- Accuracy in reporting of early research results is mandatory.
- Mechanisms of post-prostatectomy incontinence and device effects need further research.

10. CLINICAL TRIAL RECOMMENDATION

- Further randomized trials (AUS and slings; other devices).
- Standardized workup and outcome measures including QoL.
- Evaluation of the role of urodynamics in the workup.
- Complete reporting of complications and outcomes especially those for slings.
- Standardized definitions of cure/improved/unchanged/worse.
- Reporting of procedures to salvage failures.
- Long-term results (>2 years).

INTRODUCTION

In accordance with the last (2017) IC-6I report, our topic is defined as surgery for Non-Neurogenic Incontinence in women, because surgery for Neurogenic Incontinence is considered by Committee Ten. Thus, this Chapter evaluates procedures for urodynamic stress incontinence (USI), “open” surgery for refractory non-neurogenic detrusor overactivity, and surgery for mixed incontinence. The precise urodynamic diagnosis for these conditions is used in preference to the symptom complexes of Stress Urinary Incontinence and Urgency Urinary Incontinence, although the Committee recognises that not all clinicians routinely perform urodynamic tests prior to incontinence surgery in all countries.

Intravesical injection of Botulinum Toxin is allocated to the chapter on Pharmacological Treatment of Urinary Incontinence. Surgery for refractory detrusor overactivity has undergone major changes in the last 20 years with the advent of Sacral Nerve Stimulation: although evaluation of the economic implications of the procedure continues in Chapter 22 (Economics of Incontinence), surgical procedures for detrusor overactivity are considered in the second half of this chapter.

Most continence clinicians, including urogynaecologists, urologists, physiotherapists and nurse continence advisors, have a compelling interest in the topic of surgery for USI, a condition which affects up to 60% of incontinent women. Thus, critical comment about this matter is considered to be the backbone of this Chapter. The subject has undergone a series of radical changes since the first ICI report in 1997. For example, Gerry Jarvis and his Committee included a section on Bladder Neck Buttresse / Kelly plication sutures, which had been common practice for 20 years. However objective data were very limited. By this stage the colposuspension had become the first line procedure for female stress incontinence, arising from quite robust long-term outcome studies. The risks of de novo detrusor overactivity and incomplete emptying were noteworthy after the colposuspension, not to mention the need for a Pfannenstiel incision. The first report also briefly described the Aldridge abdominovaginal sling, in which strips of the rectus abdominus fascia are incised from the abdominal plane and brought to lie underneath

the urethra with midline vaginal sutures. Complications from this procedure were substantial.

Hence, in parallel, interest developed in a variety of "needle suspension" techniques, Stamey, Raz, Gittes or Peyrera sling, which did not require a full Pfannenstiel incision. The second ICI (2002) report indicated that these procedures had a substantial risk of failure, as the paraurethral sutures tended to "cut out" over time. In parallel with the development of needle suspension techniques, the colposuspension was modified in order to perform the procedure laparoscopically (albeit only two non-absorbable or absorbable sutures were applied to Cooper's ligament, rather than the three sutures employed in the open procedure). At that stage, the laparoscopic colposuspension appeared to be slightly less effective than the open procedure in longer term studies. In that report, the new concept of "paravaginal repair" was mentioned but long-term objective outcome studies were not available.

The use of autologous tissue and synthetic materials for the pubovaginal sling was also discussed in the second report. The authors made several pertinent remarks, namely that synthetic materials were associated with a risk of erosions (up to 16%) and sinus formation, as well as urethral erosion up to 5%, and a risk of sling revision or removal, ranging from 2% to 35%.

The second ICI report (2002), also gave a detailed list of 18 studies regarding the use of Bulking Agents for USI, which generally included only subjective outcomes. Confounding variables, such as whether the urethra was "fixed" or "hypermobile" were seldom considered. "Success" judged as more than 50% improvement, ranged from a low of 4%, up to 83%, and the duration of surveillance could not be stated uniformly in the Table.

At the end of the second ICI report, Tony Smith and his Committee made almost "prophetic" conclusions, which deserve to be reproduced:

"The medical press is still publishing case series of surgical procedures for stress incontinence that are scientifically flawed in many areas. This does not serve to inform and may mislead, often presenting an over-optimistic view of the outcome. A minimum data set of information should be included in the assessment of any surgical procedure. Such a data set should include the following domains:

1. Anatomical/ physiological-structured physical examination (POPQ) and urodynamics
2. Symptoms (Validated questionnaire)
3. Urine loss (pad test)
4. Quality of Life (Validated questionnaire)
5. Full documentation of all confounding variables
6. Economic costs"

These comments published in 2002 have still not been widely adopted for the evaluation of success of continence procedures.

Discussion about the value of the bladder neck buttress (BNB), the Marshall Marchetti Kransk (MMK) procedure, the paravaginal repair and the needle suspension continued during the Third Report (2005), but by the Fourth Report (2009), the following conclusions were reached:

- Anterior colporrhaphy (BNB) should not be used in the management of SUI alone [Grade A].
- The MMK procedure is not recommended for the treatment of SUI [Grade A]
- Endoscopic… bladder neck needle suspension procedures… are not recommended for the treatment of SUI. [Grade A]
- Paravaginal defect repair is not recommended for the treatment of SUI alone [Grade A]

In keeping with these Grade A Recommendations, studies employing these operations as a comparator may be cited in the text, but will not be analysed or discussed further in this Chapter.

The field of surgery for female stress urinary incontinence was radically altered by the introduction of the retropubic polypropylene mid urethral sling (eg Tension Free Vaginal Tape (TVT), which was widely adopted after the publication of robust 3 year outcome data in 1999. At long last, a highly successful operation (92% dry rate on pad test) was available that did not require a Pfannenstiel incision, nor a full general anaesthetic as for a laparoscopic procedure. Further simplification of the procedure, to avoid the retropubic space and the small risk of bladder perforation, came with the introduction of trans-obturator tape (TOT). Although small longitudinal series and randomised controlled trials with minimum of 2 year follow up have been well constructed and carefully published regarding both the TVT and the TOT, national long- term "mesh registries" were employed in very few countries in the 1990's, so that the risks of the symptoms and signs of 'foreign body mesh rejection' could not be accurately detected.

Unfortunately, since the last ICI report in 2016, there has been a large international controversy surrounding vaginal polypropylene mesh. The relatively robust MUS procedure has been grouped together in the same "basket" as the larger sheets of polypropylene mesh with four projectile arms, which are used for women with vaginal prolapse and have significantly greater risks.

The present chapter will update information about the subjective and objective efficacy and safety of currently employed surgical techniques for incontinence in women, with a focus upon the events of the last four years. Previous ICI chapters included a vast array of often short-term data about all of the relevant procedures, however in this chapter **we will focus upon studies that include objective outcome measures of success (as recommended by the Committee in 2002) for these procedures, and include complication rates.**

SEARCH STRATEGIES

As in prior editions, material collected for this chapter was based on electronic searches of Medline, EMBASE, Cinhai, Cochrane Database of Systematic Reviews and the NICE website (www.nice.org.uk). Review papers were separately searched for additional references not identified by initial database search. Individual papers were then selected from these searches for inclusion where appropriate. Search terms included; Urinary incontinence: stress, mixed, urge. Surgical procedures: minimally invasive, urogenital, gynaecologic, urologic, urinary tract, urethra, vagina, bladder, colposuspension, urethrosuspension, vesicourethral or urethrovesical, colpourethrosuspension, Burch, obturator, surgical mesh, sling, bladder, surgical or synthetic, or biological or autologous; tape; urethra, suburethra, midurethra, transurethral, pubovesical; PVS, suprapubic; pubovaginal, implant; Prostheses: injections; bulking agents, Contigen; collagen; Macro-plastique, silicones; micropar-

ticulate; hyaluronic acid; carbon particles; biocompatible materials; urinary sphincter, artificial.

In contrast to previous ICI Chapters, the Committee members agreed that publications which do not provide both objective (either pad test, valid cough stress test or urodynamic testing) and subjective (validated Quality of Life questionnaire) outcomes, preferably at a minimum of two years, may be cited in the text but not discussed in detail. Publications which discuss confounding variables that affect success, and reports that clearly document complications in a systematic way, will be emphasised. Related procedures such as urethral diverticula, new techniques, will not require such stringent long term outcomes.

EVALUATION PRIOR TO SURGERY

In keeping with Committee 13, (Surgical Treatment of Urinary Incontinence in Men) this Committee now includes our recommendations for evaluation prior to surgery, and includes comments about variations in certain countries. In keeping with the Algorithm regarding the initial assessment of urinary incontinence in women published by the last ICI report (page 2568 – 2571), a standardised history and physical examination is the cornerstone of preoperative evaluation.

The history should consider precipitating events (childbirth, menopause, weight gain, surgery or trauma) that may have led to the incontinence. History of confounding variables such as bowel dysfunction, neurological conditions (back surgery, stroke, etc) or untreated chronic cough, that may be associated with pelvic floor weakness should be noted. Previous difficult bowel resection with prolonged postoperative recovery may suggest disruption of the pelvic parasympathetic plexus with subsequent atypical bladder dysfunction. Childhood bedwetting or daywetting that is associated with a poor prognosis in detrusor overactivity should be noted. Symptoms suggesting sleep apnoea should be considered as a confounding variable in patients with detrusor overactivity and nocturia. A psychiatric history associated with use of psychotrophic medications should be noted, as these may have anticholinergic properties that can promote bladder atonia during the postoperative Trial of Void. The use of Lithium medication may be associated with a risk of permanent polydipsia and gross overconsumption of fluid, which may also promote bladder atony. Any prior conservative treatments, successful or not, should be documented. Disruption of sexual function or leakage during intercourse should be noted, as well as a history of sexual abuse that may be associated with levator muscle spasm. Medications that may promote incontinence, such as diuretics, alpha blockers should be noted, as well history of narrow angle glaucoma that precludes anticholingergic therapy. Joint hypermobility, Sjogren's syndrome and other connective tissue disorders should be noted.

A history of ataxic gait, tremor, visual disturbance, previous stroke, Multiple Sclerosis, persistent swallowing dysfunction, peripheral neuropathy or weakness, in conjunction with severe urinary and/or faecal incontinence, should prompt careful neurological assessment.

"Complicated" incontinence should be noted i.e. those with prior UI surgery, neurological conditions, elevated PVR, bladder pain or haematuria, recurrent infections, suspected or proven voiding problems, symptomatic pelvic organ prolapse, or previous pelvic irradiation, radical pelvic surgery for malignancy, or symptoms suggesting fistula. Eradication of recurrent bacterial cystitis should be considered in women with refractory detrusor overactivity prior to invasive surgical therapies, and use of topical oestriol cream or vaginal oestradiol pessaries should be considered to prevent bacterial cystitis or to reverse genitourinary symptoms of menopause (GSM).

Women with previous incontinence surgery should be considered as a separate entity, both in terms of clinical management, and in terms of statistical analysis in research studies. This concept will be emphasised in the present Chapter.

The three main groups of incontinence not complicated by the above factors should be identified, i.e. women with stress incontinence on physical activity, women with urgency, frequency with or without urgency incontinence (overactive bladder), and women with mixed urgency and stress incontinence.

The level and type of pad usage should be determined, i.e. pantyliner, continence pads, adult diapers, and the degree of bother of the incontinence in daily life, e.g. curtailment of physical activity or reduction of fluid intake to avoid incontinence. If a woman does not use any form of protection against incontinence, nor employ any change of lifestyle to avoid incontinence, then the value of surgery for incontinence needs to be carefully considered and balanced against the known risk of complications.

Documentation of severity of leakage on a pad test is recommended, and is also an important Objective Outcome Measure. This may comprise a 24 hour home pad test, a 1 hour office test, or other tests described by Committee 13 (Surgery for Incontinence in Men). The cough-stress test is also a suitable Outcome Measure, so long as the bladder volume is standardised, at least > 200 ml, (most common is >300 ml**), before and after** the intervention. The Bladder Diary is also an important Patient Report tool that should be assessed prior to surgery, to exclude over-consumption of fluid, or large bladder volumes typical of an atonic bladder, or under-consumption of fluid typical of untreated detrusor overactivity; it is also a valid Outcome Measure. (See Chapter 5A from the Sixth Report, Initial Assessment of Urinary Incontinence).

Physical examination should begin with an evaluation of the patient's general mental status, and ability to understand the risks/benefits/limitations/convalescence/etc of surgical intervention in order to gain informed consent. In the current climate of our ageing population, possible dementia should be noted in the surgical candidate, and further evaluated by her general practitioner or a geriatrician if warranted.

Measurement of height and weight, to derive Body Mass Index is important, as obesity remains a confounding variable in regard to surgical outcome and should be included in prospective trials of any surgical procedure. Severe arthritis of the hands, or significant visual impairment, may preclude clean intermittent self-catheterisation if postoperative voiding dysfunction occurs. Previous injuries that involve the sacrum or sacral plexus at S3 should be noted in candidates for sacral nerve stimulation.

Cardiovascular and respiratory disease must be considered if the patient is a candidate for a laparoscopic colposuspension with the need for prolonged Trendelberg position.

Abdominal examination is essential: large ovarian tumours, ascites, or large fibroids may precipitate incontinence. However removal of

the abdominal mass does not always resolve the incontinence, which must be discussed with the patient. Surgical scarring of the abdomen is important in patients considered for autologous sling procedures, as harvesting of a graft from the rectus fascia may not be feasible.

Leakage during coughing with a comfortably full bladder should be noted. Vaginal atrophy in the postmenopausal woman should be treated with topical oestriol cream to enhance tissue quality and wound healing. Specific examination to exclude prolapse is essential if the patient is a candidate for continence surgery. Assessment of ability to contract the pelvic floor muscle should be performed, particularly in mild to moderate incontinence, since pelvic floor muscle training is highly effective in these cases and may obviate the need for surgery (See Chapter 12, Adult Conservative Management).

A brief neuro-urological examination (perineal sensation, anal tone) should be performed in any female with neurological symptoms. Ataxia of the gait, postural hypotension, nystagmus, tremor, or obvious focal peripheral weakness should prompt specialist neurological evaluation.

In keeping with previous ICI guidelines, all women should be offered conservative therapy prior to any surgical intervention and should be given a patient decision making aid regarding what is available /feasible for them.

I. SURGERY FOR STRESS URINARY INCONTINENCE (SUI)

In the last two ICI chapters on Surgery for Female Incontinence, operations for stress incontinence have been analysed on a procedure-by-procedure basis, as if to employ the notion that any patient with stress incontinence might undergo any one of these procedures. In the current climate, “mesh operations” for incontinence have received much negative comment, for example the synthetic retropubic mid-urethral sling versus the transobturator mid-urethral sling versus various sling-incision “mini-slings”. Therefore, it seems timely to analyse each procedure partly according to its value as a primary procedure (for “uncomplicated SUI), in which urethral function may well be normal, versus its use as a remedy for the previously failed continence procedure or “complicated” incontinence, wherein urethral function is more likely to be abnormal (i.e. partially denervated, fibrosed, with low urethral closure pressure or low Valsalva leak point pressure, and be no longer hypermobile). Then procedures involving only autologous materials can be analysed separately, as no “mesh” is involved in such cases.

As per the Introduction, the Burch colposuspension had become a first line surgical procedure in the first ICI Report of 1997 (a move away from the Kelly Plication procedure). However, the autologous pubovaginal sling has also been employed as a first-line procedure in some case series/ RCTs.

1. TRADITIONAL PUBOVAGINAL SLING

The term “traditional” sling procedure is used here, in line with the terminology used in the latest Cochrane review (1). This is done mainly to distinguish open sling procedures typically placed at the region of the bladder neck from the newer, minimally-invasive mid-urethral sling (MUS) procedures. Sling procedures were first reported in 1907, using gracilis muscle wrapped around the urethra (2). Further historical perspectives are considered in previous ICI chapters. The modern autologous pubovaginal sling exists mainly due to the work of Aldridge in the 1940’s and McGuire and Blaivas in the latter part of the twentieth century (3-5).

In the first modern publication of this procedure (4), 52 patients with poor urethral function (i.e. a urethral pressure of less than 10cm), of whom 47 had undergone a previous operation for stress incontinence, and 29 (56%) had coexistant detrusor overactivity, were operated upon. The procedure entailed harvesting a 12 cm strip of rectus abdominus and external oblique fascia , then a median incision was made in the anterior vaginal wall, the vaginal mucosa was reflected laterally off the posterior urethra and bladder neck , a tunnel was established by blunt and sharp dissection on either

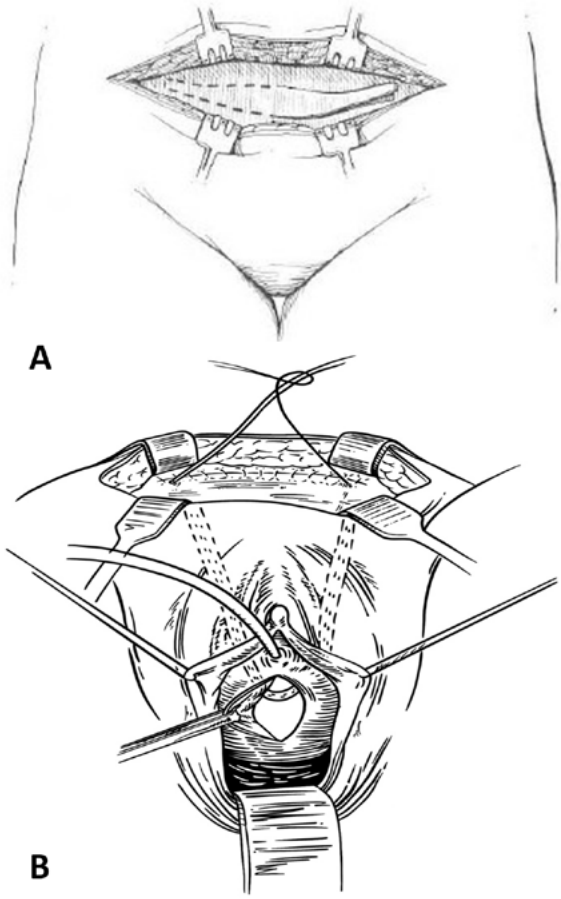

Figure 1: A. Traditional pubovaginal sling; length of autologous sling ranging from 12cm to 20cm. Published with permission from Te Linde’s Operative Gynecology, Ninth Edition Eds Rock JA, Jones HW, pub. Lippincott Williams and Wilkins Philadelphia Pennsylvania.

B. Autologous sling passes from suburethral vagina, through the urogenital diaphragm, into the rectus abdominus sheath. Drawn by artist Bailey Connor.

side of the bladder neck, so that the autologous fascia could be brought through from the vagina up into the retropubic space, and tied across the top of the rectus abdominus sheath (See Figure 1).

At a mean follow-up of 2.3 years, stress incontinence was cured on urodynamics by operation alone in 41 (80%) of cases, and coupled with anticholinergic medication in a further 6 (11%) of cases. McGuire clearly recognised that this somewhat invasive procedure was designed for those with previous failed continence operations. This technique was then reported in several standard textbooks, for example Te Linde's Operative Gynecology (6). However, when writing the chapter on pubovaginal sling for Campbell's Urology in 2002, McGuire altered the sling length to 9 cm, but stated that both ends need to lie in the retropubic space via full dissection of the urogenital diaphragm (7).

McGuire's group published a further review of 247 consecutive women having a PVS in 2000 (8). In the introduction the authors noted that "a 2% - 12% incidence of urinary retention (greater than 4 weeks) is 80% more common after PVS compared with other anti-incontinence procedures" (9). The outcome (8) was assessed by a postal UDI questionnaire. Chart review was performed at mean of 51 months (range 22-68 months). The cure rate on UDI questionnaire was 91% in those with a normal abdominal leak point pressure and hypermobile urethra, versus 84% in those with a low ALPP (88% success overall). The subset of patients with preoperative urge incontinence had a failure rate of 26%, with 5% of all patients self-catheterising for one month and 2% needing urethrolysis to restore normal voiding

As described in the previous ICI chapter, numerous biological or synthetic grafts were also employed as slings. Many synthetic grafts e.g. polyethylene, PTFE, Marlex, Gortex, were commonly accompanied by extrusion, erosion or sinus formation, and *most are no longer included in this chapter*.

The latest Cochrane review compared traditional slings with 10 other treatments including drugs or other types of surgery (colposuspension, mid-urethral slings, bladder neck needle suspension, mini-slings) (1). The review included 34 randomised or quasi-randomised controlled trials (RCTs) involving 3244 women with urodynamic stress incontinence or symptoms of stress or mixed urinary incontinence, in which at least one trial arm involves traditional sling procedures. Many trials were small and used different outcome measures. As a result, the quality of evidence for most outcomes was judged to be low or very low (Level 2-3) and most of the conclusions about traditional slings were uncertain.

The National Institute for Health and Care Excellence (NICE) committee (2019) agreed that women should be offered a choice between colposuspension, retropubic mid-urethral mesh slings and autologous rectus fascial slings, as evidence showed that there were no important differences in the short- and medium-term effectiveness. However, they emphasised that there is substantial uncertainty about the long-term complications for each procedure, and that women should be made aware of this when choosing a procedure (10). The recent AUA guideline for Surgical Treatment of Female Stress Urinary Incontinence (11) also indicates that such patients can be offered any of these procedures, in line with patient's bother, expectations, and individual risk/ benefit profile. The recent EUA guidelines (12) also indicate that any of these procedures may be offered, but that the autologous PVS has a greater risk of voiding difficulty/ CISC (RR 1.46 RR).

1.1. Traditional Pubovaginal Sling (PVS) vs. Colposuspension

The latest Cochrane review (1) systematically evaluated eight trials comparing slings with open colposuspension. Two trials involved an autologous pubovaginal sling (13, 14). Three trials used materials no longer in use; a lyodura sling (15), the Zoedler sling made of Teflon (16), and Gortex mesh (17). Only two of these trials reported follow-up for longer than five years (14, 17). Although not stated by the Cochrane reviewers, the autologous PVS used by Demirci et al (13) was only 6cm long, which is actually a "Sling-on-a-String", to be considered in Section 1.2 below.

Although dura mater slings are not currently in use, Enzelsberger (1996) performed a quasi-randomised RCT of this material versus modified open colposuspension (only two retropubic non-absorbable sutures) in 72 women with recurrent SUI after at least one previous anterior repair (15). The results remain of interest. At a minimum follow-up of 32 months, the combined objective and subjective cure rates (no symptomatic stress leak and negative stress cough test at 300mL) were 92% after dura mater sling, versus 86% after colposuspension. Significantly more women in the sling group developed postoperative voiding difficulty or urinary retention (29% vs 11%), mean duration of SPC was 15days versus 7days. More women in the colposuspension group developed a postoperative rectocoele (13%). De novo urgency occurred in 16% vs 8% **[EL=1/2]**. Therefore, the authors concluded that pubovaginal slings "***should only be used in patients with… recurrent stress incontinence, or those with a low urethral closure pressure***".

Three trials compared PVS with open colposuspension. Bai *et al* (18) randomised 92 women to either pubovaginal sling, colposuspension, or TVT. Patients with detrusor instability or ISD were excluded. Cure was defined as no complaint of stress incontinence and a negative stress test at 300ml. Pubovaginal sling was significantly superior to colposuspension at 12 months (92.8% cure vs. 87.8%), versus TVT, 87%. Demirci and Yucel (13) actually employed "Sling on a String" [see section 1.2 below]

Finally, the Urinary Incontinence Treatment Network conducted the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr) (14). This RCT measured the efficacy of <u>any</u> form of pubovaginal sling (minimum sling length of 8cm but full retropubic dissection), versus <u>any</u> colposuspension (2 or 3 sutures), in patients with stress predominant UI: detrusor overactivity was <u>not</u> <u>excluded</u>. Urethral function was only assessed by hypermobility on exam (no MUCP or ULPP). Previous continence surgery had been performed in 14% of cases: these were equally randomised. Hence the PVS, which is often used for women with failed incontinence surgery, was compared to the colposuspension, which is often considered first-line. Subset analysis of primary versus "re-do" surgery was not done.

Overall, 655 women were randomised, 79% of them (265:255) were available for 24-month outcomes. PVS was significantly superior to colposuspension both in cure of SUI (66% vs. 49%) and overall incontinence cure (47% vs. 38%) at 24 months. The low success rates are explained by the stringent "composite" criteria used to define success, including no self-reported symptoms of SUI, less than 15g pad weight in 24 hours, no leakage on a 3-day diary, a negative cough stress test, and no retreatment for incontinence. Although highly effective for SUI, the PVS was accompanied by higher rates of urge incontinence (27% vs 20%, P = 0.04), voiding dysfunction (14% vs. 2%, p<0.001), and need for surgical revision to improve voiding, when compared with colposuspension **[EL=1].** The same group assessed complications from the SISTEr trial in a separate paper (19). Women undergoing PVS had a higher percentage of

postoperative UTIs in the first six weeks (p<0.01), and a higher incidence of voiding and storage symptoms. **[EL=1]**

The same group presented their long-term results (20). Women who completed the SISTEr trial were asked to join in a long-term study for 5 years (Brubaker et al, 2012). Continence was again strictly defined, as no leakage on a three-day voiding diary and no self- reported stress leak (telephone or mail) AND no stress incontinence surgical re-treatment. Incontinent participants were more likely to enroll in the follow-up than continent patients (85.5% vs. 52.2%), regardless of surgical group (p<0.0001). Continence rates were lower in the Burch group than in the PVS group (p=0.002) at 5 years: 24.1% (95% CI 18.5% to 29.7%) compared to 30.8% (24.7% to 36.9%), respectively. Satisfaction at 5 years was higher in women undergoing a sling (83% vs. 73%, p=0.04). [EL=1]

Overall, regarding all 8 studies, the latest Cochrane review (1) concluded that the traditional PVS probably leads to more continent women in the medium term (1-5 years) (69% vs 59% after colposuspension: OR 1.70, 95% CI 1.22 to 2.37). This result was reached when both the urodynamic and symptom diagnosis were combined in the analysis. However, the data from four trials comparing slings to open colposuspension in women with urodynamic SUI (urethral pressures/ leak pressures not analysed), showed no significant difference in cure rate within a year after treatment (OR 2.70, 95% CI 0.69 to 10.55; n = 147). Data beyond five years were provided by two trials (14, 17), suggesting that women were more likely to be continent long term after PVS than after open colposuspension (OR 1.55, 95% CI 1.06 to 2.27; n = 190). Pooled data from 5 trials **showed significantly more voiding dysfunction after sling (14% vs. 2%, p<0.001, RR 6.08**; 95% CI 3.10 to 11.95,) (19) **[EL=1].**

1.2. "Sling on a String" vs. Conventional Pubovaginal Sling

The previous paragraphs, comparing autologous pubovaginal rectus fascial sling, with other procedures such as Burch colposuspension or Modified Colposuspension, have revealed considerable variation in the length of the autologous sling that is harvested from the anterior wall, ranging from 8cm to 13cm. However, McGuire wrote that the harvested graft should be 13cm or 12 cm in length (4), so that the strips of the graft proceed through the urogenital diaphragm into the retropubic space, prior to the Nylon sutures being tied across the rectus fascia. The shorter "String on a Sling" is anchored only by the sutures attached to the smaller graft (thus less dissection of the urogenital diaphragm would be needed).

In 2001, Demirci and Yucel (13) alternated 46 women with primary USI, no Detrusor Instability and a normal VLPP, to a Sling on a String (5-6cm strip of fascia, delayed absorbable sutures) versus a modified Burch colposuspension (two delayed absorbable sutures each side). "Cure" was defined as "symptom-free patients" at 12 months. "Sling on a string" had similar "cure" to colposuspension at 12 months (94% vs. 88%). (**EL = 2**]

In 2007, urologists from Wales (21) hypothesised that the shorter "Sling on a String" procedure might be equally efficacious but require less dissection of the retropubic space with attendant morbidity, and might be a valid alternative to the TVT mesh operation. The "standard pubovaginal sling" used by these authors was **20cm long** x 1.5cm wide, whereas the "Sling on a String" was **8cm long**. In their RCT of 165 women with proven USI but no DO, cure was assessed by UDI and IIQ scores, one hour pad test, and a satisfaction score, along with the need for CISC or re-operation at 12 months. Prior continence surgery occurred in 30% of the "long sling" and 30% of the "short sling" women (which mainly comprised anterior vaginal repair). UPP and VLPP were not assessed. Success was evaluated at medium term (3.5years) and long term (6.5years), by UDI and IIQ questionnaire.

The QoL Questionnaires (21) showed no significant difference between the two procedures at any time point; in the short term the Sling on a String was slightly better, but long term the larger sling appeared better. Mean pad test data at 12 months was clearly no different between groups. "Voiding difficulty" occurred in 23% of "long sling" vs. 20% of "short sling". Re-admission within 3 months occurred more often in the traditional sling group (24% vs. 11%; p=0.03). However, further continence surgery was more common in the Sling on a String group (13% vs. 5%; p=0.016) (21).

The same senior author performed a later RCT which compared the porcine dermis pubovaginal sling vs. "Sling on a String", and also vs. tension-free vaginal tape (TVT) (22). Women recruited had primary SUI. Main outcome was patient-reported improvement rates at 6 months and 1 year. At 1year, porcine dermis slings had significantly lower dry rates (22%) as compared to TVT (55%) and PVS

Table 1A: RCTs of Autologous Pubovaginal Sling versus Colposuspension (Previous RCTs versus MMK and Stamey are discussed in previous ICI Chapters)

Author, Year, Ref	Sling	Versus	N/N (n1/ n2)	F/U (mth)	Cure; effect size	EL	Comments
Enzelsberger, 1996 (15)	Dura Mater	Colpo	72/72 (36:36)	32-48	92% vs. 86% (s)	2	All patients had recurrent SUI after failed incontinence surgery; no S.S. calculation; analysis not clear if ITT
Bai, 2005 (18)	PVS	Burch or TVT	28:33:21	6-12	92.8% vs. 90.9% (s+o), p-ns; 92.8% vs. 87.8% (s+o), p-sig	2	No S.S. calculation; minimal details about randomisation; some disparities between text and tables
Albo, 2007 (14) Chai, 2009 (19)	Any PVS	Any Colpo	520/655 (326:329)	24	SUI cure: 47% vs. 38% (s+o); p-sig Overall cure: 66% vs. 49% (s+ o); p-sig	1	79% outcome assessment at 24m (265:255); voiding/storage symptoms higher in PVS group
Brubaker, 2012 (20)	Any PVS	Any Colpo	357/482 (183:174)	60	Overall cure: 30.8% vs 24.1% (s+o) p-sig	1	Participants enrolled in long term study more likely to be incontinent (85.5%) VERSUS (52.2%), irrespective of assigned surgical group (p<0.0001).

Table 1B: RCTs of Sling on a String

Author, Year, Ref	Sling	Versus	N/N (n1/ n2)	F/U (mth)	Cure; effect size	EL	Comments
Demirci, 2001 (13)	Sling on a String	Modified Colpo (2 sutures)	34/46 (17:17)	12	94% vs. 88% (0); RR 2.0; 95%CI 0.20, 20.04	2	Quasi RCT by alternation; no S.S. calculation; Colpo sutures were delayed absorbable.
Guerrero, 2007 (21)	Sling on a String	"Long String"	165/168 (81:84)	42 Range (12-78m)	81% vs. 78% per protocol	2	RCT but no method; S.S. fulfilled; ITT analysed
Guerrero, 2010 (22)	Sling on a String	TVT and Pelvicol Sling	189/201 (79:72:50)	12	Dry rate: 48% Sling on String, 55% TVT	1	S.S. done; Recruitment could not be completed (TVT increasingly popular).
Khan, 2015 (23) (FU from Guerrero, 2010)	Sling on a String	TVT (Pelvicol deleted)	162/201 (61:38)	Median 10 years (R =6-12)	Dry rate: 73% TVT, 75% sling; p=0.036	1	Postal questionnaires and telephone conversations: BFLUTS and EQ-5D

slings (48%). Long term follow-up was via questionnaires (23). The porcine dermis arm was suspended following interim analysis, and Porcine slings are no longer considered.

1.3. Pubovaginal Sling vs Other Slings

The latest Cochrane review (1) identified 9 trials comparing various types of sling operation, including materials such as porcine dermis, lyophilised dura mater, along with fascia lata, vaginal wall, autologous dermis, and rectus fascia. The results could not be pooled due to clinical heterogeneity and because different materials or types of traditional slings were used.

Eight non-randomised studies compared the outcomes of autologous and allograft slings or xenograft material (porcine dermis). All were retrospective reviews, and all studies were considered to be of poor quality, and are not considered in this chapter.

In a quasi-RCT of pubovaginal sling versus a polypropylene mesh sling (24) in 50 women (median follow-up 2 years), the PVS was **20cm x 2cm**, the polypropylene mesh sling was 30cm x 2cm. Preoperative detrusor overactivity and previous surgery was not recorded. Cure and satisfaction rates were similar, delayed voiding and wound pain occurred more often in the PVS sling group. Similar results were obtained by Maher *et al* (25), in a non-randomised study; Considerable detail about these studies is given in the ICI- 6, and are not considered further.

1.4. Traditional Sling vs Retropubic MUS

In the last Chapter in ICI-6 there were 17 trials that compared traditional PVS and MUS operations. But only 3 RCTs provided long-term outcomes of these studies ((26, 27), see Table 2,and (22), see Table 1B "Sling on a String"). Most of these previously discussed studies did not provide objective outcomes, or were not randomised trials, and two compared synthetic sling material (Porcine dermis and Prolene), which are no longer included (see previous chapter for detail).

Six RCTs compared Autologous pubovaginal sling with TVT. However, Bai et al (18) is discussed in Table 1A. Studies by Wadie et al 2005 / 2010 (26, 27), Kondo et al 2006 (28) are in Table 2; Amaro 2009 (29) had little objective data.

Trabuco et al (2009) performed a retrospective cohort study of 242 women, who underwent a 10cm long autologous PVS (n = 79)

Table 2: Traditional Sling vs Retropubic P MUS

Author, Year, Ref	RCT	Sling	Versus	N/N (n1/ n2)	F/U (mths)	Cure; effect size	EL	Comments
Wadie, 2005 (26)	Yes	PVS	TVT	53/53 (25:28)	6m	92% vs. 92.9% (o-1 week); p=ns	2	No ss calculation; may be underpowered; cure determined at first F/U visit because of results of interim analysis; UDI-6, IIQ-7 significantly decreased at 24m
Wadie, 2010 (27)				63/75 (39:24)	24m (median 54m)	93.7% vs. 95.2% (s+o); p=ns		
Kondo, 2006 (28)	Yes	PVS	TVT	60/63 (29:31)	24m	66.7% vs. 82.6% (s); p=ns 47.6% vs. 69.6% (o); p=ns	2	Subjects for analysis reduced to 21 in ARF group & 23 in TVT group about randomisation; subjective cure (IIQ) similar
Trabuco, 2009 (30)	No	PVS	TVT (Uretx)	79/163	43m/32m	52% vs. 66% (s+o); p=0.11 Adjusted risk; p=0.04		"50% of PVS had ISD and 92% of TVT had ISD. Outcome = questionnaire + no repeat surgery."
Mock, 2015 (31)	No	"Sling on a String"	Top-down MUS	91/110	13.8m	75.8% vs. 80.9% (o+s); p=ns		Patients allowed to choose which procedure (after FDA report)

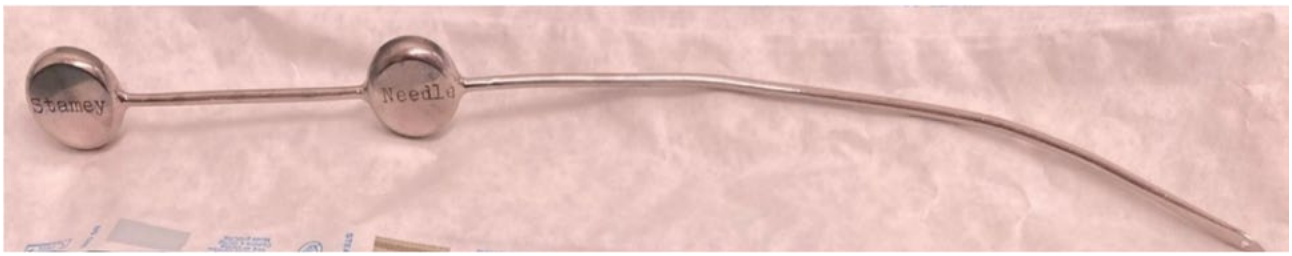

Figure 2: Stamey Needle (courtesy of St George Hospital)

or midurethral sling (n = 163) (30). Women having PVS revealed pre-operative ISD in 51%, whereas women having MUS revealed ISD in 29% (P < 0.001). Those with PVS were more likely to report any leakage of urine (P = 0.04, RR 1.6), and **were 13 times more likely to require urethrolysis (for incomplete emptying)** (P < 0.001) than patients with MUS. Patient satisfaction was lower in the PVS group compared with the MUS group (P = 0.01). [EL=3]

In 2015, Mock et al performed a non randomised prospective study of PVS versus 'top down' MUS (31). However, in the last ICI chapter it was not identified that this PVS was in fact a "sling on a string" (8 cm long, ***with the sling positioned retropubically using a Stamey needle***), shown in Figure 2. The study was interesting because, since the negative findings from the FDA re polypropylene mesh, the authors had decided to give 201 women the option between a 'sling on a string; and a 'top-down' MUS. All had no previous continence surgery; of whom 91 women (45%) chose the short autologous sling and 110 chose MUS (55%). Cure was defined as a negative supine cough stress test at 300 ml with no symptoms of stress incontinence on SEAPI score (32) ((Note that SEAPI score is validated Stothers 2004, see Appendix A). At a median follow-up of 13.8 months, the cure rate in the Sling on a String group (75.8%) was not significantly different from that in the MUS group (80.9%).

De novo urge incontinence appeared in 16.7% of the PVS group and 33.3% of the MUS group (not significant). Complications were similar between the groups (4.4% in Sling on a String vs 2.7% in MUS) (31). [EL=2] Prolonged urinary retention occured in a median of 8% (4-15) and 3% (2-4) after PVS and MUS respectively. The authors commented that 'Although our MUS retention data are consistent with published reports, the PVS group was lower. … **This single-surgeon series is from a fellowship-trained urologist practicing at a high-volume referral centre, and most contemporary series have shown a trend between lower retention rates with increasing surgeon experience."**

1.5. Traditional Sling vs Trans Obturator MUS

As regards autologous PVS versus the trans obturator tape, two RCTs compared a traditional PVS to a Trans Obturator MUS (Safyre-t). Silva-Filho et al (2006) had only 20 patients with short term data (33), but showed that pad weight at 6 months was 39g for PVS versus 8.4g after TOMUS. The RCT by Tcherniakovsky et al (2009) did not define "cure", had only 41 patients, followed up at only 12 months (34). [**EL=2**]

A retrospective study by Jeon et al (2008) of 253 women compared traditional PVS sling versus TVT, versus the TO MUS (35). Complications were not significantly different between groups. At 2 years, the cure rates on cough stress at 300 ml for the traditional sling, TVT, and TO MUS groups were significantly different (87.3% vs. 86.7% vs. 34.9%, respectively; p<0.0001). Cox proportional hazard regression revealed that the risk of failure in women having TVT was not significantly different compared with PVS, but in those who received TOT, the risk of failure was **4.6 times higher** (P= 0.0001). The 7-year cumulative cure rates of traditional sling and TVT groups were 59.1% and 55.1%, respectively. **[EL=2/3].**

1.5.1. Overview of Traditional Slings versus all Mid Urethral Slings

The 2011 Cochrane database (36) analysed 12 trials that compared traditional PVS with any MUS operation. All these studies are considered in this chapter. In summary, postoperative incontinence was reported by 31.6% of women in the traditional PVS and 25.3% of those in the MUS groups, which was not statistically significant (RR 1.23; 95% CI 0.91 to 1.66). Improvement after a year was addressed by two trials ((22) and(37)) which only involved questionaires, and included porcine dermal sling); responses were not significantly different between the two types of sling (RR 1.30; 95% CI 0.57 to 2.94).

As regards complications, bladder perforations occurred more commonly after MUS, but this did not reach statistical significance (RR 0.62; 95% CI 0.34 to 1.11). Three trials showed less de novo urgency *symptoms* after MUS (RR 3.13; 95% CI 0.96 to 10.24), not significant due to wide confidence interval, but 3 other trials showed significantly less de novo DO after MUS operations (RR 3.21; 95% CI 1.29 to 8.03).

Five trials showed that more women had postoperative voiding dysfunction after PVS than after MUS (RR 1.60; 95% CI 0.94 to 2.71) but this did not quite reach statistical significance. More women in the traditional sling group required release of sling (9% versus 2%), reported in two trials (RR 3.67; 95% CI 0.95 to 14.22 not significant).

Summary

Since ICI-6, no new studies have emerged on traditional slings, however the Cochrane met-analysis was updated in 2020 (1). Pubovaginal sling (AFS, autologous fascial sling) is the most widely evaluated biological sling and is an effective and durable treatment for SUI. [EL=1].

In comparison to other procedures: *PVS are as effective as MUS in the short term [EL=1] however operating time and LOS are significantly shorter with MUS.*

PVS is modestly more effective than colposuspension at mid-long term (EL= 1/2) albeit with a higher rate of postoperative voiding dysfunction.

The current data indicate that the "traditional" autologous Pubovaginal Sling (length of graft 13 – 20 cm with full para-ure-

thral dissection) is the gold standard for correction of incontinence, when compared by RCT to other procedures. However, this operation was initially designed for women with previous failed incontinence procedures, for which it is clearly effective. Because several studies show that it does have a higher risk of voiding dysfunction/ CISC/ UTI, and postoperative detrusor overactivity (DO), this procedure is likely to best serve the needs of incontinent women when performed in high-volume centres that focus upon women with recurrent incontinence, and is less appropriate as a primary procedure, unless surgeons are highly experienced in this procedure.

The less invasive "Sling on a String" (smaller Pfannenstiel incision, 5-6 cm length of autologous graft, less need for full vaginal dissection) may become more widely used in the future, because some women are becoming increasingly concerned about the small risks of mesh erosion after polypropylene mid-urethral slings. Preliminary studies indicate that 'sling on a string' has a similar cure rate at 12 months to the traditional sling, but prospective studies or RCTs with objective outcomes and longer term follow up of complications are necessary.

Recommendations

Traditional autologous fascial sling (PVS) is recommended as an effective treatment for female stress urinary incontinence, which has longevity for both primary and repeat surgery. [Grade A]

Research

Further long-term objective and subjective outcome data should be collected for the less invasive "Sling on a String", particularly in relation to the likelihood of voiding dysfunction/ CISC and de novo DO.

2. COLPOSUSPENSION

2.1. Open Colposuspension

The open Burch colposuspension was first described in 1961 (38). While performing a MMK procedure (39), the surgeon found that the sutures placed in the retropubic periosteum continually pulled out, so that the author used the iliopectineal (Cooper's) ligament as an alternative point of fixation for three sutures on either side of the midline, which were displayed by placing two fingers in the vagina. In the 45 cases of USI reported (of whom only four had previous continence operations), there were no failures in the short term. Burch went on to perform 143 cases over nine years, of which two were failures at six months (40). In discussion, Burch had aimed to find an operation that was more effective than the Bladder Neck Buttresse/Kelly plication, but which conferred less risk than the Aldridge sling.

Before considering randomised trials of the colposuspension efficacy, studies that report the medium and long term objective outcomes of the procedure, which have not been summarized in recent ICI chapters, are briefly reviewed. In 1979, an open colposuspension procedure comprising four bilateral Dexon sutures placed both proximal and distal to the bladder neck was performed by Stanton and Cardozo in 180 women (41). Subjective and objective outcomes (stress leak symptoms, leakage on cough stress test, and Urilos pad test) were reported; overall at 2years, patients were dry on symptoms in 79%, on stress test in 93%, and Urilos test in 86%. The 2 year cure rate in women with no previous incontinence surgery was 87.5% versus 84% in previously operated women.

In 1990, Erikson *et al* (42) evaluated 86 women who underwent modified colposuspension (two Ethibond sutures) at 5 years. "Cure" was defined quite strictly, as a dry symptom-free patient with negative cough stress test at 300ml and a positive urethral closure pressure. Cure occurred in 67% of patients (but in 71% of those with no pre-operative "motor urge incontinence"). Previous failed anterior repair did not affect success. Enterocoele occurred in 10%. Neither of these studies (41, 42) focused on post-operative voiding dysfunction.

In 1993, a follow-up study of 100 Swedish women undergoing colposuspension with four Dexon sutures bilaterally, were evaluated at 8-12years (43). "Cure" was defined as symptom-free patients, dry on all occasions, with a negative cough stress test at 300ml. Only three patients had a low MUCP. The cure rate was 90.3%. In 1994, a postal questionnaire was sent to 236 Swedish women after colposuspension, of whom 232 replied, at a median of 6years (range 2-10years) (44). Of these, 63% were completely cured. Previous incontinence surgery had been done in 16 patients, of whom only 33% were cured. Posterior vaginal wall prolapse needing surgery occurred in 15%.

Poor Outcome After Previous Failed Continence Surgery: 1n 1995, the longest objective follow-up was published (45). Of 366 women who had a modified colposuspension, 109 underwent a clinical exam and pad test at 10-20yrs (mean 14 years). The other 257 had died (10%), moved (28%), or didn't reply. Cure was defined as no stress leak on exam or pad test. Stress leak was seen on pad test in 20%, but another 11 patients (10%) had needed a repeat continence operation, so objective cure was 70%. Previous continence surgery (mainly anterior repair) had occurred in 29% of women. The cure rate in primary procedures (79%) was significantly better than in recurrent cases (61%; p=0.02).

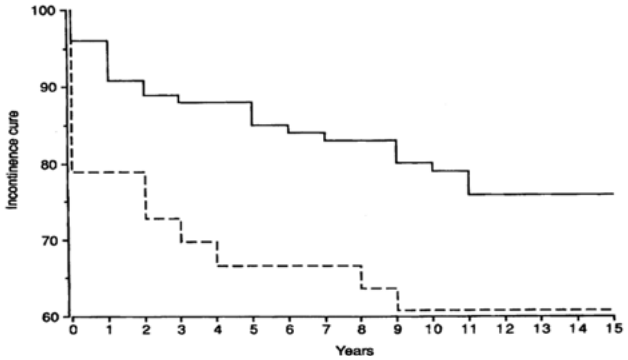

Figure 3: Survival analysis of objective incontinence cure comparing patients with primary and secondary operations. The curves are significantly different (Log rank test, P = 0.02). Solid line=primary surgery; dotted line=secondary surgery (Reproduced with permission from Alcalay, et al 1995) (45)

Four other long-term studies (follow-up at 4.2-8 years) gave absolutely no objective data.

A Cochrane review of open colposuspension versus "sling procedures" was published in 2012 (46), which included the retropubic MUS in the overall analysis (see Section 3.1.4). Findings related to the colposuspension versus PVS revealed a nearly 40% lesser

risk of developing voiding difficulties after open colposuspension as compared to sling procedures (RR 0.41; 95% CI 0.26 to 0.67). Women had a higher risk of developing new or recurrent prolapse when undergoing open colposuspension compared to sling procedures (RR 1.85; 95% CI 1.25 to 2.75). See section 3.1.4 for more detail.

2.1.1. Open Burch Colposuspension: Long Term Studies

There have been no new published randomised trials with long-term data since ICI-6. In the recent (Lapitan et al 2017) Cochrane review (47) a subgroup analysis comparing traditional PVS and open colposuspension showed better effectiveness with traditional PVS in the medium and long term (RR 1.35; 95% CI 1.11 to 1.64 from one to five years follow up, RR 1.19; 95% CI 1.03 to 1.37). Unfortunately, none of the Cochrane analyses (Forest plots) segregated the data as to whether the two operations were being performed for primary stress incontinence or for failed continence surgery.

In summary, previous systematic reviews supported by the Cochrane meta-analysis (47), indicate that the combined results show open colposuspension to have comparable subjective and objective out- comes to both traditional sling procedures and to the newer minimally invasive midurethral sling procedures; EL=1].

Recommendations

Open Burch PVS colposuspension can be recommended as an effective treatment for primary stress urinary incontinence, which has longevity. [Grade A]. It was not designed as a treatment for recurrent stress incontinence, therefore it is not recommended as a salvage procedure.

2.2. Laparoscopic Colposuspension

Laparoscopic colposuspension was introduced by Vancaillie and Schuessler in 1991 (48), as an alternative technique to open colposuspension with the advantages of reduced wound pain, a shorter length of hospitalisation, and a more expedient return to activity while avoiding the morbidity associated with the open colposuspension such as voiding dysfunction and de novo detrusor overacitivity

2.2.1. Laparoscopic versus Open Colposuspension (Table 3)

The 2019 Cochrane review of laparoscopic colposuspension (49) was published since the last ICI -6 chapter, but the Committee was disappointed to find that there have been no new trials comparing these procedures, and no further long term follow up studies of the previously included papers.

The 2019 Cochrane review includes details of 26 RCTs that include laparoscopic colposuspension (49). Of these, thirteen compared laparoscopic with open colposuspension, nine compared laparoscopic colposuspension with midurethral vaginal tapes. Unfortunately, this 2019 review also included four studies that compared variations in the surgical techniques, mainly laparoscopic colposuspension using mesh to elevate the bladder neck, but with staples attaching the mesh to the ileopectineal ligament. These studies feature throughout the Forest plots in the summary analyses. Because such procedures are no longer employed, it is necessary to look carefully at the subset analyses, which calculate the relative risk of cure solely for the traditional lap colpo, using sutures.

As regards short term follow-up from 6 – 18 months, there were 6 studies of traditional lap colpo that showed *subjective* cure, thus RR 1.04 (95% CI 0.99 – 1.08), which tended to favour the lap colpo (p = 0.09) but 8 studies of *objective* outcome using pad test or cough stress test showed cure RR 0.97 (95% CI 0.89-1.06 which favoured the open colposuspension (p=0.05,).

For subjective cure in the mid-term, at 18m–5years, only one study existed (50), which showed equivalence (RR 1.0, 95% CI 0.81d-1.25). For objective cure at 18m–5yrs, only two studies occurred (50, 51), which slightly favoured open cases (RR 0.82, 95% 0.41-1.63), but p = 0.58.

Table 3: Randomised controlled trials: Level 1 & 2 evidence relating to Laparoscopic Colposuspension.

Author, Year, Ref	Lap Colpo	Versus	N/N (n1:n2)	F/U	Cure; effect size	EL	Comments
Su, 1997 (50)	Lap Colpo	Open colpo	92/92 (46:46)	6m	80% vs. 95&: p= 0.044(o)	2	Part preference, part randomised: sample size calculation req'd 152.
Ustun, 2005 (53)	Lap Colpo	Open colpo	52/52 (26:26)	3-24m	81% vs. 81%; p=ns	2	Many concurrent procedures - varied between groups
Kitchener, 2006 (50)	Lap Colpo	Open colpo	242/291	2y	80 vs.70% (o)	1	5 had no op., & 12 changed op, after randomis'n. Objective data on 83
Carey, 2006 (54)	Lap Colpo	Open colpo	164/200 (766:88)	3-5y	72% vs. 78%, p=0.22 (o at 6m); 69% vs. 80%, p= 0.38 (s at 2y)	2	Telephone interview at 3-5y; results similar to 24 m
Ankardal 2005 (55)	Lap Colpo	Open colp	75/ 49	12m	91% vs 92% obj, p =ns Dry on 24 h pad test	1	Third arm = lap colp mesh, not considered here
Cheon 2003 (56)	Lap Colpo	Open Colpo	47: 43 RCT	12m	85% vs 86% subj	1	Pad weight: 29 to 3.6 gm versus 36 to 4.4 gm
Fathy 2001 (57)	Lap colpo	Open Colpo	74 total RCT	18 m	87.9% vs 85%, success not defined in abstract	1	Full paper not avail on line
Summit 2000 (58)	Lap Coplo	Open Colpo	"28:34 RCT"	12m	93% vs 88%, success not define in abstract	1	Full paper not avail on line

For objective cure after 5 years, there were only 2 small studies (both only scientific abstracts not fully published (51) and Morris 2001 (abstract no longer available)) which favoured the open procedure (RR 0.89, 95% CI 0.29 – 2.8, but p = 0.84), with no studies of subjective cure in the long term. In Table 3 below, references re single suture procedures and "mesh colposuspensions" are now deleted.

Note that in the ESTER study, which analysed Surface Under the Cumulative Ranking (SUCRA), the number of women cured by open colposuspension was 76.7%, versus 48.9% for the laparoscopic procedure (see full discussion at end of Surgery for Stress Incontinence section, Imamura et al (52)).

2.2.2. Complications of Laparoscopic Colposuspension

In the most recent Cochrane review (49), the traditional lap. colposuspension has a 3.8% risk of bladder perforation needing formal suturing, versus 1.5% for open cases (RR 2.1., 95% CI 0.97-4.77). The traditional lap colpo has 9.9% rate of de novo detrusor overactivity (on urodynamic study)) versus 7.5% for the open case (RR 1.29, 95% 0.72-2.3m effect size p = 0.40). The rate of voiding dysfunction was 9.25% versus 10.8 % respectively (RR 0.81, 95% CI 0.5 – 1.31, effect size p = 0.38).

Longer operating times are a significant disadvantage of the laparoscopic approach; however, women have reported significantly less pain (51, 59, 60), shorter hospital admissions, faster recoveries and quicker return to normal activities (50, 56, 61).

In summary, the data for comparison of laparoscopic versus open colposuspension remains dissapointingly limited, both in the medium term and the long term. This lack of evidence needs to be corrected, as the laparoscopic colposuspension is likely to become increasingly attractive to women in countries where the polyprolene mesh mid urethral slings are no longer available, or to women who are fearful of the risks of mesh implantation for urinary incontinence.

2.2.3. Laparoscopic Colposuspension vs. Midurethral Sling Procedures

For a more extensive discussion, see Section 3.1.4 (Retropubic MUS versus Colposuspension)

In the 2019 Cochrane review of laparoscopic colposuspension (Freites et al), nine trials have compared laparoscopic colposuspension with mid-urethral slings: there was no statistically significant difference in subjective cure rates within 18 months (RR 1.01, 95%CI 0.88 to 1.16) [EL=1].

The 2019 review did not provide data about objective cure for the Lap Colpo versus MUS comparison. However, the 2017 Cochrane review (47) did comment that the definition of objective cure varied widely between studies, yet overall the objective cure rate was higher for mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95%CI 0.85 to 0.99) [EL=1].

Although laparoscopic colposuspension is regarded as a less invasive operation than the open colposuspension, the mid-urethra tape procedures had even more significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01-0.001) as compared to the laparoscopic colposuspension. As regards Adverse Events, the risk of de novo detrusor overactivity (in women undergoing urodynamics at 18 months) was RR 0.80 (0.34 to 1.88) favouring the lap colpo. As regards voiding dysfunction, the RR was 1.06 (0.47 to 2.41).

2.2.4. Different Techniques of Laparoscopic Colposuspension

Different aspects of the laparoscopic technique have been compared including one vs. two sutures (62), sutures vs. mesh (58, 61, 63) and transperitoneal vs. extraperitoneal approach to laparoscopy (58). Two sutures on either side of the bladder neck resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95%CI 1.14 to 1.77) cure rates as compared to one (64), and single-suture colposuspension is not further discussed [EL=2].

2.2.5. Longevity of Laparoscopic Colposuspension

In 2009, Barr et al retrospectively compared 52 women who had undergone an open colposuspension 10 years previously, with 139 women who had had laparoscopic colposuspension in Manchester, using the BFLUTS questionnaire by telephone (65). Approximately 20% of patients in both groups had undergone previous continence surgery. At least two Ethibond sutures were placed bilaterally. Cure was defined as no urinary leakage in the last six months. Loss to follow-up occurred in 31% of laparoscopic and 40% of open cases (further details not provided). Subjective cure rates were 48% of laparoscopic cases at 12.8 years, versus 32% of open cases at 14.7 years (duration of follow-up significantly different; p<0.001).

The Cochrane Review concluded that the available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension 18 months postoperatively. However, the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long-term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalisable to the urogynecological/urological community at large. The NICE guidance states that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of SUI.

Summary

Laparoscopic colposuspension shows comparable subjective outcome to open colposuspension in the short term but objective outcome favours the open procedure up to medium term; longer term out- comes are unknown [EL=2]. Objective cure data at 18 m -5 years are inadequate.

Recommendations

Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise. (Grade C)

Women should be advised about the limited evidence available about the long-term durability of laparoscopic colposuspension, and the inferior outcomes compared to open colposuspension, and compared to classical or short Pubovaginal Sling. (Grade C)

Research

Objective Cure data for the laparoscopic colposuspension at 18 m – 5 years should be obtained.

3. MIDURETHRAL SLING (MUS)

3.1. Retropubic MUS

The tension-free vaginal tape (TVT) procedure for treatment of female urodynamic stress incontinence was first introduced by Ulmsten et al. in 1996 (66). The development of the TVT operation was an attempt to support the middle portion of the urethra, instead of restoring anatomy and correcting urethral hypermobility at the bladder neck. The idea of supporting the "mid-urethra" was derived from several research projects conducted during the last thirty years. The work of Zacharin in 1968 and DeLancey in 1994 had already shown that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was closer to the middle portion of the urethra than the bladder neck (67, 68). The most densely innervated portion of the urethra is well known to be the middle part, and Huisman in 1983 (69) showed in histological studies that the mid-urethra had the most abundant vascularization. Additionally, Westby et al. (in 1982) showed in radiographic studies how the urine stream was interrupted at the mid-urethra on holding in continent women (70) and Asmussen *et al.* (1983) showed that the maximal urethral closure pressure was situated at the midurethra (71). It became apparent that focusing on the mid-urethra might achieve improvement in the performance of continence surgery. Retropubic MUS is shown in **Figure 4**.

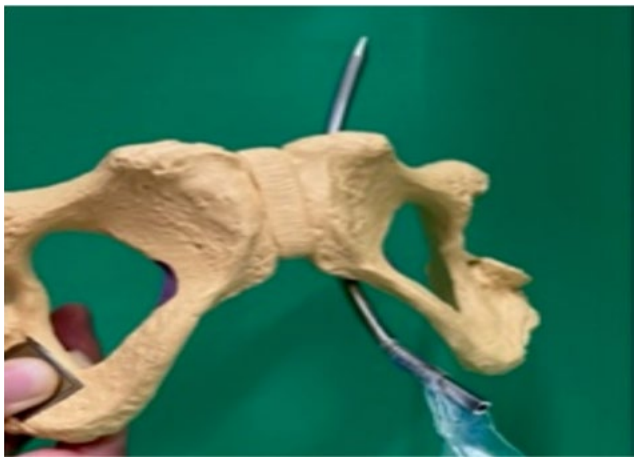

Figure 4: Retropubic mid-urethral sling (MUS) [Tensions free Vaginal Tape, TVT]

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90 % in primary cases of SUI (see references [(66, 72, 73) from ICI-6)], in recurrent cases (74), and in mixed incontinence cases (75). Retrospective case review found that repeat MUS had a 62% subjective cure rate compared to 86% in those undergoing primary MUS placement (p<0.001) at a mean follow up of 50 months (76). Preoperative intrinsic sphincter deficiency was more common among women undergoing repeat MUS compared to primary MUS. Repeat MUS was more successful using a retropubic than a transobturator approach (77). While general complication rates were similar, deno urgency and UUI were more frequent in those undergoing repeat MUS (30% vs. 14% and 22% vs. 5%, p<0.001; respectively).

Since those initial reports of success, several groups have reported long-term outcomes exceeding 5 years (78-82) and 10 years after a retropubic MUS procedure (83, 84). In 2017, 13-year follow-up data (85) on 55 of the original 63 participants found an objective cure rate of 90.9% and a subjective cure rate of 85.5%. More recently, 17-year follow-up data on 56 of the original 61 participants found an objective cure rate of 83.9% and a subjective cure rate of 78.6% (86). The cure rates for TVT are durable over the long-term with a small decline in both objective and subjective cure rates over time.

Since the last ICI review, the literature regarding the TVT and other RP MUS procedures has expanded rapidly. The number of RCTs and large cohort studies now available significantly exceeds the previous review, and there has been a recent Cochrane review in 2020 (1). Unless otherwise mentioned, only fully published studies have been included herein.

3.1.1. Retropubic MUS vs. No Treatment

No recent trial has compared RP MUS with no treatment.

3.1.2. Retropubic MUS vs. Pelvic Floor Muscle Training (PFMT)

Pelvic floor muscle training (PFMT) with or without biofeedback is an effective treatment for urodynamic stress incontinence. Labrie *et al*. (2013) published a multicentre RCT of MUS (n=215) versus pelvic floor physiotherapy (n=202) which favoured the retropubic MUS (87). Although the authors pointed out in their introduction that severe incontinence is associated with a poor physiotherapy outcome, nevertheless the randomised subjects all had moderate to severe incontinence. Women who were unable to contact their pelvic muscle were not necessarily provided with electrostimulation.

3.1.3. Retropubic MUS vs. Bulking Agents See Section 4.6

3.1.4. Retropubic MUS vs. Open Colposuspension (See also section 2.23)

A Cochrane systematic review was published from 2012, comparing open colposuspension and sling procedures (46), fully discussed in ICI-6**.** Twenty-two trials compared suburethral slings (traditional slings or trans-vaginal tape or Trans Obturator tape) and open colposuspension, involving a total of 2343 women (slings procedures n=1254, vs. open colposuspension n=1089). The authors acknowledged the variability of the data due to the different types of sling operations performed. There were non-significant differences in long-term patient reported cure rate (RR 1.11; 95%CI 0.97 to 1.27) and in objective cure rate (RR 0.70; 95%CI 0.30 to 1.64). For details, see ICI-6 but important trials are shown in Table4A.

In 2018, Trabuco et al (89) reported 2-year results of their open colposuspension vs. retropubic MUS at the time of sacrocolpopexy trial. They found retropubic MUS produced significantly higher rates of stress specific continence at 1 and 2 years (70% vs 45%, p=0.006). There was no difference in voiding dysfunction, urgency incontinence, antimuscarinic medication use or patient satisfaction.

In 2021, Karmakar et al. (95) published a 13 year follow up of a matched cohort involving 1,344 women (336 Burch colposuspension, 1008 retropubic MUS) with urodynamic SUI, without ISD.

Table 4A: Studies of Retropubic MUS versus Open Colposuspension (OC) with objective outcomes.

Author, Year, Ref	RP MUS	Vs. Open Colpo	N/N	F/U (mth)	S.S.	# Lost to F/U	% Cure	Sig. Diff.	LE	Notes
Ward, 2002* (90)	TVT	OC		6	Yes RCT	N/A	66/ 57 (o)	No	1	24hr pad test
Ward, 2004* (91)				24		19/26	63/ 51 (o)	No	1	24hr pad test
Ward, 2008* (92)				60		103/120	81/ 90 (o), 91/ 90 (s)	No	1/2	>50% lost to F/U
Liapis, 2002* (93)	TVT	OC	36/35	24	No RCT	N/A	84/ 86 (o)	No	2	1hr pad test
Wang, 2003* (94)	TVT	OC	49/49	22	No RCT	N/A	82/ 76 (o), 92/ 93 (s)	No	2	1hr pad test
Bai, 2005* (18)	TVT	OC	31/33	12	No	0/0	87/ 87.4 (s)	No	2	See table 1A

83% of the colposuspension group reported no SUI at 13 years vs. 85% of the retropubic MUS group (p=0.038). Validated questionnaires, eg Patient Global Impression of Improvement, were similar between groups, with no difference in reoperation rates, de novo overactive bladder, or voiding difficulty. Subsequent prolapse surgery was greater in the colposuspension group (3.3% vs. 1.1%, p=0.01).

3.1.5. Retropubic (RP) MUS vs. Laparoscopic Colposuspension

Since ICI-6, the Cochrane review (49) included 4 trials comparing laparoscopic colposuspension to TVT and found little difference in subjective cure between groups; however, certainty of the results was limited by the low-quality evidence. (See Table 4B). Only two trials gave objective results.

Paraiso *et al.* (98) performed postoperative urodynamic studies in 32 laparoscopic Burch colposuspension and 31 TVT patients, which showed a 18.8% rate of USI at one year in the laparoscopic Burch group, versus 3.2% in the TVT (p=0.056). At long-term follow-up of the same study, median 65 months (range 12-88 months), Jelovsek *et al.* (99) confirmed bothersome SUI symptoms in 11 and 8%, respectively (P = 0.26). [EL=2]

The conclusions of studies comparing retropubic MUS with laparoscopic colposuspension may be limited due to underpowering.

Dean *et al.* performed a systematic review of laparoscopic colposuspension (n=264) and TVT (n=290) which included 7 trials (101). The subjective cure rate between laparoscopic colposuspension and TVT was no different within 18 months (RR 1.12, 95%CI 0.98 to 1.29). However, objective cure rate was significantly higher for TVT (RR 1.16, 95%CI 1.07 to 1.25). There were no significant differences between perioperative complications, de novo DO, voiding dysfunction, procedural costs and QoL scores. The authors confirmed that the TVT procedure was quicker to perform, with a shorter hospital stay. **[EL=1/2**]. A systematic review by Fusco et al. in 2017 (102) evaluated open and laparoscopic colposuspensions together with all types of Slings and found superiority of the MUS over the Burch colposuspension. The ESTER study found that retropubic MUS had a cumulative cure (SUCRA) of 89.1%, versus lap colposuspension of 48.9% (61).

3.1.6. Standard Retropubic MUS (TVT) vs. Other Modified Retropubic MUS

There have been several modifications of the standard procedure with use of different tape materials. The 2017 Cochrane Systematic Review (103) on MUS found that retropubic bottom to top approaches were more effective than retropubic top to bottom for subjective cure (RR 1.10, 95% CI 1.01 to 1.19; 3 trials, moderate quality evidence).

Table 4B: Retropubic MUS versus Laparoscopic Colposuspension

Author, Year, Ref	RP MUS	Vs.	N/N (n1:n2)	F/U	Cure; effect size	LE	Comments
Persson, 2002 (96)	TVT	Lap Colpo	28/32	12m	89/87 (o) 57/52 (s)	1	Cost analysis
Cheon, 2003 (56)	TVT	Lap Colpo	68/79 (31:370	12m	87% vs.89% RR 0.98: 95% CI 0.82, 1.16	2	270 approached: 79 randomised. Study designed to examine costs.
Ustun, 2003 (97)	TVT	Lap Colpo	23/23	12 m Range 12-24	82.6% vs 82.6%	1	3 conversions to open in the lap group
Paraiso, 2004 (98)	TVT	Lap Colpo	71/72 (35:36)	Median 18m Range 12-43m	97% vs 81% (o), 43% vs 52% (s)	2	S.S. 130; recruitment stopped early because of slow recruitment. 63 (88) FU at 1y; 33(46%) at 2y
Jelovsek, 2008 (99)				Median 65m Range 12-88m			
Tong, 2008 (100)	TVT	Lap Colpo	67/30	9m (±10m)	99.5 vs 86.5 (s)	2	Matched cohort. No objective outcome. Paper = non English

Studies comparing TVT with "top-down" Supra Pubic Sling are no longer discussed in this Chapter, as the SPARC procedure is no longer available.

In 2019, Marschke et al. (104) reported on 303 women, 152 randomised to TVT Exact® and 151 to RetroArc®. Objective cure was similar between groups but subjective cure favoured TVT Exact® (76.1% vs. 54.3%, p=0.002). Voiding difficulty was lower in the TVT Exact® group.

3.1.6.1. Retropubic MUS in ISD, Obesity, and Previous Failed Continence Surgery

In 2019, Kim et al. (105) reviewed 28 studies (n=2,607) comparing safety and efficacy of TVT and TOT in select groups (e.g., patients with *obesity, ISD*, prolapse, *and recurrent SUI*). At a mean follow-up of 26.9 months, they found superiority of the TVT over the TOT for objective outcomes overall and in each sub-group. The TVT was superior on subjective outcomes over the TOT overall, and in patients with ISD and recurrent SUI. There was no significant difference in complications between groups.

Barco-Castillo (2020) analysed 3 RCTs of *obese* (BMI>30) women (n = 316) and non-obese women (n = 566) undergoing TVT, TOT, or "anti-incontinence surgery (106). Objective success was defined as pad test < 1 gm, negative cough stress test or no USI on urodynamics. Risk of objective failure was significantly increased in obese women (RR 1.62, 95% CI 1.26- 2.07), similar to the risk of subjective failure (RR 1.69, 95% CI 1.32 – 2.16). This analysis included a report by Brennand et al (2015), which was then further followed up in 2017 showing similar results (107).

Laterza et al (108) performed a secondary analysis of a TVT vs TVT-O RCT demonstrating that higher age and higher BMI was associated with greater objective failure at 5 years in both groups.

3.1.6.2. Risk of Voiding Dysfunction/ Need to Cut Tape After Retropubic MUS

Adverse events after mesh midurethral slings are not uncommon. In the Trial of Midurethral Slings (TOMUS, 2011), Brubaker et al (109) found that voiding dysfunction requiring surgery occurred in 9 participants (3%; all in TVT group) and 16 participants (3.4%) experienced voiding dysfunction (10 in TVT group, 6 in TOT group).

Laurikainen et al performed 5 years follow-up (110) from their RCT comparing TVT to TVT-O, revealing that 4.6% of the TVT group and 5.7% of TVT-O group had post void residual (PVR) volumes >100 ml.

3.1.6.3. Risk of Mesh Extrusion, Mesh Pain After Retropubic MUS

The TOMUS trial by Brubaker et al (2011) reported 4.7% of women experienced a mesh "complication" following TVT surgery at 2 years of follow up (109).

In 2021, MacCraith et al (111) performed a systematic review of synthetic mesh erosion and chronic pain, which contained 13 studies regarding mid-urethral slings, additional to the TOMUS trial. In their summary table, the risk of mesh erosion varied extremely widely, from 0.22% to 17.99%, but the overall risk was 1.9%. The duration of followup for these studies varied from 12 months to 84 months. The mean duration from surgery to onset of mesh erosion was 357 days +/- 183 days. A subset analysis of erosion after TVT versus TOT showed that the risk was slightly higher after TVT (1.43% versus 1.23% after TOT) which was not significant (p = 0.8). The risk of chronic pain for all mid-urethral slings was 0.6%, with a mean duration of onset at 428 +/- 238 days (no subset analysis for TVT versus TOT).

3.1.6.4. Sexual function after MUS

A recent systematic review performed in 2020 (112) to look at the impact of MUS on sexual function revealed 22 trials utilising validated questionnaires. Sexual function scores significantly improved following MUS, with sustained improvement at 24 months post-op. Sexual desire, arousal, orgasm, lubrication, satisfaction, and dyspareunia all significantly improved postoperatively (all p < 0.05). A significant reduction in coital incontinence (risk ratio 5.78; 95% CI 3.16-10.58; P<.00001) was observed.

3.1.7. RP MUS vs. Single-Incision Mini-Slings (SIMS)

Single-incision mini-slings (SIMS) were introduced as an attempt to decrease complications associated with retropubic and transobturator slings. These procedures theoretically require minimal anesthesia and may be performed under local anesthestic (Figure 5). A Cochrane Review in 2017 (113) evaluated 31 trials (*n* = 3290) comparing single incision slings to retropubic MUS. Several trials included the mini-sling TVT-Secur which is no longer on the market. The meta-analysis reported significantly more patients had ongoing incontinence after surgery in the SIMS group (41% vs. 26%; RR 2.08, 95% CI 1.04-4.14). The meta-analysis concluded that TVT-Secur was considerably inferior to MUS for treatment of stress incontinence and not enough evidence is available on alternative SIMS to allow reliable comparisons.

Figure 5: Single Incision Sling (courtesy K H Moore)

In 2018, Melendez-Munoz et al (114) compared TVT Abbrevo™ to MiniArc™ in 183 women by RCT. The TVT Abbrevo was designed to evoke less groin pain. The subjective cure for MiniArc at 12 months was 73.6%, the objective cure (negative cough stress test with a "comfortably full bladder") was 90.5%, versus subjective/ objective cure of 76.9% and 96% for the TVT Abbrevo (difference not significant). All groin pain resolved by 5 weeks. The MiniArc has been withdrawn from the market. In 2020, Braga et al (115) published 3 year open prospective data for the TVT Abbrevo in 41 women, with 90% subjectively cured and 92.5% cured on a cough stress test at 400 ml, with de novo OAB in 15%.

3.1.8. Comparison Studies of the Retropubic MUS vs. Trans-obturator MUS

Because much of the literature on the trans obturator (TO) MUS comprises various comparisons with the retropubic MUS (eg RCT or Cohort study) these comparisons are considered here. Studies that only feature the TO MUS are discussed in the next section

A notable complication of the retropubic MUS procedures has been inadvertent puncture of the bladder or urethra and, on rare occasions, intra-abdominal viscera or neurovascular structures. The bladder is most commonly punctured; rates vary from 0.8% to 21% in different studies (116). Two systematic national registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide (117) and one from Austria including 2795 operations (118). The rates of bladder perforation were 3.8% and 2.7%, respectively.

In an effort to minimise the incidence of bladder injuries, Delorme in 2001 introduced a modified tape procedure in which the tape was brought to support the mid-urethra from the groin through the obturator foramina to enter the vagina, bilaterally ('outside-in', most commonly called TOT or 'Monarc') (119). **See Figure 6.**

Figure 6: Trans-obturator Outside–In Tape (Monarc) (Courtesy KH Moore)

De Leval further modified the outside-in TO MUS procedure to be an 'inside-out' procedure, now called the tension-free vaginal tape-obturator (TVT-O) (120). These terms are used in future commentary.

As per ICI-5, probably the largest RCT comparing retropubic MUS with TO MUS was published by Richter et al (2010) (121). This was a multicentre equivalence trial of 597 women (94% completion) with objective and subjective outcomes at 12 months. Objective success was strictly defined, as negative cough stress test, negative 24 hour pad test and no retreatment for stress incontinence. The objective success rates met the criterion for equivalence (80.8% for TVT versus 77.7% in TOT group) but the subjective success rates did not meet the criterion (62.2% versus 55.8%). Voiding dysfunction requiring further surgery was greater in the retropubic group (2.7% versus 0%, p=0.004) but the rate of neurological symptoms e.g. 'leg pain" were higher in the TO group (4.0% versus 9.4%, p=0.01 **[EL=1]**

The comparison between the Retropubic and TO MUS procedures has been the subject of numerous publications. ICI-6 reported the results of two Cochrane systematic reviews (122, 123), and one review from EAU (124). The first two reviews by Ogah and Novara showed no difference for subjective cure between procedures, but objective cure rate was significantly higher for the retropubic route (122, 124).

In the most recent 3rd Cochrane review [Ford et al 2017], of TO MUS and retropubic MUS (103), fifty-five trials with a total of 8652 women were included (sample size range n= 20 to 597). The meta-analysis reported non-significant differences in subjective cure rate at 12 months (RR 0.98, 95%CI 0.96 to 1.00) Long-term subjective cure was also similar between groups (RR 0.95, 95%CI 0.80 to 1.12, slightly favouring the retropubic approach). Long term objective cure (RR 0.97, 95% CI 0.9-1.06) was similar. In terms of complications/ adverse events, TO MUS are characterized by lower risk of voiding dysfunction, vascular/visceral injury, operative blood loss and length of stay. On the other hand, TO MUS are clearly associated with a higher risk of groin pain (see section 3.1.8.1 below), and repeat anti-incontinence surgery may be more frequent in TO MUS versus retropubic MUS (103). The following Table 4C includes studies of currently available MUS at least 12 months' objective data.

An important RCT (132) of TVT versus Monarc (TOT) in women with a low MUCP (intrinsic sphincteric deficiency) was performed in 164 women, with an adequate sample size, showing a markedly reduced cure rate for the Monarc in ISD (objective cure 55% versus 79% at 6 months; p=0.004). Most studies of MUS do not evaluate the MUCP as a confounding variable. Long term results of this study were presented in 2019 [(77), see Table 4C) with similar results.

In Albo 2012 (143) the TOMUS trial participants (253 TVT and 263 TOT) were followed at 2 years. Objective (negative stress test, negative pad test and no re-treatment for SUI) and subjective (no self-report of stress leakage, no leakage on 3-day bladder diary and no re-treatment for SUI) success was analysed. The predetermined equivalence margin was 12%.

At 2 years, the subjective (55.7% versus 48.3%, 95%CI for difference of 7.4%: -0.7, 15.5%) and the objective cure rates (77.3 versus 72.3%, 95%CI for difference of 5.1%: -2.0, 12.1%) were similar. Neither objective nor subjective success rates met the prespecified criteria for equivalence. Occurrence of mesh exposure (retropubic 4.4% vs transobturator 2.7%, p =0.26) were not significantly different. The retropubic mid urethral sling group had higher rates of voiding dysfunction requiring surgery (3.0% vs 0%, p = 0.002)), whereas the transobturator group had more neurological symptoms (9.7% vs 5.4%, p = 0.045). The 2 year data showed widening difference in benefit for TVT / TOT, favouring the TVT.

Bohlin 2015 (144) gathered postoperative (8 weeks and 1 year) data from the Swedish National Register for Gynecological Surgery of all MUS procedures (retropubic MUS, n=4,539; TO MUS, n =1, 769) performed over 6 years; multiple logistic regression analyses were performed between the outcome variables. Cure was defined on questionnaire as no leak, or leak < 3 times per month. and BMI and smoking, presented as adjusted odds ratios (adjOR) with 95%CI; Subjective 1-year cure rate was 88.3% with RPMUS and 85.2% with the TO technique (p=0.002). Lower cure rate was seen in women with a BMI >30 (0.49; 95%CI 0.33–0.73), in diabetics

Table 4C: Retropubic MUS versus TO MUS, with medium term objective outcomes (at ≥12 m – 5 ys).

Palos et al in 2018 (145) compared retropubic sling to TOT at 12 months (*n*=81) and found objective cure rates (on cough stress test) of 100% with retropubic MUS and 93% with TOT (p=0.03). Subjective cure rates were 92% for the retropubic sling and 90% for the TOT (p=0.02). On intention to treat analysis, TOT was found to be inferior to the retropubic sling. The retropubic MUS was associated with higher rates of voiding difficulty only in the first 7 days (37.5% vs 9.7%, p=0.007).

3.1.8.1. Complications After Retropubic Versus Trans Obturator Mus

The rate of vaginal extrusion was slightly higher following TO MUS in the review by Navara (2010) possibly due to the use of ObTape which was removed from the market due to high risk of erosion/ extrusion (124). However, the Cochrane review by Ogah et al (2009) showed no significant difference (122).

In these two early reviews, the retropubic MUS showed no significant difference from the TO MUS in the need for repeat incontinence surgery, postoperative DO, de novo urge incontinence (122, 124). There was a significantly higher occurrence of groin pain (**12%**) in women with a TO approach, versus a higher incidence of suprapubic pain in women with a retropubic sling (**1.7%).** However, postoperative voiding dysfunction occurred significantly less frequently in the TO route group (4% versus 7%, RR 0.63, 95%CI 0.44 to 0.89) in one of these reviews (122).

As expected, bladder perforation was less common after TO MUS compared with retropubic MUS (RR 0.13, 95%CI 0.08 to 0.20), as was major vascular/visceral injury (RR 0.33 95%CI 0.19 to 0.55). Mean operating time was lower (RR -7.54 95%CI -9.31 to -5.77); many surgeons do not perform mandatory cystoscopy after TO MUS. Postoperative voiding dysfunction was less frequent following TO MUS (RR 0.53, 95%CI 0.43 to 0.65). Postoperative de novo urge incontinence was no different between groups (RR 0.98, 95%CI 0.82 to 1.17). Groin pain was much higher in the TO MUS group (**RR 4.12**, 95% CI 2.71 to 6.27) whereas suprapubic pain was lower (RR 0.29, 95% CI 0.11 to 0.78). There was no difference in vaginal tape erosion/ exposure/ extrusion (RR 1.13, 95%CI 0.78 to 1.65) or bladder or urethral erosion (RR 0.34, 95%CI 0.01 to 8.13) between the two groups.

Repeat incontinence surgery in the long term was highly significantly more likely with the TO approach as compared to retropubic MUS (**RR 8.79**, 95%CI 3.36 to 23.00).

A subsequent systematic review (Maggiori et al 2017) including 11 RCTs and 5 non-RCTs (146) found that TVT and TOT had similar long-term objective and subjective cure rates with no significant difference in complications. Later that year Fusco et al (2017) published their meta-analysis, revealing that patients treated with TVT had higher subjective (OR: 0.83, p=0.03) and objective (OR: 0.82, p=0.01) cure rates than those treated with TOT but with higher risk of intraoperative bladder or vaginal perforation, hematoma, UTI and voiding symptoms (102). However, the morbidity of intra-operative bladder perforation with the TVT trocar (diameter 1.2 cm) is small, usually requiring overnight catheterization.

3.1.8.2. Effect of Obesity Upon Results

A study (147) on 760 women who had TVT showed that the overall cure rate in women of normal weight was 81.2% compared with 52.1% in the very obese (BMI >35).

In 2010, Stav et al performed a retrospective review of 950 retropubic MUS (TVT) and 270 TO MUS (mostly TVTO/ Monarc, to seek features that predicted failure (62). At mean follow-up of 50± 24 months (range, 12–114), the subjective cure rate (on UDI by telephone) was 84.7%. Multivariate analysis revealed that BMI >25 was the most significant risk for failure (OR, 2.9, $p < 0.001$). The next highest risk factors for failure were urodynamic mixed incontinence (OR, 2.4) and previous continence surgery (OR, 2.2) both $p < 0.001$, followed by intrinsic sphincter deficiency (OR, 1.9, $p = 0.01$).

Jeong 2014 (148) was a retrospective study at 36+ months; when dividing women by the route of approach, the success rates in the TO approach became worse with increasing BMI (P=0.037), while success in the retropubic approach did not differ according to the BMI groups (P=0.06). On multivariate logistic regression, only preoperative MUI (clinically-defined) was a risk factor for failure in all patients.

The Brennand 2015 study (107) is subset of original RCT by Ross 2009 (135). TO and retropubic MUS were grouped together in this analysis. The probability of objective cure remained significantly higher for non-obese women than obese women (85.6% versus 67.8%, (p=0.018, RR 1.26, 95%CI 1.04–1.52). Surgery type was not significantly associated with cure (p=0.492, RR 0.95, 95%CI 0.83–1.10). Brennand 2017 (149) followed these women for 5 years and found obese women continued to experience lower rates of cure.

In 2016, Pereira et al (150) compared TVTO outcomes in women with BMI at < 30 and > 30 at 4 years, however almost half of the retrospective participants had mixed incontinence and the drop-out rate was nearly 40% in both groups. Success rates (on cough

stress test) declined over 4 years from 98 % to 96% in non-obese, versus 95.1% to 90% in the obese.

In 2018, Laterza et al (108) performed a secondary analysis with respect to obesity of a RCT at 5 years, including TVT and TVT-O RCT together (the Austrian Study Group). At 5 years a positive cough stress test was seen in 56/277 (20%) women. The probability to have a positive stress test at 5 years significantly increased with higher BMI (p = 0.01) (I.e. a high BMI (>35) had a failure rate of 30% versus failure rate of 10% for BMI of 25)

Barco-Castillo (2020) analysed 3 RCTs of obese (BMI>30) women (n = 316) and non-obese women (n = 566) undergoing TVT, TOT, or "anti-incontinence surgery (106). Objective success was defined as pad test < 1 gm, negative cough stress test or no USI on urodynamics. The risk of objective failure was significantly increased in obese women (rr 1.62, 95% CI 1.26- 2.07), which was similar to the risk of subjective failure (RR 1.69, 95% CI 1.32 – 2.16).

Summary

Retropubic MUS has demonstrated equal or superior efficacy compared to other procedures for female SUI (LE=1/2).

Retropubic MUS is at least as effective as open colposuspension in the short and medium term, and may be superior to laparoscopic colposuspension although most studies are small/ underpowered (EL=1/2). The rate of complications of retropubic MUS and colposuspension are similar. However, the rates of specific complications (e.g. bladder perforation, need for subsequent POP surgery, etc.) differ between the procedures. Retropubic MUS is associated with a shorter operative time and hospital stay. (EL=1/2)

Overall, retropubic MUS and TO MUS procedures perform equally at a short-term follow-up of 6 to 12 months. (EL= 1/2). At longer term follow up, repeat incontinence surgery is highly significantly more likely with the TO approach as compared to retropubic MUS (**RR 8.79)** The overall rate of vaginal MUS erosion is no different between these techniques. (EL=1/2)

The rate of bladder puncture, postoperative voiding dysfunction, and haematoma formation lower after the TO approach versus the retropubic MUS approach. Groin pain is more common with the TO approach **(RR 4.12**). [EL=1/2]. However, bladder puncture by the small trocar involved seldom requires more than overnight catheterization, and haematoma formation is generally managed conservatively, whilst cure of groin pain often requires substantial surgical exploration to remove mesh from the groin.

Recommendations

Retropubic MUS is recommended as an effective and durable treatment for stress urinary incontinence. [Grade A]

For both the retropubic and trans obturator procedure, substantial evidence from retrospectively analysed RCTs now indicates that obese patients have a poorer outcome than non- obese patients [Grade B].,

Although the risks of bladder perforation and haematoma are significantly higher for the retropubic approach, substantial evidence from systematic reviews indicates that the risk of groin pain and reoperation for incontinence is significantly higher for the trans-obturator approach. [Grade A]

3.2. Trans Obturator Tape Long Term Results

As explained in Section 3.1.8 (Comparison of Retropubic versus Transobturator MUS), Delorme modified the TVT to minimise the incidence and morbidity of bladder and urethral injuries. The polypropylene mesh tape was brought from inside the thigh through the obturator foramen to support the mid-urethra (119).

De Leval further modified this "outside-in TO MUS" procedure to be an "inside-out" procedure, now called the tension-free vaginal tape-obturator (TVT-O™; Gynecare (120), made of Amid type I polypropylene mesh, with less risk of mesh adverse events (151). The "outside-in" and "inside-out" techniques are important categories for consideration of outcomes, but are not always described.

In 2017, a systematic review with meta-analysis (146) exclusively regarding long-term (>5 years) outcomes of MUS was published, comparing the retropubic vs transobturator approach. The definition of "cure" varied widely, ranging from negative cough stress test to "no self-reported stress incontinence". The authors concluded that both TVT and TOT are associated with similar long-term objective (OR: 0.87 [95% CI: 0.49-1.53], p = 0.62) and subjective (OR: 0.84 [95% CI: 0.46-1.55], p = 0.58) cure rates. Similarly, no significant difference was observed between TTOT-OI and TVT-O) in objective (OR: 3.03 [95% CI: 0.97-9.51], p = 0.06) and subjective (OR: 1.85 [95% CI: 0.40-8.48], p = 0.43) cure rates. This study also shows that there was no significant difference in complication rates for all comparisons: TVT versus TOT (OR: 0.83 [95% CI: 0.54-1.28], p = 0.40), TOT-OI versus TVT-O (OR: 0.77 [95% CI: 0.17-3.46], p = 0.73) (146).

Other long term outcome studies with duration of 48 months to 10 years have emerged (see Table 5) (150, 152-160)]. This table only lists studies that reported objective outcomes, only using standardized tools such as a pad test or at least a cough stress test under standard conditions. With regard to subjective outcomes, we preferred to consider the studies that used the bladder diary.

In Costantini 2016 (158), a Kaplan–Meier survival curve showed that the continence rate decreased for up to 25 months after surgery, with stabilisation thereafter for the TVT group while continuing to drop in the TO MUS group. **Figure 7.** Patients in both groups were highly satisfied at long-term follow-up

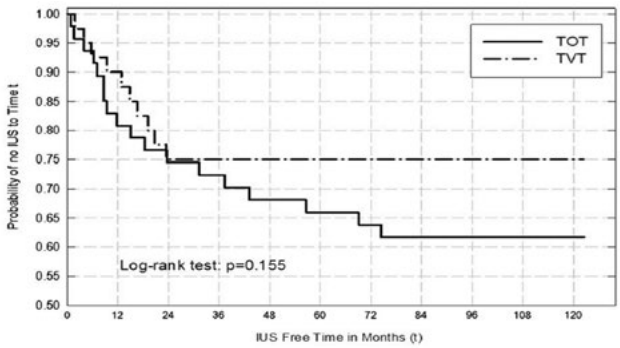

Figure 7: Free survival times from UI subdivided according to surgical techniques, reproduced from Costantini et al 2016 with permission

Laurikainen 2014 (110) is a 60-month update of Palva *et al*. (127), showing no differences between groups (TVT and TVT-O). In Kenton 2015 (161), a per protocol analysis at 5 years showed retropubic MUS success rate was 7.9% greater than TO MUS (95%CI -1.4 to 17.2), and did not meet the pre-specified criteria for equivalence. (The 95% CI included 0%, indicating non-significant results).

Ross 2016 (162) followed 176 women for 5 years; serious adverse events and tape effectiveness did not differ between groups. However, palpable (non-exposed) TOT occured in 48.5% vs. 22.4% in TVT; p=0.001. Tammaa et al in 2018 (163) compared TVT to TOT at 5 year follow up and found subjective and objective cure rates were stable and similar between groups.

Offiah et al 2021 (164) reported results of a multicentre RCT comparing retropubic and transobturator MUS at a mean follow up of 12.8 years (via postal questionnaire). Data was available on 110 of the 180 original participants. While at 1 year there was no significant difference between groups, at 12.8 years they found TVT to be superior to TOT for subjective SUI cure (41.8% vs 21.8%, p=0.045). This represented a significant decline in efficacy since 1 year, particularly for the TOT. There were no differences in severe groin or vaginal pain, or complications between groups.

The data (Table 5) appear to confirm that objective cure rates and subjective satisfaction are generally greater than 80% at ten or more years after the procedure. The reported rates on extrusions, exposures and other mesh-related complications are < 5%, with except for the study by Costantini et al that reported 15% of cases of extrusions (158).

3.2.1. Mesh Related Extrusions and complications

After the warning issued by the US Food and Drug Administration in April 2019, which ordered the manufacturers of surgical mesh intended for transvaginal repair of pelvic organ prolapse to stop selling all devices, the use of mesh intended for treatment of SUI has also been widely questioned, especially transobturator mesh midurethral slings. The Scottish government suspended all mesh surgery in 2014 then halted its use in 2018, which was followed by a national “pause” in England and Ireland, pending further evidence (Imamura et al, 2019 [61]).

Table 5: Long-term Outcomes of TO MUS with objective outcome measures

MUS: midurethral sling; N: number; F/U: follow-up; AEs: AEs; TO MUS: transobturator midurethral sling; m: months; y=years; med: median; VLPP: valsalva leak point pressure; UTI: urinary tract infection; PVR: post-void residual; MUI: mixed urinary incontinence; SUI: stress urinary incontinence; KHQ: King’s Health Ques-tionnaire; BMI: body-mass index.

The recent NICE guidelines (10) on management of female incontinence no longer recommends transobturator slings for first line therapy for SUI. One reason for this statement is that TO-MUS presented a higher rate of mesh exposure than Retropubic-MUS (OR, 3.25, 95% CI, 1.02-10.36), as reported in the ESTER systematic review (166). However, the distinction between the terms "extrusion" and "exposure" are not very clear in the few studies that assessed these outcomes, whereas the rate of tape/mesh erosion or extrusion are similar for both procedures (OR, 1.10, 95% CI, 0.70-1.70).

Morling et al. (2017) (167), in a large cohort study of 13,133 women undergoing a first, single incontinence procedure with mesh in Scotland, showed that compared with non-mesh open surgery (colposuspension), mesh procedures had a lower risk of immediate complications (adjusted relative risk [aRR] 0·44 [95% CI, 0·36-0·55]) and of subsequent prolapse surgery (adjusted incidence rate ratio 0.30 [0.24-0.39]), and a similar risk of further incontinence surgery (0.90 [0.73-1.11]) and later complications (1.12 [0.98-1.27]).

Also, Gurol-Urganci et al (2018) (151) published a retrospective cohort study from England of 95,057 women (60,194 women underwent retropubic insertion and 34,863 underwent transobturator insertion). Using actual raw data from the Hospital Episode Statistics, they examined long-term mesh removal and reoperation rates in all women who had a first midurethral mesh sling insertion for SUI. The rate of midurethral mesh sling removal overall was 3.3% (95% CI, 3.2-3.4) at 9 years. When separating MUS from TOT, the 9-year removal risk after transobturator insertion (2.7% [95% CI, 2.4-2.9]) was lower than the risk after retropubic insertion (3.6% [95% CI, 3.5-3.8]. The raw data did not capture the cause of the mesh removal (eg voiding dysfunction versus groin pain), nor could the data distinguish between partial or complete mesh removal. The overall rate of reoperation for stress incontinence was 4.5% (95% CI, 4.3-4.7) at 9 years (no subset analysis).

Serati et al, in their 13yr follow up study (160), found four cases of sling exposure (2.5%), but all appeared between the 10-year point (159) and the 13-year follow-up. It seems that there is a border-line significant increase ($P = .05$) of the incidence of sling exposure over 10 years after the sling.

3.2.2. Groin pain

Post-operative groin pain is one of the most debated issues about TO MUS. The original work by De Leval described 16% of patients developing immediate postoperative pain. This was treated with simple analgesics and abated within 2 days and always by 1 month (120). A review by the same group in 2009 showed a low incidence of persistent groin pain/discomfort after the TVT-O procedure (168). Unfortunately, the vast majority of available data are regarding the immediate postoperative period, and few reports on the medium- and long-term persistence of groin pain exist.

It is evident that groin pain is more frequent after transobturator MUS than retropubic MUS [6.3% vs. 1.3%; OR: 3.80]. The short-term rate reported is about 1-5% (166). In an RCT comparing TVT with TVT-O, a pain score was significantly higher in the TVT-O group in the initial postoperative period, but not at 24 months (139). In the longest available follow-up study, Serati el al (160) reported a low rate of persistent groin pain (<1%), 13 years after the surgical procedure [EL=3].

Several case reports presented different possible managements of persistent groin pain after TO MUS (169-171). Persistent pain may be due to adductor muscle strain, osteitis pubis, obturator/groin abscess, structural adhesions, and inflammation, edema or nerve entrapment of the anterior branch of the obturator nerve (172). A review article on this topic (173) concluded that pain after TOT suburethral sling is a relatively uncommon occurrence requiring specialist intervention. Up to 1% of patients will require removal of some or all of their tape owing to pain. Long-term support with the involvement of a pain management team may be required.

3.2.3. Outcomes in elderly patients

A RCT evaluating risk factors for failure of TVT vs TO MUS (TVT-O) found that age is an independent risk factor (OR: 1.7 per decade) for the recurrence of SUI symptoms at one year of follow-up (174). Another prospective evaluation of 655 women at 2 years follow-up showed that older age is associated with a higher risk of objective and subjective recurrence or persistence of SUI (175). However, a cohort study published by Serati et al (2013) (176) revealed quite different results. The authors enrolled 181 women undergoing TVT-O surgery and found that women over 70 had similar outcomes to women under 70 in terms of cure rates (92.5% vs 88.3%, p = 0.40), voiding dysfunction, vaginal erosion and groin pain, at a median follow-up of 24 months (176).

A systematic review of the efficacy of treatments of UI in older patients confirmed that TO MUS are associated with the same subjective and objective outcomes in patients ≥ 65 years vs women < 65 years (177).

3.2.4. Learning curve

In 2011, Ito et al. (178) investigated data regarding a learning curve for the transobturator sling procedures, but have only shown that this learning curve for this technique is shorter than for retropubic slings. Four years later, Serati et al. (179) assessed several outcomes of TO MUS potentially influenced by the experience of the surgeon. They found that postoperative pain levels decreased with the increase in the level of expertise (pain levels: 1-day: from 6.6 (±3.3) to 4.3 (±3.1); 95%CI: -0.01603 to 0.001235, p=0.04; 2-day: from 5.6 (±4.1) to 3.6 (±3.7); 95%CI: -0.02092 to -0.002497, p=0.01; 12-month: from 0.1 (±0.7) to 0 (±0); 95%CI: -0.001814 to 0.05019, p=0.07). The change in ICIQ-sf (from 12 (±8.7) to 14 (±6.0); p=0.04) improved over the time. Therefore, they concluded that a higher experience of the surgeon could significantly improve the subjective cure rate and could reduce postoperative groin pain.

More recently, a study (180) that evaluated the number of procedures required for an untrained resident surgeon to learn TVT-O procedures showed that ten procedures were needed to improve outcomes. There appears to be a learning curve for TO MUS, in particular to minimise postoperative pain; however, this period appears to be shorter than for retropubic MUS. Previous studies of the incidence of groin pain have not considered the level of experience of the surgeon.

3.2.5. TO "Inside-Out" Approach vs. "Outside-In" Approach

Nine trials in the Cochrane review (Ford et al 2017 (103)) compared the inside-out approach with the outside-in approach (82, 123, 181-186). Median sample sizes were 110 (range 74 to 341). Median follow-up was 12 months (range 3-36 months). In terms of subjective and objective efficacy, the Cochrane review concluded that, when comparing transobturator techniques of a medial-to-lateral versus a lateral-to-medial insertion, there is insufficient evidence to support the use of one approach over the other. There was moderate quality evidence that voiding dysfunction was more frequent

in the medial-to-lateral group (RR 1.74, 95% CI 1.06 to 2.88; 8 trials, 1121 women), but vaginal perforation was less frequent in the medial-to-lateral route (RR 0.25, 95% CI 0.12 to 0.53; 3 trials, 541 women).

A systematic review and meta-analysis of inside-out vs. outside-in TO tapes summarised five RCTs and three cohort studies (187). As in the Cochrane Review, there was no significant difference in short-term subjective cure/improvement. In 2019, Serdinšek et al. (188) published the first 10-yr follow up of their randomised trial comparing the two different approaches of TO MUS. The authors did not find any statistically significant difference in terms of **objective cure rate, subjective satisfaction**, sexual function, complication rate. The only significant difference in terms of **complications** reported both in the Cochrane review and in the recent metanalysis published by Fusco et al. is the risk of vaginal perforation that is lower in the inside-to-out TO MUS (102).

Three trials in the Cochrane Review evaluated post-operative **sexual function** following inside-out and outside-in TO MUS (185, 189, 190). There was a significant improvement in PISQ-12 scores following surgery, but no significant difference between the two groups at follow-up

3.2.6. Overview of All Surgeries for Stress Incontinence In Women (excluding Bulking Agents): The ESTER Study

In 2019, Imamura et al conducted the largest meta-analysis of surgical procedures to date, comprising 175 studies of which 147 were listed in Cochrane reviews and 28 from additional studies (52). Bulking agents were excluded as no trials were found that compared this with other surgical interventions. Using sophisticated WinBUGS software, they estimated the ranking probabilities of the different surgical treatments for cure and improvement using the surface under the cumulative ranking curves (SUCRA), which gives probabilities of each intervention being ranked the best (ie, having the highest proportion of women cured or improved)." Note that "cure" was defined by patient subjective response or pad tests, but cough stress test and bladder diaries were not used. These analyses are shown in Figure 8, and have been discussed in previous sections where relevant.

Overall Summary and Recommendations Re Mid Urethral Slings: Retropubic versus Trans Obturator Procedures

The retropubic mid urethral sling is a robust procedure which is equivalent or superior to the open colpuspension in short term and long-term studies (without the increased risk of rectocoele and enterocoele), and which confers a lower risk of voiding dysfunction and de novo detrusor overactivity. Short term and mid-term studies show that the retropubic sling has superior success

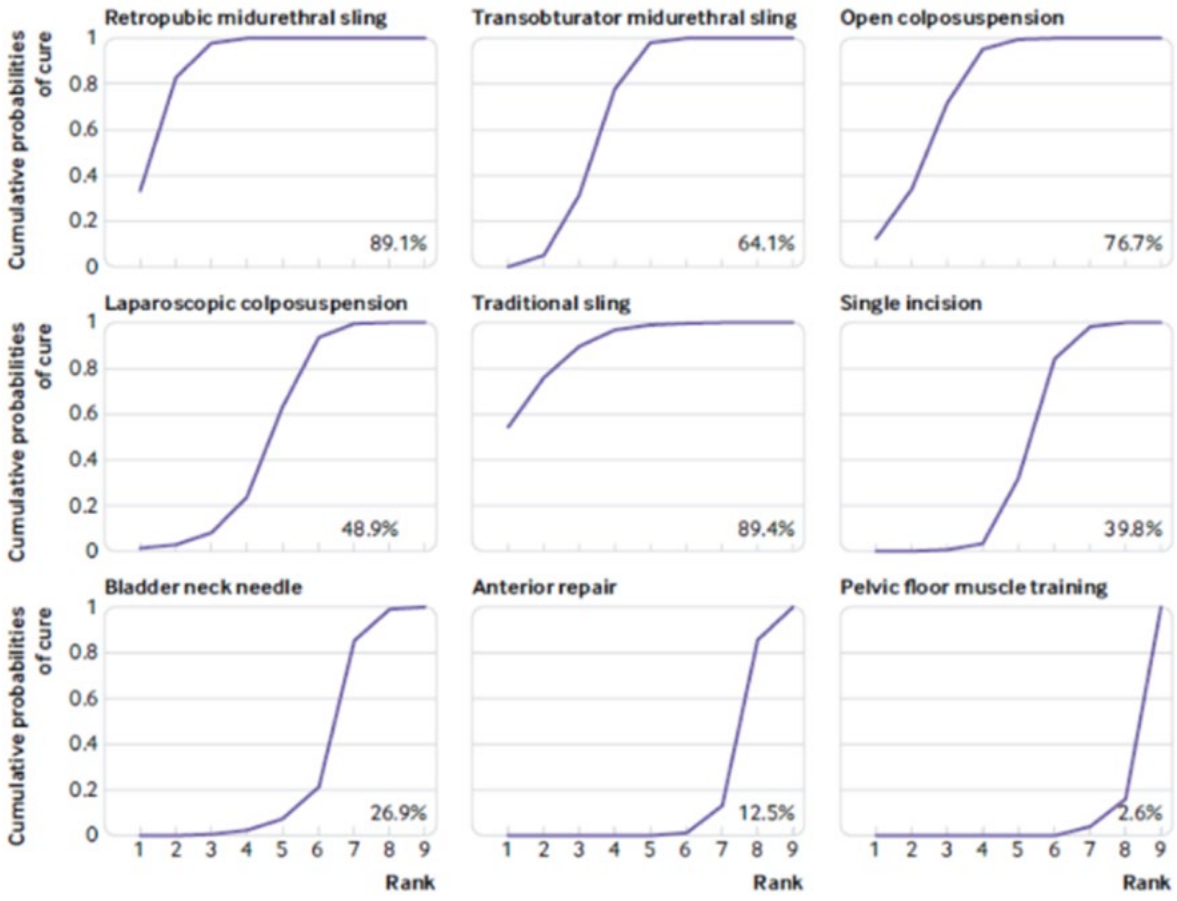

Figure 8: Surface under cumulative ranking curves (SUCRA) for number of women showing improvement of urinary incontinence symptoms (Reproduced with permission from Imamura et al, 2019 (52)

rates to the laparoscopic colposuspension. The comparison of trans obturator tape with these two procedures has received little attention.

As regards adverse events, several meta-analyses have demonstrated a significantly higher risk of thigh/groin pain with TOT compared with TVT. This applies particularly for the inside-out technique (3.1% TOT vs 15.7% TVT-O) where the trocar is directed more laterally in this critical area thus getting much closer to the nerve stem. More serious complications in this area include myositis, fascitis, and abscess formation. The 2017 Cochrane review of TVT versus TOT (103) found a significantly higher risk of groin pain after the trans obturator procedures (RR 4.12, 95% CI 2.71 – 6.27). [EL = 1/2]

Analysis of data regarding the risk of groin pain is difficult because these data are not systematically reported in all studies. Mesh exposure versus extrusion not always accurately reported, and may not be observed in short duration studies eg 12 – 18 months Note that complete removal of a retropubic MUS can be performed by a combined vaginal and laparoscopic procedure, but complete removal of a trans obturator MUS requires vaginal surgery as well as substantial groin incisions bilaterally.

As regards re-operation rates, in the medium term, more women required repeat continence surgery in the TOT group RR 21.89 (95% CI 4.36–109.8), with a similar trend in long term studies RR 8.97 (95% CI 3.36-23.00).

Research: Further longer term data regarding risks of groin pain, need for groin dissection to entirely remove trans-obturator tapes, and risks of repeat continence surgery after the trans-obturator approach are needed.

4. URETHRAL BULKING AGENTS

Stress continence is reliant on effective coaptation of the urethra during increases in intra-abdominal pressure. If the “water-tight seal” is inadequate, SUI results. Urethral bulking agents are designed to address defective coaptation and may be injected either trans-urethrally or peri-urethrally in a retrograde fashion, using either direct cystoscopic, ultrasonographic, or implacer-guided device implantation. The procedure may be performed under local, regional, or general anesthesia. Device implantation optimally occurs in the mid-to-proximal urethra (see Figure 9), and the need for possible reinjection at some point should be explained. Clinical trials have defined specific injection protocols (usually three injections); however, the optimal injection technique has yet to be standardised.

Many clinicians feel that injection of urethral bulking agents is generally more successful in the presence of a non-mobile urethra, which provides a fixed background against which the agent can sit firmly. As regards Intrinsic Sphincter Deficiency, in the 1990’s, a group from London published a 7 year follow-up study of 37 women, in which Cox regression analysis showed that low MUCP (<20cm) was significantly correlated with failure of collagen injections (p = 0.034) (191). However, many studies do not analyse their data in terms of urethral mobility or MUCP. Also, at least half of the publications do not indicate the percentage of patients who had received repeat injections at the time of outcome assessment.

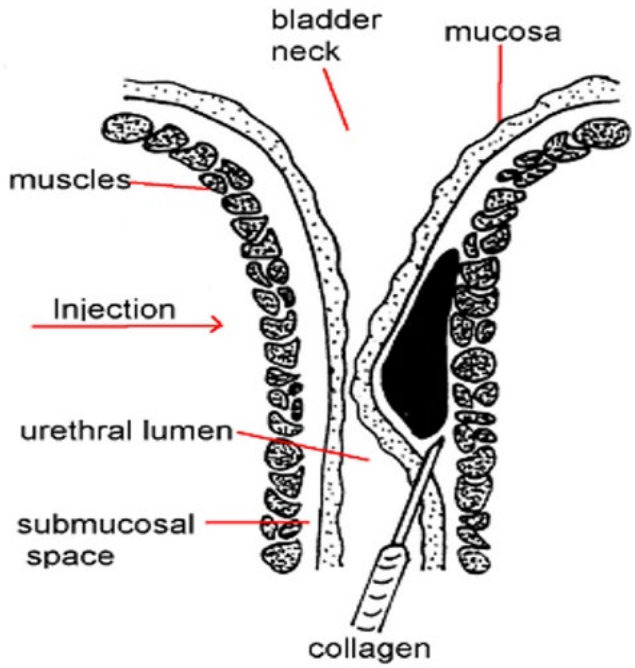

Figure 9: Trans urethral injection of bulking agent (collagen was the typical agent initially).(Courtesy of Alfred Yu , Medical illustration Dept, St George Hospital)

The duration of effectiveness of bulking agents is often quite high for 9-12 months but tends to fall off over time. The conclusions from ICI-6 were that multiple injections are required for optimal outcomes and that no single bulking agent, location, or method of injection was superior to another. This section emphasises new developments since ICI-6 and highlights long-term studies with objective outcomes.

4.1. Available Agents

Due to manufacturing cessation (delayed skin reactions, arthralgia, (192)), bovine collagen (Contigen®) was obsolete at the time of ICI-5, not included in this chapter except for comparison with other agents. Limited data were published regarding **stabilised hyaluronic acid/dextranomer** (NASHA-dx; Zuidex®), but the latest Cochrane Review (192) noted that women treated with NASHA-dx had significantly higher rates of injection site complications compared to bovine collagen (16% vs. 0%, respectively; RR 37.78, 95% CI 2.34 to 610) and this product was withdrawn from the U.S. market (192) but is available for vesicoureteric reflux. Similarly, the 2017 Cochrane review noted that evidence of particle migration has stopped the clinical use of **Polytetrafluoroethylene** (Polytef paste).

a) **Carbon coated zirconium beads** (Durasphere®), available USA, Europe, Australia (Hoe 2021, 214)

b) **Calcium hydroxyl apatite** (Coaptite®), available in USA and Turkey

c) **Polydimethylsiloxane elastomer** (PDMS; Macroplastique®), UK, Europe, Australasia, USA

d) Polyacrylamide hydrogel (PAHG; Bulkamid®). UK, Europe, North America, Australasia

e) Urolastic (Urogyn) consists of **vinyldimethyl terminated PDMS, tetrapropoxysilane cross-linking agent, platinum vinyltetramethyl siloxane complex catalyst, and titanium dioxide radiopacifying agent**.

4.2. Outcomes of Recent Studies

- Before reading this section, a few comments about the Outcome Measures employed in these studies of bulking agents may enhance understanding. This topic is particularly relevant because many patients are expressing increasing interest in such agents, in their effort to avoid polypropylene mesh Mid Urethral Slings (e.g.which are not available in the UK).

- The Stamey Grade is often reported as a measure of overall cure, but it comprises 4 simple questions about degree of leakage and is actually a subjective outcome. The PGII has 4 levels of response (cured, improved, no change, worse) but unfortunately 'cured' and 'improved' are often combined. The cough stress test needs to be performed at a standardised volume (commonly 300 ml) for it to be considered a valid objective measure, which is often not specified. The results of a pad test should ideally be reported as raw data, thus a 50% reduction in pad test weight is not a standard outcome measure.

4.2.1. Cohort Studies

4.2.2. Carbon-Coated Zirconium Beads;' DURASPHERE

There have been no novel studies of periurethral carbon-coated zirconium beads since ICI-6.

4.2.3. Calcium Hydroxyl Apatite; COAPTITE

There have been no novel studies of calcium hydroxyl apatite since ICI-6.

4.2.4. Polydimethylsiloxane Elastomer (PDMS) MACROPLASTIQUE

Outcomes of studies of Macroplastique by Ghoniem et al. (2009, 2010, 2013) are fully described in ICI-6 (193-195), including a RCT comparing PDMS vs. bovine collagen (194), in which mean pad test weight was 24 g at baseline and 4 gm at 12 months. A systematic review by Ghoniem and Miller of literature from 1990 to 2010 (195) showed cured/dry rates on Stamey grade were 43%, 37%, and 36% at <6, 6-18, and >18 months, respectively. Higher reinjection rates were associated with improved long-term SUI outcomes.

A prospective database of women undergoing Macroplastique/PDMS injections at University of Texas has yielded two recent manuscripts. Rosenfeld et al (2016) evaluated PDMS in 3 groups of women: Naive (Group I), Prior Anti-Incontinence Surgery (Group II), and combined Prior Bulking Agent and Anti-Incontinence Surgery (Group III) (196). The title of this paper stated that all participants had ISD but this entity was not defined. "Success" was defined as sufficient improvement after one injection that no retreatment for SUI was needed at last follow-up. In 59 women at a mean follow up of 9 months,the success rate was 83% for Group I, 70% for group II, and 69% for Group III (p=0.54).

Carroll et al. evaluated the aforementioned cohort at a median follow-up of 20 months (range: 6-71), and defined success after the last Macroplastique injection as a UDI-6 Question 3 score of 0 (dry) or 1, and no reoperation for SUI (with no objective outcomes) (197). From 2011-2017, in 106 of the original 142 women, success rate was 41% for Group I, 40% for Group II, and 65% for Group III (p = 0.22. The completely dry rate was highest in those with the most "fixed" urethra, Group III at 29%, compared to 4% for Group I and 15% for Group II (p = 0.05).

Serati et al (2019) reported on 85 women at 3-year follow-up after Macroplastique injection (198). The subjective (via PGI-I, ICIQ-SF) and objective (via cough test during urodynamics) cure rates were 49% and 47%, respectively. A history of radical pelvic surgery and a "low surgeon's skill" were significantly associated with failure.

Montera et al (2018) prospectively studied 47 women who had occult stress incontinence on a 300 ml cough stress test when the bladder was replaced into the vagina (despite no symptoms of USI in daily life), in whom Macroplastique was injected at the time of prolapse repair (199). Patients with ISD (UPP < 20 CM OR VLPP < 60 CM), previous continence surgery, or detrusor overactivety were excluded. Cure of occult USI was defined as no leakage on stress test during postop urodynamics at 12 months. Success rate (87.3%) was similar to that of a historical control group who had prolapse with a TVTO (cure 89.7%) or prolapse surgery alone (78%). However, the TVTO group had a 5% mesh erosion rate, with a 7.6% "severe pain" rate. The cure rate for macroplastique with repair, versus surgery alone, was significantly greater (p = 0.05).

Dray et al. retrospectively reported on 73 women who underwent urethral bulking (38 PDMS, 35 collagen) after failed autologous sling or MUS (66%) (200). Macroplastique was injected at either 3 clock and 9 oclock, or 6 oclock, depending on surgeon's preference, whereas Collagen was always injected at 3 and 6 oclock. After an average of 2.6 injections, 26% had complete symptom resolution, 71% had at least partial symptom resolution at their first post-injection follow-up. Pad usage fell from 3.2 pads per day to 2.1 pads/day (200).

Plotti et al. reported on 63 women, median age greater than 75 years, who underwent PDMS, with a mean follow-up of 8.3 years (range 3.5 to 18 years) (201). Cure was defined as resolution of SUI symptoms (including those ''Improved'' on the PGI-I; ''Urine never leaks'' on the ICIQ-SF; and no new symptom or side effect.) Improvement was defined as persistence of stress symptoms but with a decreased number of incontinent episodes (including ''Improved'' on the PGI-I; ''Once a week''/''Daily''/''All the time'' answer to the question ''How often do you leak urine'' on the ICIQ-SF) Fifteen (24%) women were cured, 12 (19%) were improved, and 36 (57%) failed.

Finally, Siddiqui et al (2017) performed a systematic review of English literature regarding Macroplastique and Bulkamid, which is described under Systematic Reviews (202).

4.2.5. Polyacrylamide Hydrogel (PAHG) – BULKAMID

Outcomes of several studies have been summarized in ICI-6 which are now included in the reviews below.

Several systematic reviews of Bulkamid have been published. A major review by Kasi et al (2016) included in ICI-6 (203) involved eight prospective, retrospective, and RCT studies, total = 767 women. In order to achieve adequate efficacy, 186/767 women (24.3%,

range 12-35%) required **reinjection**. Both the number of incontinence episodes/24hr and pad test loss /24hr lost were significantly reduced at one year but only 3 of the 8 studies gave pad test data (which seemed to show cure in all subjects).

The previously mentioned systematic review of Macroplastique and Bulkamid by Siddiqui et al (2017) is considered under Systematic Reviews (202).

4.2.6. Vinyldimethyl-terminated Polydimethylsiloxane Polymer (VDM-PDMS)- UROLASTIC

A theoretical advantage of Urolastic is that it polymerizes in situ into a uniform elastomer which adapts to its environment and theoretically reduces the risk of migration (204, 205). Two studies from the same centre were included in ICI-6 (206, 207). In the latter study, 19 women were followed up at 24 months. Outcomes included Stamey Grade, 1-h pad test, pads/day, incontinence episodes/24-h, and I-QoL questionnaire. "Improved status occurred in 66% at 24-months (vs. 89% at 12 months). About 45% of the patients were dry (Stamey=0) at 24-months (vs. 68% at 12 months). The 1-h pad-weight test showed >50% reduction in 84% at the 12-month follow-up.

Futyma et al (2016). reported an objective success rate after Urolastic injection in 66 women with recurrent SUI of 32.7% at 24 months (208). The completely dry rate was 22.4%. Complications were observed in 25.8%, including an "oval shaped mass" inside the bladder in 4.5%. De Vries et al. reported on 65 women, where 76-88% showed subjective improvement (via chart review) at 12-25 months of follow-up (209). In Dindo et al (2004), complications >Grade II were observed in 24-33% (210).

4.3. Method and Location of Injection

The Cochrane Review concluded that there was no difference in periurethral vs. transurethral delivery, although there was a non-significant trend towards higher early complications with periurethral injection (192). There has been no new information since ICI-6. Several agents have proprietary delivery methods/ devices , such that comparison of delivery techniques across different compounds is not valid.

4.4. Systematic Reviews

Multiple systematic reviews and meta-analyses have been published since ICI-6. Capobianco et al. searched PubMed, Scopus, and Cochrane Central Register for records up to December 2018, and found 42 full texts (of which 21 were selected (211). The pooled subjective cure rate was 26% and 21% at follow-up of ≤1 and >1 year. The pooled objective success rate was 46% and 7%, respectively. Adverse event rate was 0.4%.

In 2017, Siddiquie et al (202) from Birmingham UK published a systematic review of English language studies regarding Macroplastique and Bulkamid using MEDLINE and EMBASE databases from 2006-2016. This was prompted by the removal of MUS from the NHS in the UK, which engendered increased interest in bulking agents. The authors noted that NICE guidelines recommended bulking agents for patients with significantly decreased urethral mobility.

Eight studies of Macroplastique were included; two were RCTs (194, 212). Subjective success was measured by I-QOL, IIQ-7, UDI-6, and VAS. Objective success was measured by urodynamics, 24-hour pad test, cough test, and leakage episodes on diary. Repeat injection was reported in three of the eight studies and ranged from 9% to 44%. Objective cure (given in 6 studies) was 71%% at 3 months, 55% at 6 m, 35% at 10 m, and at 12 months was 42%. The UTI rate was 9%.

Twelve studies of Bulkamid were included (one RCT, (213)). Subjective success = Likert scale, ICIQ, IIQ, and PGIQ, while objective success = urodynamics, 24-hour pad test, and cough test. All studies showed improvement in all subjective indices. Repeat injection was reported in six of the twelve studies and ranged from 8% to 65%. Objective cure (given in 5 studies) were 38%, 47.2%, 73%, 79.3% all at 12 months, and at 22 months cure rate was 19.6%. The UTI rate was 11%.

The most recent and largest systematic review is by Hoe et al (2021) (214) from Melbourne (also partly stimulated by patient avoidance of mesh MUS in Australia). They screened 583 articles from the Ovid Medline, Embase and PubMed databases and included 56 articles in their analysis (214). Higher long-term success rates were found with Bulkamid (42%-70%), Coaptite (60%-75%), and Macroplastique (21%-80%) on qualitative review. UTI rates were similar between agents (4%-10.6%) although temporary acute urinary retention was more commonly associated with Coaptite (mean: 34.2%), and *de novo* urgency in Durasphere (mean: 24.7%). Significant complications such as migration into lymph nodes was reported with Durasphere. Erosion was reported with PDMS, calcium hydroxyl apatite, and VDM-PDMS, with a rate as high as 24.6% in one study of VDM-PDMS. Bulkamid appeared to have a more favourable safety profile, with no cases of erosion or migration of the product. Direct comparisons of bulking agent cure rates could not be performed because of incomplete or highly variable outcome reporting.

4.5. RCTs Comparing Bulking Agents

The Cochrane analysis (updated in 2017) concluded that all bulking agents appeared to provide similar overall improvements as compared to bovine collagen (192). Fourteen trials compared different agents and all results had wide confidence intervals. No improvements were shown to be more or less efficacious than bovine collagen. The authors concluded that the available evidence base remained insufficient to guide practice.

4.6. Bulking Agents vs. Sling Surgery

Several trials included in ICI-6 confirmed that women undergoing anti-incontinence surgery achieved higher continence rates and satisfaction than women undergoing bulking agents (215-217). The incidence of adverse effects, including urinary retention, voiding dysfunction, and UTI, was significantly higher in the surgery group. In the two trials in the Cochrane Review that compared injection therapy with surgical management, better overall objective cure was obtained after surgery vs. injection (RR 4.77, 95% CI 1.96 to 11.64; and RR 1.69, 95% CI 1.02 to 2.79) (192).

Recently, Itkonen Freitas et al. (2020) performed a controlled non-inferiority clinical trial in women with primary SUI who were randomised to TVT or Bulkamid (88). Primary outcome was patient satisfaction and secondary outcomes were reduced urinary leakage and complications at 1-year. Of the 224 women 111 were randomised to TVT and 113 to PAHG. At 1 year, a VAS ≥80 (range 0 to 100) was reached in 95% and 60% of women treated with TVT and Bulkamid, respectively. As a result, Bulkamid did not meet the noninferiority criteria. The cough test was negative in 95% and 66%

of TVT and PAHG cases, respectively (difference 28.6%, 95% CI 18.4-38.5). Not unexpectedly, most perioperative complications (19 TVT vs. 3 PAHG) and all six reoperations due to complications were associated with TVT.

Bach and Toozs-Hobson examined the British Society of Urogynaecology surgical database to analyse 1386 patients who had periurethral bulking and 18,763 who underwent MUS (218). The primary outcome was patient-reported PGI-I for incontinence with secondary outcomes of change in SUI, OAB, and complications. SUI was the most common urodynamic diagnosis (bulking 67%, MUS 77%) but there was a higher proportion of complex diagnoses in the bulking group. The percentage of women reporting "very much/much better" on PGI-I was 59% and 91% in the bulking and MUS groups, respectively. Twenty-eight percent of women felt their SUI symptoms were cured following bulking vs. 77.6% after MUS. There was no difference in outcomes when using periurethral bulking agents as a primary or secondary procedure. There were no intraoperative complications with bulking and fewer post-operative complications compared to MUS (3.6%).

4.7. Role of Bulking in Special Populations

4.7.1. Bulking in the Elderly

Since the publication of ICI-6, a number of studies commented on the results of bulking in elderly women. At a mean follow-up of 8.3 years (range 3.5 to 18) 63 women with a mean age >75 years underwent PDMS injection (201). Cure = complete resolution of SUI symptoms, while improvement was defined as the persistence of SUI with fewer incontinence episodes. Twenty-four percent of women were cured, 19% were improved, 57% failed treatment. Elmelund et al. performed a post hoc analysis of a previously published, randomised, 33-centre study of PAHG vs. collagen injection (219). Cure was achieved after one year if there were no SUI episodes per bladder diary and no SUI symptoms on the ICIQ-UI-SF, while improvement was achieved with ≥50% reduction in SUI episodes. Of the 345 women who were initially randomised 291 were included in this study. A total of 191 women received PAHG and 100 received bovine collagen. At one year 74 women (25%) were cured, 164 (56%) were improved and 53 (18%) showed no effect. On multivariate logistic regression analysis **age 60 years or greater** and fewer than 2.5 daily SUI episodes were associated with cure.

4.7.2. Recurrent SUI; Bulking agents after previous continence surgery

Several studies have been published since ICI-6. Dray et al (2019) reported 73 women who had urethral bulking after failed sling (66% MUS, 27% fascial sling, 7% both). After an average of 2.6 injections (38 PDMS, 35 collagen), 71% had at least partial symptom resolution at their first post-injection follow-up (200). Forty women had long-term follow-up (mean 39.6 months post-injection), but only two of them reported total resolution of SUI symptoms.

Zivanovic et al (2017) included 60 women who had Bulkamid due to recurrent SUI or MUI after a previous MUS, reporting cure based on a negative cough test, <2g urine on a 1-hour pad test, and VAS score improvement by ≥90% (220). Women deemed improved had a loss of a few drops on cough test, 2-10g urine loss on the pad test, and ≥75% improvement on VAS. The combined cure/improved rates were 93.3%, 88.3%, and 83.6% at 1, 6, and 12 months, respectively. Resolution of the urge component was seen in 38.9%. UTI rate was 3.6% at 12 months. Adverse events were <4% of women.

Rodriguez et al (2020) evaluated Macroplastique success after suburethral sling removal for synthetic sling complications (221). Success was defined as a composite score of a UDI-6 question 3 score of 0 to 1 at last visit and no additional anti-incontinence therapy (no objective criteria). In 70 women (mean age 62.7 years), success after the first injection was 46% at a mean follow-up of 46 months. When indicated, a repeat injection yielded an overall 69% success rate for the entire cohort (with 83% of the patients reporting subjective improvement and 78% reporting reduced pad usage). On multivariate analysis, age, body mass index, previous hysterectomy, hormone replacement therapy, type of sling removed, and baseline urodynamic results were not predictors of failure.

Daly et al. presented a retrospective case series of women having their first bulking from 2010-2018, 135 of whom had bulking as a primary treatment and 38 who had a salvage procedure (222). The primary outcome was patient-reported improvement, based on PGII but treatment 'success' defined as 'cured' or 'improved'. Median follow-up was 33 months; complete follow-up was obtained for 114 women (66%). Success was not significantly different between the salvage group (75%; 21/28) and primary group (67%; 58/86) (p=0.407).

4.7.3. Radiation-Associated Incontinence

Dobberfuhl recently reviewed the impact of bulking therapy on irradiated patients, with a focus on the studies in the Cochrane Review by Kirchin et al. (192, 223). Interestingly, of all the surgical treatments for SUI, only bulking agents have been studied prospectively in irradiated women. Plotti et al. observed that 10 women were cured (42%) and 10 improved after PDMS injection (with five of 24 women having previous radiotherapy) (224). Krhut et al. treated 46 women with PAHG, 24 of whom had previous radiotherapy (225). At a mean of 12.4 months of follow-up, complete continence was achieved in 25% of women after radiotherapy (compared with 36.4% of those without radiotherapy). The interval between radiotherapy and injection was a mean of 93 months (range 16-384).

4.8. Complications

As mentioned in several studies above, bulking therapy is infrequently associated with severe complications. The most frequent adverse event is UTI, with dysuria, urgency, urinary retention, and hematuria also reported. Occasionally, the injectables themselves cause unique complications. Chapple and Dmochowski summarized that foreign-body granulomas, erosion and migration/material extrusion, and loss of bulk have been observed in connection with the particle-based products (226). Several of the particle-based agents previously used for bulking have been discontinued or withdrawn from the market due to these complications. The list includes hydrophilic dextran polymer/hyaluronic acid base, polytetrafluoroethylene/glycerine/polysorbate, and ethylene vinyl alcohol copolymer. PAHG (a non-particulate bulking agent) may be mechanistically less liable to these events; however, there are minimal data directly comparing the particle-based and non-particulate bulking agents.

Summary

Only 1 new RCT (of Bulkamid versus TVT) has emerged since publication of ICI-6. While bulking agents provide a treatment option for primary SUI, optimal results may be obtained with repeated injections as effects wane with longer follow-up. The few RCTs that exist suggest that outcomes are similar regardless of

bulking agent used, with no single bulking agent demonstrating superiority to bovine collagen (no longer available). (Level 2b/3)

There appears to be no difference in outcomes whether the transurethral or paraurethral technique is used. (Level 2b). Data suggest that bulking is inferior to surgical treatment for both primary and recurrent SUI (Level 2).

Limited, non-randomised data suggest benefit of bulking agents in special populations, such as women with SUI following pelvic irradiation (Level 4).

The National Institute for Health and Care Excellence (NICE) and The American College of Obstetricians and Gynecologists (ACOG) guidelines suggest that periurethral bulking agents should be considered as one of several treatment options for patients with significantly decreased urethral mobility (Level 2)

Overall complication rates associated with bulking agents continue to be relatively low (Level 2b/3b/4); however, the particle-based agents appear to be associated with adverse events such as extrusion and foreign-body reaction.

Recommendations

Bulking agents should not be offered as first-line therapy for those women desiring a “one-time” durable solution for primary or recurrent SUI (Grade B).

Bulking therapy is an option for selected individuals with SUI (e.g., poor candidates for anti-incontinence surgery or those desiring an office-based, minimally invasive procedure) after appropriate counseling regarding lack of long-term durability (Grade B)

Bulking agents may be offered as therapy for recurrent or persistent SUI following anti- incontinence surgery, although these outcomes are likely inferior to repeat anti-incontinence surgery in the long term, particularly in the presence of Intrinsic Sphincteric Deficiency (Grade C).

Conclusions

While multiple bulking agents are available, their use is typically associated with improvement rather than resolution of SUI, waning effects over time, and a high rate of retreatment. They may have more benefit in women with poor urethral coaptation, such as those with a poorly mobile urethra, previous radiation, and vaginal/periurethral scarring [Grade B]. Their ease of use and minimal anaesthetic requirements should be balanced against potentially high costs, partly due to the frequent need for repeat injections.

Research: Further data regarding subjective and objective success rates in those with normal urethral function versus those with ISD are needed**.**

5. LASER THERAPY FOR STRESS INCONTINENCE

5.1. Introduction

The use of laser-based urogenital therapy has increased in recent years. In ICI- 6, the use of trans urethral laser therapy for USI was briefly described. However, in the only sham-controlled trial of 110 women, 48% of the treatment arm **and** 44% of the sham showed >10 points improvement in their IQOL score (227). These treatments were connected to adverse event effects such as dysuria, urinary retention and post-procedure pain (228). The relevant Cochrane review concluded that there was insufficient evidence to show benefit (229). Recently Gaspar & Brandi (2017) from Argentina studied trans-urethral laser treatment in 22 patients (mean age 57.9y) who all had ISD (VLPP < 60 cm) (230). Two sessions of Er:YAG were given 3 weeks apart. At six months, an ICIQ- of zero ocurred in 46%, with a pad test of < 8 gm in 50% (230). A study of trans-urethral radiofrequency (temperature 65-75° C) in pigs showed that valsalva leak point pressure was greater after treatment ($p = 0.06$) (231).

Also in ICI-6, used of Trans-Vaginal Laser therapy was discussed. As per Fistonic et al (2012), the theoretical aim of non-ablative laser treatment is to induce selective, heat-induced (61°C - 63°C) denaturation of dermal collagen that leads to subsequent new collagen deposition with as little damage to the epidermis as possible (228). Unfortunately, the histological studies that provide this information are often obtained from reports in the field of dermatology (for details see (228)) and Section 5.2 below.

Two main types of laser therapy are used currently: Erbium YAG (2940nm) laser and CO_2 laser.

CO2 Laser is used in gynaecology, dentistry, oral and maxillofacial surgery, is usually intended for cutting, excision, vaporization, ablation, and/or cauterization. This form of ablative therapy creates ablative zones and columns of deep thermal damage (50–125 nm), which increases tissue firmness and increase structural support for tightening and strengthening the vaginal walls.

Erbium-doped: Yttrium Aluminum-Garnet (Erbium:YAG or Er:YAG) uses heat only (60–63°C) to cause shrinkage of mucosal tissue. It was first used in 2000 for treatment of human papilloma virus infections, cervical ectropion, vulva intraepithelial neoplasia, etc and a side effect of vaginal tightening was noted.

Erbium Yag has 10–15 times the affinity for water absorption compared with the CO_2 at a wavelength of 10,600 nm and enables a deeper secondary thermal effect and controlled heating of the target mucous membrane of the vaginal wall. This allows controlled heating of the subepithelial layer without burning the vaginal epithelium. On the other hand, CO_2 lasers (10,600 nm) cause tissue denaturation.

Currently, three different laser modalities have been published for treating SUI: the microablative fractional carbon dioxide (CO_2) laser therapy (10,600 nm) (232); dual-phase erbium-doped yttrium aluminium garnet (Er:YAG) laser therapy (2,940 nm) combining fractional cold ablation and thermal ablation (232); and non-ablative Er:YAG laser therapy (2,940 nm) with SMOOTH mode technology (232) (for details see (228)).

5.2. Histological studies of Laser therapy

Three publications were found that actually investigated histological changes after laser to the vagina in women with stress incontinence. Gonzalez Isaya et al (2018) (233) and Alcalay et al (2021) (234) are discussed below as part of clinical studies. Lapii et al 2017 from Novosibirsk studied biopsies from the anterior vaginal wall taken from 18 women before and 6 weeks after they had two laser treatments (full paper translated from Russian (235)). Light microscopy and electron microscopy were performed but EM photomicrographs were not published. Most of the findings are quite descriptive, not quantitative, and do not actually mention increased density of **collagen fibres**. The epithelial thickness, number of capillaries, and density of capillaries per unit volume were all significantly increased ($p< 0.05$).

Two publications from Italy investigated histological changes after fractional CO2 laser to the vagina in women with vaginal atrophy (***no incontinence***). Vaginal samples were taken either on the same day of treatment (236) or one to two months after CO_2 Laser (237). The same-day study (n=5) showed "mild ablative effects". The longer term study showed substantial thickening of the squamous epithelium with papillae-form projection of the connective tissue rising up under the thickened epithelium. Neither study employed **any stains for collagen**.

5.3. CO2 Laser Therapy for SUI

Gonzalez Isaza et al (2018) from Colombia (233) studied 161 women aged 45-65 with mild stress incontinence. All had four sessions of CO_2 Laser (Mona Lisa) at the urethro-vesical junction every 30-45 days, then further treatments at 12, 24 and 36 months. Drop-out rate was zero. After the 4 treatments, 32% had moderate incontinence. The 1hour ICS pad test fell from a baseline 9.9 gm to 3.5 gms at 12, 24 and 36 months but the "dry rate" was not given. The ICIQ fell from 14.3 (SD+/- 2.65) to 7.5 (+/- 0.94) at 12 months, which persisted at 36 months. These authors obtained *punch biopsies* from the urethrovesical junction in one patient at baseline, 6 weeks and 6 months. Staining with H&E showed thickening of the epithelium and thickening of the underlying connective tissue with papillae-form projections of connective tissue under the epithelium. **Stains for collagen were not employed**.

In 2019, fractional CO_2 Laser (Mona Lisa) was given every 4-6 weeks for 3 treatments in 58 women with SUI, who attended a private facility in Australia (238). The primary outcome was one SUI question on Australian Pelvic Floor Questionnaire (AFPQ); a cough stress test was mentioned but not uniformly reported. Postmenopausal women (44/45) were also on vaginal oestrogen cream. Of the 58 women, 55 were seen at 3 months when 25 women (45%) had no stress leak on AFPQ. At 12-24 months, 36 women were seen (no reason for 22 drop-outs); 10/36 women (28%) had no stress leak on APFQ,

In 2020, Palacios and Ramirez (239) treated 25 women who had stress or mixed incontinence with three CO2 Laser treatments every 4-6 weeks (CO_2RE Intima); outcomes were measured at the time of the third treatment. Two patients dropped out because of vaginal candidiasis (one further follow-up loss). The baseline ICIQ (13.4) fell to 8.2 ($p < 0.001$) The cure rate was not given. Response in stress or mixed incontinence was not significantly different, but severe leakage responded as well as mild or moderate leakage.

Alcalay et al. (2021) from Israel studied 52 patients with proven USI, restricted to mild/ moderate severity (234). Three fractional micro-ablative CO_2 treatments were provided at monthly intervals, but only 42 completed the 12 month follow-up (i.e. 9 months after last therapy) with no reason given. Mean 1 hour pad test fell from 6.3 g (sd 1.6) down to 3.7 g (sd 1.4g), $p =<0.05$, "dry" rate was not given. Bladder diary showed leaks per day fell significantly just after the third treatment, but was no different from baseline at 6 or 12 months. In 29 women who agreed to have 6 month urodynamics, 41% had no USI. These authors also performed baseline and 6 month *biopsies of the posterior vaginal wall*; light microscopy H&E stain showed marked thickening of the squamous epithelium but specific staining for collagen was not performed.

In 2020, Dabaja et al from Israel studied 32 women which satisfied their sample size, based on a 16 point difference in UDI from baseline (240). All had a pure USI diagnosis based on urodynamics and cough stress test (which were also repeated 3 months after the third treatment). Mixed incontinence was excluded, age was limited (18-52 years). All women had 3 treatments, 4 weeks apart, using the Lumenis Acupulse System with the FemTouch vaginal handpiece. Side effects were vulvar sensitivity that lasted up to 3 days (in 30%), no cases of cystitis or vaginitis. The main outcomes were done at baseline and all four follow-ups (Table 6 below). Three months after the third treatment, both UDI and ICIQ showed significant benefit (both $p < 0.0001$), with partial benefit on USI. **However, these benefits were not sustained by 6 months after the third treatment, and data returned to baseline levels.**

This study is one of the few to report an actual sample size/ power calculation, and to give full data for outcome measures eight months after the first treatment, which reveal no benefit whatsoever.

Franić et al. (2021) from Slovenia studied 85 patients with SUI diagnosed on cough stress test (241). They had two sessions of CO_2 one month apart, with follow up 6 months later. However, 37 women (43%) were lost to follow-up, with no mention of the reason. Severity of SUI was significantly reduced on ICIQ from a baseline of 12 (range 4-15) down to 3.5 (range 0 -6.7), at six months ($p < 0.001$) and 45.8% of full participants had no symptoms, cured, on ICIQ. Younger women <39yr had a much better response than older women $\geq$ 60yr.

Table 6: Outcomes following CO_2 laser treatment.(Dabaja et al, 2020) (240)

	Pre-treatment	Post 1Rx	1m post 3Rx	3m post 3Rx	6m post 3Rx
+cough test (N)	25	–	–	23	–
+urodynamics (N)	30	–	–	19	–
No. of pads					
median (range)	**12 (6–18)**	12 (5–16)	9 (2–12)	7 (2–10)	**12 (7–18)**
UDI-6 score, mean (SD)	**45 (20)**	43 (19)	33 (17)	29 (15)	**45 (19)**
ICIQ-UI score, mean (SD)	**16 (4)**	15 (4)	9 (4)	8 (3)	**15 (4)**

Note that two Randomised Controlled Trials of CO2 laser versus oestriol cream have been conducted in women with vaginal atrophy but no incontinence. Cruz et al (2017) showed increased benefit for Laser over oestriol cream in 45 women on a symptom score (242). The VeLVET trial by Paraiso et al (2020) showed no difference for Premarin cream on 4 symptom scores in 62 women, but the vaginal maturation index showed greater improvement on Premarin cream (243).

5.4. LASER Erbium Yag Therapy for SUI

In ICI-6, a large study by Ogrinc et al (2015) of 175 patients with SUI and MUI was discussed (244). One Erbium Yag procedure (see Figure 10) was performed in 12 patients (7%), two treatments in 54 (31%), and three in 109 patients (62%). At one-year, 108 patients (62%) reported no incontinence. On average, they received 2.54 (SD 0.65) procedures. In the 29 patients (16%) whose grade of UI remained unchanged 2.68 (SD 0.55) procedures were given. In 38 (22%) patients, worsening of UI (in terms of UUI) was noted after therapy. The data are difficult to interpret because the ICIQ was used, but the numerical values of this score were compressed into 4 categories of the Incontinence Severity Index. Adverse effects comprised: mild transient discomfort/pain during procedure (6%) or new UUI (4%).

There have been three reports from Taiwon. In 2017, Lin et al studied 30 patients who had 2 sessions of Erbium:YAG laser, 4 weeks apart (245). The 1h-pad test baseline value of 13.2 gm (SD 17.7) fell to 6.1gm (SD 11.6) at 3 months (p = 0.04). At 12 months telephone appointment, the ICIQ fell from baseline of 10 (SD 3.7) to 5.5 (SD 4.2). All patients had OAB symptoms despite a urodynamic diagnosis of USI; they noted that the OABSS fell from baseline of 8.2 (SD 5.0) down to 7.9 (SD 6.0) at 12 months (p = 0.58). The 12 month follow up was a retrospective study, but the percentage of the original numbers who actually answered the telephone follow up was not provided. Figure 10 shows the Erbium:YAG laser equipment.

Figure 10: Photograph of the 2,940 nm Er.YAG laser device. Reproduced with permission from Ogrinc, Senčar and Lenasi (2015) (244).

Also in 2017, Tien et al performed one ErYAG Laser treatment (Fotona, Slovenia) in 35 women with USI; of these, 14 women also had OAB (246). A 20 minute cough stress test (cure < 1 gm) and the UDI 6 (cure = score 0 on question 3) were performed at baseline and 6 months. Three dropouts occurred. The objective and subjective cure rate was 39%.

Also from a different group in Taiwon, Lin et al (2019) evaluated 100 patients with SUI who had three Erbium:YAG laser treatments (interval not stated) (247). Only 41 women completed the protocol, because the remainder were reportedly “much improved after 2 treatments and declined to return”. Main outcomes were the ICIQ and urethral bladder neck mobility on ultrasound. At six months after treatment, the ICIQ fell from 7.2 (SD 4.5) to 3.7 (SD 3.5), p < 0.001. The descent of the bladder neck on Valsalva improved from 16.1 mm (SD 6.4 mm) to 10.5 mm, SD 4.6, p = 0.04 (247).

In 2018, Neimark et al (the same group from Novosibirsk who performed the histology study) treated 98 women (aged 37-63yrs), who had mild – moderate SUI (248). Laser treatment was performed with a 2940 nm Er:YAG laser (Fotona, Slovenia) using a SMOOTH mode. Outcomes were PFIQ-7 and PISQ-12 questionnaires, uroflowmetry, laser Doppler flowmetry and biopsy of the anterior vaginal wall at baseline and 1-2 months after treatment. Only the abstract was given in English, full paper in Russian, which states that “the effectiveness of treatment was 73%”. On PFIQ-7 and PISQ-12, patients with mild incontinence had the greatest benefit. Uroflowmetry parameters improved in most patients. Doppler flowmetry demonstrated improvement of blood flow in the microvascular bed. The authors referred to their previous histology study, saying that “an important feature of the vaginal biopsy after laser exposure was an increase in neoangiogenesis.”

In 2018, Blaganje et al from Ljubljana conducted an RCT of ErYAG laser versus Sham; the same instrument was inserted in the vagina, but no laser energy was applied (249). All 112 women had pure USI; age was limited to 35-65 years. Only one treatment of non-ablative “smooth” pulse was applied, with outcome measures at 3 months. The Sham baseline ICIQ of 12.41 SD 3.3, fell by -1.05 score points. The baseline of the ErYAG laser group was 12.0 SD 4.2, which fell by 3.86 points (p = 0.01 for ANCOVA between groups). The ICIQ score was zero/ dry in 3.6% of sham versus 21.4% of Laser treatment. This appears to be the only Sham- RCT that gives objective outcomes after only one treatment (e.g measures the true biological effect), but the 3 month results are disappointing.

Okui (2019) from Japan sequentially enrolled 50 women to have TVT operation, 50 to have TOT, and 50 to have Er:YAG laser [non-ablative “smooth” Fotona device] (250). Women were allocated “by numerical order of their medical charts”. Urge-predominant MUI was excluded (but MUI was accepted), with no urodynamics. The 3 baseline groups were similar in age and 1 hour pad test (approx. 35 gm). Er:YAG was performed three times every alternate month. At 12 months, the 1 hour pad test was 0 gm in 69%, 68% and 50% in TVT, TOT, and Er:YAG respectively (p< 0.001, data not tabulated). The ICIQ data were only shown graphically and fell from 13 scorepoints in all groups to post therapy value of approximately 2.0 in all groups.

In 2020, Erel et al from Istanbul looked for features that could predict success or failure of Er:YAG (251). After a mean of 2.11 sessions given to 82 women with either pure USI (42) or MUI (40), follow up occurred at a mean of 25 months. The ICIQ fell from a baseline of 13.6 (SD 4.55) down to 7.17, (SD 5.8). Cure rate was not given. Those with pure SUI had greater benefit than MUI (p =0.008). Premenopausal women had greater benefit than postmenopausal women (p=0.032), as did those with a normal BMI (versus those who were obese). Treatment benefit persisted up to 15 months.

5.5. Adverse Events

Most of the studies summarised so far in this section do not indicate any systematic effort to record adverse events.

As per a review from Robinson et al. (2020), a number of complications have been recorded on the MAUDE database from 2015 – 2019 (252). There were 45 separate events recorded, the most common being pain (vagina, bladder, urethral, or unspecified) and 11 patients reported burning or numbness. Some evidence of chronic adverse events was noted, such as long-term pain, numbness, burning, bladder disturbances, dyspareunia, worsening symptoms, aggravation of lichen sclerosis, scarring, and disfigurement.

In 2021, Molina et al from Spain published a case report of a 48 year old woman who developed a complete transverse vaginal septum after 2 ErYAG Laser therapies, with a pseudo-haematocolpos (8 cm diameter collection of blood in the vagina, above the septum) which required surgical division and prolonged vaginal dilatation to restore normal vaginal calibre (253).

5.6. Long term Results

In 2020, Kuszka et al from Germany (232) followed 59 women for a maximum of two years after 5 monthly treatments of ablative Er:YAG. All had urodynamic USI or stress-predominant MUI. Atrophic patients were given vaginal oestrogen. Outcome data were segregated as to whether patients had Stamey grade mild (32 women), moderate (16) or severe (11), resulting in small numbers for each subset. In the mild group, pad weight fell from 7 gm (IQR 6-8) down 2 gm (1-3) and on histogram, approximately 62% were cured (< 2 gm). In the moderate group, pad test fell from 15 gm (14-18) down to 8 gm (3-12). Leakage in the severe group was slightly reduced over 2years (35 gm to 28 gm). No statistical analysis of these changes was provided. This study provided the longest term follow up so far available, but the presentation of the data was disappointing.

This study was the subject of an editorial comment in European Urology by Braga et al (2020) from Switzerland, Greece and Italy (254).

"Although intravaginal laser therapy should strengthen the suburethral and pubocervical fibromuscularis along with their surrounding fascial supports (255), its use in female SUI is a controversial and debated topic. There is currently insufficient evidence to offer intravaginal laser therapy as an effective modality for the treatment of SUI. In fact, no studies comparing erbium: YAG or CO2 laser therapy for SUI treatment to pelvic-floor muscle training …. are available. The study by Kuszka et al (232) has merit in its investigation of subjective and objective outcomes of laser treatment in a 2-yr follow-up period, especially the focus on dose finding. However, data on the number and duration of treatment sessions and the maintenance regimen remain largely arbitrary (255). In addition, the follow-up duration varies considerably, with a mean follow-up period of 6 mo.

In 2018 the US Food and Drug Administration issued a warning against the use of energy-based devices (EBDs), including laser and radiofrequency devices (256). The alert also concerned the use of EBDs for treatment of urinary incontinence. To avoid a scenario similar to that for mesh vaginal surgery for genital prolapse, we urgently need randomised controlled studies to evaluate the safety and efficacy of EBD for treatment of SUI".

Similarly, an IUGA Committee on laser therapy for stress incontinence (and other conditions) published their detailed review (255) of the literature as follows:

Evidence from robustly conducted RCTs with long-term follow-up comparing laser with placebo or hormonal treatment are lacking. Similarly, well-designed case– control studies are required to further investigate potential benefits, harm, and efficacy of laser therapy for treating GSM, VL, and SUI symptoms. The therapeutic advantages of nonsurgical laser-based devices in urogynecology can only be recommended after robust clinical trials have demonstrated their long-term complication profile, safety, and efficacy" (255).

5.7. Conclusions

The mechanisms of action for Laser therapy remain open to question because none of the histopathology studies of its use in incontinence have employed stains for collagen, despite several claims that it stimulates de novo collagen synthesis. The outcome measures presented so far place a heavy emphasis upon improvement, but the "cure" rate is often not provided. Only one "sham" RCT study has been performed, yielding a 21% dry rate at 3 months (versus 4% in sham). Very few reports indicate in the Methods or Results that the authors have systematically elicited adverse events. These deficiencies indicate that Laser therapy has not yet reached the minimum standard required for general introduction of a new therapy.

Recommendation/ Future Research

At this time, laser therapy is not recommended for the treatment of female stress incontinence in the clinical setting.Studies that correct deficiencies regarding mechanism of action, long term cure rate, and adverse events are needed before Laser therapy can be recommended for use outside of Clinical Trials (Grade C).

6. ARTIFICIAL URINARY SPHINCTER FOR WOMEN

While artificial urinary sphincter (AUS) implantation has been used to treat female patients with stress incontinence due to intrinsic sphincter deficiency (ISD) and neuropathic incontinence for almost five decades (257), its adoption by urologists and urogynaecologists varies greatly internationally (258). While In France, it is recommended as the gold standard in women with SUI due to ISD (259), it's use is limited to selected, highly complex patients in the United Kingdom, Canada and most of Europe (260). Because of lack of FDA approval in the USA, it is rarely used there (261) and in Asia (262).

Initially, the AUS was performed as an open procedure. While several high-volume teams reported satisfactory outcomes with open AUS implantation (263-265), this remains a technically demanding procedure with up to 43.8% rate of intraoperative bladder neck injury, up to 25% rate of intraoperative vaginal injury, and explantation rates up to 45.3% after 84 months reported in smaller volume centres (265, 266). However, in large-volume centres, the results for the Open procedure are much more robust. For example, in 2011, Vayleux et al (263) followed 215 women over 22 years; the revision rate was 15% at median of 8.5 years, with a 7% explantation rate; 74% of patients were cured, using 0 – 1 pad per day. In 2014, Phe

et al (267) followed 34 women for 17 years (IQR 12-19 yrs), finding a 20% explantation rate at 15 years, with a social continence rate (0 or 1 pad per day) of 61%.

The largest long-term analysis was published by Costa et al. (264). Over a 20-year period, 376 devices were implanted in 344 women by open approach. At mean follow-up of 9.6 years, 86% of patients were fully continent. Interestingly, the two largest studies reported the lowest rates of intraoperative bladder neck and/or vaginal injury (263, 264). The post-operative complications rates varied widel, from 4.1% to 75% in open series (265). After mean follow-ups ranging from 28 to 204 months, the rates of explantation, extrusion/exposure and mechanical failures in open cohorts ranged from 0% to 45.3%, from 0% to 14.3% and from 0% to 44.1% respectively.

In the 6th Edition of the ICI text, several small reports of laparoscopic implantation of the AUS, and then early reports of robotic implantation, were provided. In this chapter, we provide longer term outcome data for large series of these new technical advances.

6.1. Surgical Principles of the Female AUS

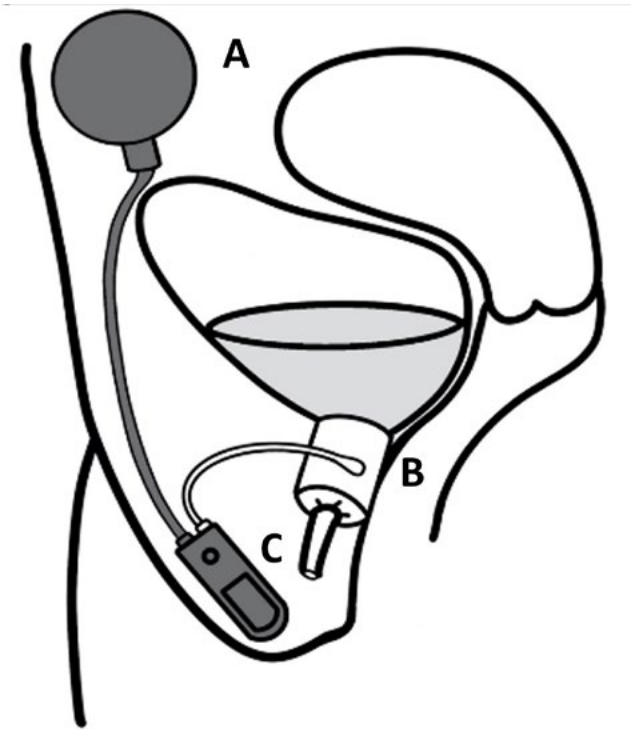

Figure 11: Artificial urinary sphincter for women. A. Pressure regulating balloon in the abdominal cavity. B. Cuff around the bladder neck. C. Pump in the labia majora. Figure thanks to B Peyronnet and C Richard, France.

In order to understand the difference between results for the open, laparoscopic and robotic procedures, a brief summary of surgical principles is needed. The artificial urinary sphincter (AUS) is a silicone device made of three main pieces: a cuff, a pressure regulating balloon (PRB) reservoir and a pump connected altogether with tubing (268). The whole system is filled with fluid**.** **Figure 11**. In females, the cuff is placed around the bladder neck; the pump is placed in the labium majus and the PRB in the abdominal cavity, either intraperitoneal or extraperitoneal (269)(See Figure 11). The rationale for bladder neck implantation is that the tissues are thicker at the bladder neck which may decrease the risk of device related complications (269). During storage of urine, the cuff is filled with fluid and exerts a predetermined pressure on the bladder neck wall circumferentially, which results in closure of the bladder neck and proximal urethra. Hence, the AUS corrects SUI/ ISD by increasing urethral resistance during storage. To void, the patient squeezes the pump located in the labium majus, which pumps the fluid away from the cuff to the reservoir, thus the bladder outlet opens. Therefore, in contrast to pubovaginal slings, the AUS theoretically increases outlet resistance during storage but maintains low outlet resistance during voiding (which has not been proven on urodynamic studies, however).

6.2. Indications

Although the use of AUS varies across the world, there is a global consensus that AUS is almost exclusively used in females with SUI predominantly due to ISD (258, 265, 269). As described in Chapter 4 (Pathophysiology of Incontinence), two main mechanisms may underpin SUI in women: urethral hypermobility and weak urethral closure pressure; those two features are a continuum. AUS serves best in female SUI where ISD is predominant. There is no universally accepted definition for ISD (270), but one relevant feature is the lack of urethral mobility, also described as a fixed urethra (259).

Thus, AUS is indicated in female SUI due to predominant ISD, i.e. with a positive cough stress test and poor urethral mobility with previous anti-incontinence procedures, severe SUI with low MUCP/VLPP. In daily practice, this represents mostly two patient groups: women with one or more failed SUI surgeries and patient with neurogenic ISD (mostly spina bifida, spinal cord injury and cauda equina syndrome), as per the literature (265). Salvage AUS in non-neurogenic patients account for the vast majority of female AUS patients (265). Because AUS may potentially cause less bladder outlet obstruction than other surgical options traditionally offered to these patients (271), it may be of particular interest in those with detrusor underactivity. The only formal contraindication to AUS in females is the inability to manipulate the pump, either due to abdominal obesity, lack of manual dexterity or cognitive dysfunction.

6.3. Surgical Approach

The technical challenge inherent to AUS implantation has likely been one of the main limitations to its widespread adoption. The main technical complexity lies in the placement of the cuff around the bladder neck owing to its location deep in the bony pelvis and the subtle dissection needed to find and follow the surgical plane between the bladder neck and the vaginal wall. This carries a high risk of intraoperative bladder neck or vaginal injury which might increase the risk of device infection/erosion postoperatively. The vaginal approach was largely used in the 1980s' but has been abandoned for more than three decades by most teams due to high rates of device infections/exposure (265).

With the rise of minimally invasive surgery in urology in the 2000s', a few surgical teams started to develop laparoscopic techniques for AUS implantation with the following rationale i) the pneumoperitoneum may decrease the bleeding from vaginal wall veins which often hamper proper vision during the bladder neck dissection ii) videoscopy may allow direct visualisation during the dissection of the posterior aspect of the bladder neck which was impossible with the open approach iii) The overall better vision may decrease the risk of bladder neck/vaginal injury and facilitate the early detection/ repair

of these injuries and improve the teaching/learning of the technique iv) the overall morbidity of the procedures and risk of device-related complications might be reduced (272, 273).

The first series by Mandron (n=25 patients) and Roupret (n=12 patients) reported promising outcomes with > 75% patients dry in both series, 0 and one intraoperative complication respectively and 0% and 8% of explantation/erosion after median follow-up of 12 and 26 months respectively (272, 273). These encouraging findings were recently confirmed by two larger series with longer follow-up. Schroeder et al analysed 49 patients at a median of 4 years, with 14.3% rate of explantations and 83.6% of patients being socially continent (0 to 1 pad per day) (274). Bracchitta et al reported on 74 patients (275) at a mean 44.5 months, in which 78.3% of patients were totally continent (no pad) The extrusion rate was 4%, the vaginal exposure rate was 2.7% and explantation rate was 10.8%.

On the grounds of these promising laparoscopic experiences, several teams started to use a robotic approach since the mid-2010s' (276-280). In the largest series published so far, Peyronnet et al reported 49 cases across five centres with 85.7% having an history of previous anti-incontinence surgery. At median of 18.5 months, 81.6% of patients were fully continent (explantation 2%) (279). An international multicentre experience of 123 patients implanted robotically in 14 institutions from four European countries was presented as an EUA/AUA abstract in 2020, confirming these findings with only four explantations for at median follow-up of 13 months (3.3%) (281).

Although most of the published robotic female AUS series used an "anterior" approach, mimicking what was done in the historical open technique [with an initial opening of the Retzius space to dissect the bladder neck "from above"], a handful of teams have recently reported an alternative "posterior" robotic technique with dissection of the bladder neck being carried out "from below". This involves an extensive dissection of the vesicovaginal space from the vaginal fornix to the posterior aspect of the bladder neck prior to reaching the anterior aspect on each side (280, 282, 283). The outcomes reported were broadly similar to those of the anterior technique although the higher rates of intraoperative urinary tract/vaginal injuries (29.6% and 50% in the Chartier-Kastler and Broudeur series respectively) may raise concerns and should prompt longer term data (280, 283).

6.4. Functional Outcomes: Overview

Since the last Chapter, a 2019 systematic review of the literature was conducted by a group of international experts upon invitation of the ICS (265). Of 886 records screened, 17 met the inclusion criteria. All were retrospective or prospective non-comparative series reporting mostly on open implantation (12/17). The vast majority of patients had undergone at least one anti-incontinence surgical procedure prior to AUS implantation (69.1-100%). The 61-70 cmH_2O pressure regulating balloon was the most commonly used, with the 51-60 cmH_2O and 71-80 cm H_2O being favoured in two and one open series respectively. The median cuff size ranged from 60 to 80 mm (265). After mean follow-up ranging from 5 to 204 months, the complete, social and improved continence rates ranged from 61.1% to 100%, from 71% to 100% and from 81.3% to 100% respectively (265). Seven series, all reporting on open AUS implantations, had a mean follow-up over 5 years (range: 72 to 204 months) (263, 264, 266, 267, 284-286). At the latest follow-up, 61.1% to 85.6% of patients reported being fully continent.

Since publication of this 2019 systematic review, aside from the robotic and laparoscopic female AUS series mentioned, two important studies have been published. Tricard et al analysed 63 women who underwent open AUS implantation up to 2007 (287). At median follow-up of 11.6years, 55.6% of patients remained completely dry, with 25.5% explantation rate. A study focusing on AUS in women aged > 75 years showed (median follow-up 36 months), 68.9% of the 45 patients were continent (288).

Overall, these results suggest that, when remaining in situ, AUS yields satisfactory functional outcomes in female SUI patients, comparable or better than what has been reported in male AUS series.

6.5. Level of Evidence/ Summary

As mentioned above, there is currently no high level of evidence studies published on female AUS (265). All data come from retrospective series or prospective database studies, which is a major barrier to widespread adoption of the AUS. High level of evidence studies are clearly needed to better determine the role of AUS in females. It should be noted that two prospective studies are underway: the SUACT trial (clinicaltrials.gov identifier: NCT02490917) a RCT comparing adjustable periurethral balloons to AUS in females with SUI due to ISD, and the VENUS study (clinicaltrials.gov identifier: NCT04114266), a prospective cohort study on female AUS involving 25 centres throughout Europe and conducted by the EAU Research Foundation. Their findings should shed light on female AUS.

Summary

No high-quality data are available regarding the use of AUS in women with SUI. (EL=3). AUS has been mostly used to treat women with SUI due to predominant ISD, i.e. patients with failed previous anti-incontinence procedures or neurogenic SUI. (EL=3)

In the existing literature, the functional outcomes reported were satisfactory with 61.1% to 85.6% of patients being dry in the long-term. (EL=3)

Safety concerns have been raised in some series with high perioperative complications and explantation rates which seem to be attributable to the technically challenging AUS implantation procedure. (EL=3)

Laparoscopic and robotic implantation techniques have recently been described with promising outcomes in terms of morbidity but with relatively short-term follow-up. (EL=3)

Recommendations

AUS is an option for some women with SUI due to ISD, i.e. with a poorly mobile urethra, most of whom failed previous SUI surgery and some neurogenic patients (Grade C), with implantation by surgeons with appropriate training and expertise.

Patients should be appropriately counseled regarding the likely need for revision over time and the lack of long term RCT data (Grade C).

Research: Longer term data regarding use of laparoscopic and robotic implantation techniques are needed, in relation to cure rates, complications, and explantation rate.

7. STEM CELL TECHNOLOGY AND BUCCAL MUCOSA GRAFTS TO THE URETHRA

Since the last edition of the ICI, there has been progress in the use of stem cell technology in the treatment of female SUI. Translational research in this novel field has evolved from non-primate animal pre-clinical studies to Level 1 clinical data in humans. The findings are summarised below along with historic background information.

7.1. Mechanism of Action

Stem cell therapy is a broad term encompassing both embryonic and adult cell types. Embryonic stem cells are totipotent, whereas adult stem cells are generally unique to the specific tissue they are derived from, with limited capacity for differentiation. Current clinical research in SUI focuses on adult stem cells and can be broadly categorised into the cell types they are derived from:

1. Muscle derived stem cell (MDSC),
2. Adipose derived stromal stem cell (ADSC),
3. Serum (i.e. platelets),
4. Bone marrow
5. Cord blood stem cells.

They all share mesenchymal stem cell (MSC) properties which allow differentiation into smooth muscle or neural cells, that are potentially therapeutic in SUI and ISD.

MDSC and ADSC remain the 2 most studied types of adult stem cells in both preclinical and clinical trials (290), owing to their ability to differentiate into smooth muscle cells in vitro (291) and abundant tissue source that can be easily harvest via muscle biopsy or liposuction with minimal morbidity (292). Sources of MDSC and ADSC in clinical studies are all autologous, which avoids issues of host reaction and rejection. In most studies, after muscle biopsy or liposuction, stem cells are treated by a process of expansion where progenitor cells are incubated and multiplied until appropriate volume of cells are obtained, frozen and later injected back into patients (293). Volume and sites of injection vary between periurethral, transurethral, intrasphincter or submucosal methods.

The mechanism of how stem cells improve continence is still not completely understood, but thought to result from regeneration of the rhabdosphincter and possible repair of neuropraxia (290). In vivo mouse studies show physiological improvements in the urethral sphincter resistance post injection of MSC with smooth muscle incorporating into the sphincter on later biopsy (294). Injections of MSC have also led to enhanced neuromuscular recovery of the pudendal nerve, thus supporting the neuropraxia hypothesis (295). In the porcine model, where urethral histology resembles humans closely, injection of stromal vascular fraction (a type of ADSC) into recently damaged urethra was associated with reduction of urethral injury at day 30 and increased maximum urethral pressure compared to controls without ADSC (296).

In human studies, urethral biopsies are unable to be performed, thus it is unclear whether clinical improvements arise from tissue incorporation of stem cells and increased sphincter function, the bulking effect of cells injected, or a combination of these effects.

7.2. Clinical Trials

Historical aspects of how stem cell evolved from animal studies to early small human studies were discussed in the previous ICI -6 and will not be reiterated here. Of relevance, one systematic review of cohort studies (292) and two double blinded placebo controlled RCTS have examined the efficacy of stem cells in the treatment of female SUI since the last ICI review (297, 298).

The systematic review found 16 small non-randomised studies of varying cohort sizes (n=11-123) with MDSC as the most common cell type used. Cure rates ranged from 11-90% at 12 months follow up, but surprisingly, worsening of incontinence was reported in 8.5% of patients (292). A meta-analysis was unable to be performed due to the high variability in methodology, unclear in- vivo culture technique and cell volume injected and variable concurrent use of collagen bulking agent at the same time.

To date there is only one published placebo controlled RCT of autologous MDSC in women with SUI with 2 year follow up. The study utilised outpatient thigh muscle biopsy and 13 weeks of laboratory culture to produce 150x106 MDSC (containing 84% myocytes and 16% fibroblast) suspended in 2ml patented cryopreservation solution and 2ml normal saline. The solution was injected into the midurethra and intra-sphincter in a circumferential pattern with low side effect profile. Choice of dose was based on a dose finding study of 80 women (293), where higher stem cell volumes injected (200x106) was associated with statistically significant reduction in pad test.

The primary composite outcome of this RCT was a >50% reduction in leakage severity on 24hour pad test at 12 months. Unfortunately, the trial was stopped at 61% recruitment (n=150) due to a high placebo response. Post hoc analysis found this composite outcome to be too liberal, and suggested subsequent studies use >75% reduction stress leak episodes as a primary outcome to reduce placebo effect. While not reaching statistical significance, in the subgroup of patients with recurrent SUI and prior continence surgery, complete continence rate (36.4% vs 16.7%) and >75% improvement in SUI episodes (63.6% vs 16.7%) were higher in the stem cell group compared to controls. This pattern was not seen in the subgroup without prior continence surgery (297).

Very recently, the same group presented preliminary data of another Phase III multicentre RCT of 297 women injected with autologous MDSC (2:1 Stem cell to placebo ratio) with 12month follow up. A high placebo effect was seen again in the control group, when using >50% reduction in leakage as the outcome measure (298). However, patients with severe incontinence (stratified as >10 leaks/ 3 days at baseline) saw a 2-fold increase in complete continence rate compared to placebo (20% vs 11%).

In a subgroup analysis of the same RCT, 75 women with severe recurrent SUI defined as >10 leaks/ 3 day with a history of previous continence surgery, revealed more promising results (299). Using >75% reduction of stress leak episodes as the outcome measure, the stem cell group showed a statistically significant reduction in leakage (40% vs 16%, p=0.037) and significant improvements in QoL (p<0.002) compared to controls. The dry rate was not reported. This and the findings of the previous RCT support the notion that MDSC may have significant therapeutic benefit in ISD and recurrent SUI. This is in line with the proposed stem cell mechanism of action in repair of urethral sphincter damage. Based on the above evidence, Cook Medical ® has obtained the USA Regenerative Medicine Advanced Therapy designation in Dec 2020.

Despite the novel findings discussed above, there is still a lack of long-term outcome data beyond 2 years. Given the relative short-term effect of traditional bulking agents, long term data will help to determine the true efficacy of MDSC.

Summary

The scientific basis of stem cell use for SUI has evolved in the last 5 years with new evidence supporting autologous muscle derived stem cells for treatment of female SUI. However, direct comparisons between stem cell types are lacking and there is currently no consensus on the optimal cell type, location to inject, volume/ concentration of cells, or ideal target population. Long term outcome is also lacking. These areas remain a focus for future studies.

Recommendation/ Research

The use of stem cell technology for treatment of female SUI remains investigational with promising results. Such therapy should only be offered in the setting of clinical trials (Grade D).

7.3. Buccal Mucosa Reconstruction of the Urethra

Urethral extrusion of synthetic midurethral sling can result in devastating complications (300). Removal of the synthetic material is the option of choice in the vast majority of these patients. Immediate reconstruction usually involves direct suturing of the native urethra. However, if the urethral defect is large, direct suturing may involve high risk of urethral stricture. In these situations, the use of autologous tissue may be necessary (300-302). Mainly two types of autologous materials can be used in these situations: local vaginal flap and buccal mucosa graft (303). They are mostly used as onlay and can be either placed on the dorsal or ventral aspect of the urethra (301, 302). Both of these tissues can also be used to repair post- sling excision urethral stricture or urethrovaginal fistula (in case of large urethral defect and along with Martius flap in most instances) (301-303).

Harvesting the buccal mucosa graft entails excising a triangular portion of the mucosa from the inside of the oral cavity on the inner aspect of the cheek, approximately 4 cm x 3 cm. Care must be taken to avoid nerve fibres located under the mucosa, with meticulous haemostasis. The graft is laid down flat, then perforated and stretched gently. While dissecting the peri-urethral tissue, the graft is stored in a moist saline soaked solution (as for the rectus fascia graft harvested for pubovaginal slings). Once the sub-urethral dissection is completed with meticulous haemostasis, the graft is laid under the urethra and tacked into place with 4.0 absorbable sutures. A vaginal pack is kept in position for 24 hours, as haematoma formation is highly undesirable. Prophylactic antibiotics and urinary catheterization are needed for at least 48 hours. Currently available publications (301-303) do not describe long term objective outcomes.

Recommendation

Harvesting of buccal mucosal grafts requires specialised training at a supra-regional centre. The concept of harvesting autologous mucosa to lay under the damaged urethra appears biologically attractive and warrants formal long term series of patients with objective outcome measures. (Grade D)

II. SURGERY FOR NON-NEUROGENIC UUI

1. SACRAL NEUROSTIMULATION (SNS)

1.1. SNS – Technical Considerations

SNS was developed in the early 1980s by Tanagho and Schmidt (304). They showed that continuous stimulation of the sacral root S3 with an electrode connected to an implanted pulse generator could modulate detrusor and sphincter activity (305). Initially, the therapy involved an invasive surgical procedure with a large incision over the sacrum to anchor the lead. Continual improvements in SNS have been introduced and it is now a minimally invasive technique. InterStim® Therapy (Medtronic, Minneapolis, MN, USA) was the first technology licensed by regulatory agencies worldwide for the treatment of urge incontinence (UI) (the subject of this section). The introduction of the percutaneous tined lead (306) has made this procedure easier, improved patient comfort and enabled a longer testing period with less lead migration improving the success rate of the test phase.

The original InterStim™ system had a large implantable pulse generator (IPG) with a battery life of approximately 5-8 years, which was later replaced by the smaller, InterStim™ II SNM system, with a battery life of approximately 4-5 years (see figure 12).

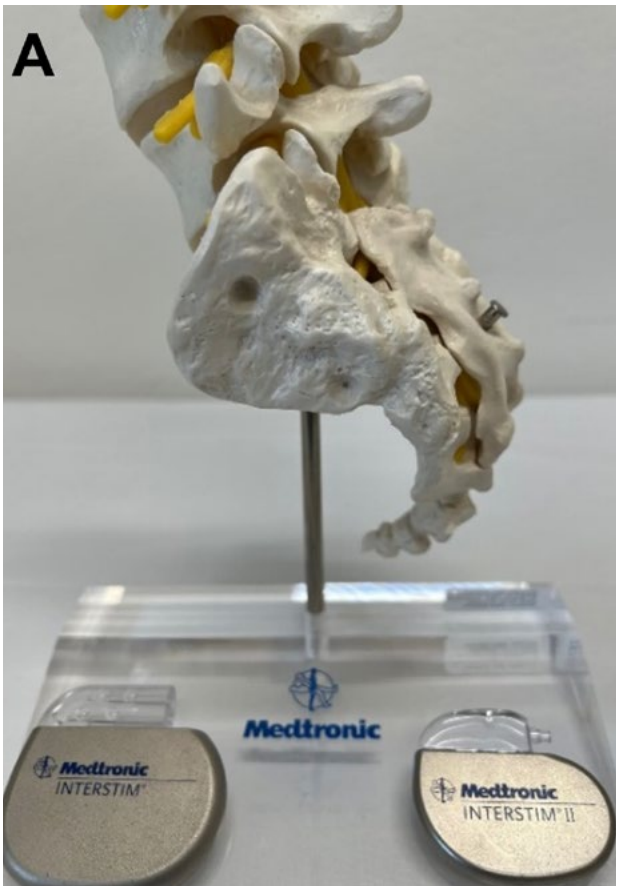

Figure 12: Original and later version of Interstim IPG (courtesy K H. Moore)

More recently, a rechargeable system (InterStim™ Micro system) with new leads that are MRI compatible (InterStim SureScan MRI leads) was developed, allowing full-body 1.5 and 3 Tesla MRI-conditional scans. The new InterStim™ Micro system is a current-controlled system, while the InterStim™ II SNM system is voltage controlled.
Axonics Modulation Technologies, Inc. (Irvine, CA) is a new manufacturer of SNS that has been introduced in Europe and USA. Their new devices (Axonics r-SNM System) are rechargeable and conditional magnetic resonance imaging (MRI)-safe. The Axonics r-SNM System is a current-controlled system, adjusting the voltage automatically to maintain continuous and stable stimulation of the nerve. The implantation technique for both technologies is very similar. An electrode is implanted in the S3 foramen and connected to an implantable pulse generator (IPG). The sequential technique to place a SNM system has been refined (306) and recently well described (308). It involves passing the electrode into the upper medial aspect of the S3 sacral foramen, utilising the ideal curve of the electrodes to place them adjacent to the nerve and allowing low thresholds on all four electrodes, with placement confirmed by fluoroscopic images.

Usually, a test phase determines whether SNS has provided at least a 50% benefit on 2 week bladder diary before implanting the IPG in the upper buttock. The test phase may be performed in two ways: by peripheral nerve evaluation (PNE) using a monopolar short-term electrode which is always removed after the test period and is not designed for long term therapy, or by staged implantation of a permanent, quadripolar tined-lead electrode which is designed for potential long-term use after a successful test period (309). Because PNE may underestimate treatment effect and result in significant false-negative rates, many surgeons utilise the staged implantation of a tined-lead for the first stage (309-312). Although the PNE approach is less invasive, less costly and may be performed in the office setting, there may be problems with lead migration. The conversion rates to IPG implantation in OAB patients are inferior to those with the staged implant (309). More recently, single stage implantation without a test phase has been suggested to improve the patients' experience and reduce complications such as lead infection (313, 314).

1.2. Mechanism of Action

The mechanism of action of SNS is not completely understood. The therapeutic benefits of SNS may arise from the effects of electrical stimulation on afferent and efferent nerve fibers connecting the pelvic viscera and the spinal interneurons to the central nervous system. Little evidence exists demonstrating permanent remodeling, re-innervation or alteration of pathways in the central and/or peripheral nervous systems in humans. SNS seems to predominantly influence sacral afferents and modulate spinal cord reflexes and brain centres involved in lower urinary tract function (315-317). Using functional MRI or positron emission tomography, recent studies have shown that SNS affects activity in supraspinal centres involved in the control of detrusor contraction, bladder filling and micturition timing (318-320).

The impact of SNS on brain activity depends on the level of stimulation. Using functional MRI, Gill et al showed that subsensory stimulation deactivates the pons and periaqueductal grey matter, while sensory stimulation deactivates the parietal lobes but activates the insula. Suprasensory stimulation led to widespread activation, including an increase in activity in the somatosensory region (319). Thus, brain responses to SNM vary with stimulation intensity. In addition, Wenzler et al evaluated the effect of SNM on afferent sensory nerve pathways by recording bladder current perception thresholds (CPTs) and found higher CPT values after SNM therapy, providing further evidence that SNM impacts the sensory function of the bladder (321). These data provide evidence that afferents play a key role in modulating spinal reflexes and brain centres. The fact that neuromodulation techniques with stimulation at different sites in the body (transcutaneous spinal stimulation, transcutaneous/ percutaneous tibial nerve stimulation, and pudendal nerve stimulation) may provide similar effects to SNS is also regarded as evidence for the importance of bladder afferents in SNS (317).

1.3. Efficacy and Safety

The introduction of new technologies and the use of the optimal lead placement technique have impacted on the results of SNS. In this section we mostly discuss studies reporting on SNS technology that is still available in clinical practice.

1.3.1. SNS vs No Therapy

See previous ICI-6 Chapter.

1.3.2. SNS vs Medical Therapy

The InSite trial was a two-phase study including a prospective, multi-centre, RCT comparing Interstim SNS with to standard medical therapy (SMT) eg anticholinergic medication, for patients with refractory **mild to moderate** symptoms of OAB, including urge incontinence (UI) and/or urgency-frequency (UF), within a six-month follow-up period (311). The primary hypothesis of the RCT portion of the study was that SNS is superior to anticholinergic drugs in OAB patients for whom at least one medication had been tried, but other pharmacologic agents were still available. The second phase was a prospective long-term evaluation of the safety/ efficacy of SNS. This was an FDA requirement to evaluate the cumulative five-year rate of AEs including need for surgery, rates of infection and lead migration as well as success/ QOL. See results for one (322), three (323), and five (324) years of follow-up:primary outcome measure for the RCT phase (on voiding diaries at 6-months (311)) was ≥ 50% improvement in average leaks/day or voids/day from baseline, or a return to normal voiding frequency (<8 voids/day). QOL, impact on sexual function and depressive symptoms between groups using the ICI Modular Questionnaire (ICIQ)-OABqol, the ICIQ—Male/ Female Lower Urinary Tract Symptoms-Sex, and the Beck Depression Inventory II were also compared.

Overall, 147 subjects were randomised (70 to SNS and 77 to SMT); 93% were female, mean age 58. Subjects randomised to SNS underwent a staged procedure using InterStim with a 14-day test stimulation period. Of these 70 SNS subjects, 59 underwent test stimulation and 51/59 (86%) received a full implant. The primary ITT analysis showed OAB success was significantly greater in the SNS group (61%) than in the anticholinergic drugs group (42%; P=0.02). Complete continence was almost doubled in the SNS group (39% vs 21% in SMT; P=0.06). Significant improvements in QOL (all P<0.001), sexual function and depression were both superior to SMT. Device-related AE rate was 30.5%; the medication-related AE rate was 27.3% (none serious). The most common SNS device-related AE's were undesirable change in stimulation in 10.2%, implant site pain 8.5%, lead migration/ dislodgment 3.4% , and implant site infection 3.4% . For the 51 SNS full implant subjects, the 6-month post-op surgical intervention rate was 3.9%. The most common OAB medication-AE were constipation in 9.1%, drug toxicity in 6.5% and dry mouth in 5.2%. (Level of evidence 1)

1.3.3. SNS vs OnabotulinumtoxinA (BTX-A)

SNS and BTX-A injection are approved third line therapeutic options for the treatment of refractory OAB (12, 325). SNS is more invasive but has the potential to offer long-term efficacy whereas treatment with BTX-A injections is less invasive but needs to be repeated on a regular basis to provide sustained efficacy. Each treatment modality has its own range of possible AEs. The only head-to-head study comparing the efficacy and safety of the two therapies for OAB is the ROSETTA Trial (Refractory OAB: Sacral Neuromodulation vs Botulinum Toxin Assessment). It was a multicentre, open-label, RCT comparing SNS with Interstim versus intradetrusor injection of 200 U BTX-A in women with refractory OAB (312). Of 386 women randomised, 369 were treated; 364 were available for primary outcome analyses (mean age 63 years). More than 80% of both groups rated themselves as severely or very severely incontinent. In the SNS group, women underwent a two-stage procedure. The rate of clinical response — defined as a reduction of at least 50% in urge leaks on 3-day bladder diary — was similar in the BTX and SNS groups (83% vs 84%), measured at 1 month in the Botox group and during the test phase in the neurostimulation group.

In both the ITT and clinical responders outcome analyses, the BTX-A group had significantly greater mean reduction in daily urge leaks compared to the SNS group (−3.9 vs −3.3 leaks/ day; mean difference, 0.63; 95% CI, 0.13 to 1.14; P =0.01). More patients in the injection group than in the SNS group had complete symptom resolution at 6 months (20% vs 4%; P<0.0001) and a reduction of at least 75% in leaks/day (46% vs 26%; P=0.0002). OABQ scores were significantly improved in both groups but change from baseline was greater in the injection group than in the SNS group (–46.71 vs –38.5; P =0.002). Treatment satisfaction was better in the Botox group than in the SNS group (P=0.01).

At two-years [data available for 260/298 (87%)] (326), there were 72% (115/159) of the BTX-A participants requesting a second injection [median interval 350 days, IQR 242–465] and 48% (55/115) requested a third injection. Median interval between second and third injections was 273 days [IQR = 224–350]. No difference in the reduction of UUI episodes was found between groups over 24 months (-3.88 vs -3.50 episodes/d, [95%CI] =-0.14-0.89; p=0.15]. UUI resolution was similar in both groups. Satisfaction with treatment was higher among women from the BTX-A group, with no difference in QOL.

The UTI rate was higher in the Botox A group versus SNS group at 6 months (35% vs 11%; P<0.0001). In the Botox group, intermittent catheterization (CISC) was needed by 8% of patients at 1 month, 4% at 3 months, and 2% at 6 months. In the SNS group, 3% required surgical revision or removal. At two-years, recurrent UTIs were higher after BTX-A (24% vs 10%; p<0.01). After the second BTX-A injection, 6% needed CISC, with median CISC duration of 29 days [IQR = 17–56]. After the third injection, CISC rate was 2%. Of the 189 Botox participants, 45 (24%) required CISC at any point over two years. In the SNM group, 58% (81/139) required reprogramming, with 17% (14/81) requiring ≥3 reprogrammings (most commonly for decreased efficacy). SNM revision and removals occurred in 3% and 8.6% respectively. Reasons for removal included infection, decreased efficacy, subject's desire and pain.

The authors concluded that both treatments offered sustainable UUI improvement. Women in the BTX-A group had higher satisfaction but with a higher chance of UTI. (Level of evidence 1)

1.4. Long Term Results

Figure 13: Intraoperative setup for SNS. Courtesy St George Hospital, Sydney

The introduction of new technologies and the use of the optimal lead placement technique have favourably impacted the results of SNS. Groen et al (2011) evaluated the long-term 5 year results of SNS in 60 patients with refractory UI (327). The success rate gradually decreased from 87% at 1 month to 62% at 5 years. Complete continence persisted in 15%. There were 41 patients at the 10-year follow-up; 61% of these were still on active SNS. The 10-year success rates were not different from the 5-year results, suggesting that a deterioration of the results is observed during the first 5 years. A total of 57 AEs occurred in 32 (53%) patients, the majority related to hardware failure and pain or discomfort at various sites. A total of 23 reoperations, including two explantations, were done in 15 patients (25%).

Other long-term studies (discussed in ICI-6) evaluated results of SNS for OAB patients. At 5 years post-surgery, >50% improvement was seen in 68% of those with UI and 56% of those with UF (328-330).

The InSite study was a multicentre prospective trial that evaluated efficacy and safety of SNS with InterStim™ therapy for OAB patients. In ICI-6, results were presented for one (322), three (323) years; five-year (324) follow-up has just been reported. A total of 340 subjects underwent test stimulation, 272 were implanted (91% female, mean age 57 years). Patients with incontinence had an average of 3.1 leaks/day. The success rate was 85% at 1 year and 82% at 5 years. A mean reduction of 2.2 leaks/day was observed after one year, 2.3 leaks/day after three years and 2.0 leaks/day after five years. At five years, subjects with urgency-frequency had a mean reduction of 5.4 voids per day. Sustained QOL improvements were reported from baseline to 5 years in all ICIQ-OABqol domains along with sustained improvements in female sexual function and pelvic pain measures.

At five years, the cumulative rate of AEs related to the tined lead that required surgery after full system implantation was 22.4%. An undesirable change in stimulation was the most common AE, which occurred in (22%), followed by implant site pain in (15%) and product ineffectiveness in (13%). Surgical intervention was performed (30.9%) due to an AE and (33.5%) underwent a surgical intervention due to battery replacement. In total, 19.1% (52/272) of subjects underwent device explantation. The main reason for explant was AE (11%) or lack / loss of efficacy (8.5%). (Level of evidence 2)

The SOUNDS study is a large-scale prospective, multicentre observational study that captured real-world results of SNS, demanded by the French health authority. Results for 12 (331) and 36 (332) months have been reported, but 5 year data collection is ongoing. The study enrolled 291 patients with OAB of which 169 (62%) received a de novo InterStim system, 60 (22%) received a replacement and 45 (16%) patients were tested but did not receive a permanent implant (17 patients were screening failures). For 169 patients receiving a de novo SNS implant, the voids/ day decreased from 12.6 at baseline to 9.1 for the OAB dry subgroup. The leaks/ day decreased from 4.4 at baseline to 1.7 for OAB wet, at 34 months. "Response" was defined as ≥ 50% reduction in leaks/ day for OAB wet, and ≥ 50% reduction in voids per day or <8 voids per day for OAB dry. Response rates at 34 months were 72% in OAB wet and 33% in OAB dry. Complete continence was achieved in 30% of the OAB wet patients.

Device-related AEs rate was 49% (134/274). The most common AEs were implant site pain (6%), implant site infection (4%), battery-related events (5%), device use error (5%), and device failure (7%). Overall, 12% of patients (34/274) experienced a serious AE. Most were managed by lead removal (11%), neurostimulator removal (8%), reprogramming (7%), or antibiotics (6%) or analgesics (4%). Surgical revisions, including replacement, repositioning, or removal of components occurred in 33% of patients who had received a full implant (permanent device removal in 13%.)

There are no studies with long-term data on SNS using the Axonics r-SNM SystemTM but two studies presented two-year outcomes (307, 333). The Artisan-SNM study was a prospective, multicentre, study performed to gain FDA approval. Results for 6 (334), 12 (335) and 24 months (307) have been reported. The study enrolled 129 participants (mean age 59.3 years) with urge incontinence (UUI) who had implantation of the rechargeable Axonics System in a single, nonstaged procedure. At 2 years, 93% were responders (≥ 50% reduction in Urge leaks/ day); 37% were dry. Daily UUI episodes reduced from 5.6 ± 0.3 at baseline to 1.0 ± 0.2. Improvements in ICIQ-OABqol were significant. All subjects were able to recharge their device; 94% reported that recharging frequency and duration were acceptable.

Device-related AEs occurred in 20 (16%) patients and procedure-related AEs occurred in 15 (12%) patients. Uncomfortable change in stimulation was the most frequent AE (9%), usually managed with device reprogramming. Surgical interventions (n=14) were performed in 9%, including lead revision in 2%, neurostimulator revision in 3% and device explantation in 4% (because of infection at INS site, pain and insufficient therapy effectiveness).

The RELAX-OAB study was a postmarket, prospective, multi-centre study in Europe designed to test safety and efficacy of the Axonics system for two years. Data for three months (336), 12 months (314) and 24 months (333) results have been reported, for the 51 participants (mean age 51 years; 75% women) with OAB. At 2 years, 76% (28/37) of the subjects were responders (≥ 50% reduction in urge leaks/day and/or ≥ 50% reduction in voids per day or <8 voids per day). Daily UI episodes reduced from 9.3 ± 0.8 at baseline to 3.6 ± 1.1 at 2 years, with significant improvement in QoL. Device-related AEs occurred in 26% patients (most commonly uncomfortable stimulation 20%), all managed with device reprogramming. Device explantation was needed in 14% [most commonly for insufficient effectiveness].

1.5. Testing Procedure: PNE vs Staged Tined Lead vs Single Stage Implant

As described in Section 6.1, the test phase of SNS may be performed by PNE using a temporary monopolar electrode, or by staged implantation of a permanent, quadripolar tined-lead electrode. More recently, single stage implantation without a test phase has been suggested to improve patients' experience and reduce complications (313, 314). The PNE approach is less invasive, less costly and can be done in the office, but there may be problems with lead migration. The conversion rates to IPG implantation after PNE are inferior to those with the staged implant (309).

In a retrospective study of 92 patients screened for SNS, 35/76 patients (46%) who underwent PNE met the criteria for permanent implantation, compared with 11/16 (69%) patients who underwent screening with the tined lead (337). Of the 41 patients who failed PNE and then had screening with tined lead, 18 (44%) had a successful response and were implanted with SNS. Bannowski et al (2008) examined urodynamic and clinical outcomes of the two different testing techniques. Permanent quadripolar electrodes led to significant benefit in the overall response rate (81.8% versus 47.6%) and urodynamic parameters (max detrusor pressure, bladder capacity) compared to PNE (338).

A prospective single centre study compared the response rate to PNE to that of the stage tined-lead placement test (FSTLP). Of 100 patients with refractory idiopathic OAB or non-obstructive UR, who were screened with both PNE and FSTLP, positive response rate PNE was 47%, versus FSTLP 69% ($P<0.001$). Because of the increased sensitivity of the staged tined-lead placement test for identifying good responders, the most recent prospective studies involving SNS have used this method for the test phase (311, 312, 324, 332). (LE=2)

Single stage implantation without a test phase has been suggested to improve patients' experience, reduce complications and decrease costs of anesthesia and hospitalisation. Lee et al ((2020) found that of 15 consecutive patients who underwent single stage SNM implant with InterStim™ II system, 14 (93.3%) had a ≥50% improvement. The authors calculated total cost savings of $85,366 due to a reduction of 233 minutes in operative time (313). Future studies comparing 1-stage vs 2-stage SNS procedures are awaited.

1.6. Unilateral vs Bilateral SNS

Standard SNS is based on unilateral lead implantation. **Figure 13**. However, there is experimental evidence that bilateral stimulation of the sacral nerves could improve SNS results (339-341). The exact mechanism is still not fully understood, and bilateral SNS remains controversial, see further discussion in ICI-6. A retrospective study of 124 subjects by Pham et al (340) compared unilateral lead technique (55 patients, 44%) to bilateral lead placement. Success occurred in 58% and 76% respectively ($P=0.03$) with no difference in wound infection/ other AEs.

In a prospective randomised crossover trial, Scheepens et al investigated 33 patients who underwent unilateral or bilateral implantation of a temporary test lead (339); 8 were excluded due to lead migration. Of 25 patients analysed, a significant/ comparable response was seen during test stimulation for both methods. The authors concluded that bilateral is in general not superior to unilateral SNS but a few cases may have improved results with bilateral SNS.

A recent multicentric, parallel, randomised, open pilot trial was conducted to compare treatment success rate [improvement of OAB

symptoms] between unilateral and bilateral SNS testing (342). Patients were randomised (bilateral n = 28) or unilateral (n = 27) (342). The primary outcome was the rate of patients with least 50% of clinical improvement at 1 month. The rate of patients presenting at least one significant clinical improvement at month 1 was 62% in the bilateral group, versus 84% in the unilateral group. More complications were seen in the bilateral versus unilateral groups (9 [47%] vs 4 [16%]).

1.7. SNS and Different Programming Parameters

The success of SNS for the treatment of bladder and/or bowel disorders depends not only on the placement of the electrode lead but also on the programming of the neurostimulator. Optimised lead placement focusses on placing the lead along the nerve, allowing more programming options and reducing the need for reprogramming and for changes in the stimulation amplitude. The main programming parameters of SNS are the electrode configuration (selection of the anode and cathode), stimulation amplitude, pulse frequency, and pulse width (the duration of each electrical pulse). In addition, SNS may be continuous or intermittent.

Electrode Configuration: The electrode configuration with the best sensory response at the lowest amplitude is typically chosen. It is usually assumed that the best sensation site is a midline perineal, genital or anal sensation, while leg, buttock, or back sensations constitute a poor response (343). The electrode configuration may be monopolar (when IPG is used as the anode [+]) or bipolar (two contact points used) with no evidence in favour of either one (343). With four electrodes as possible contact points for the cathode, various programs can be used for SNS.

Stimulation amplitude: Optimal lead placement allows for lower amplitude stimulation and lower energy consumption (308, 344). The InterStim™ II IPG works on a constant voltage basis. The Axonics r-SNM System and the InterStim™ Micro system are current-controlled system, adjusting the voltage automatically to maintain continuous and stable stimulation of the nerve. If the impedance is stable, both systems deliver the same amount of energy to the sacral nerve. There is no evidence that one stimulation modality is clinically superior to the other (345, 346).

Pulse frequency: Pulse frequency is typically set at 14 Hz for most urological patients. Beneficial variations of programming have been discussed in ICI-6. It has been shown that frequency changes may have an impact on symptom control. Marcelissen et al evaluated the effect of four different pulse rates in patients with suboptimal response to SNS (347). Although they were not able to show the superiority of any of the different pulse rates tested, they showed that 76% of the patients had an improvement in symptoms by changing the pulse rate. (343, 347).

Pulse width: The standard pulse width is 210 µs (348). When the pulse width is increased, the current or voltage required to stimulate a neural tissue decreases (332).

Continuous vs intermittent SNS: It has been proposed that intermittent SNS could be beneficial for the long-term efficacy and for battery life. A prospective, randomised, multicentre, single-blind, 4 x 4 crossover study was conducted in 2018 by Siegel et al. to see the effect of 4 cycling settings (continuous, 16 seconds on/8 seconds off, 10 minutes on/ 10 minutes off, and 30 minutes on/23.5 hours off) on efficacy, quality of life, and safety (349). Results showed no significant cycling or period effect on UI. There was a statistically significant interaction between cycling and period (P = 0.0032).

Programming parameters in recent prospective studies: In the Insite study (324) with the InterStim™ II system, based on the 140 subjects who reached the 5-year visit and had programming data available: 60.7% were programmed to an amplitude of less than 2 V. In most subjects the pulse width was 210 µs, in 63.6% the stimulation frequency was programmed to 14 Hz and 67.9% were on continuous stimulation. In the RELAX-OAB study (333), based on 39 subjects who reached 2-year visit and had programming data available, the stimulation frequency was programmed to 14 Hz in 82% and the pulse width was 210 µs in 90% of subjects. All participants were on bipolar electrode configurations and all were on were on continuous stimulation.

The circumstances in which reprogramming is necessary have recently been described by Dudding et al. in a systematic review regarding all of the above parameters (343). A recent systematic review evaluated the clinical efficacy of nonconventional stimulation parameters (350). They concluded that altering stimulation parameters may improve efficacy of SNM in implementation of short cycling intervals. (Level of evidence 2)

1.8. Predictors of Outcomes

Most studies investigating predictors of success for SNS in OAB patients are retrospective. Parameters such age, severity of incontinence, obesity, prior medication use, previous spinal surgery, urodynamic findings etc. been analysed.

Yazdany et al (2011) showed that patients with >10 incontinence episodes per day were more likely to have a successful stage I trial compared to those with less than 5 episodes/day (351). Levin et al (2012) reported on the impact of obesity (352). In 149 patients, 80 (53.7%) were obese (BMI mean 37.3): success rates for non-obese patients (83%) was comparable to obese patients (78%).

Peters et al (2015) evaluated the impact of age (353). In a prospective study of 266 patients the rate of IPG implant (89-90%) and explant (9.3-13%) did not vary between different age groups (<40 years, 40-64 and >/=65) but there was a tendency for higher complication rates in younger patients (23% vs. 15% vs. 8.5%, respectively; P=0.08). Angioli et al (2016) reported results of SNS in older patients, mean age 76 years (354). At 12 months, 55.5% of patients reported complete cessation of UUI episodes. Overall, UUI episodes decreased from 6.3/day to 0.5/day

The predictive role of urodynamics was reported by Groenendijk et al (2008) in 111 patients who had permanent SNS after successful PNE: 67 had, and 44 did not have, DO on urodynamics (355). Both groups improved bladder volume at first sensation and at maximum capacity. Resolution of DO occurred in 51% overall., However success in resolved-DO patients was not significantly different from those with persistent DO. Interestingly, patients with UUI and no DO tended to have a higher rate of success (73%) than those with UI and DO (61%) (not statisticaly significant). South et al (2007) had similar results (356). Recently, in 99 patients with idiopathic refractory DO, Nobrega et al (2018) investigated whether urodynamics predicted success of first stage tined lead placement (357). Urodynamic parameters were mean voided volume, peak detrusor overactivity pressure, bladder compliance, capacity, and volume at first detrusor overactivity. None of these parameters was associated with outcome.

Recently Morgan et al (2021) reviewed medical records of 198 women having SNS from 2007 to 2018 for OAB, with or without non-obstructive urinary retention (UR), and fecal incontinence

(FI) (358). At median follow-up of 4.4 years (range= 3.3-14.0 yrs) "success" was entirely subjective. They found that age > 65 years (OR=0.2, 95% CI=0.06-0.8) and prior onaBoNT-A (OR=0.2, 95% CI=0.06-0.9) were negative predictors for completion of stage II implant. Also, prior pelvic floor physical therapy was a significant negative predictor of post-operative success (OR=0.25 95% CI=0.1-0.6) the rationale for this was not explained. There was no correlation between intra-operative motor responses (with either all 4 or <4 electrodes) and device success (358).

High et al (2021) conducted the largest multicentre retrospective study of women with OAB, to evaluate if age and comorbidities were associated with implantation of a SNS device and with long-term therapy outcomes (359). Of 864 patients, 785 (91%) had implantation, which was more likely in younger (62 yrs) than older (67 years) women [OR 0.73]. At a median of 2 yrs (range 0.3 to 15 yrs), success (eg no need for additional therapies) was achieved by 69%. Multiple comorbidities such as cardiovascular disease, chronic pain (narcotics use), diabetes and neurological disorders did not correlate with implantation rates or success. Having past vertebral or disc surgeries or cognitive impairment also did not affect success, but sample sizes were low for this analysis. After SNS, 31% of women had additional therapy, more common in older women. Of the 142 women followed for 5 years, 25% had explantation.

Pizarro-Berdichevsky et al (2018) investigated whether motor responses during intraoperative electrode testing were associated with durability of SNS therapy (360). They retrospectively reviewed 176 lead placements at a single centre, and quantified motor responses into separate subscores, including bellows and toe response subscores (each range 0 to 4), possible maximum score of 8. Primary outcome was the need for revision surgery. Median follow-up was 10.5 months (range 2 - 36 m). Lead revision was performed in 34 (19%) patients. Revision was negatively associated with the total electrode response score (p = 0.027) and the toe subscore (p = 0.033) but not with the bellows subscore (p = 0.183). On logistic regression, patients younger than 59 years and those with a total electrode response score less than 4 were more likely to undergo revision (OR 5.5, 95% CI 2-14 and 4.2, 95% CI 1.4-12.8, respectively).

A systematic review of 78 studies, Jairam et al (2021), investigated factors that could predict the outcomes of SNS (361). In four out of 10 studies, women had a higher chance of success, but in 5 studies, gender was not predictive. Several studies reported younger age as a predictive factor of SNS success. Many factors did not influence SNS outcomes: history of prior back surgery, surgery for stress incontinence, presence of affective symptoms and duration of complaints. However, the majority of the studies had a low level of evidence (3b).

At the International Consultation on Incontinence-Research Society (ICI-RS) meeting in 2019, a Think Tank was convened to discuss how advances in the basic science study of SNS may be translatable into clinical practice to phenotype patients and improve patient selection (Malde et al,2020) (362). The presence of urodynamic DO has not been shown to be related to SNS success. The role of factors such as obesity, comorbidities and medications have not been well studied. The role of psychological comorbidities has yielded conflicting results. The authors concluded that, based on current evidence, the presence of psychological/psychiatric conditions does not seem to be a prognostic factor.

1.9. Effect of SNS on Sexual Function

The effect of SNS on female sexual function has been investigated in mostly retrospective studies. Lombardi et al reviewed nine studies that examined impact on sexual response in OAB (363). Most women were menopausal age, three studies included sexually inactive women. The Female Sexual Function Index (FSFI) was used in six studies, with significant improvement in at least one FSFI domain. In the InSite study, sexual function was a secondary outcome. Women who had SNS noted greater improvement in sexual function based on Female LUTS-sex Q than those having anti-cholinergics after 6 months (311), which was maintained at the 12, 36 months and 5-year evaluations (322-324).

In the Rosetta RCT, onabotulinumtoxinA (n = 190) or SNS (n = 174) a planned sub-analysis focused on sexual function (364). Outcomes were the (PISQ-12) and the IUGA-Revised (PISQ-IR). There was a significant improvement in PISQ-12 score in both the BTX and SNM groups; no difference between groups (p=0.99). (Level of evidence 1-2)

1.10. Magnetic Resonance Imaging (MRI) Recommendations

MRI has been a relative contraindication for patients who have an implanted SNS. Magnetic fields produce currents in electrodes, and heating of the leads has been demonstrated in vivo and in vitro (365-367). Whereas the clinical significance of the small temperature change observed in the leads is questionable, the potential exists to produce nerve damage, and the magnetic field may change the generator itself (368). Until recently, the manufacturer advocated removal of the device before elective MRI (369). The recent introduction of MRI compatible technologies should change the situation. The Axonics r-SNM System is conditional magnetic resonance imaging (MRI)-safe. Also, the InterStim SureScan MRI leads allow full-body 1.5 and 3 Tesla MRI-conditional scans.

However, there is a paucity of real-world data. In a prospective study of Axonics r-SNM SystemTM with 129 participants, at 24 months, a total of 13 MRIs were performed in 12 patients (9%). Eight MRIs were performed on the body/spine/torso, the remaining five MRIs on the head/neck (368). No adverse events or lead migrations were reported after any of the MRIs. The authors did not mention which MRI technology was used in these patients (1.5 vs 3 Tesla).

Patients who received the new models of Interstim II, but not the InterStim SureScan MRI leads, may be eligible to have MRI of the head only. However, the manufacturer indicates that MRI must be performed after certifying eligibility with the manufacturer support team or review the MRI Guideline for the Interstim Neuromodulation Systems. Limited evidence based on small case series indicate that full body MRI may be performed with no harm (370, 371), but is not recommended by the manufacturer.

The safety of nonhead MRI in patients with an implanted SNS system (InterStim II) and its effectiveness one month after the exam was prospectively studied by Guzman-Negron et al (372). Eleven patients had lumbosacral 1.5 Tesla MRI (55% for lower back pain). All SNS devices were turned off before patients entered the MRI scanner. Patients completed validated symptom questionnaires before and after MRI. During the imaging, one patient reported mild discomfort at the site of the implantable pulse generator and two patients reported warmth at the same area. There were no other adverse events and no significant changes in sensory thresholds, stimulation localisation, impedance and battery life.

In a recent study, Karrer-Warzinek et al assessed data from 55 patients with a SNS system (InterStim II) who underwent at least one MRI subsequently (373). A total of 191 MRIs were included in the study, median of 3 scans per patient. The scans were performed with 1.5 Tesla (92%, 176) or 3 Tesla. The majority of 1.5 Tesla (58%) and 3 Tesla (56%) assessed body regions other than the head, including the lumbosacral region, the trunk/ pelvis and the lower extremity. Complications related to the MRI occurred in 2 (1%) scans and consisted of transient electrifying pain and heat sensation during MRI (implantation site of the neuromodulator). The authors concluded that MRI involving body regions other than the head with 1.5 Tesla is safe in patients with SNM (InterStim II) with the device turned off.

1.11. Pregnancy

Electrical stimulation has the potential to induce teratogenicity or abortion and SNS has been considered contraindicated in pregnant women. However, whether it can cause abortion or malformation is not known. Wang (374) reported no adverse effects of electrical stimulation on pregnant rats.

Roulette et al (375) evaluated the outcomes of pregnancy and the results of SNS in women who became pregnant while having SNS. They mailed an online questionnaire to physicians listed in the InterStim enCaptureTM National French Registry. Questions were related to pre-pregnancy health and SNM efficacy, deactivation of the device, its impact on LUTS, childbirth, the infant, its reactivation and postpartum effectiveness. Twenty-seven pregnancies were recorded among twenty-one women. Five (18.5%) women had the device disabled prior to conception. The others had their device disabled during the first trimester and did not reactivate it before delivery. Complications were reported in 25.9% of pregnancies: six women had urinary infections, including three of the four treated for chronic retention of urine (CRU), and 1 woman had pain at the stimulation site. There were 24 live births (including one premature birth and four Caesarians), one spontaneous miscarriage and two voluntary terminations of pregnancy. No neonatal disorders were reported. Effectiveness of sacral neuromodulation decreased in 20% postpartum, regardless of mode of delivery.

Recently, Agnello et al (376) evaluated patients who had SNM devices and became pregnant (14 pregnancies in 11 women). Indications for SNM were urinary retention (7) and dysfunctional voiding (4). Two patients continued two and three pregnancies, respectively, with the device turned off since first trimester. They both had to return to self-catheterization and developed recurring UTI. No major urological complications were recorded in the remaining nine women who kept the device on during pregnancy. A cesarean section was performed in four cases for obstetric reasons; in seven cases it was planned by the urologist/ gynecologist to avoid lead damage/ displacement. Three pregnancies resulted in a vaginal delivery, and no association with term of delivery or duration of labor was observed. No congenital abnormalities related to SNM were reported, and only one patient required device removal because of significant loss of efficacy after childbirth. The authors concluded that SNM during pregnancy appears to be safe, without morbidity for the fetus. (Level of evidence 4)

1.12. Use of Computed Tomography (CT) for Lead Placement

In an attempt to improve the efficacy and accuracy of neuromodulator lead placement into the S3 foramen, investigators have evaluated alternative imaging techniques as compared to fluoroscopic guidance. Amoroso et al used CT with 30 patients in the prone position to identify the location of S3 foramina and guide PNE placement (377). Electrode placement was successful at the first attempt in 36/38 attempts (8 patients had bilateral PNE test). Two cases required several attempts. In one patient who had a nonconsolidated sacral fracture, CT guidance enabled insertion of the electrode inside the only practicable foramen, which would probably not have been possible under fluoroscopic guidance. A positive response to the PNE was obtained in 18/30 patients (60%). The procedure lasted about 45 minutes. Other authors successfully used CT guidance for lead placement in small case series and recommend that it should be considered especially in patients with an altered anatomy in the sacral region (378, 379). (Level of evidence 4)

1.13. Neurostimulation with Pudendal Nerve Stimulation

Pudendal nerve efferent activation directed toward the urethral sphincter is an important mechanism for the control of bladder contractions. In addition, many of the sensory afferent nerve fibers contained in the sacral spinal nerves originate in the pudendal nerve. Thus, the pudendal nerve fibers are important targets for neuromodulating the inhibitory reflex on the micturition reflex (380). Pudendal nerve stimulation has been used with different techniques to treat numerous pelvic floor dysfunctions such as urinary and/or fecal incontinence, urinary retention and constipation. There have been no new reports of this technique since ICI-6.

Summary

There is evidence for long term efficacy for SNS up to five years. (LE = 2). Maintenance of therapeutic effect requires reprogramming and surgical revision rate in a substantial number of patients. (LE= 1)

Preoperative predictors of optimal patient response to this invasive therapy remain unclear except for a positive response to PNE or staged implant (LE=2)

Recommendations

SNS is an effective therapy for selected individuals with urgency/frequency and UUI refractory to behavioural therapy and oral medications (Grade A).

Patients should be counseled regarding the potential for AEs, need for long term monitoring and intervention/adjustment of the implant, and additional surgeries to maintain therapeutic effect. (Grade A)

Research: Longer term data regarding efficacy and the risk of explantation for SNS is needed.

2. IMPLANTABLE POSTERIOR TIBIAL NERVE STIMULATION (PTNS)

In ICI-6, extensive discussion of the mechanism of action of PTNS, and clinical data regarding non-implantable PTNS treatment has been given. In ICI-7, current update for non-implantable devices is given in Chapter 8 (Adult Conservative Management). Recently, two types of surgically implantable posterior tibial devices have

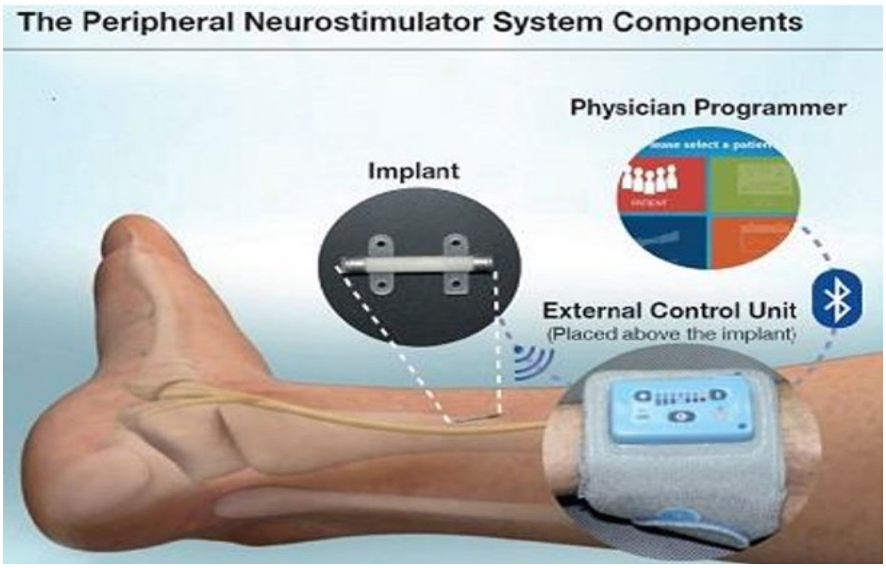

Figure 15: Bluewind Renova Device Reprinted with permission van Breeda et al, 2017 (381)

been employed, which are summarised here. Because PTNS requires 30 minutes of treatment in the office, weekly for 12 weeks, then ongoing treatment at least once per month, the notion of an implantable device that no longer required office visits was appealing. In 2017, van Breeda et al from Nijmegen published the first 3 months follow up of 15 patients, who had the BlueWind Renova device implanted (381). As shown in **Figure 15** , the device consists of a 3.4 mm diameter cylinder with 4 small fixating wings – the cylinder contains an electrical power receiver and 2 bipolar electrodes. Frequency can range from 5 to 40 Hz, pulse width is between 50 – 800 microseconds, amplitude ranges from 0-9 mA. The implantation requires a 5 cm skin incision above and behind the medial malleolus (with preoperative antiobiotics). Test stimulation of the device to ensure a motor response to stimulation was done before fixing the device with non-absorbable sutures. After 4 weeks postoperative wound healing, the External Control Unit (Figure 15) is applied for 30 minutes six times per week. Outcomes were bladder diary with a score for urgency and a score for leakage severity, ICIQ-FLUTS, and UDI. As shown in Table 7a, voids per day, urge episodes, severe urge leaks and pad test loss were all significantly reduced, as were results for the QoL tests.

The same group (Heesakkers et al, 2017) then implanted the same device in 36 patients but after stimulation 6 times per week for 3 months, patients then used the stimulator 3 times per week for 6 months (with the same parameters). Outcomes were 3day bladder diary, OABQ, and the number of pads per day. Success was defined as $\geq$ 50% reduction in reduction in number of leaks/day OR number of voids/day, OR episodes with degree of urgency>2. Two patients were not treated, one withdrew from the study, and one had device explanted due to pain and swelling with suspected infection but negative cultures. As per Table 7A, clinical response occurred in 71%, with significant benefit in voids/ day, leaks/ day and pads/ day ($p < 0.05$). However, implant site pain and suspected infection and wound complications occurred in 47%, which the authors pointed out is lower than the adverse event rate for sacral neuromodulation implants. Most recently, Dorsthorst et al. (2020) continued to follow these subjects: all 34 participants in the above study were invited to rejoin for a 3year continuation study, of whom 20 agreed, reason not given for the other patients declining. The baseline demographics/ OAB features of those who continued and those who declined were very similar. Outcomes remained 3day

Table 7A: Outcomes for Bluewind Device

Study	Design	N value	Results	Comments
Van Breeda et al. (2017) (381)	3-month prospective study	Bluewind (n=15)	Decrease in 24-hr frequency (11.8 to ->8.1, p = 0.002), urge episodes (6.5->2.0), severe UUI leaks (2.8->0.3), pad test (243->55gm) p = 0.038	AE: prolonged antibiotic treatment (20%), pain (20%). Removal of implant in 1 patient (7%)
Heesakkers et al. (2018) (382)	6-month multicentre prospective study	BlueWind (n=34)	71% of participants had >50% response Voids/ day 12 >9.4 Leaks/ day 6.6 > 3.9 Pads/ day 3.1 > 2.2	AE: Implant site pain (13.9%), suspected infection (22.2%), wound complications (8.3%)
Dorsthorst et al. (2020) (383)	3-year prospective study	BlueWind (n=20)	75% overall success rate. 73% improvement in QoL scores	Removal of 1 implant No reports of implant migration. Treatment frequency varied from once every 4-6 wks to 1-2 per day.

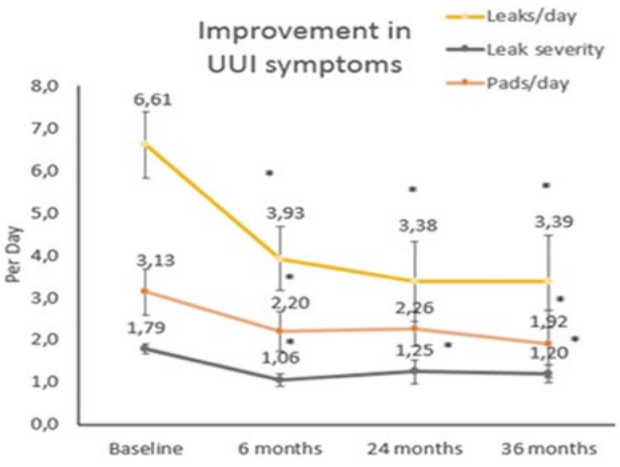

Figure 16: Improvement in the wet OAB symptoms during BlueWind continuation study period in the PP analysis. * indicates p < 0.05 Reprinted with permission from Dorsthorst 2020 (383)

bladder diary and OABQ with same definition of treatment success, which occurred in 75% (Table 7a).

The response seen for leaks per day, and pads per day, as shown in Figure 16 above, were obviously significant. Continued benefit on OABQ was shown in 75% of patients in the extension study, and there were no additional explantations, no serious adverse effects, and no new surgical interventions.

The E-coin device is smaller than the BlueWind device, being the size of a US quarter (25c) coin. The cathode is located at the centre of the device, with circumferential anodic ring, thus creating a wide electrical field. It is implanted under local anaesthetic (using a pre-designed template shown in Gilling et al, 2021 (384)). Once activated after 4 weeks of wound healing, there is no externally applied stimulator needed (unlike the BlueWind device). A trained field clinical engineer programs the device, with pulse amplitude of 0.5 – 15 mA, pulse width 0.2 ms. Therapy was delivered for 30 minutes every 2 days for 12 weeks then every 15 days thereafter.

Preliminary 3 month data were reported by MacDiarmid et al (384), 20% of subjects were continent (Table 7B). The same 46 participants from the USA and New Zealand were followed for 12 months. All had at least one episode of urge incontinence per day. Outcomes were 3day bladder diary, I-QOL and PGII. 26% of patients were continent (Table 7B) with significant reduction in urge leaks. There were 8 cases possible infection / pain that responded to treatment.

Figure 17: eCoin Device

A similar small device prototype was originally published in 2013, and 7 patients were followed up for 9 years clinically and on x-ray of the lower limb. Safety was remarkably adequate with only 2 minor adverse events (tenderness at the implantation site, and sporadic sensory impulses), but this device discontinued manufacturing for technical reasons (386).

Summary

Implantable PTNS devices appear to yield quite significant reduction in urge leakage with improved QoL and overall, about 70% clinical response, with one follow up study at 3 years. The rate of adverse events differs considerably between devices. With the recent advent of Trans Cutaneous PTNS, which patients can also use at home after initial instructions, the chief benefit of these implantable devices (no requirement for office visits) will require further comparative analysis.

Table 7B: Outcomes for e-coin devices

Study	Design	Intervention	Results	Comments
MacDiarmid et al. (2019) (385)	6-month multicentre prospective study	eCoin (n=46)	70% of participants had >50% decrease in episodes of UUI. 20% were continent. I-QOL scores improved by mean of 48%.	1 participant developed wound cellulitis treated with antibiotics.
Gilling et al. (2021) (384)	12-month follow-up prospective study	eCoin implantable device (n=46)	65% of participants had >50% decrease in episodes of UUI. UUI 4.2 reduced to 1.7 p< 0.001 **26% were continent.** I-QOL scores improved by mean of 86%. 70% better on PGII	1 participant experienced 1cm posterior migration of implant, 8 cases of possible infection which responded to treatment
Janssen et al. (2013) (386)	9-year follow-up study	Urgent-SQ implant (n=8)	7 patients still had implant. 6 out of 7 patients had response on stimulation.	Implants were intact with no migration and/or displacement. 1 report of localised ankle discomfort.

Recommendations/ Research

Implantable PTNS devices appear to show promise but require longer term objective evaluation in studies involving larger numbers of patients. Grade C

3. AUGMENTATION (ENLARGEMENT) CYSTOPLASTY (AC)

3.1. Enterocystoplasty

Enterocystoplasty is the main form of AC and involves a segment of the bowel that is removed from continuity with the fecal stream, detubularised, and patched into the bisected bladder. This method increases bladder capacity and decreases bladder pressure caused by uninhibited detrusor contractions. Virtually any portion of the GI tract can be utilised for entero-cystoplasty, and each segment has its own unique favourable properties as well as inherent complications (387, 388).

Other than idiopathic OAB, indications for enterocystoplasty include mainly small capacity bladders due to fibrosis, tuberculosis, radiation, chronic infection or neurogenic DO (NDO) (389) and as a last resort in refractory OAB. With the introduction of therapies such as SNS and BTX-A, there has been a dramatic decline in the use of AC, with only one additional publication since the 5th ICI.

3.1.1. Efficacy and safety

There is no RCT published to compare the efficacy/ safety of AC with other methods. The 2015 AUA/SUFU Guideline Amendment for Diagnosis and Treatment of OAB (Non-Neurogenic) in Adults recommend that AC should only be considered in extremely rare cases (390).

In 2013, El-Azab et al (391) compared UDI-6, IIQ-7 and OAB-Sat questionnaires after AC versus injection of BTX. Patients chose their treatment on personal preference (N= 31 including 16 for BTX and 15 for AC). At six months, significant benefits in LUTS and QoL occurred after both treatments but were greater in patients who underwent AC. The AC group had worse scores on the UDI-6 voiding difficulty question (1.7 vs 0.81 for the BTX group; p= 0.004). Four (26.7%) patients required CISC after AC and two in the BTX group. The need for repeat treatments was the primary reason for dissatisfaction in those who received BTX. (LE= 4)

Apart from the inherent risks of open, laparoscopic or robotic abdominal surgery, associated with bowel and bladder anastomoses, AC carries several distinct long-term risks. These include kidney or bladder infections, new-onset recurrent UTIs, metabolic derangements, mucus production, and, in rare cases, bladder tumours (392). As a segment of bowel is used for AC, the available absorptive surface area of the bowel is reduced, and the incorporation of bowel segments into the urinary tract may have metabolic consequences (393). Hyperchloraemic metabolic acidosis can occur if ileal and/or colon segments are used, as well as malabsorption of vitamin B12 and bile acid after the use of ileal segments. Blackburn et al demonstrated a reduction in serum B12 level with time following ileocystoplasty in 44% of their patients at 7-year follow-up (394).

The incidence of secondary malignancies that may develop as a long-term consequence of bladder augmentation remains a concern. The carcinogenesis pathway is still not clearly understood. In 2016, Biardeau et al (392) systematically reviewed the risk of malignancy after AC. The probability to develop a malignant tumour ranged from 0 to 5.5%, the estimated incidence ranged from 0 to 272.3 per 100,000 patients/year. Adenocarcinoma was the commonest (51.6%) type. Malignant lesions predominantly occurred at the entero-urinary anastomosis (50%). Mean latency period was 19 years and most tumours were diagnosed more than 10 years after AC (90%). Long-term surveillance by cystoscopy is still controversial because of its lack of efficiency. Tumours were often diagnosed at an advanced stage within surveillance protocols, because of other LUTS symptoms (64.1%). The authors recommended that studies regarding carcinogenesis and surveillance strategies should be performed to develop a more efficient follow-up protocol and allow early diagnosis. The authors cautioned that the level of evidence of the studies was usually poor and results should be interpreted with caution. (LE=4)

3.1.2. Other Evidence

Most reviews on AC feature patients with a neurogenic bladder (388, 395). The few reports that have examined the results of AC in adults with idiopathic OAB are case series (LOE=4).

Several variations on the standard AC have been described, most of which were applied to children or adult patients with neurogenic DO or contracted bladders, and are reviewed in the last chapter ICI-6. Overall, due to its invasive nature and potential for long-term adverse effects, AC is considered to be one of the last choices of treatment in refractory IDO cases (390).

Summary

There have been no randomised controlled trials, double blind or sham-controlled trials or long-term cohort studies which have examined the effects of enterocystoplasty for the treatment of idiopathic OAB. (LE=4)

Recommendations

Enterocystoplasty for idiopathic OAB should only be considered in rare cases where other therapies have been deemed unsuccessful or are not suitable. (GRADE D)

Patients undergoing enterocystoplasty should be counselled regarding the potential life altering changes postoperatively (e.g. need for self catheterisation, etc.) and the need for long term follow-up (GRADE D). See previous ICI Chapter for details.

3.2. Autoaugmentation

Initially described by Cartwright and Snow in 1989, auto augmentation of the bladder was developed as an alternative option to AC, especially in children with neurogenic DO. The procedure is discussed in ICI-6, with no new reports published.

Summary

There have been no randomised controlled trials, double blind or sham-controlled trials or long-term cohort studies which have

examined the efficacy and safety of autoaugmentation for the treatment of adult idiopathic OAB. (LE=4)

Recommendation

Autoaugmentation is not recommended as a therapy for adult idiopathic OAB. (GRADE D)

III. URETHRAL DIVERTICULA

Urethral diverticulum (UD) is an outpouching of the urethral lumen into the surrounding periurethral connective tissue. This is a relatively rare condition with an estimated annual incidence of 17.9/1,000,000 (396). UD are thought to arise from repeated obstruction, infection and subsequent rupture of periurethral glands into the urethral lumen, resulting in an epithelialised cavity that communicates with the urethra (397). Iatrogenic damage to the urethra may also play a role, as up to 20% of women with urethral diverticula are noted to have a history of prior urethral surgery, dilation, or traumatic delivery (398). Iatrogenic UD formation associated with MUSs has also been reported (399, 400). The clinical manifestations of UD are often vague and variable resulting in a prolonged time to definitive diagnosis (401).

Urinary incontinence occurs in between 20 and 60% of patients with UD at presentation (402, 403) and which may be mixed, stress, urgency or paradoxical (insensate) incontinence. It may also present with a vaginal mass, irritative LUTS, dyspareunia, pain, dysuria, recurrent urinary tract infections, watery vaginal discharge and post-micturition dribble (402, 404, 405). About 20% of patients are asymptomatic (403).

At presentation, SUI is more commonly associated with UD than urge leak. Those with post-micturition dribble may have insensate incontinence due to urine accumulation in the pouch during normal voiding, with subsequent discharge of the accumulated urine out through the urethra upon movement (406). Finally, persistent or de novo incontinence may occur after surgical repair. Patients having autologous sling concomitantly with UD repair have a lower risk of needing subsequent continence surgery, compared to those undergoing UD repair alone (407).

1. PREOPERATIVE ASSESSMENT INCLUDING URODYNAMICS

Careful history, physical examination, and appropriate tests are needed to evaluate suspected UD. Imaging modalities including ultrasound **(see Figure 18**) (408, 409), voiding cystourethrography (410), and MRI (411, 412) help to define the UD anatomy and to plan surgical intervention. Cystourethroscopy will most commonly reveal the ostia of the UD in the dorsolateral midurethral segment.

Urethral pressure profilometry has also been utilised by some authors in the assessment or diagnosis of UD noting a biphasic pattern, or pressure drop at the level of the lesion during the study (413, 414).

Video- urodynamics are often used to assess patients with UD and LUTS (413-415). Approximately 50% of women with UD will have

Figure 18: Ultrasound of Urethral Diverticulum where arrow is pointing to U = Urethra, S = symphysis pubis, B = bladder. Figure courtesy of HP Deitz

Urodynamic Stress Incontinence (USI) (416). Fluid accumulation in the UD may be seen on fluoroscopy and will help to delineate the size and location of the diverticulum (e.g. whether it is circumferential or just a simple pouch). Resting and straining images on fluoroscopy may show an open BN at rest, suggesting a compromised proximal sphincter mechanism that may further support the need for continence surgery.

2. UD AND STRESS INCONTINENCE

UD are most often located at the level of the midurethra thus co-existent incontinence is usually USI. The midurethral location of UD often overlaps with the external sphincter but UD may also extend proximally toward the BN at the proximal sphincter mechanism, or completely around the urethra (417). The more proximal, larger, complex lesions are at greater risk for postoperative SUI (412, 418, 419).

Patients with symptomatic USI are generally offered simultaneous continence surgery, after discussion. One series showed good results with BN suspension (416), but more recent series use autologous pubovaginal slings in such patients (401, 407, 420, 421) with success in >90% of cases in some series (420, 421). The high likelihood of curing the USI must be balanced against the longer operative time, convalescence, and risks of needing CISC or aquiring de novo DO. Note that resolution of USI may occur in about 50% of cases after surgical excision UD alone (407, 422). The mechanism underlying this is not clear but may result from elimination of post-void dribbling, or due to reconstruction and bolstering of a damaged sphincter mechanism during UD repair (422).

Midurethral synthetic slings are not recommended as a continence procedure at the time of urethral diverticulectomy (423). Synthetic material adjacent to a fresh suture line in the setting of potentially infected urine may increase the risk of urethral erosion and vaginal extrusion of the sling material, as well as urethrovaginal fistula and foreign body granuloma (EL=4).

Urethral diverticulectomy alone may be associated with de novo incontinence in 7-16% of cases. Risk factors for de novo SUI may include the size of the diverticulum (>30 mm), more proximal location (418, 419), and wide excision (419). Another important cause

is iatrogenic urethrovaginal fistula, occurring in up to 6% of cases (398, 404, 418, 419, 424).

Significant postoperative de novo SUI may occur in 7-16% of those undergoing urethral diverticulectomy without a concomitant continence procedure (418, 419). Risk factors for de novo SUI may include the size of the diverticulum (>30 mm), more proximal location (418, 419), and wide excision (419). Another important cause is iatrogenic urethrovaginal fistula, occurring in up to 6% of cases The pathophysiology of this is not well understood. It may be due to surgical trauma to the sphincteric mechanism during UD excision/repair or unmasking of "occult" SUI in the setting of partial obstruction from the UD (425), especially when the UD is proximal and greater than 3cm in size (426). UD repair may be bolstered by placement of a Martius flap (427) which may reduce the chance of de novo SUI (422).

3. UD AND URGE INCONTINENCE

UD may also be associated with storage symptoms and urge incontinence. Bladder outlet obstruction due to the mass effect of the UD, urinary retention, or irritative LUTS e.g. urgency and urge incontinence may present secondary to UD (425). Pain and dysuria associated with UD may also result in acquired voiding dysfunction.

Stav et al (2008) reported that storage symptoms decreased significantly from 60% to 16% after diverticulectomy (418) but at least one small series reported no improvement in urgency and UUI (410). Other long term studies have shown rates of postoperative urgency of 54% (424), and de novo urge incontinence in 36% (419). Such symptoms may herald UD persistence, UD recurrence, de novo urethral obstruction or may simply reflect persistent preoperative symptoms unrelated to surgery.

Summary

The evidence pertaining to UD and urinary incontinence consists of retrospective, poor quality small- to medium-size case series with limited follow-up (428) demonstrating that urinary incontinence and other voiding dysfunctions are significantly associated with this condition (EL=3). Surgical repair of UD will often improve associated urinary incontinence and other lower urinary tract symptoms, but de novo or persistent lower urinary tract symptoms are possible.

Recommendations

Patients with UD should be carefully questioned and investigated for co-existing voiding dysfunction and urinary incontinence. (Grade C)

Patients with UD without SUI should not be offered concomitant prophylactic SUI surgery at the time of urethral diverticulectomy. (Grade C)

Following appropriate counselling, bothersome SUI can be addressed at the time of urethral diverticulectomy with concomitant non-synthetic sling (Grade C)

Patients should be counselled regarding the possibility of de novo or persistent lower urinary tract symptoms including urinary incontinence despite technically successful urethral diverticulectomy. (Grade C)

IV. CONFOUNDING VARIABLES

Confounding variables were discussed as a separate issue in the last ICI-6 chapter. However, as per the Introduction to this chapter, we have systematically included such variables (age, obesity, previous continence or spinal cord surgery, co-existence of detrusor overactivity preoperatively, and Intrinsic Sphincteric Deficiency under the discussion for each procedure, wherever they appear in the literature.

V. CLINICAL TRIAL OUTCOMES USED IN UI RESEARCH

The reported outcomes from surgery for urinary incontinence have recently been scrutinised, following concerns raised regarding the failure to capture important long-term results. A 2017 Cochrane review examining outcomes from mid-urethral sling surgery, perhaps the most commonly performed continence surgery, described the quality of published evidence as "moderate at best" (103). In 2020, a UK parliamentary review looking at mesh inserted for SUI (and pelvic organ prolapse) criticised the quality of evidence in this area and commented that "There is no reliable information on the true number of women who have suffered complications" (429). In 2019, Doumouchtsis et al further underlined this in a study which examined outcomes from 108 RCTs about treatment of stress incontinence, finding that several important outcomes were under-reported (430). These included pain, sexual dysfunction, dyspareunia and surgical site infection. Despite the widespread reporting of outcomes relating to cure or improvement, the authors noted significant heterogeneity in the outcome measures used. In another study of outcomes reported from 66 stress incontinence surgical trials, similar findings were noted (431): for both "subjective cure" and "quality-of-life" more than 20 separate terms were used. Both of these studies called for the development of a core outcome set which could be used by researchers to facilitate both comparison of different treatments and meta-analyses of clinical trials.

Currently, outcome measures for SUI surgery remain non-standardised in clinical trials. Unlike cancer treatments with a readily defined outcome, or even prolapse surgery where an anatomic outcome can be objectively assessed, SUI is a quality-of-life condition which can be difficult to measure. However, objective quantitation of the severity of urine loss on pad testing remains useful, and essential for research studies. Because surgery for SUI can improve or worsen other LUTS such as detrusor overactivity or incomplete emptying, the most meaningful evaluation we can make often comes from randomised trials where the same outcomes for different treatments and complications rates are applied.

It would appear that the same degree of heterogeneity is found when the health- economic analyses of surgical trials for incontinence are examined. In a systematic review of economic evidence which looked at 26 economic evaluations the authors concluded that "methods used for the economic evaluation of surgical treatments for SUI vary widely in terms of study design, analysis type, compared alternatives, time horizon, costing methodologies and

effect outcomes" and called for consensus in order to improve economic evaluation (432).

1. HISTORY OF SUI MEASURES

Surgical outcomes are broken down into subjective and objective measures. Early reports of outcomes for SUI surgery were largely subjective. Often, they were nothing more than surgeons asking the patient at the post-operative appointment if they were "better". Of course, both the patient who decided to have the surgery, and the surgeon who did the surgery, were invested in the outcome: hence success rates greater than 95% were not uncommon. This physician-reported subjective outcome has been severely criticised. In a very early systematic review of SUI surgery, Jarvis (1994) commented that such subjective assessments of cure are clearly unsatisfactory for robust scientific assessment (433). The AUA SUI Guidelines Panel report (1997) noted the paucity of clinical studies that met minimal criteria for good science in the conduct of clinical studies (9). The panel **recommended 5 year outcomes** with specific measures including history/questionnaire, physical exam, diary, pad test, post void residual urine volumes, and assessment of complications/morbidity, including urinary retention, and de novo urgency (9). Ten years later when Rovner et al reviewed the literature no articles met all criteria, but most complied with at least half of the recommendations (434).

Most SUI studies now report both subjective and objective measures and most of the Cochrane reviews of SUI surgery compare subjective and objective outcomes. The Standardization Committee of the International Continence Society (ICS) is the main body that has governed terminology and outcome measures in the field of urinary incontinence since 1978. Objective parameters typically include stress tests, pad tests, voiding diaries, urodynamic studies and the advantages and disadvantages of these measures are included in Table 12. Over time urodynamic studies have been used less commonly as an SUI surgical outcome, because objective measurement of degree of leakage is accurately determined by the less-invasive pad test.

The voiding diary was often used in the past, but only measures output. The Bladder Diary is a more useful outcome measure because it indicates:

- The number of leaks per 24hr (or convert to leaks per week by averaging)
- The number of voids per day ("frequency")
- The episodes of nocturia (after patient goes to bed, must be indicated)
- Whether patients fluid restrict (often for fear of urge leak)
- Whether patients are drinking more than 2 litres/day ("over-drinking")
- Factors that precipitate leak, such as cough/ sneeze/ lifting are written down

The 7-day diary is the most sensitive and accurate, but compliance is poor. As the first 3 days and the last 4 days of a 7-day test correlate well (r = 0.9), the 3-day Diary is the most common research tool.

The One-Hour Pad Test was introduced 1983 and recommended by the ICS in 1988. The patient is asked to attend with a comfortably full bladder (which they may be reluctant to do). They are given a pre-weighed continence pad, then given 500 ml water to drink over 15 min, then perform a standard series of activities to provoke leakage (which can be onerous). The wet pad is re-weighed.

Unfortunately, the 1-h pad test has poor sensitivity (up to 40 % false negative rate). It was, however, the first objective method that could be used to define mild (1–10 g leakage per 1 h), moderate (11–50 g/h), and severe (>50 g/h) incontinence; thus, it was used in many publications.

The 24-Hour Pad Test was designed because of the problems with the 1-h test. It is conducted at home, in "real-life" conditions. The patient is given a set of (usually 5) pre-weighed pads in sealed plastic bags (**See Figure 19**). The pads are worn at home for 24 h, whilst ordinary provocative activities are carried out, and the patient returns the pads, which are re-weighed (436). The amount of leakage does not evaporate in the sealed bag for up to 2 weeks, so they can be returned via post. The 24-h pad test is more sensitive than the 1-h test (10% false negative rate).

Normal ranges on the 24-h pad test are controversial. In small samples of women (n = 23–78), using simple kitchen scales, the normal values were 3–10 g. Later, the normal values were redefined (n = 120) using scales accurate to 0.1 g which revealed a median value of 0.3 g (95th centile 1.3 g) was obtained (436). The test correlates with the ICIQ (437).

The 24hour pad test can also be used to define mild (1.3 – 2.0 gm), moderate 21 – 74 gm), and severe leakage (>75gm). This helps to define women with "mild" leakage who are more likely to respond to conservative therapy, versus severe leakage that is more likely to require surgery (438). Even so, Richter et al (2011) showed that

Table 12: Female SUI Objective Outcome Measures

Measure	Advantages	Disadvantages
Cough Stress test	Noninvasive, Inexpensive Specific for stress incontinence A positive test is predictive for urodynamic stress incontinence (435)	Should be standardised (position of patient Volume to be 'comfortably full', at least 200ml, often done at 300+ ml
Pad test (1 hr or 24 hr)	Quantitative; raw data can be compared pre-op and post- op then compared via T-test etc.	Not SUI specific 1hour test requires nurse time 24hour test requires patient compliance
Bladder diary (3 day or 7 day)	Can differentiate stress from urgency events.	7day diary is burdensome but most sensitive
Urodynamics	Can detect urodynamic stress incontinence and DO	Invasive, uncomfortable, expensive

larger pad weights were predictive of greater risk of surgical failure (439).

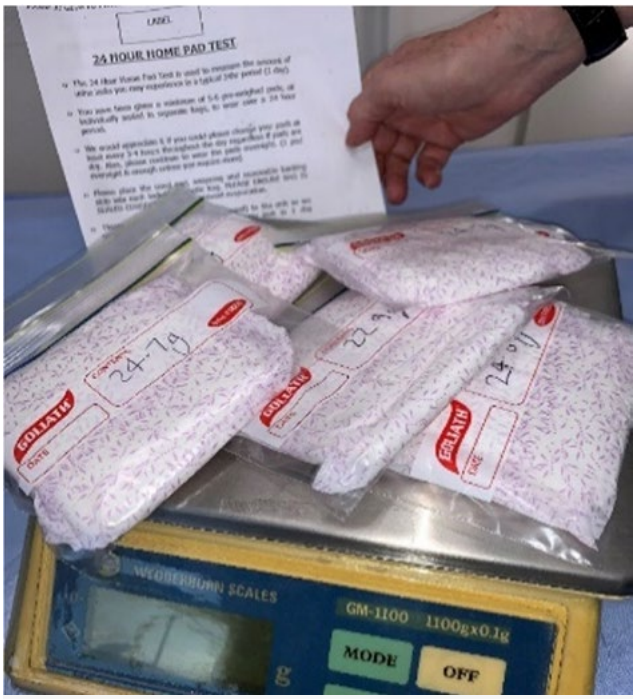

Figure 19: Five pre-weighed pads in sealed zip log plastic bags for 24hr Home Pad test.

2. PATIENT REPORTED OUTCOMES

While many of the subjective self-reported measures can be considered "patient reported", the concept of true Patient Reported Outcome Measures (PROMs) is more complex and encompasses a more global assessment. PROM's should measure patient impressions in a more global context by encompassing 4 domains: 1) Symptoms, 2) Functioning, 3) General Health Perception and 4) HRQOL. The NIH recently established the Patient Reported Outcomes Measurement Information System (PROMIS) for women with urinary incontinence (440). The International Consultation on Incontinence has adopted the use of PROM's and established the ICI Modular Questionnaire (ICIQ) Project that includes the assessment of a wide spectrum of urinary, bowel and vaginal symptoms along with their impact on HRQOL. **Table 13** demonstrates PROM's which have received an A grade from the ICI for female SUI outcomes from prior Consultations.

The *ICIQ-SF* was validated by the ICI many years ago. It records incontinence symptoms and severity, with a simple quality of life question. The final ICIQ comprises three scored items (maximum score 21) and a self-diagnostic item on the impact of the incontinence upon the patient's "bother". It is probably the most widely used outcome test for general urinary incontinence (www.iciq.net).

3. COMPOSITE MEASURES

There are deficiencies with any single subjective or objective SUI research outcome measure. Therefore, multiple measures are often included which are not used by any other others which makes definitive conclusions difficult. For this reason, especially with the advent of clinical trial networks, investigators have increasingly used composite outcomes **(Table 14**).

Table 13: Female SUI patient reported outcomes with ICI Grade A recommendations

Tool	Measures	Items
ICIQ FLUTS	QOL, Treatment outcome	34
ICIQ-UI SF	Symptoms and impact	4
IIQ (Incontinence Impact Questionnaire)	Impact of UI on HRQOL	30
IIQ-7	Short version of IIQ	7
I-QOL (Incontinence QOL)	Incontinence specific QOL	22
ISS (Incontinence Symptom Severity Index)	Severity of storage and voiding symptoms	8
KHQ (ICIQ-LUTSqol) King's Health Questionnaire	Symptom impact of LUTS	21
LIS (Leicester Impact scale)	LUTS QOL	21
UISS (Urinary Incontinence Severity Score)	Severity and impact of UI	10
LUSQ (Leicester Urinary Symptom Questionnaire	Presence and severity of storage abnormalities	10
PGI-I (Patient Global Impression of Improvement)	Symptom bother	1
PGI-S (Patient Global Impression of Severity)	Symptom bother	1
PPBC (Patient Perception of Bladder Condition)	Impression of bladder condition	1
UDI (Urogenital Distress Inventory)	Symptom bother related to UI	19
UDI-6	Symptom bother related to UI/LUTS	6

Table 14: Examples of composite primary outcomes used in RCT's of SUI surgery with more than 200 subjects.

1st Author, Year (ref)	Surgery	Composite Outcome
Ward, 2002 (90)	TVT vs. Burch	No USI and Negative pad test
Albo, 2007 (14)	Fascial sling vs Burch	Negative pad test and No UI on 3 day diary and Negative cough stress test and No self-reported SUI on MESA and No SUI retreatment
Barber, 2008 (130)	PVS vs. TO	Abnormal bladder function defined by presence of Incontinence symptoms of any type Positive cough stress test Retreatment of SUI Elevated PVR
Rinne, 2008 (126)	TVT vs TVT-O	Objective Negative stress test Negative pad test Subjective condition-specific quality of life Q and general EQ-5D Q.
Wang W, 2009 (136)	TVT vs TVT-O	Negative cough test Negative pad test Reduction by 50% of incontinence episodes
Richter, 2010 (121)	PVS vs TO	Objective Negative stress test Negative pad test No SUI retreatment Subjective No self- reported SUI symptoms No UI on 3day diary

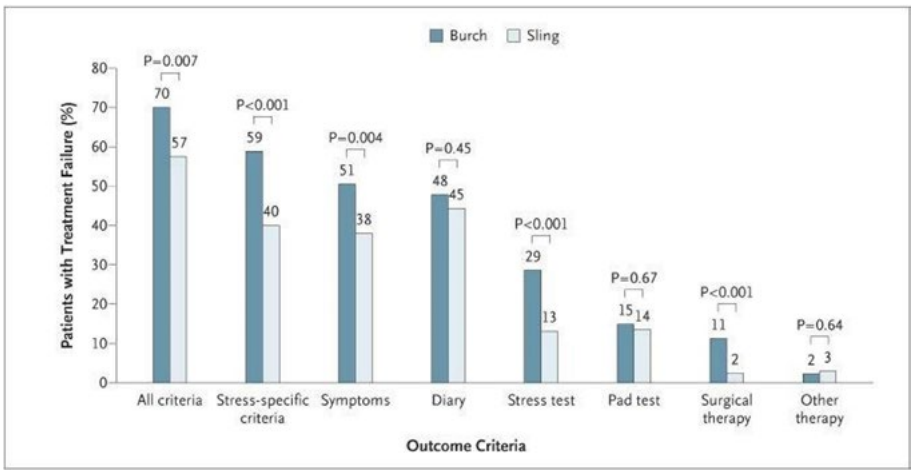

Figure 20: Proportion of subjects with treatment failure at 2years according to different criteria in the UITN randomized trial comparing Burch vs. Autologous sling (14)

While they do provide more comprehensive assessments, composite outcomes often create a stricter definition of success and thus lower success rates especially if all of the components of the composite must be satisfied. Investigators should also consider reporting the results of the individual components of the composite measure. An example of the reporting of individual composite components is shown in Figure 20.

4. SURVIVAL ANALYSIS REPORTING FOR SUI OUTCOMES

When assessing outcomes, it is important to determine if the study used a survival type analysis (typically reported on a Kaplan-Meier graph which follows patients over time) or just assessed the patient at one specific postoperative time point. In these survival analysis types of studies an assumption is made that once a patient reports

incontinence she will continue to have incontinence and she is considered a failure for the course of the study. This may not fit the natural history of SUI symptoms, which can change over time. Survival analysis reporting will lead to lower success rates than single time reporting and may not be consistent with the patient's reported outcome.

5. SUCCESS RATES ARE DEPENDENT ON THE RIGOR OF THE ASSESSMENT

Further complicating the issue of outcome assessment is that few of our SUI treatments make a woman completely dry and therefore success rates decline with the rigor of the assessment. An example of both a rigorous outcome measure and a survival analysis approach is found in the UITN's randomised trial of Burch vs PVS which was criticised for low overall success rates of less than 50% in both arms (14). In this study a composite measure was used which included administering a 3 day diary, a 24hour pad test and a 15-question incontinence survey (MESA) every 6 months for 2 years. Any positive response during any assessment resulted in a failure for the duration of the study. In this study with composite rigorous assessments and survival analysis methodology, the low overall success rates of less than 50% were however inconsistent with patient satisfaction rates of 78 and 86% in the 2 groups (14).

If the definition of SUI surgical success is too rigorous outcomes will not meet face validity. In 2001, the NIH defined cure of stress urinary incontinence as: 1) resolution of the stress incontinence symptoms; 2) resolution of the sign (negative full bladder cough stress test, performed under the same conditions as before treatment); and 3) no new symptoms or side effects which could include new urinary symptoms such as urinary urgency, frequency, urge incontinence, with or without urodynamic changes of DO (detrusor instability); change in sexual function; development or worsening of POP; adverse effect on bowel function; onset of urinary tract infections; surgical complications, etc. (441). As Hilton noted in an editorial, if this definition was applied to the United Kingdom TVT vs Colposuspension RCT, cure rates in the 2 arms would be 6 and 9% (442).

6. MIXED INCONTINENCE AS A CONFOUNDER

Many patients undergoing stress incontinence surgery also have urgency incontinence (mixed UI) and this urgency component may worsen, remain the same, or improve after SUI surgery. Hence continence surgery failures often result from worsening or de novo urgency incontinence. The true "pure" SUI patient is rare. In support of this, in the SISTeR trial where all women were reported to have pure or predominant SUI for study inclusion, the range of women with mixed incontinence ranged from 8.3% if mixed incontinence required DO on urodynamic studies to as high as 93.3% if they reported "yes" to any urgency incontinence question (443). The inclusion criteria for studies vary, the amount of mixed incontinence in the sample varies, thus comparison between studies can be inaccurate.

Any instrument that is stress incontinence-specific may give results about the surgery's effect on stress leakage but may not give an accurate assessment of what the surgery did for overall LUTS (urgency, frequency, urgency incontinence, or voiding difficulties). Therefore, an overall bladder assessment tool is recommended for measuring SUI surgical outcomes. Patient reported bladder outcomes with ICI Grade A recommendations are shown in Table 13 and include the: ICIQ-UISF, ISS, KHQ, UISS, PPBC, UDI, and UDI-6. However, several scores exist for urgency incontinence, chiefly the OABQ.

7. GLOBAL MEASURES

Another outcome that has recently gained popularity is the patient global impression of severity (PGIS) and the patient global impression of improvement (PGI-I). Use of such global assessment instruments provides a single response which is easy for the patient and clinician to understand (444). Furthermore, the measurement is all encompassing since the subject takes success and complications into account when responding. The PGI-I was part of the composite primary outcome in the UITN randomised trial evaluating preoperative urodynamics (435).

Summary

The last two decades has seen a massive expansion in the field of SUI research. While initially criticised for poor quality research, significant advances have been made especially in the development of clinical trial networks that have allowed large scale multisite surgical studies necessary for high quality studies. We have also seen a maturation of outcome tools including validated patient reported outcome instruments. The standard clinical trial for SUI now is a prospective randomised comparative efficacy trial using patient reported outcomes as a component of the primary outcome. However further standardisation is needed to allow for data-pooling and meta-analyses of different trials.

Recommendations

Patient reported outcomes using ICI Grade A bladder symptom and incontinence-specific quality of life instruments should be utilised in stress incontinence clinical trials (Grade D).

A cough stress test standardised to bladder volume and patient position provides an objective assessment of the presence of absence of stress continencee (Grade D). However a weighed 24 hour pad test pre operatively and post operatively provides quantitative continuous data which is more suitable for statistical analysis (Grade A)

Composite measures address inadequacies of any individual stress outcome measure, but rates using these composite measures are often lower than any individual measure, so the individual components must also be reported. (Grade D)

VI. RESEARCH RECOMMENDATIONS

As regards autologous pubovaginal sling, further long-term objective and subjective outcome data should be collected for the less invasive "Sling on a String" versus the traditional PVS, particularly in relation to the likelihood of voiding dysfunction/ CISC and de novo DO.

As regards the laparoscopic colposuspension, further objective and subjective data regarding success rates at 18 m – 5 years needs to be obtained.

As regards trans-obturator rmid urethral slings, further longer term data regarding risks of groin pain, need for groin dissection to entirely remove trans-obturator tapes, and risks of repeat continence surgery are needed.

As regards bulking agents, further data regarding subjective and objective success rates in those with normal urethral function, versus those with ISD, are needed**.**

As regards Laser Therapy, Studies that correct deficiencies regarding mechanism of action, long term cure rate, and adverse events are needed before Laser therapy can be recommended for use outside of Clinical Trials.

As regards Artificial Sphincter for urinary incontinence in women, longer term data regarding use of laparoscopic and robotic implantation techniques are needed, in relation to cure rates, complications, and explantation rate.

The use of stem cell technology for treatment of female SUI remains investigational. Such therapy should only be offered in the setting of clinical trials.

As regards Sacral Neuromodulation, longer term data regarding efficacy and the risk of explantation is needed. The safety of MRI investigation, and pregnancy, in patients having the more recently developed devices, needs to be continually monitored and reported.

As regards Implantable PTNS devices, longer term objective evaluation in studies involving larger numbers of patients is needed.

APPENDIX A: Validated SEAPI scoring system (Stothers, 2004 (32))

1. Stress related leakage	2. Emptying ability	3. Anatomy	4. Protection	5. Inhibition
0–no urine loss	0–no obstructive symptoms	0–no descent during strain	0–never used	0–no urge incontinence
1–loss with strenuous activity	1–minimal symptoms	1–descent, not to introitus	1–only used for certain occasions	1–rare urge incontinence
2–loss with moderate activity	2–significant symptoms	2–descent through introitus with strain	2–used daily for occasional accidents	2–urge incontinence at least once a week
3–loss with minimal activity or gravitational leakage	3–voiding only in dribbles, or urinary retention	3–through introitus without strain	3–used continually for frequent accidents or constant leakage	3–urge incontinence at least once a day

WHERE: 1, 2 AND 5 ARE DETERMINED BY PATIENT HISTORY, 3 BY PHYSICAL EXAMINATION OF BLADDER NECK DURING COUGH AND VALSALVA MANEUVER, AND 4 RELIES ON PATIENT REPORTED USE OF PADS OR DEVICES FOR

COMMITTEE 12

SURGERY FOR NEUROLOGICAL URINARY INCONTINENCE

Chair

Kessler, Thomas. Chair (Switzerland)

Members

Apostolidis, Apostolos (Greece)
Castaño, Juan (Colombia)
Corcos, Jacques (Canada)
Game, Xavier (France)
Hamid, Rizwan (United Kingdom)
Liao, Limin (China)
Padilla Fernández, Bárbara Yolanda (Spain)
Sekido, Noritoshi (Japan)
Stoffel, John (United States)
Trigo Rocha, Flavio (Brazil)

Acknowledgements

We thank Silvan Büeler very much for his help in editing the manuscript, creating the Endnote library and formatting the references.

COMMITTEE 12

SURGERY FOR NEUROLOGICAL URINARY INCONTINENCE

ABBREVIATIONS 1366

I. INTRODUCTION 1366

II. METHODS 1367
1. Methods and literature search 1367
2. Level of evidence (LE) 1367
3. Grade of recommendation (GR) 1367

III. SURGICAL TREATMENTS 1367
1. Botulinum toxin injections 1367
1.1. Botulinum toxin injections into the detrusor 1367
1.1.1. Efficacy 1367
1.1.2. Disease-specific outcomes 1368
1.1.3. Doses 1368
1.1.4. Effect on quality of life (QOL) 1369
1.1.5. Administration technique 1369
1.1.6. New indications in neurogenic detrusor overactivity 1370
1.1.7. Safety 1370
1.2. Botulinum toxin injections into the external sphincter 1371
2. Invasive neuromodulation / neurostimulation 1371
2.1. Sacral anterior root stimulation (SARS) combined with dorsal rhizotomy 1371
2.1.1. Indications 1372
2.1.2. Results 1372
2.2. Sacral neuromodulation 1373
2.3. Other invasive neuromodulation techniques 1373
3. Urethral, prostatic and bladder neck surgery 1373
3.1. Urethral / prostatic stents 1373
3.1.1. Temporary prosthetic sphincterotomy 1374
3.1.2. Permanent prosthetic sphincterotomy 1374
3.1.3. Prosthetic versus endoscopic sphincterotomy 1375
3.2. Sphincterotomy 1376
3.3. Urethrotomy 1378

I. INTRODUCTION

There was no independent chapter dealing with surgery for neurological urinary incontinence in previous International Consultation on Incontinence (ICI) reports, but the topic was covered partly in the very broad chapter on "Neurologic urinary and faecal incontinence". The structure of this newly implemented chapter has been developed and agreed by the chapter authors using the Delphi method. The chapter fully focus on neurological patients and complements information provided for the non-neurological population in other ICI chapters.

Due to the complex, still not fully understood multilevel control of the lower urinary tract, many neurological disorders such as multiple sclerosis (MS), Parkinson's disease (PD), stroke, spinal cord injury (SCI), spina bifida, diabetic neuropathy, Alzheimer's disease, etc. frequently result in neurogenic lower urinary tract dysfunction (NLUTD). The site and nature of the lesion in the neurological axis determine the type of lower urinary tract dysfunction which is reflected in the patient's symptoms (Figure 1) (1).

Little has changed in terms of the description of the different types of lower urinary tract and pelvic floor dysfunction that occur with specific neurological disorders since the last edition (6th edition, 2017) of the consultation. For a more detailed description, the reader is referred to pages 1093-1308 of the previous edition.

The aims of the neuro-urological management are to preserve upper urinary tract function, to control urinary tract infection, to improve quality of life, and to maintain a low-pressure bladder that is both continent and capable of emptying completely (1-4). These goals are ideally achieved without an indwelling catheter or a stoma, and in a manner that is socially and vocationally acceptable to the patient, whilst avoiding complications such as recurrent urinary tract infections, urethral strictures, calculus disease, hydronephrosis, and renal failure.

In daily practice, it is straightforward to base the neuro-urological management on the clinical and urodynamic dysfunction pattern to determine the appropriate therapeutic strategy to preserve both upper and lower urinary tract function, and to achieve or maintain urinary continence. In patients with detrusor overactivity, the therapeutic concept is to convert the overactive into a normoactive or underactive detrusor. Although antimuscarinics are the pharmacological treatment of choice, they have limited effectiveness and many patients discontinue their use because of adverse events. Beta-3 adrenergic agonists have recently been introduced as an alternative to antimuscarinics for treating the non-neurogenic overactive bladder, but research into its application in the neuro-urological patients is still limited. For refractory neurogenic detrusor overactivity, intradetrusor onabotulinumtoxinA injections are a highly effective, minimally invasive, and generally well-tolerated treatment that improves health-related quality of life. In the case of failed onabotulinumtoxinA treatment, augmentation cystoplasty is an established treatment option, but requires abdominal surgery with interposition of an intestinal segment (usually ileum) into the bladder and/or partial replacement of bladder by an intestinal substitute. In highly selected patients, cystectomy with continent or incontinent urinary diversion becomes necessary as a salvage procedure.

In patients with an under-active/acontractile detrusor and/or with detrusor-sphincter dyssynergia (DSD), intermittent (self-)catheterization is recommended to assist bladder emptying. Passive voiding by abdominal straining (Valsalva manoeuvre) or, particularly, by suprapubic downwards compression of the lower abdomen (Credé manoeuvre) is not recommended since it creates un-physiological and high intravesical pressure which puts the upper urinary tract at risk and causes compression of the urethra, i.e., a functional obstruction resulting in an inefficient emptying. Nevertheless, some patients are not able and/or not willing to perform intermittent self-catheterization and therefore an indwelling transurethral or suprapubic catheter is potentially the only alternative.

In patients with refractory neurogenic detrusor overactivity and/or neurogenic voiding dysfunction, sacral neuromodulation may be a valuable treatment option. However, the evidence is limited, and it is unclear which neurological patients would be most suitable.

In the case of stress urinary incontinence due to low bladder outlet resistance, electrical stimulation of the pelvic floor can help to restore urinary continence in patients with incomplete lesions. In some neurological patients, the implantation of an autologous urethral sling or an artificial urinary sphincter may become necessary. However, it needs to be considered that artificial urinary sphincters generally do not continue working indefinitely and the probability for revision surgery is high.

In conclusion, there is no uniform management strategy for neuro-urological patients and a rather individualized, patient-tailored approach aiming to achieve an optimal quality of life and to protect the upper and lower urinary tract is needed for this special patient population (1-4).

II. METHODS

1. METHODS AND LITERATURE SEARCH

A literature search was performed by the chapter authors using the Agency for Healthcare Research and Quality (AHRQ) database, BIOSIS, the Cochrane Library, Embase, MEDLINE, Science Citation Index, and Scopus to identify studies published from January 1st 1946 to June 30th 2021. Search terms included Medical Subject Headings (MeSH) and keywords for interventions and surgeries related to neurogenic lower urinary tract management. No language restrictions were applied. Studies were reviewed by chapter authors and characterized as systematic reviews and meta-analysis of randomised controlled trials (RCTs), RCTs, non-randomised cohort studies, case control studies, case series, and expert opinion. Levels of evidence and grades of recommendation were determined according to the International Consultation on Urological Diseases (ICUD) system which can be mapped to the Oxford system (5).

2. LEVEL OF EVIDENCE (LE)

LE 1: Meta-analysis of trials or a good quality RCTs

LE 2: Lower quality RCTs or meta-analysis of good quality prospective studies

LE 3: Good quality retrospective and case series studies

LE 4: Expert opinion

3. GRADE OF RECOMMENDATION (GR)

GR A: Assigned to LE 1 unless dangerous, unethical, or prohibitively expensive

GR B: Assigned to LE 2 and 3 or majority evidence from RCTs

GR C: Assigned to LE 4 or majority evidence from LE 2/3 studies or expert opinion

GR D: Assigned when no recommendation can be made

The Delphi method was used by sub-chapter authors identify expert opinion levels of evidence. The Delphi method was also used when reviewing sub-chapter recommendations by panel of additional chapter authors to finalise chapter recommendations.

III. SURGICAL TREATMENTS

1. BOTULINUM TOXIN INJECTIONS

1.1. Botulinum toxin injections into the detrusor

1.1.1. Efficacy

Ten years have passed since botulinum neurotoxin type A (BoNT/A) intradetrusor injections became the newest approved treatment for urinary incontinence in adult neurological patients with inadequate response to (or reduced tolerance of) an antimuscarinic medication (US Food and Drug Administration (FDA) approval) in the onabotulinumtoxinA (Botox®) format. Similar approval has been granted in European countries and worldwide. Several systematic reviews (6-11), meta-analyses (12-16), and RCTs (LE 1) (17-24), two active comparator-controlled trials (LE 1-2) (25, 26), four LE 2 studies (27-30), as well as numerous LE 3 studies have confirmed the efficacy of BoNT/A in the treatment of refractory neurogenic detrusor overactivity incontinence. Clinical improvement is accompanied by significant ameliorations in bladder function, as urodynamic parameters that matter in the management of neurogenic detrusor overactivity, namely maximum cystometric capacity, maximum detrusor pressure and reflex volume, gain substantial benefits (6, 7, 10, 31). Almost all studies have published on two BoNT/A preparations, onabotulinumtoxinA (Botox®) and abobotulinumtoxinA (Dysport®) (7, 8). Although both products are efficacious in neurogenic detrusor overactivity, onabotulinumtoxinA has been more comprehensively studied than abobotulinumtoxinA (7). Two LE 1 studies have been published reporting abobotulinumtoxinA (23, 28). The two formats are not interchangeable and there is scarce data on direct comparisons for dose, efficacy and safety, at least in urological indications. A retrospective case-control study concluded that intradetrusor injections of abobotulinumtoxinA 750 units provided better outcomes than injections of onabotulinumtoxinA 200 units in patients with neurogenic detrusor overactivity. The authors found similar success rates of abobotulinumtoxinA 750 units and onabotulinumtoxinA 300 units but the interval between injections tended to be longer with onabotulinumtoxinA 300 units (32). An LE 3 study suggests that onabotulinumtoxinA may be more efficacious than a novel BoNT/A preparation, Prosigne® (Chinese botulinum toxin serotype A), in the treatment of refractory neurogenic detrusor overactivity (33).

The mean duration of efficacy of a single injection is 6-16 months for onabotulinumtoxinA and 5-12 months for abobotulinumtoxinA (7). The FDA regulatory trials (275 and 416 patients, respectively) demonstrated a mean duration of effect of 37-42 weeks for onabotulinumtoxinA compared to 13 weeks for placebo (19, 21). Complete continence was achieved in 36-38% and 40-41% respectively with the 200 units and 300 units doses of onabotulinumtoxinA as opposed to 7.6-10% with placebo. Interestingly, significantly higher post-treatment continence rates have been reported in single-centre studies with both preparations (a mean 71% with onabotulinumtoxinA and 65% with abobotulinumtoxinA) (7). Similarly, reduction in the number of daily leaks was significantly superior in LE 3 compared to LE 1&2 studies (80% versus 63%, p=0.01) (8), but the majority of LE 3 studies had used 300 units onabotulinumtoxinA. Several retrospective studies (30, 34-44) and a single prospective trial (45) now attest to the sustained efficacy of repeat treatment sessions with either of the two formulations. In prospectively followed-up patients opting for repeat injections, the median duration

of effect was ≥9 months, with one in four patients enjoying an even more lasting effect of at least one year (45).

The concomitant use of antimuscarinics does not appear to provide additional benefit (46), although this needs to be confirmed in specifically-designed studies. In those taking antimuscarinics, onabotulinumtoxinA initially reduces the dose of antimuscarinics needed, but this tends to increase again at longer follow-up (47, 48). A head-to-head comparison between onabotulinumtoxinA 300 units and oxybutynin 5mg transdermal (TD) in a small RCT of neurologically stable, self-catheterising patients with SCI showed clear superior improvements in the number of incontinence episodes, maximum cystometric capacity, maximum detrusor pressure, bladder compliance and quality of life in the toxin group (all p<0.001 except for p=0.006 for bladder compliance) (26). However, all patients had been on oral antimuscarinics before the study, and it is not clarified whether they had oral oxybutynin as first treatment in the past (since this was the treatment of choice in the country of origin). This may be reflected in the 10-fold increased probability of complete-dry rates (60% with onabotulinumtoxinA as opposed to only 6% with oxybutynin).

Earlier systematic reviews and meta-analyses reported failure rates of 5-25% for onabotulinumtoxinA and 10-32% for abobotulinumtoxinA (7). Clinical predictors of success/failure in neurogenic detrusor overactivity are increasingly being investigated. A study of patients with SCI proposed that the level of injury may be important as patients with thoracic and lumbar injury had better clinical and urodynamic outcomes compared to cervical injury patients (49). A longer duration of MS has been proposed as a predicting factor for treatment failure (14) (LE 3). In PD patients, a lower pre-operative post-void residual (PVR) and a lower maximum detrusor pressure during maximum flow rate (PdetQmax) were associated with treatment success, while in male patients both the bladder outlet obstruction index (BOOI) and the bladder contractility index (BCI) were associated with treatment failure. Also, a higher pre-treatment PVR was associated with increased risk of post-injection need for intermittent catheterisation (50). The evidence linking treatment failure with the formation of neutralizing BoNT/A antibodies has been conflicting; a wide range of antibody formation rates following treatment has been reported (0-35%) (51-54). A small, mid-term, controlled study in children (LE 1-2) found no association between antibody formation and treatment failure, but reported an increased rate of antibody formation in those receiving repeat versus single injections (71% versus 38%) (55) up to 4 months post treatment. In the long-term, antibody titres returned to control levels. The long-term extension study of the registrational RCTs for onabotulinumtoxinA found a very low percentage of neutralizing antibodies development (8/381 patients, 2.1%) (56). The low number of patients did not allow for clinical associations, but the median time between injections in patients who developed antibodies was 5 months, less than the study average of 9 months. By contrast, a large retrospective study reviewing 2'700 injections in 414 patients found a correlation between neutralizing antibody formation and the duration of BoNT/A therapy (p=0.015), the mean number of BoNT/A injections (p=0.011) and the time interval between BoNT/A injections (<7 months, p=0.022). Significant differences were also seen in urodynamic parameters where the formation of antibodies was seen more commonly in patients with lower post-treatment values of maximum cystometric capacity (<225 mL, p=0.038) and higher detrusor pressures (>45 cmH2O, p=0.040) (57). Patient-related factors also affect adherence to treatment; in a long-term study with a mean 12-year follow-up, 21% of patients discontinued treatment due to inadequate efficacy, but another 19% opted for other treatments (antimuscarinics, sacral neuromodulation) despite the toxin's efficacy (44). In another study, only 59.3% of SCI patients were satisfied with repeat treatments and only 20% continued after a fourth injection, with 33.9% reporting inadequate efficacy and 6.8% discontinuing due to adverse events (43). More recent studies have examined long-term continuation rates up to 10 and 15 years after the first injection. A Danish study of SCI patients reported 59% (95% CI 50.0–67.8) probability of continuing treatments after 5 years and 50% (95% CI 40.1–59.3) after 10 years. Younger patients (31–50 years old) were more likely to continue treatment compared with those aged >50 years (p=0.008) (58). Another mixed population (SCI and MS patients) 10-year study with a mean follow-up of approximately 7 years and a mean of 9 injections per patient reported treatment failure rate of 26% with discontinuation occurring after a mean 76 months (59). Finally, in a 15-year study, occasional or consecutive failures were seen in 46.6% of patients (60). In another study of long-term outcomes in patients with neurogenic detrusor overactivity the failure rates were 12.6% after 3 years, 22.2% after 5 years and 28.9% after 7 years (61). The study proposed that the presence of pre-treatment urinary incontinence, higher maximum detrusor pressure, a higher number of febrile urinary tract infections (UTIs) and decreased bladder compliance were related with a higher probability for treatment failure.

Nevertheless, in treatment failures toxin switch could be more effective than re-injection with the same toxin (51.7% versus 24.1%). Patients treated with a switch from abobotulinumtoxinA to onabotulinumtoxinA and those treated with a switch from onabotulinumtoxinA to abobotulinumtoxinA had similar success rates (52.9% versus 50%) (62).

1.1.2. Disease-specific outcomes

The majority of the studies involved participants with neurogenic lower urinary tract dysfunction due to SCI or MS, often mixed, while smaller case series investigated efficacy in patients with PD, multiple system atrophy or cerebrovascular accident (63-67) (50, 68, 69). Comparisons of efficacy between neurological subpopulations are generally lacking, although a small LE 3 study suggested better continence outcomes and more significant improvements in maximum detrusor pressures in SCI patients compared to those with cerebrovascular accident (66). The largest RCTs which involved MS and SCI patients conclude that the toxin is highly efficacious in both subpopulations (19, 21). A lower placebo effect in the SCI subpopulation could be noted, although the studies were not designed for head-to-head comparisons. More recent studies explored the effect of lower doses (100 units onabotulinumtoxinA) in patients with MS (69) or PD (50), results are reported in the following section.

1.1.3. Doses

The FDA registration studies demonstrated a similar efficacy and adverse event profile for the 200 units and 300 units onabotulinumtoxinA doses, suggesting a plateau in the efficacy of the toxin. Similar conclusions were drawn by a smaller randomised study (30). Providing the best benefit/risk ratio, the 200 units onabotulinumtoxinA dose was recommended for the treatment of refractory neurogenic detrusor overactivity incontinence (19) (21). To date, only 2 real-life studies have investigated the effect of switching from the earlier used 300 units to the newly approved 200 units onabotulinumtoxinA (70, 71). In the former, although 94% of patients continued to experience symptomatic improvement, 25% reverted back to the original 300 units dose. Somewhat greater reductions in daytime frequency and nocturia were recorded with 200 units versus 300 units (87.5% and 81.3% respectively *versus* 75% and 75%) but lesser urgency improvements (75% versus 81). At three-year follow–up, 82% of patients who had switched to the lower dose were happy and keen to continue receiving 200 units onabotulinumtoxinA

(70). In the latter, no significant differences were found between the 2 doses in urodynamic parameters, proportion of patients with incontinence, daily pads number, frequency of bladder emptying or in the use of concurrent neurogenic detrusor overactivity medication (71). A LE 2 study suggested a trend towards better clinical and urodynamic improvements with 750 units as opposed to 500 units abobotulinumtoxinA (51). Other, non-randomised and inadequately powered studies (LE 3) (27, 28, 72) could not identify a clear dose-response for higher doses of abobotulinumtoxinA, although 1000 units abobotulinumtoxinA might produce a beneficial effect of greater duration than that with 500 units (28).

Novel data exists on lower doses. Following a pilot LE 3-4 study suggesting that 100 units onabotulinumtoxinA could be effective in MS patients and minimize unfavourable side-effects, particularly the need for intermittent catheterisation (67), a randomised, double-blind, placebo-controlled phase III study in non-catheterising patients with MS demonstrated significantly greater improvements in urinary incontinence episodes, urodynamic parameters and quality of life in patients who received active treatment. Complete cure of urinary incontinence was achieved in 53.0% of onabotulinumtoxinA-treated patients as opposed to only 10.3% of the placebo arm. Intermittent catheterization rates were 15.2% for onabotulinumtoxinA compared to 2.6% for placebo, and these were lower than previously reported with onabotulinumtoxinA 200 units (73). A LE 1 dose-response study confirms a more significant clinical benefit of the 200 units dose as opposed to the 50 units and 100 units doses of onabotulinumtoxinA in patients with SCI (22). The largest to-date study on PD patients used 100 units of onabotulinumtoxinA in 24 patients and achieved a subjective improvement in 79.2% but complete resolution of incontinence in only 29.1%. Despite the lower dose used, the post-void residual increased significantly (from 17.6 to 125.3 mL, $p<0.001$) and 12.5% of the participants required intermittent catheterisation after the 1st injection. The overall incidence of intermittent catheterisation was 10.2% including repeat injections (50). These results are contradicting earlier reports of preserved micturition with either 100 units (65) or 200 units (63, 68) onabotulinumtoxinA in smaller case series in which post-void residual increased but did result in the need for post-treatment intermittent catheterisation.

1.1.4. Effect on quality of life (QOL)

Both preparations have been shown to improve patients' QOL in RCTs. The Incontinence QOL (I-QOL) questionnaire has been used in the majority of LE 1 studies. Patients with neurogenic detrusor overactivity incontinence receiving a single injection of 500 units abobotulinumtoxinA, diluted in 25 mL saline and injected into 25 injection sites, had a more significant change in clinical, QOL and urodynamic parameters when compared to placebo at 26 weeks, in addition to reduced use of anticholinergics (18). Similarly, 200 units and 300 units onabotulinumtoxinA administered into 30 injection sites improved QOL scores significantly more than placebo in all LE 1 studies (19-21, 74-76). Moreover, onabotulinumtoxinA-treated patients achieve their treatment goals at significantly higher proportion than placebo-treated patients (LE 1) (77). Fully published data on QOL following repeat treatments is sparse; in a 3-year extension study of the registration trials, QOL improvement was sustained with repeat injections (up to six) in parallel with clinical benefits (56).

1.1.5. Administration technique

A large variance in the number and volume of injections has been described. However, in the majority of studies onabotulinumtoxinA was given at 30 injection sites (range 10–40) at a dilution of 10 units per 1mL per injection site (total volume of 30 mL, range 3–30 mL), as described in the original publication by Schurch et al. (78). The same dilution and number of injection sites was used when administering either 300 units or 200 units onabotulinumtoxinA in the registrational trials. Administration of abobotulinumtoxinA is less standardised (10–30 injection sites, total volume of 5–30 mL), but a total 30 mL given at 30 injection sites appears to be the most common again (7). The effect of these variables on outcomes has little been studied. A recent LE 1 study compared 15 to 30 injection sites (abobotulinumtoxinA 750 units or the equivalent placebo) and concluded that a reduction of injection sites does not affect efficacy (23). Urodynamic results were more robust than the clinical ones, the small sample size possibly affecting the statistics. A randomised, non-controlled study on onabotulinumtoxinA existing only in short report format (79) compared 10 to 30 injection sites (300 units onabotulinumtoxinA), and found no significant difference in number of incontinence episodes or cystometric capacity, but a significant reduction in post-procedure pain in the 10 injection-sites group. More recently, however, in a non-randomised non-controlled study of a mixed neurogenic / idiopathic detrusor overactivity population minimisation of the number of injection sites to 3-4 did not affect efficacy of the treatment as the complete continence rate was as high as 81%, and the mean duration of effect was a spectacular 34.9 weeks, comparable to earlier studies which typically used more injection sites (80). Another non-RCT using 100-300 units onabotulinumtoxinA in a mixed neurogenic / idiopathic detrusor overactivity population explored a further reduction of the injection sites to only 1-3 and reported also very satisfactory results, with 87% of the patients with neurogenic detrusor overactivity reporting subjective success of the treatment, 52% achieving complete continence and a mean duration of effect of 31 weeks (81).

The vast majority of studies reported injections into the detrusor sparing the trigone, as in the original technique (78). There is, however, now LE 1 evidence to suggest that combined detrusor and trigonal injections may produce better continence rates than detrusor injections alone, more significant improvements in incontinence episodes, symptom severity, detrusor pressures and volume at first desire to void (29, 82). In addition to these parameters, another LE 1 study found higher improvements in the mean voided volume, the percentage of patients with detrusor overactivity and the duration of first detrusor contraction in the patient group where 40 of the total 200 units onabotulinumtoxinA were injected in the trigone compared to the intradetrusor only injection group (82). There is also LE 1-2 evidence suggesting that submucosal injections are comparable in efficacy to intradetrusor injections, with the exception of voided volume (83) and detrusor compliance (84). An impressive difference was found, however, in patient satisfaction favouring the suburothelial injections (88.8% versus 64.3% of patients satisfied) (84). Furthermore, a meta-analysis found no differences in the incidence of vesico-ureteral reflux, haematuria, general weakness, bladder discomfort, increased post-void residual, and urinary tract infection between submucosal injections and intradetrusor injections (85).

Alternative delivery techniques into the bladder are being investigated, however, to date, almost exclusively in non-neurological patients (overactive bladder (OAB) and interstitial cystitis / bladder pain syndrome (IC/BPS) patients) (see review (86)). These include intravesical instillation of BoNT/A encapsulated in liposomes (87), via electromotive drug administration (EMDA) (88), TC-3 hydrogel embedding BoNT/A and low energy shock waves to promote intravesical BoNT/A delivery to the urothelium (86). In small, short-term, placebo-controlled trials (89, 90) (LE 1-2), intravesical instillation of liposomal onabotulinumtoxinA (200 units) improved micturition frequency and urgency severity scores over placebo at 4 weeks, but not urgency episodes or urgency incontinence. No urinary re-

tention episodes were reported though. However, in a placebo-controlled trial, liposomal onabotulinumtoxinA could not produce better improvements in bladder pain than placebo in patients with IC/BPS (86). The EMDA method has been tested in a pilot LE 3-4 study in children with myelomeningocele. Significant improvements were reported in maximum cystometric capacity, detrusor pressure, urinary incontinence, vesico-ureteral reflux and even faecal incontinence (91), but results need to be confirmed in controlled trials. The TC-3 hydrogel method has produced promising results in a RCT in OAB patients and in a single-arm prospective cohort study in IC/BPS patients (see review (86)). Finally, in a small case series, although histopathological findings showed that low energy shock waves help BoNTA pass through the urothelium it did not result in a significant clinical effect in IC/BPS patients (see review (86).

1.1.6. New indications in neurogenic detrusor overactivity

In patients with neurogenic vesico-ureteral reflux due to SCI, the co-administration of onabotulinumtoxinA with a bulking agent (Macroplastique) resulted in significantly higher treatment rates of vesico-ureteral reflux in the combination group, while urodynamic parameters significantly worsened in the monotherapy group, suggesting a protective role for onabotulinumtoxinA from the post-vesico-ureteral reflux treatment changes occurring in the bladder (92). In addition, in patients with long-stay catheters and refractory bladder pain and catheter bypass leakage, the majority of whom were neurological patients, intradetrusor injections of 200 units onabotulinumtoxinA achieved adequate management of symptoms in 94% of patients and a significant reduction in urine leakage in 83% of them (93). Finally, results of the ENTEROTOX study suggest that BoNT/A could be used as salvage therapy in cases of failed augmentation cystoplasty for refractory neurogenic detrusor overactivity; 58% of the study patients had a clinically significant outcome and requested re-injection, with significant improvements also in key urodynamic parameters (maximum cystometric capacity and maximum detrusor pressure) (94).

1.1.7. Safety

The treatment appears to be overall safe in currently used doses and techniques. The most common adverse event is the significant increase in PVR in patients not using intermittent catheterisation prior to treatment. In onabotulinumtoxinA placebo-controlled trials, 12-22%, 30-47%, and 42-49% of patients in the placebo, 200 units, and 300 units groups, respectively, initiated intermittent catheterisation post-treatment (19) (21). Rates of de novo intermittent catheterisation appear to be reduced after repeat treatments: in a 4-year study with up to six onabotulinumtoxinA injections, de novo intermittent catheterisation rates were 29.5, 3.4, and 6.0% (200 units), and 43.0, 15.0, and 4.8% (300 units) for treatments 1-3, respectively; de novo intermittent catheterisation rates were 0% for treatments 4-6 (56).

Although earlier studies had reported a reduced incidence of UTIs in patients with neurogenic detrusor overactivity treated with BoNT/A (39, 95, 96), recent large RCTs (19, 21) as well as systematic reviews (9) and meta-analyses (12) suggest a higher incidence of UTIs in those treated with onabotulinumtoxinA as opposed to placebo-treated patients. This might be associated with the increased rate of de novo intermittent catheterisation in the onabotulinumtoxinA-treated population. In prospective, long-term, follow-up trials UTIs remained the most common adverse event, but with no increased incidence over time (45, 56). Long-term controlled trials could clarify these apparent discrepancies. Importantly, however, there appears to be significant inconsistency regarding the definition of UTI in the BoNT/A studies, with only half (54%) using diagnostic criteria for a UTI, albeit with a wide range of definitions, most of which did not comply with either the EAU criteria or the National Institute on Disability and Rehabilitation Research (NIDRR) standards (97).

A debate regarding the role of preoperative asymptomatic bacteriuria and the need for antibiotic prophylaxis is ongoing. The treatment of asymptomatic bacteriuria in patients with neurogenic detrusor overactivity is not recommended, and it appears to be very common among patients treated with BoNT/A (38.8-73% in urine specimens taken before treatment) (44, 98). However, there is conflicting data about its association with post-BoNT/A development of UTIs; one study found it to be associated with a 16-fold risk for post-BoNT/A UTI (98) while another found no difference between those with and without asymptomatic bacteriuria (44). Both studies, however, agreed that pre-treatment asymptomatic bacteriuria was not associated with the efficacy of the treatment (98) (44). Nevertheless, as the use of peri-operative antibiotics can reduce the risk of post-BoNT/A UTIs by almost 5-fold (99) and febrile UTIs were found to be associated with treatment failure (61) it has been proposed that treatment failures should be screened for occult UTIs and that fierce UTI prevention strategies should be followed (100).

Pain/discomfort from the procedure might be an issue for patients with preserved sensation. An RCT demonstrated that an alkalinized lidocaine solution could significantly reduce the pain from the procedure compared to a lidocaine-only solution (2.37 ± 0.31 versus 4.44 ± 0.36, $p<0.01$). Pain scores were similar one hour after the procedure (24).

Haematuria, constipation and flu-like symptoms have also been described (7, 19, 21), while inclusion of trigonal injections does not appear to produce vesico-ureteral reflux (LE 2-3) (29, 101, 102). A study in SCI male patients found a post-treatment decrease in the volume of ejaculate accompanied by improvements in semen quality, sperm mobility and vitality, as well as semen culture (103). Further research is needed to confirm these results and explore whether they are due to local re-organization of autonomic function which also affects the reproductive system.

The most serious adverse event is generalized paraparesis / fatigue, which has been described in 0.005% of patients receiving onabotulinumtoxinA and in 0.026% of patients receiving abobotulinumtoxinA (7). The effect resolves spontaneously after 4-6 weeks and appears to be dose-related, with most cases reported in those patients injected with 750-1000 units abobotulinumtoxinA or 300 units onabotulinumtoxinA (21, 37, 104).

As BoNT/A studies in skeletal muscles have identified autonomic, histological and other secondary effects (105, 106), further investigation is needed on safety issues, especially after repeat injections (6). Preclinical studies provided evidence for transport of the toxin from the bladder to the central nervous system and vice versa (107, 108). A single study to-date prospectively examined distant effects post-BoNT/A bladder injection using single-fibre electromyography: One-third of the patients had findings of neuromuscular jitter post-treatment, but there was no placebo arm or pre-treatment data for comparison (109) (LE 3). Frequency and severity of autonomic dysreflexia episodes were reported to be reduced following onabotulinumtoxinA bladder injections (LE 3)(110). Other studies produced histological evidence of reduced or no additional fibrosis after one or multiple injections, including in children (111-113).

Future research should highlight the gaps in our knowledge of long-term treatment with focus on patient-reported outcomes and satisfaction, safety and tolerability issues as well as technical aspects

such as alternative techniques of application, ways to minimize post-treatment voiding dysfunction in patients who void freely and larger studies in select patient populations.

1.2. Botulinum toxin injections into the external sphincter

Sphincter injections were historically the first application of BoNT/A in the lower urinary tract (114), but there is still inadequate evidence to support its use. The most commonly injected volume is 4mL of either the onabotulinumtoxinA or the abobotulinumtoxinA preparations. Usually 100 units onabotulinumtoxinA or 150 units abobotulinumtoxinA have been delivered transperineally or transurethrally (115, 116). No direct comparison of injection techniques exists; there is low evidence (LE 4) to suggest the two delivery approaches are equally effective (115).

In a LE 1 study, the effects on DSD of botulinum toxin versus placebo was studied in 86 MS patients (117). The study employed a single transperineal injection of onabotulinumtoxinA, 100 units in 4 mL normal saline, or placebo, into the striated sphincter with electromyography guidance. The primary endpoint was PVR at 30 days. The secondary endpoints included voiding and urodynamic variables. OnabotulinumtoxinA failed to decrease PVR in this group of MS patients, although it increased voided volume and reduced pre-voiding and maximum detrusor pressures. These findings differ from those in patients with SCI and may be due to lower detrusor pressures in MS patients. A small LE 1-2 study (n=13 patients) showed a superior effect of onabotulinumtoxinA over lidocaine 0.5% injected in the urethral sphincter in MS patients (116). Another small (n=21 patients), controlled study (LE 1-2) in cerebrovascular accident patients with urethral sphincter pseudo-dyssynergia reported superior clinical efficacy in the active treatment group (91% response rate and higher improvements in QOL and symptom scores with 100 units onabotulinumtoxinA) despite highly significant urodynamic benefits noted in the control group (reduction in voiding pressures and increase in maximum flow rates) (118). In MS patients there is also LE 3 to suggest that a combination of detrusor and sphincter injections may facilitate bladder emptying (119). In children with neurogenic detrusor overactivity and DSD due to myelomeningocele there is LE 1-2 from a single study to suggest that sphincter injections additional to the detrusor injections accomplish significant improvements in post-void residuals, as well as more significant benefits in urinary incontinence, constipation, vesico-ureteral reflux and creatinine levels (120).

Since the ICI update of 2012 there have been only LE 3 studies investigating the effect of urethral BoNT/A injections in neurogenic DSD (121-126). A study in SCI patients with neurogenic detrusor overactivity and DSD compared urethral injections of 100 units onabotulinumtoxinA to intradetrusor injections of 200 units onabotulinumtoxinA depending on the main symptoms (voiding dysfunction versus neurogenic detrusor overactivity incontinence) and found less patient satisfaction in the urethral injection group (60.6% versus 77.3% in the intradetrusor injections group) as well as greater improvements in the Urinary Distress Inventory-6 (UDI-6) and Incontinence Impact Questionnaire-7 (IIQ-7) scores in the intradetrusor injection group, despite significant urodynamic benefits in both groups (121). Not unexpectedly, patients in the urethral injection group were dissatisfied due to increased degree of post-onabotulinumtoxinA incontinence whereas the intradetrusor injection group suffered higher rates of post-treatment voiding difficulty.

A multicentre study of SCI patients who received 200 units onabotulinumtoxinA into the detrusor and 100 units onabotulinumtoxinA in the urethral sphincter reported significant reduction in mean maximum detrusor pressure, maximum urethral closure pressure, duration of first detrusor contraction and DSD for up to 12-weeks post-treatment (122). Additionally, the authors claim significant improvements in the I-QOL questionnaire, voided volume, urinary incontinence episodes and complete dryness which were sustained 16 weeks post-treatment.

Another 3 studies investigated predictive factors of successful treatment of DSD by urethral BoNT/A injections. In all 3 studies, 100 units onabotulinumtoxinA were injected in the urethral sphincter. No robust video-urodynamic factors could be identified as predictors of successful treatment except for an open bladder neck during voiding in a cohort of 95 patients with non-neurogenic or neurogenic detrusor underactivity (16). A lower efficacy was reported for the neurological population, but with similar duration of effect of a little over 7 months. This result contradicted another study by the same group of researchers which reported significantly shorter duration of effect in the neurological population (9.55 ± 4.18 versus 7.44 ± 2.91 months, p=0.033). This study found that a significantly smaller volume at first sensation of filling (p=0.046), greater detrusor pressure (p=0.027), higher maximum flow rate (p=0.017), and smaller post-void residual (p=0.006) were predictors of efficacy, together with an open bladder neck upon video-urodynamics (85). Another cohort of SCI patients found that poor outcome was related to the presence of concomitant bladder neck dyssynergia, the absence of detrusor contraction in standard cystometry, the severity of DSD, and the pre-treatment PVR (125). Finally, in another mixed patient cohort higher maximum flow rates and smaller PVR were predictive of successful results in patients with neurogenic voiding dysfunction (126). The efficacy rate was reported to be about 60%.

Overall, the highest level of evidence for studies exploring the efficacy of urethral sphincter BoNT/A injections in treating neurogenic DSD remains within RCTs or quasi-RCTs in comparison to placebo or active comparators which were considered to be of limited quality due to the small sample sizes, the heterogeneity in the protocols, and with a high risk of bias (127). Thus, results of this Cochrane review still stand that intraurethral BoNT/A injections improve some urodynamic parameters at 30 days post-injection but future high-quality research is needed to establish the efficacy and the optimal parameters for a successful treatment outcome in neurogenic DSD.

2. INVASIVE NEUROMODULATION / NEUROSTIMULATION

2.1. Sacral anterior root stimulation (SARS) combined with dorsal rhizotomy

Neurostimulation of the sacral anterior roots in humans, was introduced by Giles S. Brindley from London, UK, in the early 1970s. He aimed at restoring bladder emptying in patients with NLUTD due to SCI by electrical stimulation of the sacral nerves (S2-S4). By selective stimulation of these sacral roots, micturition was induced by detrusor contraction. Together with the company Finetech Ltd a silicon embedded implant was developed that consisted of an array of electrodes, connected to a subcutaneous receiver that could be stimulated by electromagnetic transmission from an external transmitter (128, 129). The first implantation was performed in a human in 1976 (130). However, at that moment the treatment did not address the problem of detrusor contractions and incontinence between episodes of micturition. Later, Brindley together with Sauerwein from Bad Wildungen, Germany, combined the implantation of the electrodes with posterior rhizotomies at the S2-S4 levels. These rhizotomies result in sacral deafferentation (SDAF) as the sacral

reflex arch is interrupted hence abolishing the reflex contractions of the detrusor at low filling. Hence urinary incontinence is abolished and bladder capacity and compliance significantly increased. The combination of sacral anterior root stimulation using the Brindley stimulator and posterior rhizotomy has become known as the Brindley procedure (130, 131). The mechanism of action is based on the so-called “post-stimulus voiding” which is characterized by an intermittent stimulation pattern that allows the urethral sphincter to relax while the detrusor pressure remains elevated. The result is an intermittent flow pattern until complete bladder emptying.

2.1.1. Indications

Suprasacral lesions are typically characterized by the presence of detrusor overactivity and DSD and are associated with high risk for upper urinary tract deterioration (130). For those patients who do not respond adequately to conservative treatments of the detrusor overactivity (antimuscarinics or onabotulinumtoxinA), sacral deafferentation eventually in combination with the implantation of a sacral anterior root stimulator may be a suitable alternative to other irreversible procedures such as augmentation cystoplasty or urinary diversion (4).

From a purely medical perspective, SDAF is indicated in patients with or at risk of:

- Autonomic dysreflexia
- Renal failure
- Urinary incontinence
- Recurrent UTIs
- Difficult or traumatic bladder catheterization
- Failure of conservative bladder management with persistent low compliance
- Failure of conservative therapy because of unacceptable side effects

From the point of view of bladder function the requirements for SDAF and SARS are:

- Motor and sensory complete SCI (informed consent should be obtained as loss of sensation in the segments S2-S5 will occur)
- Patients with SCI can be candidates if the lesion is non-progressive or very slowly progressive
- Intact spinal reflex arcs in the S2-S4 segments
- Intact detrusor function (no organic fixed fibrosis, no acontractility because of overdistension)
- Security of a long term therapeutic program for the SCI patient
- Support and understanding of family and friends given the irreversible nature of the rhizotomies with in male patients loss of reflex erections (132)

Advantages of dorsal rhizotomies include: detrusor areflexia which provides continence, significant increase in bladder capacity and compliance, correction of DSD and abolishment of autonomic dysreflexic attacks triggered by the bladder and rectum. However, section of all six of the S2-S4 posterior roots abolishes reflex erection. Also, genital sensation and reflex ejaculation is lost if these were present, and the patient has to be informed of these consequences.

SDAF and SARS are contraindicated for patients with the following characteristics:

- Poor or inadequate bladder reflexes
- Active or recurrent pressure ulcers
- Current sepsis
- Implanted cardiac pacemaker
- Not fully matured skeletal structure

Different approaches have been described to perform the rhizotomies and the electrode implant, the main ones being the intradural and extradural technique, each of them has its pros and cons. An increased risk of cerebrospinal fluid fistula and an increased risk of incomplete rhizotomies and motor nerve injury is described for the intradural and extradural technique, respectively. However, some authors have recently reported similar results with the extradural approach without comparatively higher rates of motor injury or incomplete rhizotomies (133). Combined approaches (intradural rhizotomies and extradural electrode placement) have been reported but are not frequently used.

2.1.2. Results

Since this surgical technique includes rhizotomies of the dorsal roots S2-S4 (SDAF) plus the implantation of an electric stimulator for the ventral roots S2 to S4 (SARS), both storage and voiding disorders are treated with one single procedure: the first part of the operation (SDAF) produces sensory deafferentation by interruption of the sacral reflex arch which suppresses detrusor overactivity and DSD thus achieving low bladder pressure and also decreases autonomic dysreflexia (134). With the second part of the surgery (SARS), patients regain physiological urination, mediated by a stimulated detrusor contraction, thereby eliminating urethral catheterization, the use of antimuscarinics and prophylactic antibiotics. With long term follow-up a decrease of the number of UTIs and associated complications has been observed, reducing the number of hospitalizations and the associated costs (135). This outcome has a relevant positive impact on the QOL of the operated patients (136).

During the last 40 years more than 2’000 patients were implanted (137). Many groups have since reported their experiences with the Brindley procedure some of them with a follow-up of up to 12 years. The treatment was found to be able to achieve a continence rate of 57% to 100%, increase the bladder capacity by 122% to 375%, reduction of PVR <50 mL in 70% to 91% of patients, and decrease the incidence of UTIs (132, 133, 138, 139).

Bladder compliance and storage detrusor pressure have been reported to be improved with SDAF/SARS (139, 140). Krebs et al compared pre- and post-SDAF/SARS urodynamic parameters and found that detrusor compliance and storage detrusor pressure values at short-term follow-up after surgery were greater than 20 cmH2O and smaller than 40 cmH2O, respectively. This indicates a return to physiological values. Furthermore, they found an increasing and decreasing tendency in bladder compliance and storage detrusor pressure, respectively, during the long-term follow-up period (141). This indicates that further improvement of the urodynamic parameters seems to continue after SDAF.

The stimulation of the anterior root especially of S2 may facilitate erection and the stimulation can maintain the erections, which otherwise would be of short duration. Vignes et al. (142) informs that although the device is effective for erections in 60% of patients, it is only used for this purpose by 30% of them. Its utility is better evidenced in the initial period (as for bowel function) but in the longer term the stimulation is rarely used.

Castaño et al reported that 88% of patients use the device to assist in bowel function, while other authors indicate that the neurostimulator is used in up to 91% of patients for bowel evacuation (133).

In a cross-sectional study in which 93 patients with the Brindley stimulator were compared with a matched control group of 70 pa-

tients, the implanted patient group had a significantly better Specific Impact of Urinary Problems score, a better general QOL index (Qualiveen), a better continence rate, and fewer UTIs, even for those patients who for some reason no longer used the neurostimulator. These patients continued to have the benefits of the rhizotomies as the quality of life and clinical parameters were better (136).

With regard to complications, Brindley et al. (131) reviewed the outcome of 50 patients, and reported 7 cases of pain over the sacral dermatomes during micturition with the neurostimulator. In 2 patients, the pain was severe and they abandoned the use of the device. The potential risk of pain also underlies the principle that the procedure should be performed only in patients with complete SCI or in some well selected incomplete SCI patients.

The damage of the motor roots is one of the most serious complications since it puts at risk the effect of stimulation. Brindley reported any grade of anterior root damage in 23 of 50 patients (131), although most recovered by 1 year. Cerebrospinal fluid leaks also occurred in 14 patients. To minimize cerebrospinal fluid leaks, Brindley and Sauerwein (143) also attempted extradural implantation, especially in patients with previous arachnoiditis, which may pose significant technical difficulties for intrathecal procedures. The trade-off is an increased risk of anterior nerve root damage. More recently, a study comprising 104 patients who had undergone extradural implantation reported significant improvement in bladder capacity, urinary incontinence episodes and UTIs without any increase in the incidence of anterior root damage (133).

2.2. Sacral neuromodulation

Sacral neuromodulation (SNM) has become a widely adopted treatment modality for non-neurogenic urgency urinary incontinence, urgency-frequency syndrome, non-obstructive urinary retention, and faecal incontinence since its FDA approval in 1997, 1999, 1999, and 2011 (144). However, the efficacy of SNM in patients with NLUTD remains unclear. It is important to mention that RCTs in the neurological population are still lacking (145), that means the level of evidence of the published studies is low, the risk of bias is significant, the sample sizes are small, the patient population is heterogenous, and there are relevant variations in terms of outcome parameters as well as technique.

SNM mechanism of action relay on the effects of electrical stimulation on afferent and efferent nerve fibres connecting the bladder and pelvic floor to spinal interneurons and central nervous system (146). This is attained by the permanent or intermittent electrical excitatory impulse at a central or peripheral somatic sensitive nerve in order to restore the normal afferent signal from the detrusor to spinal cord by restoring the balance between the excitatory and inhibitory control (147). Since SNM influences sacral afferents and modulates spinal cord reflexes and brain centres which control the lower urinary tract, this therapy is usually indicated for patients whose neural system is intact or only partially damaged (148).

Van Ophoven et al. (145) updated the systematic review and meta-analysis by Kessler et al. (149) and evaluated SNM for NLUTD over 20 years' experience. Forty-seven studies were included in the systematic review and twenty-one studies (comprising a total of 887 patients) in the meta-analysis of SNM testing. The pooled success rate of SNM testing was 66.2% (95% CI 56.9–74.4). Twenty-four studies with a total of 428 patients were included in the meta-analysis of permanent SNM. The success rate of pooled permanent SNM was 84.2% (95% CI 77.8–89.0). The most common adverse events were loss of effectiveness, infection, pain at implant site, and lead migration with adverse event rates of 4.7%, 3.6%, 3.2%, and 3.2%, respectively.

In patients with SCI undergoing SNM for NLUTD, another recent meta-analysis shows success rates of 46% and 76% for the test and permanent phases, respectively (150). Recommendations from the ICS best practice statement recommends SNM limited to AIS D and E and an additional benefit in the outcomes if the presentation is upper motor neuron injury since this one does not affect afferents integrity and contractility of the detrusor (147).

According to a review by Puccini et al. the success rate of SNM testing was around 60%, with a final subjective cure rate of 45% and a global satisfaction of 85% in patients with MS (151) being more successful in patients with neurogenic detrusor overactivity and DSD rather than an underactive detrusor. Recent publications reported not very encouraging results of SNM for patients with PD and spina bifida (144).

SNM is a safe and reversible minimally invasive procedure with a low risk of nerve damage or surgical site infection (152). Most typical complications are primary failure, pain, discomfort, and lead migration. Barriers for applying this therapy in NLUTD were mainly related to magnetic resonance imaging incompatibility, size of the implantable pulse generator, and battery depletion. Newer devices are up to 80% smaller than previous models, they are also rechargeable with a longer battery life which can last up to 15 years. Additionally there are compatible with magnetic resonance imaging (153). However, the characteristics of ideal patients for a rechargeable device are still unclear since they patients require manual dexterity to manipulate and recharge the device for optimal performance. Therefore, an ideal patient selection is crucial.

2.3. Other invasive neuromodulation techniques

Other invasive neuromodulation techniques such as epidural spinal cord stimulation (154, 155), deep brain stimulation (156), and invasive pudendal (157) and tibial (158, 159) nerve stimulation may have beneficial effects on the lower urinary tract but specifically designed high-level evidence studies are needed in neuro-urological patients.

3. URETHRAL, PROSTATIC AND BLADDER NECK SURGERY

3.1. Urethral / prostatic stents

In 1990, Shaw *et al.* proposed using a wire mesh stent (Urolume) to treat patients with spinal injury presenting with DSD (160) (LE 3). Since then, various stents have been used. Table 1 lists the types of stents used for DSD, according to classification criteria (161, 162). They can be placed in the prostatic urethra, through the striated sphincter or more distal in the sub-sphincteric urethra.

Table 1. Stents used in neurogenic DSD

Temporary stents					
Stent	**Expansion method**	**Size**		**Material**	**Maximal duration (months)**
		Calibre (French)	**Length (mm)**		
Not specific to the striated sphincter First-generation					
Urospiral (163)	Non expandable	21	40-80	Stainless steel	<12
IUC (164)	Non expandable	16-18	25-80	Polyurethane	<6
Second-generation					
Memocath (165)	Heat	22/34	30-70	Nitinol	<36
Specific to the striated sphincter					
Diabolo (166)	Self-expansion	18	38	Medical steel	>12
Permanent stents					
Stent	**Expansion method**	**Size**		**Material**	
		Calibre (French)	**Length (mm)**		
Urolume Wallstent (167)	Self-expansion	42	20-40	Steel alloy	
Titan (168)	Balloon	43	19-58	Titanium	
Memotherm (169)	Heat	42	20-80	Nitinol	
Ultraflex (170)	Self-expansion	42	20-50	Nitinol	

3.1.1. Temporary prosthetic sphincterotomy

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheter use, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this testing period, it is possible to study how the bladder empties in the seated position, and assess the necessity of additional treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. As this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition and leaving the possibility to discuss any fertility and sexual issues, and considering the possibilities of preserving sperm. For patients with SCI, early temporary stent placement (within six months of trauma) theoretically has the added advantage of waiting for recovery of upper limb motility to enable intermittent catheterisation. After using a temporary stent, the patient may choose the mode of bladder emptying, i.e. return to the former state, change to another temporary stent, replace it by a permanent stent, or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Only the temporary stent Diabolo (166) is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series (171) (LE 3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean 10-month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequelae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. Memokath is another device that has been studied in neurological patients (172-177) (LE 3-4). Several authors report complications (32-100%) using this stent, which seems to induce a lot of bladder stones and is quite difficult to remove, especially if it is left longer than 18 months. When used as second-line treatment following failed sphincterotomy, Memokath successfully reduced PVR, but failed to improve urodynamic parameters including bladder capacity, detrusor leak point pressure, bladder compliance, and maximum detrusor pressure (172).

3.1.2. Permanent prosthetic sphincterotomy

Permanent stents are designed to integrate with the urethral wall (178). They resist the striated sphincter and prevent its closing during reflex contraction. They can be removed if necessary, or at the patient's request, with recovery of striated sphincter contraction (179, 180). Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single thread (e.g. Urolume) or several threads (e.g. Ultraflex). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume, Memotherm and Ultraflex. All can be placed under local anaesthesia. Table 2 summarizes the principal series published on these devices. Only Urolume was studied according to strict prospective criteria (181) (LE 1-2). Using stringent clinical and statistical methods, they classified the stent as LE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with SCI (mean age 36.3 years) in 15 North American centres, were treated prospectively with Urolume for DSD. Urodynamic parameters for voiding pressure, PVR and functional bladder capacity were measured before treatment and then annually up to 5 years afterwards. Mean voiding pressure, the primary criterion, was significantly lower 5 years after stenting. PVR decreased significantly and was sustained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the remaining. Autonomic dysreflexia resolved in 70% of cases. The indwelling catheters could be removed in 63

Table 2. Main series of permanent prosthetic sphincterotomy

	Stent	Year	LE	n	Efficacy (%)	Mean follow-up (Months)	Migration (%)	Complications

Hamid et al. 2003 (173)	Urolume	2003	3	12	77	144	NR	16
Abdul-Rahman et al. 2010 (186)	Urolume	2010	3	12	80	144	0	80

of the 86 (84.9%) patients catheterized before surgery. The percentage of positive urine cultures remained unchanged after stenting. No cases of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. Fourteen cases of prosthetic encrustation occurred; one during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic incision in 20 cases). In the mid-term, prosthetic sphincterotomy using a Urolume stent appears to be satisfactory. However, the situation is not so clear over the longer-term. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis (182-185) (LE 3). A small study (n=12) following patients up to twenty years after insertion, suggests a high rate of complications, as 5/6 patients who completed the 20-year follow-up developed bladder neck dyssynergia requiring incision, 2 patients developed obstructive encrustations within the first year of insertion and another patient developed bladder cancer (186). However, in those patients who completed the 20-year follow-up, sustained significant improvements in maximum detrusor pressure and duration of detrusor contraction were recorded.

3.1.3. Prosthetic versus endoscopic sphincterotomy

Whether patients should be offered prosthetic or endoscopic sphincterotomy is not yet agreed. Endoscopic sphincterotomy is the preferred standard treatment for DSD when intermittent catheterisation cannot be performed. Two prospective studies carried out in the US in 1994 indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with SCI, and offered advantages in terms of morbidity, duration of hospitalization, and costs (188, 190). The two studies were not randomised. Follow-up was short (mean 15 months), with a potential risk of bias, since the conclusion that external sphincter balloon dilatation is as effective as endoscopic and prosthetic sphincterotomy is not borne out by long-term outcomes (191).

A prospective, multicentre, randomised study comparing endoscopic sphincterotomy with prosthetic sphincterotomy was published in 1999 by Chancellor and Rivas, using the Urolume stent (189). Fifty-seven patients in three specialised SCI centres were included. The study concluded that prosthetic sphincterotomy was as effective as endoscopic sphincterotomy and required shorter hospitalization. Polguer et al published their experience with the Ultraflex (n=11) and Memotherm (n=11) during 56 months in patients with DSD. Complementary procedures after stenting included five stent prolongations or displacements (mean interval 7.6 months), six bladder neck incisions (12.2 months), three urethrotomies (42 months), an ten obstructions treated by laser (47.3 months). Eight patients had a change of their urinary pattern: four underwent ileal conduit diversion, one had a continent urinary diversion, one chose intermittent self-catheterisation, two were under indwelling catheterisation waiting for another treatment. Stent retrieval was either harmful or impossible for four of them. Three patients were free of complementary procedures. They conclude that nitinol urethral stent was an effective treatment initially. However, after years urethral stenosis and hypertrophic growth of the urethral mucosa usually require extra endoscopic procedures (0.31 per patient per year). They recommend yearly endoscopic follow-up (192).

A recent study in 41 male patients with neurogenic DSD identified maximum detrusor pressure as a predictor of the success of either

prosthetic or endoscopic sphincterotomy. Twenty-six patients had a sphincteric stent placement (Memokath) and 15 had endoscopic sphincterotomy. The combined success rate was 76%. Significantly higher mean preoperative maximum detrusor pressure was recorded in patients with immediate successful outcomes (59.6 versus 29.7 cmH_2O; p=0.002), but also at 6 months (p=0.008). The threshold of 40cmH_2O for maximum detrusor pressure was associated with even higher success rates (≥90%). The technique used (stent placement or incision) had no impact on immediate or 6-month success rates (193).

3.2. Sphincterotomy

The aim of sphincterotomy is to produce reflex micturition into a condom catheter which acts as a pressure relieve valve, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to perform intermittent catheterisation. It is invasive, irreversible and the patient has no adaptation period (194, 195) (LE 3).

Sphincterotomy recommendation supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesico-ureteral reflux, autonomic dysreflexia or recurrent UTIs secondary to poor bladder emptying. Patients should have failed or refused intermittent catheterisation. Main contra-indications are (196, 197):

- Impossibility to retain a condom catheter. All sphincterotomy techniques (including stenting) are contra-indicated in men who cannot retain a condom catheter (hence also for women). A semi-rigid penile prosthesis can be placed to help retain the condom catheter (198) (LE 3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with SCI, as opposed to only 2.7% in the general population (199, 200) (LE 3).
- Detrusor acontractility or hypocontractility. Patients with SCI and no reflex detrusor contraction during urodynamics are poor candidates for the various techniques of sphincterotomy.
- Patients who wish to father children and are candidates for vibrostimulation or electro-ejaculation and an artificial insemination program.

Emmett et al. (201) first described in 1948 cervico-prostatic incisions as endoscopic sphincterotomy in patients with SCI, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross et al. (202). They carried out cold-blade surgery and placed a catheter (22-26 French) for tamponade, since nearly all patients required transfusion (one of the ten patients in the series died after surgery). A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later, but due to their complexity and frequent serious complications these approaches were abandoned (203, 204). Sphincterotomy with electrocoagulation was finally found to be the best technique. Besides the conventional transurethral electrocautery sphincterotomy, Perkash first reported in 1994 the use of contact neodymium-doped yttrium aluminium garnet (Nd:YAG) laser with similar results (205).

Endoscopic sphincterotomy morbidity includes haematuria, which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (LE 2-3). Incision at the twelve o' clock position, first described by Madersbacher and Scott in 1975 (206), seems to offer the lowest risk of haemorrhage, with three and nine o' clock sphincterotomies entailing the highest risk (207) (LE 4).

Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series (208-211) (LE 3). More recent series (Table 3, LE 2-3), most using a median, or slightly deviated incision, have not affected sexual function. However, it should be noted that the population concerned may have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction. When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. The fear of this sequel sometimes causes the patient to decide against surgery. The use of an incontinent prosthesis as first-line therapy can enable the patient to gain insight into this potential consequence of endoscopic sphincterotomy.

If striated sphincter section fails, the possibility of bladder neck stenosis should be investigated. This is seen in 2% to 21% of the patients (LE 2-3). Bladder neck incision may then improve voiding but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

Results of endoscopic sphincterotomy are summarized in Table 3 (LE 2-3). Any analysis is made difficult by the absence of unequivocal criteria of success. Some patients are improved by sphincterotomy, even with a PVR of 200 mL. Most authors use indirect urodynamic criteria to evaluate success (decrease in detrusor pressure during voiding, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic UTIs, although chronic bacteriuria is not improved (181). The reported results concerning resolution of hydronephrosis and vesico-ureteral reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients (195, 212, 213) (LE 3). Riccotone et al. (213) reported 82% recurrence of symptoms after ten years of follow-up (LE 3). Juma et al. (195) describe similar results after 11 years, with patients undergoing an average of 1.7 sphincterotomies (LE 3). Pan et al. (214) reported a mean duration of benefit of almost seven years, which could be sustained with a repeat procedure. Some impairment of the upper urinary tract can be developed in 30-68% of patients (195, 214), so regular monitoring after surgery is advised.

There is little evidence available to address predictive factors for a successful sphincterotomy. In a retrospective study by Pannek et al. (172), although detrusor leak point pressure and retrograde perfusion pressure were found to be superior to PVR in predicting sphincterotomy success, results were not statistically significant. On the other hand, a retrospective study by Hourié et al. (193) including patients who underwent surgical sphincterotomy (with electrocautery or laser) or urethral stent placement, showed that 90% of patients with a preoperative maximum detrusor pressure (Pdetmax) >40 cmH_2O achieved a successful outcome (PVR <150 mL) that was maintained at least 6 months after surgery; in contrast to 41% of patients with a Pdetmax below this figure (p=0.003). Another study by Takahashi et al. (215) also highlighted that the mean preoperative Pdetmax in the group that continued using a condom catheter after sphincterotomy (81.5 ± 6.0 cmH_2O) was significantly higher than that in the failure group (49.9 ± 8.5 cmH_2O).

Vainrib et al. (216) published their long-term data on 97 patients who underwent bladder neck incision with external sphincterotomy over a period of 40 years. During the period reviewed, a solitary redo bladder neck incision with external sphincterotomy was done in 46 patients, a second redo bladder neck incision with external sphincterotomy was done in 23 patients, and a third redo bladder neck incision with external sphincterotomy was done in 7 patients

with success rates of 50%, 68.2%, and 85.7%, respectively. The most common reasons to indicate a redo bladder neck incision with external sphincterotomy were elevated PVR and recurrent UTI. Remarkably, all patients had a normal serum creatinine level at the end of the follow-up. Mean elapsed follow-up after the last redo bladder neck incision with external sphincterotomy was 119 months (range, 6-408 months) for all patients evaluated. Mean durability of successful redo bladder neck incision with external sphincterotomy was 109.1 months.

Table 3. Studies of endoscopic sphincterotomy (all studies report on SCI patients)

	LE	Number patients	Mean Follow-up (months)	Success criteria	Redo rate
Pan et al. 2009 (214)	3	84	76	• Absence of recurrent urinary sepsis • No evidence of DSD in video-urodynamics • Stable upper tract on imaging • Eradication of detrusor overactivity • Primary procedure success rate: 32% • Secondary procedure success rate: 43%	35.70%
Perkash 2007 (217)	3	46	65	• * Previous sphincterotomy in 32.6% • Decrease systolic and diastolic blood pressure during urodynamics • Improved autonomic dysreflexia (91.3%) • Decrease in mean PVR • Decrease in maximum voiding pressure (not statistically significant)	4.35%
Chancellor et al. 1999 (181)	2	26	24	• PVR decrease • Hydronephrosis (100%), VUR decrease (100%) • Improved micturition comfort (80%) • Improved autonomic dysreflexia (100%)	8%
Catz et al. 1997 (218)	3	32	NR	• * Previous sphincterotomy in 43.75% • Significant decrease in PVR (84%) • Decrease in UTI (74%) • Disappearance of hydronephrosis (66%) and VUR (40%) • Improved autonomic dysreflexia (100%)	NR
Fontaine et al. 1996 (219)	2	92	20.6	• Decrease in hydronephrosis, VUR (100%, 90%) • Significant decrease in PVR, micturition pressure (83.7%) • Decrease in febrile UTI (76.7%) • Improved autonomic dysreflexia (93.2%) • Subjective improvement in 73%	8.10%
Noll et al. 1995 (194)	3	105	55.2	No statistical management of the data, but: • Improved autonomic dysreflexia (42% to 17%) • Decrease in mean PVR (180 to 70 mL) • Decrease in leak point pressure (from 97 to 37 cmH2O) • Decrease in frequency of UTI (8.1 to 3.6 per year)	30% standard sphincterotomy 15% laser sphincterotomy
Rivas et al. 1995 (220)	2	22	14	• Improved autonomic dysreflexia (44%) • Significant decrease in PVR, voiding pressure • Decrease in hydronephrosis (40%)	13.60%
Juma et al. 1995 (195)	3	63	132	• Renal function (creatinine): normal in 97% of patients • Upper urinary tract complications in 30% of patients: VUR, renal calculi, renal scaring, hydronephrosis, kidney atrophy	50.80%
Vapnek et al. 1994 (212)	3	16	39	• Eight patients using condom catheters • Eight patients with suprapubic cystostomy: recurrent UTI (high PVR), autonomic dysreflexia, skin problems	31.30%
Carrion et al. 1979 (221)	3	60	6-12	• VUR disappeared (86%) • Significant decrease in VUR: 75% • Decreased PVR: 65%	1.60%

DSD: detrusor-sphincter dyssynergia; LE: level of evidence; NR: not reported; PVR: post-void residual; SCI: spinal cord injury; UTI: urinary tract infection; VUR: vesico-ureteral reflux.

3.3. Urethrotomy

Urethral strictures are one of the most feared complications in neuro-urological patients because they could hinder lower urinary tract management. However, the available literature on the topic is scarce. Urethral strictures are thought to occur due to repetitive urethral trauma. They are more common in patients with indwelling urinary catheters (222, 223), although some authors have reported a higher rate in patients on intermittent catheterisation (224). Furthermore, it has been suggested that urethral strictures are more common in patients on intermittent catheterisation when they have had a previous indwelling transurethral catheter (225). Strictures appear more commonly in the bulbar urethra, but the penile urethra and the urethral meatus can also be affected.

Management of urethral strictures can be conservative with urethral dilatation or surgical with direct vision optical internal urethrotomy (226, 227).

Krebs et al. (224) (LE 3) identified 415 patients undergoing intermittent catheterisation, from which 105 men were diagnosed of stricture by a retrograde urethrography. However, only 38 men underwent internal urethrotomy (9.2%) due to intractable difficulties with intermittent catheterisation. During surgery, the stricture was incised at 12 o'clock with a cold knife, and if there was no bleeding, the catheter was removed after 24 h. Urethrotomy was repeated up to 5 times in 36.8% of patients with a median follow-up of 14 years. In the study by Cornejo-Dávila *et al.* (227) (LE 3), 14/333 patients on intermittent catheterisation (4.2%) developed urethral strictures. Twelve of them underwent internal urethrotomy with a single cold cut at 12 o'clock, and a 16-Fr silicone Foley catheter was placed for two weeks. At a mean follow-up of 1 year, no recurrence was noted.

3.4. Urethroplasty

The literature on urethroplasty (urethral reconstruction) in patients with NLUTD is sparse and there are only a few series involving a limited number of patients making comparisons among studies difficult.

Urethroplasty in the neurological patient has been considered a challenging procedure not only surgically but also due to postoperative complications and the high risk of recurrence, depending on the type of urethral injury, evidenced by the poor success rates historically reported (228-230). Different approaches have been described depending on injury characteristics such as erosion, stricture length, combined defects, tissue characteristics, previous interventions and the surgeon's experience. Penile grafts or skin flaps, primary closure in some cases of erosion, excision and primary anastomosis, and novel techniques for diverticula management has been used (231-234). There is no consensus of which technique will represent a better option for each patient, some classical concepts can be extrapolated from the urethral stricture management in the general population, and depending on the location, length, past medical history and surgeon's experience would be considered to take an appropriate decision (232, 234).

There is no actual evidence to emit any weighted recommendation about the proper surgical management of urethral stricture in SCI patients and limited information has been published about it.

Schreiter et al. in 1989 reported on 96 patients with complex urethral stricture who underwent a mesh graft urethroplasty using a split thickness skin graft or foreskin (228), but patient characteristics are not presented in this study, therefore outcomes in certain patients are difficult to acquire. In females, there are some reports that describe success rate for urethral closure up to 66% (229), appearing to be a promising approach for female urethral injury in patients with SCI.

Although urethral surgery in neurological patients has a generally high failure rate, some of the best series has shown success rates up to 70%, and as high as 85% for urethral stricture management as described by Casey in 2008 (230, 233, 234).

Anterior urethra seems to be the most affected urethral location after analysing the current available data. The most common site of injury is bulbar urethra followed by penile urethra, different series have reported up to 90% affection of bulbar urethra (230, 231, 233, 234). Erosion and stricture are the most common affection as showed in Table 4.

Techniques must be individualized depending on urethral lesion (erosion, stricture, diverticula, fistula, etc.), length, location, but it seems that urethroplasty using buccal mucosa graft, excision and primary anastomosis might be used as a safe and successful management in selected neurological patients (233, 234).

Many patient related factors can affect surgical outcomes, such as poor nutrition, low hygiene, lack of social support, environment and persistent insults to the involved tissues, all of them would probably contribute to negative results. When these issues cannot be adequately addressed, perhaps initial diversion is the best choice.

Table 4. Urethroplasty in patients with NLUTD

Study	Number of patients	Neurological disorder	Aetiology	Type of injury	Site of injury	Management	Result	Comments
Andrews et al. 1998 (229)	18 (women)	MS=6 SCI=6 Other causes=6	Traumatic due to indwelling catheter	Not described	Female urethra	Closure=18	Success rate 66%	12 patients were dry and 6 leaked after management
Secrest et al. 2003 (230)	18	SCI=16 Other causes=2	Traumatic due to intermittent catheterisation	Erosion=4 Stricture=6 Diverticula=1 Fistulae=3 Combined=3	Erosion anterior urethra=9 Stricture bulbar urethra=2 Penile urethra =2 Not described= 2	Urethroplasty=13 Diverticulectomy=2 Extensive reconstruction=1 No reconstruction=1 Skin flap, Byars flap=1	33% success rate	11 patients required further urinary diversion
Ronzoni et al. 2004 (233)	48	SCI=48	Traumatic due to indwelling catheter	Diverticula=48	Bulbar urethra=43 penile urethra=5	Urethroplasty Monseur modified technique=48	Non clear results reported with this management	26 patients reported positive outcomes 15 years after procedure
Casey et al. 2008 (234)	23	SCI=16 Others=7	Traumatic due indwelling catheter=10 Traumatic due to intermittent catheterisation=5 Others=8	Erosion=10 Stricture=7 Others=6	Penile=15 Bulbar=7 Penobulbar=1	Erosion Primary closure=5 Urethroplasty=5 Stricture Urethroplasty=7 (EPA=4, BMG=3) Others=6 (diverticulectomy=4, primary fistula closure=2)	Overall success in 69% patients	60% success for erosion 85% success for stricture 66.6% for diverticula and fistulae
Meeks et al. 2009 (231)	11	SCI=11	Traumatic due indwelling catheter =9 Not described=2	Erosion=11	Penile urethra=11 No stricture identified	Primary closure=6 Urethroplasty=3 (substitution with penile skin graft)	63% success rate	4 patients had recurrence, more frequent with flap use

SCI: spinal cord injury; MS: multiple sclerosis; EPA: excision and primary anastomosis; BMG: buccal mucosa graft

3.5. Transurethral resection or incision of bladder neck and other de-obstructive surgeries

3.5.1. Transurethral resection or incision of bladder neck

Currently, patients with NLUTD who cannot void safely from a video-urodynamic standpoint are usually managed with intermittent catheterisation instead of undergoing transurethral resection of bladder neck (TURB) or transurethral incision of bladder neck (TUIBN). Therefore, most studies cited in this section are relatively old retrospective studies, which means that many studies include subjects treated before the widespread use of intermittent catheterisation. These include:

- SCI: 7 studies in the 1970's (235-240), 2 in the 1990's (241, 242), and 2 in the 2010's (216, 243)
- MS: 3 studies in the 1970's (244-246) and 1 in 1980's (247)
- Diabetes mellitus: 1 study in 1970's (248)
- Other aetiologies: 1 study in 1970's (249)

3.5.1.1. Spinal Cord Injury (SCI)

TURBN and TUIBN are performed to achieve a balanced bladder function as well as a decrease in the incidence of recurrent UTI and an improvement of an impaired upper urinary tract in patients with NLTUD who are managed with an indwelling catheter or with

voiding despite an unbalanced bladder. The subjects in each study are mainly male and relatively small in number: less than 50 cases, 5 articles; 50 to 100 cases, 3 articles; and more than 100 cases, 3 articles. Only one study (243) clearly mentioned that demonstrating detrusor bladder neck dyssynergia on video-urodynamics was an indication for TUIBN. It should be kept in mind that 9 of 11 studies on SCI included patients undergoing sphincterotomy and/or transurethral resection of the prostate (TURP). As expected, in SCI, sphincterotomy is needed to overcome a concomitant functional obstruction at the membranous urethra due to DSD when TURBN/TUIBN fails or they occur in a combined manner. Although complete high-level SCI would frequently require a sphincterotomy (237), whether it should be performed simultaneously or sequentially remains to be determined. In TURBN, a 3- to 9-o'clock resection is a popular procedure (235, 236, 239), while circumferential resection as well as resection of prostate tissue down to the verumontanum is also reported (237, 242). In all but one (6-o'clock incision, (238)) TUIBN, 5- and 7-o'clock incisions are performed.

3.5.1.1.1. Transurethral resection of bladder neck (TURBN)

3.5.1.1.1.1. Efficacy

It should be noted that endpoints and the time of evaluation for TURBN are not standardized, and that many studies include patients with simultaneous as well as sequential sphincterotomy. The main efficacy outcomes are:

- Catheter free: 75% (235) or 35% (TURBN alone) to 58% (TURNB followed by sphincterotomy) (242)
- Balanced bladder: 12% (TURBN alone) to 58% (TURBN followed by sphincterotomy) (242)
- Free of UTI: 60% (235)
- Sterile urine: in upper motor neuron lesion, 17% (males) and 33% (females); in lower motor neuron lesion, 50% (males) and 25% (females) (236)
- PVR <100 mL: 20% (235) to 55% (TURBN alone) (239) and 50% (235) to 79% (TURBN combined with sphincterotomy) (239), in upper motor neuron lesion, 67% (male) and 17% (female); in lower motor neuron lesion, 50% (male) and 75% (female) (236)
- Improvement of hydronephrosis: 74% (235)

3.5.1.1.1.2. Re-operation

The rate of re-operation varied: 9.4% (235), 13% (236), and 18% (239). O'Flynn et al. (237) reported that of 139 SCI patients who underwent bladder outlet surgery including sphincterotomy, 72 patients (52%) underwent various secondary procedures. Fifty-six per cent of these 72 patients initially underwent TURBN, while 31% of them initially underwent TURBN combined with sphincterotomy (237). Moreover, secondary procedures were more likely to be necessary in complete and high-level lesions; 59% of complete cervical lesions, 57% of complete thoracic lesions, and 50% of complete lumbar lesions, required a secondary operation (237).

3.5.1.1.1.3. Complications

Although complications were not reported in a standardized manner in the cited literature, postoperative bleeding, ejaculatory dysfunction, and sepsis as well as renal dysfunction occurred with low frequency (235-237, 239-242).

3.5.1.1.1.4. Predictive factors

Fellows et al. (239) reported that a closed bladder neck on cystourethrogram did not predict efficacy of TURBN, while cervical SCI patients with maximum urethral closure pressure higher than 100 cmH_2O never benefited from TURBN. Al-Ali et al. (241) reported that based on their previous operative outcomes, they planned to perform TURBN combined with sphincterotomy for complete SCI or SCI above T9 and TURBN for incomplete SCI below T9; this was the only prospective cohort of the cited reports in this section. As a result, no patients required an additional sphincterotomy after TURBN with a decrease in PVR (320 mL to 30 mL) and a decline in infected urine (70% to 23%) (241).

3.5.1.1.2. Transurethral incision of bladder neck (TUIBN)

Morrow et al. (250) performed TUIBN combined with sphincterotomy on 75 patients with NLUTD (SCI: 72, myelomeningocele (MMC): 2). Seventy-seven per cent of the patients who needed indwelling catheterisation preoperatively were freed from catheter, while all the 32 patients who had large PVR preoperatively showed a clinically significant decrease in post-void residual. Hydronephrosis improved in 88% of the patients who had hydronephrosis preoperatively. The incidence of UTI decreased in most patients, while sterile urine persisted in the long-term in only 8 patients. Twenty-three per cent of the patients who underwent surgery for the intention of removing the indwelling catheter and 6.3% of the patients for the intention of decreasing PVR needed re-operation. In terms of complications, post-operative bleeding and urethral injury occurred in 9.3% and 1.3%, respectively. In addition, they evaluated erectile function in these patients (239), which showed complete/permanent loss of, diminished, and unchanged/improved erectile function in 8.2%, 16.8%, and 74.8%, respectively.

Sharpe et al. (240) reported that after TUIBN in 21 female patients with NLUTD (SCI and MS: 50% each), 33% of them achieved PVR <50 mL as well as urinary continence without medication and UTI, while 48% of those achieved PVR <50 mL with carbachol as well as one UTI or one minor procedure. Although only two patients needed repeat TUIBN, UVF and stress urinary incontinence occurred in 3 and 1, respectively. Two other retrospective studies (216, 243) were published in 2010's.

Ke et al. (243) evaluated outcomes of TUIBN in 22 SCI patients (above mid-thoracic-level) with detrusor bladder neck dyssynergia by video-urodynamics with or without autonomic dysreflexia (AD) (216). A decrease of more than two points in IPSS QOL was obtained in 83% of the patients, while 86% of them became able to empty their bladder by reflex voiding with an open sphincter. DSD and AD disappeared in 27% and 88%, respectively. High detrusor pressure (>15 cmH_2O) was improved in 70% of the patients with high detrusor pressure, while mean detrusor pressure (45.7 to 26.1 cmH_2O), and mean maximum flow rate (Qmax) (3.7 to 8.3 mL/s), and mean PVR (288 to 110 mL) improved significantly in them. Moreover, in the patients with low detrusor pressure (<15 cmH_2O), all the patients showed a significant increase in mean detrusor pressure, and mean detrusor pressure (6.0 → 26.9 cmH_2O), mean maximum flow rate (0.46 to 12.1 mL/s), and mean PVR (369 to 117 mL) improved significantly. Eventually 82% of the patients became catheter-free or decreased the frequency of CIC. No postoperative complications were encountered. The AIS scale, level of SCI (between cervical and thoracic cord), time from SCI, type of DSD, and the presence or absence of AD did not affect the clinical outcomes.

Vainrib et al. (216) performed TUIBN combined with sphincterotomy in an earlier period and the suitable procedures based on the findings of VUDS in the later period. They retrospectively reviewed outcomes in 97 SCI patients. Success rates were 53%, 50%, 68%, and 86% after 1st, 2nd, 3rd, and 4th, operation, respectively. Postoperative bleeding was a main complication, and urosepsis occurred in one patient.

3.5.1.2. Multiple sclerosis (MS)

Jakobsen and collaborators (244-246) as well as Petersen et al. (247) retrospectively reviewed outcomes of TURBN for patients with MS, which were published in the 1970's and 1980's. The indications for TURBN were not clearly mentioned in their studies.

Jakobsen et al. (244-246) performed various surgeries that mainly included 3- to 9-o'clock TURBN in the earlier period and circumferential TURNB in the later period in 139 MS patients. At 6 months postoperatively, 50% of the patients with complete urinary retention were rendered catheter-free, while 97% of patients with occasional retention were rendered retention-free (244). Voiding difficulties decreased in more than 60% of patients, and about 50% of patients did not complain of any voiding symptoms postoperatively (244). The mean reduction in PVR was 30% (244). Sixty-one per cent of the patients with urgency urinary incontinence improved with 35% becoming continent (245). Urinary continence was maintained in 34 of 35 patients who were continent preoperatively (245). Eventually 23% of the patients showed complete resolution of storage/voiding symptoms or very mild residual symptoms (245). Pyuria and symptomatic UTI disappeared in 36% and 70% of the patients, respectively (244). The re-operation rate was 53% (251). Complications reported were postoperative bleeding (6.5%), UTI (2.2%), sepsis (0.7%), and fever (19%) (246). It should be noted that 33% of the patients showed neurological progression during the observation period (244).

Peterson et al. (247) evaluated 21 female detrusor overactivity patients (MS: 18, other aetiologies: 3). At 3 months postoperatively, urinary incontinence episodes were significantly reduced (2.5 to 1.3 times/d) with 58% of the patients improved. Although improvement in symptoms did not correlate to urodynamic findings, urodynamic studies revealed a significant increase in volume of the first detrusor overactivity and effective bladder volume with a 33% reduction in PVR in patients showing symptomatic improvement.

3.5.1.3. Diabetes mellitus

Zincke et al. (248) reviewed outcomes of TURBN in 39 patients with PVR more than 50 mL: 23 patients had diabetic cystopathy, 11 had diabetic cystopathy with benign prostatic hyperplasia, and 5 had diabetes mellitus with benign prostatic hyperplasia. PVR was reduced to less than 50 mL in 56% and to 50−200 mL in 13%, while sterile urine was achieved in 53%. Eventually, excellent to good results were obtained in 74%. Postoperative urinary incontinence occurred in two patients.

3.5.1.4. Other aetiologies

Petri et al. (249) reported outcomes of TURBN or TUIBN in 86 neuro-urological patients with various aetiologies (MMC, MS, SCI, lumbar prolapsed disc, cerebrovascular disease, abdominoperineal resection, and abdominal radical hysterectomy), in which the indication for the procedures was large post-void residual or UUI. Symptomatic improvement was attained in 72% and 80% in TURBN and TUIBN, respectively. PVR disappeared in 38% and decreased in 41%, while urinary incontinence decreased from 8% to 3%. Sixty per cent of the patients had persistent UTI preoperatively, and sterile urine was achieved in 18% postoperatively. Re-operation was performed on 2%. Postoperative bleeding and VVF occurred in one patient each.

3.5.2. Other de-obstruction surgeries

Apart from TURBN and TUIBN, most studies evaluated outcomes of TURP for benign prostatic hyperplasia as de-obstruction surgeries in NLUTD (236, 251-260). Laser enucleation as well as vaporization of benign prostatic hyperplasia, urethral lift, and prostatic stent have not been evaluated in patients with NLUTD.

3.5.2.1. Spinal cord injury (SCI)

Only one study retrospectively evaluated outcomes of TURP in 17 SCI patients (236). Although the indication for TURP was unclear, sterile urine was attained in 18% and 17%, respectively, of patients with upper and lower motor neuron lesion, and PVR decreased to less than 100 mL in 64% and 50%, respectively.

Koyanagi et al. (252, 253) retrospectively reviewed outcomes of radical TURP in 89 SCI patients. Radical TURP is different from conventional TURP because authors resected not only the transition zone but also the peripheral zone, which was named surgical sympathectomy or modified sphincterotomy by the authors. The indications for radical TURP were 1) inability to void after maximum conservative management, resulting in permanent indwelling or intermittent catheterisation, 2) inability to void efficiently as well as safely (PVR rate >20%, Qmax <1.7 mL/min, detrusor pressure >70 cmH2O); or 3) the presence of hydronephrosis, renal impairment, bladder deformity, VUR, and prostatic reflux on imaging studies. Success was defined as stable voiding efficiency, catheter-free status, and no exaggeration of upper urinary tract deterioration. The final success rate including 12 patients undergoing additional procedures was 90%. Mean PVR rate (44% to 9%) and mean maximum flow rate (0.9 to 3.4 mL/s) significantly improved. On imaging studies, VUR was resolved in 65% and improved in 23%, while hydronephrosis and bladder deformity were resolved in 90% and 81%, respectively. On urodynamic studies, mean bladder compliance significantly improved (29.0 to 51.5 mL/cmH_2O), while detrusor overactivity disappeared in 40% and was suppressed in 47%. Interestingly, DSD was resolved in 29% and reduced in 52%. Postoperative urinary incontinence developed in one patient. No groups other than Koyanagi's group have reported outcomes of radical TURP in SCI patients.

3.5.2.2. Cerebrovascular disease

One study (254) using claims data from Taiwan's National Health Insurance Research database compared outcomes of TURP between cerebrovascular and non-cerebrovascular disease patients. Compared with non-cerebrovascular disease patients, cerebrovascular disease patients showed significantly more postoperative UTI (odds ratio 1.37), postoperative urinary retention (odds ratio 1.89), in-hospital mortality from 1 month to 12 months (odds ratio 8.27), and worse medication-free survival rates (hazard ratio 1.24). In addition, significantly more cerebrovascular disease patients used α-blockers at 3 months (odds ratio 1.41) and bethanechol until 12 months (odds ratio: ～1.39−1.55), compared with non-cerebrovascular disease patients. Interestingly, the use of anticholinergics showed no significant difference between the two groups.

Lum et al. (255) and Moisey et al. (256) reported outcomes of TURP or open prostatectomy in patients who had a prior history of cerebrovascular disease. Preoperatively, 56% and 73% of their patients, respectively, suffered from urinary retention.

Lum et al. (255) showed that 50% of the patients had satisfactory results (urinary continence with good flow) that were associated with the site of cerebrovascular disease (85% of left-side lesions, 31% of right-side lesions, 0% of bilateral lesions, and 50% of brain stem lesion), time from cerebrovascular disease (77% of cerebrovascular disease >12 months), and neurological deficit (67% of grade 1 patients, 53% of grade 2, and 17% of grade 3).

Moisey et al. (256) reported that 73% of the 28 patients regained normal micturition, while six cases who continued abnormal micturition had poor recovery from cerebrovascular disease and additional neurological co-morbidities.

3.5.2.3. Parkinson's disease (PD)

Staskin et al. (251) and Roth et. al. (257) retrospectively reviewed outcomes of TURP in patients with PD, while Chandiramani et al. (258) reported clinical characteristics and therapeutic outcomes in patients with PD and multiple system atrophy (MSA), which included patients with PD (n=11) and MSA (n=5) undergoing TURP.

Staskin et al.(251) reported that in 36 patients with PD, the rate of urinary incontinence increased from 17% preoperatively to 28% postoperatively. Moreover, de novo urinary incontinence developed in 20%. Voluntary regulation of the external urethral sphincter evaluated by concentric needle electromyography was strongly associated with the postoperative continence status: of 26 patients with normal external urethral sphincter control, 25 patients were continent postoperatively, while of 10 patients with abnormal external urethral sphincter control, only one patient was continence postoperatively.

Roth et al. (257) reported that 16 of 23 (70%) patients improved after TURP. Significant improvement was demonstrated in median IPSS (19 to 7), median IPSS QOL (4 to 2), maximum flow rate (5 to15 mL/s), and median voided volume (110 to 330 mL). Ten patients had urgency urinary incontinence preoperatively, which resolved in 5 and improved in 3. No patient developed de novo urinary incontinence. Age, Hoehn and Yahr scale, and time from onset of PD were not significantly associated with the clinical outcomes of TURP. Roth et al. (257) speculated that the patients who showed de novo urinary incontinence in Staskin's study probably suffered from MSA, not PD. Therefore, Roth et al. (257) concluded that "PD should no longer be considered a contraindication for TURP provided that preoperative investigations including urodynamic assessment indicate prostatic bladder outlet obstruction. For these patients we strongly recommend urethral or anal sphincter electromyography. This is a robust investigation for supporting the diagnosis of MSA as selective atrophy of the anterior horn cells that innervate the urethral and anal sphincter is a characteristic feature of MSA but not of PD."

The results of the study reported by Chandiramani et al. (258) were almost in line with the previous studies described above. TURP brought about good results in 3 of 5 patients with PD, while of 11 patients with MSA, urinary incontinence was exaggerated in 9 patients and urinary incontinence was temporarily improved in the remaining two patients, but recurred within one year postoperatively. Eventually, no patients with MSA regained urinary continence.

3.5.2.4. Diabetes mellitus

Two studies compared outcomes of TURP between diabetic and non-diabetic patients, but neither study mentioned the presence or absence of diabetic cystopathy (259, 260).

Soleimani et al. (260) showed that the decrease in IPSS was insignificantly larger in non-diabetic compared to diabetic patients. The rates of perioperative complications also did not differ significantly.

Lin et al. (259) used Taiwan's National Health Insurance Research database and showed that postoperatively, diabetic patients had significantly less UTI (odds ratio 0.78), higher urinary retention (odds ratio 1.35), and worse medication-free survival (hazard ratio 1.14) compared with non-diabetic patients. In addition, significantly more diabetic patients used anticholinergics within three months (odds ratio 1.23) and α-blockers from three to 12 months (odds ratio 1.18), compared with non-diabetic patients.

3.6. Bulking agents

Despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with neuro-urological disorders (4, 261).

3.7. Urethral slings

3.7.1. Autologous sling procedures

In women with NLUTD, the use of an autologous fascial sling (usually close to the bladder neck) has been widely used to treat stress urinary incontinence. The aim of the procedure is to compress the urethra and to elevate it to an intraabdominal position to create resistance and thus increase the passive bladder outlet resistance and leak point pressure. In men, the sling can be placed just distal to the prostatic urethra or a the bladder neck (262).

The tissue more frequently harvested, especially when concomitant bladder augmentation is considered, is the rectus fascia, but *fascia lata* and bladder pedicles are also used (262, 263). It is common to perform the sling procedure in conjunction with other procedures such as bladder augmentation; long-term series have shown that, when the patients only underwent the sling, 12-30% of them developed afterwards increases in detrusor pressure and/or uninhibited contractions leading to review of anticholinergic therapy or augmentation (264-266). The most extended approach is open surgery, although robot-assisted surgical series have been described when bladder neck procedures with bladder neck sling and appendicovesicostomy are performed (267).

In a systematic review performed by the EAU Guidelines on Neuro-Urology group, it has been shown that reporting on stress urinary incontinence surgeries in neuro-urological patients is heterogeneous, identifying 16 different outcome parameters and nine definitions of cure, mainly using subjective outcome parameters (268). Table 5 summarizes the results of published case series. Complete continence is observed in 57 to 89% of the patients (LE 3). Some series suggest that girls have better outcomes than boys (263, 269-271). It should be emphasized that many patients will be dependent on bladder emptying using intermittent catheterisation or suprapubic catheterisation, because the patient's neurological dysfunction may preclude voluntary voiding and because the sling is usually inserted under tension in order to compress the urethra, correcting neurogenic intrinsic sphincter deficiency. All the series report a low morbidity rate from the procedure, including urethral erosion.

3.7.2. Suburethral synthetic slings

Midurethral synthetic slings have taken a major role in the management of stress urinary incontinence in the non-neuro-urological population, but limited evidence is available regarding neurogenic stress incontinence; concerns about the risk of urethral erosion due to the high tension needed to compress the urethra have been raised (272) (LE 3). Furthermore, intrinsic sphincter deficiency represents the usual pathophysiology in neurogenic stress urinary incontinence, contrasting with urethral hypermobility in non-neurological women.

Data on the efficacy of midurethral tension-free tape operations in adult women with NLUTD is scarce. Both the retropubic and the transobturator route have been used, including single-incision mini-slings (273). Table 6 summarizes the available evidence on the topic; studies with less than 12 months of follow-up and in which mi-

durethral slings were performed concomitantly to other procedures have been excluded. Continence rates range from 50 to 83.3%, and urethral erosion or other complications are rare. Hamid et al. have published two studies reporting on the results of 12 women with neurogenic stress urinary incontinence due to different spinal lesions (traumatic, stenosis and lumbar surgery) undergoing a retropubic midurethral sling with a median follow up of 2.3 (274) and 10 years (275). Although 3 patients were lost from follow-up in the second study, continence rate was acceptably maintained (83.3 and 77.8, respectively).

El-Azab *et al.* (276) reported a prospective, non-randomised study in 40 adult women with spinal pathology at or below S2 and neurogenic stress urinary incontinence comparing pubovaginal slings (n=20) with synthetic midurethral slings (n=20); inclusion in either group depended on the preference of the patient and surgeon. Cure rates were 80% for the midurethral and 85 % for the pubovaginal sling group; one patient had mesh erosion. Both groups showed significant reductions in UDI-6 and IIQ-7 scores after surgery.

The role of male synthetic slings in post-prostatectomy incontinence is well defined, but little evidence is available for patients with neurogenic stress urinary incontinence. Table 6 summarizes the available evidence. Initial experiences with small case series on MMC and SCI patients report a dry rate of 45-56% (277-279). Attention should be paid to possible infection of the sling and abscess formation. The use of synthetic male slings should be very cautious until further data emerge from clinical trials (LE 4).

3.8. Artificial urinary sphincter (AUS)

The AUS is recognized as one of the most effective treatments for stress urinary incontinence. It has the inherent advantage that it provides an adequate urethral closure pressure during the urine storage phase of the micturition cycle but then allows voiding to take place in the face of a low bladder outlet resistance. In patients with stress urinary incontinence, it can provide either complete or "social" continence in 75% to 87% with satisfaction rates ranging between 85% and 95%. These rates are provided by published case series that mostly include patients with post-prostatectomy stress urinary incontinence, along with some neurological patients. However, outcomes are probably similar for patients with neurogenic stress urinary incontinence and a low-pressure bladder reservoir (LE 4) (287). It should be noted that most of the published data on the use of the AUS in neurogenic stress urinary incontinence relates to men, although the device is also used in female patients with neurological disease in few case series (LE 3) (288-291).

Before using the AUS in neurogenic stress urinary incontinence, several factors must be considered:

- The risk of implant infection and erosion is probably higher than in the post-prostatectomy stress urinary incontinence population. It is generally recommended that patients undergo pre-operative urine culture and sterilization of the urine before surgery (292) (LE 4). A recent study has evaluated the risk AUS and/or penile prosthesis infection in patients with untreated asymptomatic bacteriuria and patients with negative urine culture and found no difference in infection rate between both groups over 15 months follow up and only 7% of the infected devices showed the same organism as in pre-operative urine culture (LE 3) (293).
- Manual dexterity must be sufficient to allow the patient to use the AUS pump - either to open the cuff to urinate, or to allow intermittent catheterisation (287). They must also accept the need for intermittent catheterisation should the bladder have reduced contractility. However, some studies seem to indicate that the cycling activation of the pump could be avoided in patients performing intermittent catheterisation (LE 3) (294, 295). Bersch et al. (294) have described a modified technique.
- The cuff implantation site in adult patients with NLUTD is debated. The cuff can be implanted via a retropubic approach at the level of the bladder neck or around the prostatic apex. Alternatively, the cuff can be implanted around the bulbar urethra using a perineal incision. Proponents of the retropubic approach argue that perineal incisions may cause healing problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS (296) (1 to 5.5% in contemporary series), although it is recognised that intermittent catheterisation is possible in AUS implanted patients (297), the risk of traumatic catheterisation and subsequent cuff erosion might be higher when the bulbar urethral site is used. Recent study looked at the difference between a cohort of patients who underwent bladder neck or peri-bulbar cuff implantation that have found no difference in risk of erosion in univariate or multivariate analysis between bladder neck or peribulbar cuff site. The only factor that has been associated with reduced device survival was the use of intermittent catheterisation (LE 3) (298). Bladder neck cuffs are usually larger, which might allow the passage of large bore rigid cystoscopes if needed for treatment of bladder stones for instance (LE 4) (299). On the other hand, inserting an AUS cuff around the bladder neck is technically more difficult in adults in comparison with peri-bulbar implantation (LE 4). Laparoscopic approach has been used for bladder neck sphincter implantation (LE 3) (289, 300-306). The use of robot assisted approach have described in men but mostly in women (290, 291, 307, 308) with acceptable short term follow up results in experienced centres (LE 3). One study has compared robotic female AUS implantation to open approach and found comparable continence rate and lower peri-operative complications in robotic group (LE 3) (309). Challenges in robotic approach have been described. Inadequate measurement of the cuff size due to loss of tactile sensation might lead to oversizing of the cuff and failure of the procedure which will require cuff revision (LE 4) (310).
- It is necessary to know the ejaculatory status of males in order to discuss the possible impact of the device on ejaculatory function. Cuff implantation around the bladder neck may allow patients to achieve antegrade ejaculation (311) (LE 4).

A thorough urodynamic evaluation of the bladder is mandatory in order to evaluate the potential impact of bladder compliance following AUS implantation. This has been reported in several retrospective series (LE 3) (262, 283, 294, 296, 312-323). The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with MMC (316, 318-320, 322). In the event of any doubt about the quality of the bladder reservoir, bladder augmentation should be performed. The main results of published series are summarized in Table 7. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients). The risk of infection when bladder augmentation is done simultaneously was found to be similar if it was done staged and similar to the risk of infection if no augmentation is done (LE 3) (303, 323), but earlier infection was noted in patients with simultaneous AUS and augmentation in one study (LE 3) (324).

The oldest series include some patients with the previous version of the AMS 800 (AMS 792); Therefore, it is possible that the long-term outcomes for patients being implanted today may be better than those seen in the past as a result of technical modifications of the device. Device infection, cuff erosion into the urethra and loss of fluid from the implant are the main causes of loss of an AUS. Infection and erosion typically occur in the early months after implant but late erosions are seen (315) (LE 3). The majority of the authors consider AUS to be the "gold standard" procedure to treat neurogenic stress urinary incontinence in men (LE 3).

In a systematic review of 30 case series, comparing outcomes of various treatment options for stress urinary incontinence in neurological patients, bulking agents were found inferior to AUS (77+/-16% versus 27+/-20%, P = 0.002) but not with sling procedure (58 +/- 25%). The overall continence rate of AUS was lower in neurological patients (77%) than reported in the literature in non-neurological patients (approaching 100%). The overall complications (AUS 32 +/- 27%, slings 14 +/- 14%, bulking agents 4 +/- 6%) and reoperation (AUS 51 +/-25%, slings 7 +/- 9%, bulking agents 12 +/- 14 %) were higher in AUS in comparison to urethral bulking agents and urethral sling procedures (LE 3) (325).

Few case series have evaluated the use of AUS in women with and without NLUTD by open, laparoscopic and robot assisted approaches around the bladder neck (LE 3) (288-291, 309, 326, 327). The overall continence, complication, and reoperations are comparable to male AUS cases in intermediate to long term in expert centres (LE 3), which might limit the generalisation of these results. There are no randomised studies comparing the female AUS to other treatment options in female neurogenic stress urinary incontinence such as fascial slings and spiral slings.

To conclude we have to knowledge the good performance of AUS in neurological and non-neurological patients and the relative du-

rability of the device if we accept minor revisions (such as pressure balloon change) as part of the normal life of an AUS. Recent long term follow- up articles are encouraging but emphasise the need to keep these complex surgeries in the hands of specialised centres (328-332).

**** AUS modified***

*****AUS modified and two groups of patients depending of their age at AUS***

3.9. Adjustable continence devices

Options beyond AUS comprise autologous bulbar and pubo-cervical slings, alloplastic static sub-urethral slings (transobturator or retropubic), adjustable periurethral balloons, bulking agents, and re-adjustable sling type devices such as ATOMS®, Virtue®, transobturator adjustable slings and retropubic like REMEEX®.

Rudimentary perineal urethral compressions were abandoned before 1980 due to ineffectiveness, the difficulty of dissection and the poor results (287). Grégoir (334) in 1956 had already proposed the use of urethral suspension for the management of stress urinary incontinence, and he specified the use of fascia bands in contact with the membranous urethra with strong tension. This Grégoir principle has resurfaced and given way to the use of tension-free vaginal tapes. Autologous slings in the overall male neurological population present a complete continence rate of 58 +/- 25% and a failure rate of 22 +/- 22%. The complication and re-operation rate are 14 +/- 14% 7 +/- 9 %, respectively (325).

Studies on synthetic sub-urethral slings are scarce in this subset of patients. Bulbourethral slings were described in patients after radical post-prostatectomy stress urinary incontinence by Schaeffer et al. with a total or partial success rate of 75%, reoperation erosion and infection of 27%, 6% and 3%, respectively (335). While there is a growing interest in the minimally invasive management of neurogenic stress urinary incontinence in men, the evidence is still very limited.

There are retrospective studies in patients with SCI or MMD and neurogenic stress urinary incontinence that are low-level evidence from small samples and retrospective design. In a 2001 study, Comiter reported the use of a polypropylene sling anchored to the pubic bone in 21 male patients with stress urinary incontinence of which only 1 had a neurological aetiology (MMC) with neurogenic overactive detrusor. The continence rate in this study was 76% including the patient with MMC, with no infection and no erosion of the tape (336). The only reported series on the use of the male readjustable system MRS II REMEEX® in neurological patients showed not very promising outcomes. Pannek et al. (279) presented a retrospective series of 16 SCI patients with neurogenic stress urinary incontinence showing the results of the use of re-adjustable sling REMEEX® (n=3) and non-adjustable male alloplastic transobturator tape sling (n=13). None of the patients managed with REMEEX® improved, i.e. none achieved continence. In addition, one patient required removal of the tape because of infection and in another a perineal abscess with urethral erosion occurred that required urethral sealing and permanent derivation with suprapubic tube. Ammirate et al. reported initial experience using the adjustable transobturator male sling (ATOMS®) in 8 males with stress urinary incontinence due to MMC and cauda equina syndrome. During a 12 months follow-up, they reported complete continence in all of the patients and a low complication rate (2 grade 1 complications according to the Clavien-Dindo system) (279).

The use of adjustable devices in neurogenic stress urinary incontinence is underreported. Fears regarding infection and urethral complications such as erosion precludes its use in patients who catheterize their bladders transurethrally. Since small case series is the only actual evidence concerning efficacy and safety of REMEEX® or ATOMS® in the neurological population and the outcomes were unfortunate, with 2 relevant infectious and no efficacy for the REMEEX ® and too short follow-up for ATOMS®.

Adjustable continence therapy has surge as an option in male and female neurogenic stress urinary incontinence. It consists of two silicone balloons attached to a titanium port each one though a tube. Retrospective, small series including SCI patients demonstrate a 44% continence rate per patient and 41% per device, with 19% rate of erosion, 6% infection, 31% explantation, none of them requiring subsequent AUS (337).

At a long term of 48 months of follow up in a neurogenic population (males and females) 92% of whom performed clean intermittent catheterization, 55% indicated more than 50% improvement of incontinence of whom 39% were fully continent (338).

Rate of migration is lower in patients with upper motor neuron lesion compared to those with lower motor neuron lesion.

A recent study specifically assessing ProACT device in female neurological versus non-neurological population found no significant continence difference, 39% versus 36% respectively (p=0.69, improvement rate 31% and 34% or overall complications (24% versus 35%) or explantation rate (20% versus 19%) (339).

3.10. Bladder neck and urethral reconstruction / closure

Complete bladder neck or urethral closure of the bladder outlet may be required if alternative approaches to manage refractory stress urinary incontinence or incontinence associated to urinary fistulae were inappropriate or have failed. This procedure can be considered especially in SCI patients with untreatable osteomyelitis due to urinary fistulae draining through the scars (340). In women, bladder neck closure can be achieved either via a vaginal or an abdominal approach. In men we use an abdominal approach. In some cases without severe perineum lesions the urethra can be closed through a vaginal incision in women or períneal incision in men (341). More recently, a robotic approach has been used with success to perform surgeries in the bladder neck including its closure (267). Bladder drainage is maintained using a continent catheterisable abdominal conduit (Mitrofanoff or Monti procedure using large or small bowel), a suprapubic catheter or an ileo-vesicostomy (342). In a single surgeon series in 35 patients with 4-13 years follow-up, bladder neck closure was done simultaneously with suprapubic catheter diversion. Indications for bladder neck closure included severe urethral erosion in 80%, decubitus ulcer exacerbated by urinary incontinence in 34%, urethrocutaneous fistula in 11%, and other indications in 9%. The overall complication rate was 17%. All but two patients were continent at follow-up (343).

In a retrospective series, suprapubic catheters seemed to be associated with fewer complications and emergency rooms admissions than Mitrofanoff or ileo-vesicostomy procedures (344). Bladder neck or urethral closure can be technically difficult and a secondary operation to close a persistent fistula may be needed in some cases (345). Interposing vascularised tissue between the bladder neck suture line and the urethral or vaginal closure is a well-described aid to the avoidance of closure failure; a flap of rectus abdominis can be used for this purpose. Bladder neck closure has also been used in children where other means of correcting SUI have failed or are felt to have a limited chance of success. The published series of cases provided some reassurance that children with closed bladder necks do not suffer from excessive complications in the form of renal deterioration, bladder rupture or stone formation. As a general principle, urethral closure should not be undertaken in cases where it is possible to maintain urethral patency using alternative approaches to treat stress urinary incontinence. For example, patients with NLUTD are at high risk of stone formation in the bladder or upper tracts and it is desirable to maintain easy endoscopic access to the bladder in order to allow potential endoscopic treatment. Finally, preserving the natural urethra may constitute a

safety measure if high bladder storage pressures are present or in the event of any complication with bladder access via a continent catheterisable abdominal conduit or suprapubic catheter (346).

The last guidelines of European Society for Pediatric Urology (ESPU) and European Urological Association (EAU) reviewing the period 2000-2017 postulated that the creation of a continent catheterisable stoma in association with bladder neck closure is an option for the treatment of complex cases of incontinence in children and adolescent patients (347). However due to the high incidence of metabolic and surgical complication close follow-up is mandatory to detect and treat consequences early.

In selected patients urethral closure may represent a simpler alternative to complete closure of the bladder neck in neurological patients with severe incontinence or urinary fistulae. In a retrospective series including 12 (four males and 8 females) patients, 9 with SCI and 3 with progressive MS, the authors achieved urinary continence in all but one patient in a 20 months follow-up. All patients had a urinary diversion, either an ileo-vesicostomy, or an augmentation cystoplasty and construction of a neourethra. Four patients had one additional procedure to gain continence, but five patients required 3.8 procedures/patient to achieve continence. Closure of the male urethra was more easily accomplished than closure of an extensively damaged eroded female urethra (341).

4. BLADDER COVERED BY STRIATED MUSCLE

Voiding function for an acontractile bladder can be restored when the bladder is covered by striated muscle that can be stimulated electrically, or that can be contracted voluntarily. The rectus abdominis (348) and latissimus dorsi (349) were used in patients with NLUTD (350, 351). However, this technique is not suitable for smaller bladders, and intermittent catheterisation may still be needed due to persistent PVR (352).

5. BLADDER AUGMENTATION

Bladder augmentation or augmentation cystoplasty is a generally accepted therapy for a small-volume, high-pressure bladder. The purpose of bladder augmentation is to increase bladder storage capacity, decrease bladder pressure, improve bladder compliance, protect upper urinary tract function, provide urinary continence, resist infection, and offer a convenient method of voluntary and complete bladder emptying. The technique has been in existence for >100 years, and has recently been performed laparoscopically or robotically. Currently, the bladder augmentation techniques available in clinical practice include autoaugmentation (vesicomyotomy), intestinal cystoplasty (ileum), colocystoplasty (sigmoid), gastrocystoplasty (stomach), ureterocystoplasty, seromuscular augmentation, and tissue engineering cystoplasty (353).

The aim of auto-augmentation is to reduce detrusor overactivity or increase low bladder compliance. The advantages include low surgical burden, low rate of long-term adverse effects, positive effect on QOL, and it does not preclude further interventions (354-357). Bladder auto-augmentation with rectus muscle backing may become an alternative surgical technique for carefully selected patients to improve bladder capacity and compliance. However, this technique is indicated only in cases without anterior abdominal wall anomalies (352).

Replacing or expanding the bladder by intestine or other passive expandable coverage will improve bladder compliance and at least reduce the pressure of detrusor overactivity (358, 359). In patients with severely thick and fibrotic bladder wall, bladder substitution with bowel after performing a supratrigonal cystectomy (359) to create a low-pressure reservoir is indicated. To improve NLUTD and protect kidneys from damage, augmentation uretero-enterocystoplasty can be performed as reported by Liao et al (353, 360). It refers to the procedure that combines bladder augmentation with simultaneous ureteral anti-reflux implantation and ureteroplasty. The ureteral anti-reflux implantation can be performed with ureteroplasties (ureterolysis and tailoring/shortening) because of megaureter, severe tortuous ureter, and constricting ureteric stenosis. Ureterolysis refers to mobilization and straightening of the ureter. Tailoring refers to shortening the length of the ureter, and reducing the diameter only for megaureters (353, 360). The augmentation uretero-enterocystoplasty may be beneficial for patients with low-pressure or high-grade VUR, ureterovesical junction obstruction or ureter tortuosity and adhesions, and/or severe upper urinary tract damage, especially for those patients with a long medical history (359-361). In a study of 173 patients who underwent bladder augmentation, Wang and Liao showed that concomitant ureteral reimplantation (160 patients) could be beneficial for the following indications: VUR grade III or greater, VUR at low pressures (less than 10 cm H2O), upper urinary tract dilatation grade III or greater, and ureterovesical junction stenosis. After surgery, only one patient (0.6%) had persistent VUR, though 14 patients (8.1%) developed ureteral stricture (360). Improved QOL and stable renal function have been reported during long-term follow-up, even though intermittent catheterisation may become necessary after this procedure, which is more prevalent in neuro-urological population (362). Long-term complications included bladder perforation (2%), mucus production (13%), metabolic abnormalities (3%), bowel dysfunction (15%), and stone formation (10%) (362). Though more research is needed to better evaluate the morbidity of different surgical techniques and the indications for concomitant surgeries, enterocystoplasty associated with supratrigonal cystectomy remains the gold standard for bladder augmentation (363).

The long-term scientific evidence shows that bladder augmentation is a highly successful procedure that stabilises renal function and prevents anatomical deterioration; however, lifelong follow-up is essential in this patient group given the significant morbidity associated with this procedure (362). Special attention should be paid to patients with pre-operative renal scars since metabolic acidosis can develop (364). Poor compliance with intermittent catheterisation can increase the risk of chronic renal failure (363). Patients with lower baseline renal function may be at higher risk for developing chronic renal failure following bladder augmentation than patients with a normal preoperative creatinine clearance (363). For better evaluation of both lower and upper urinary tract dysfunction, a new comprehensive classification system has been proposed by Liao (353, 365-367), using magnetic resonance urography in combination with video-urodynamics. The appearance of calyces and dilation of the renal pelvis, tortuous and dilation of the ureter, and thinning of the renal parenchyma are key factors in the magnetic resonance urography upper urinary tract dysfunction grading system. This new system better discriminates among grade changes in upper urinary tract function, allowing for better informed clinical decision-making and long-term follow-ups (353).

Experimental methods of bladder augmentation with tissue engineering are a promising area for further investigation. Small intestinal submucosa had been applied as a scaffold for rebuilding a functional bladder with partial long-term success rate in patients with

NLUTD. With regard to the pilot clinical experience with 8 cases in 2014, assertion had been arisen on the limited ability of small intestinal submucosa grafted surface for bladder expansion (368). Liao's group is encouraged to continue the bladder augmentation with small intestinal submucosa and prospectively followed this cohort to determine if the mid-term results are maintained. They reported the ongoing clinical experience with small intestinal submucosa mediated bladder reconstruction based on the long-term follow-up data in 2019 (369). A total of 15 patients with poor bladder capacity and compliance underwent small intestinal submucosa BA. The duration of follow-up ranged from 4.5 to 8.3 years (mean: 6.3 years). A total of 9 patients showed stable improvement, leading to the overall success rate of 60%. Four patients experienced gradual decrease in incontinence episodes. Two patients had no symptomatic benefit. Compared with the pre-operative status, the results indicated significant increases in bladder capacity and significant decreases in the detrusor pressure profile at 1, 2–3, and 4–5 years postoperatively. In addition, bladder compliance significantly increased at 2–3 years postoperatively. The results of patients with successful and unsuccessful procedures were reported separately. There were no significant differences between groups with successful and unsuccessful procedures in preoperative video-urodynamic parameters. Macroscopic examination showed that the regenerated bladder wall was not distinguishable from the native bladder based on ultrasound, cystogram, and endoscopy. Histologic examination showed a complete conversion of small intestinal submucosa, leaving the bladder wall containing smooth muscle, vessels, and relatively thick connective tissue. This technique helps increase bladder volume, alleviate upper urinary tract dilation, and offer some patients with relatively safe conditions for intermittent catheterisation during long-term follow-up. Despite known complications and a relatively low success rate, small intestinal submucosa bladder augmentation has the advantage of a simpler surgical procedure and avoidance of bowel-based complications compared with enterocystoplasty. However, this procedure cannot be recommended as a substitute for enterocystoplasty, especially in patients with seriously damaged bladder, high-grade VUR, severe upper urinary tract deterioration, and/or detrusor fibrosis. Careful patient selection remains of the utmost importance, and patients need to be motivated to perform regular intermittent catheterisation (368, 369). In addition, the combination of 3D bioprinting technology and in situ in vivo bioprinting may be the main research direction in the future (370).

6. URINARY DIVERSION

When no other therapy is successful, urinary diversion must be considered for the protection of the upper urinary tract and for the patient's QOL.

6.1. Incontinent urinary diversion

Incontinent diversion with a urine-collecting device is indicated, if catheterisation is impossible. It could be considered in patients who are wheelchair bound or bed-ridden with intractable and untreatable incontinence, in patients with lower urinary tract destruction, when the upper urinary tract is severely compromised, and in patients who refuse other therapy. An ileal segment is used for the deviation in most cases (371-374). Compared with the ileal conduit, it was suggested that the colonic conduit has fewer complications (347). Patients gain better functional status and QOL after surgery (375).

To avoid pyocystitis and to prevent bladder cancer, a cystectomy is usually performed at the same time.

6.2. Continent urinary diversion

This should be the first choice for urinary diversion. The creation of a continent catheterisable channel should be offered to patients with difficulties performing transurethral intermittent catheterisation. Patients with limited dexterity, particularly those with relapsing-remitting disease and/or degenerative neurological condition, may prefer a stoma instead of using the urethra for catheterization (376-378). A high revision rate needs to be considered (347). The literatures concluded that continent catheterizable tubes/stomas are an effective treatment option in neuro-urological patients unable to perform intermittent catheterisation through the urethra (379). For cosmetic reasons, the umbilicus is often used for the stoma site (380-385). However, the complication rates were significant with the post-operative events requiring re-operation (379).

6.3. Undiversion

Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of detrusor pressure and incontinence. The patient must be carefully counselled and must comply meticulously with the instructions (386). Successful undiversion can then be performed (387).

IV. CONCLUSIONS

In surgery for neurological urinary incontinence, the LE is limited and varies widely from LE 1 to 4 (LE is mostly 3).

1. RECOMMENDATIONS FOR PRACTICE

Botulinum toxin injections into detrusor / external urethral sphincter

- Intradetrusor onabotulinumtoxinA injections are effective and safe if antimuscarinics failed. Generally, 100-300 units are used having a duration of effectiveness of 6-14 months. Abobotulinumtoxin A is not yet licensed although the outcomes are promising.
  (LE 1; GR A)

- Intrasphincteric botulinum toxin injections may be effective and safe to treat DSD but are not yet licensed. The optimal dose and mode of injection is unclear and the duration of effectiveness is about 3 months.
  (LE 2; GR B)

Invasive neuromodulation / neurostimulation

- Sacral anterior root stimulation combined with sacral deafferentation (dorsal rhizotomy) is a valuable therapeutic option in carefully selected patients with complete SCI.
  (LE 3; GR C)

- Sacral neuromodulation may be effective and safe but there is a lack of RCTs in the neurological population and it is unclear which neurological patients would be most suitable.
  (LE 2; GR B)

Urethral, prostatic, and bladder neck surgery

- Urethral / prostatic stents are rarely indicated. Adverse events are relevant and stent removal is a challenge.
  (LE 3; GR C)

- Sphincterotomy may be considered in carefully selected male patients. The recurrence rate is high and the decrease of intravesical pressure often unsatisfactory.
  (LE 3; GR C)

- Urethrotomy is indicated in the case of urethral strictures hindering urethral catheterisation.
  (LE 3; GR C)

- Urethroplasty is a challenging procedure and a patient-tailored stepwise approach is crucial.
  (LE 3; GR C)

- TURBN / TUIBN is performed in the case of relevant PVR due to a fibrotic bladder neck. TURP is an option in pure PD patients with urodynamic prostatic obstraction (exclude MSA!).
  (LE 3; GR C)

- Treatment with bulking agents is minimally invasive but outcomes are mostly disappointing in the medium- and long-term.
  (LE 3; GR C)

- Autologous (preferable) and synthetic urethral slings can be used for treating neurogenic stress urinary incontinence. Preoperatively, relevant detrusor overactivity and VUR has to be excluded / treated. Patients have to be informed about the risk for postoperative de novo urinary urgency (incontinence).
  (LE 3; GR C)

- AUS is still the gold standard for treating neurogenic stress urinary incontinence. However, relevant complications and redo surgeries are common. The laparoscopic approach is promising.
  (LE 3; GR C)

- Adjustable continence devices are mainly used in post-prostatectomy stress urinary incontinence and the experience in neurological patients is very limited.
  (LE 3; GR C)

- Bladder neck / urethral reconstruction / closure is rarely indicated and combined with suprapubic catheter or urinary diversion.
  (LE 3; GR C)

Bladder covered by striated muscle

- Voiding function of an acontractile detrusor can be restored when the bladder is covered by striated muscle (rectus abdominis or latissimus dorsi) that can be stimulated electrically or contracted voluntarily. However, the evidence is very limited.
  (LE 4; GR D)

Bladder augmentation

- Bladder augmentation improves bladder compliance and decreases intravesical pressure. It is considered in patients after failed botulinum toxin treatment or in those not willing / not suitable to undergo regular intradetrusor botulinum toxin injections. Careful patient selection is of utmost importance and adherence to intermittent catheterisation is required.
  (LE 3; GR C)

Urinary diversion

- Incontinent diversion preferably with an ileal segment is indicated if intermittent catheterisation is not possible or in the case of severely impaired renal function.
  (LE 3; GR C)

- Continent urinary diversion is the first choice, but relevant complications and redo surgeries are common. In the case of limited manual dexterity or spasticity a catheterisable stoma through the umbilicus (instead of catheterisation through the urethra) should be considered.
  (LE 3; GR C)

- Undiversion is rarely indicated. It has to be meticulously planned and patients have to be carefully informed.
  (LE 4; GR D)

2. RECOMMENDATIONS FOR RESEARCH

Considering the limited LE, well-designed, adequately powered and sampled prospective studies are urgently needed in surgery for neurological urinary incontinence. However, while awaiting high-level evidence studies, current best clinical practice management is justified.

I. GENERAL INTRODUCTION

Fistulae are usually complications of obstructed labour or of pelvic surgery or radiotherapy, although congenital and fistulae with rare aetiologies also occur. The vast experience of high volume surgeons in large fistula centers in the developing world and the more advanced techniques used by surgeons in the developed world to repair fistulae, is in sharp contrast with the limited amount of high quality publications on this topic. There is a clear need for prospective randomized studies.

Because of the nature of the literature on fistulae, not only systematic reviews and meta-analyses and randomized controlled trials are reported, but also cohort studies and even relevant case studies. We hope that this chapter will inspire people to setup and run future trials on fistula prevention, treatment and complication management.

II. EPIDEMIOLOGY

1. VESICOVAGINAL FISTULAE

1.1. Obstetric fistulae

Epidemiological studies on obstetric fistulae (OF) are difficult to manage, given the local circumstances in developing countries. Many of them are based on retrospective case series from a single fistula centre (hospital –based) or use questionnaire based approaches (community –based). A questionnaire-based study in Pakistan in 9134 women, showed that the region of origin (e.g. Punjab), delivery by caesarean section or women reporting complications during the pregnancy were more likely to develop OF (OR = 1.96, 95%CI = 1.19-3.16).[1] A population-based cross-sectional study in India of 3939 women showed an incidence of 0.3%. [2] A systematic review by Adler et al. found 19 studies that could be evaluated.[3] The studies included data from West Africa, Bangladesh, Turkey, Jordan, Ethiopia, Egypt and India. The number of new fistulae ranged from 0.09 per 1000 recently pregnant women in community-based studies to 0.66 per 1000 pregnancies in hospital-based studies. A study in Mozambique on a selected cohort of recently delivered women, found a fistula incidence of 1.1 per 1000. [4] The WHO has suggested that over two million women, mostly from sub-Saharan African and Asian countries, have fistulae. Given an estimated population of 645 million women of reproductive age in sub-Saharan Africa and South Asia in 2010 (http://esa.un.org/wpp/unpp/p2k0data.asp), this would suggest that 3 per 1000 women of reproductive age have a fistula, which is considerably higher than other estimates. They estimated the pooled prevalence from population studies at 0.29/1000 pregnancies. For Sub-Saharan Africa this number rises to 1.6/1000 and for South Asia to 1.2/1000. The incidence was estimated at 0.009/1000 recent pregnancies. Rural areas probably under report the real prevalence. [5]. Cowgill et al. performed another systematic review, also looking at the association of stillbirth and fistula.[6] They included 62 studies. Incidence estimates ranged from 0 to 4.09 OF cases per 1000 deliveries, while prevalence estimates were judged more prone to bias and ranged from 0 to 81.0 OF cases per 1000 women. Reported frequency of still birth (SB) associated with OF ranged from 32.3 % to 100 %, with estimates from the largest studies around 92 %. The major risk factors appear to be young age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend ante-natal care, low socio-economic status, low social class, lack of employment and illiteracy. Misconceptions regarding the cause of OF persist, mostly in rural areas and most in men. Misuse of family planning, intercourse during the menstruation, curses by relatives, sexually transmitted diseases (STD) and rape or gender-based violence are still seen as potential causes.[7] Education programs should be directed against these misconceptions. Health system causes such as poor quality obstetric care, staff unaccountability, late referral, poor nursing standards are very prevalent in sub-Saharan Africa and rural areas of Pakistan and other parts of Asia. [8, 9, 10]

The systematic review by Swain et al. calculated that the prevalence of OF is 1/1000 in low and middle income countries and 1.57/1000 if only sub-Saharan Africa and South-Asia data are taken into account.[2, 11]

Author	Year	Region	Incidence	Prevalence
Adler et al. [3]	2016	Africa, South Asia	0,29% (95%CI: 0,00-1,07)	5,68% (95%CI: 5,04-6,40)
Swain et al. [2]	2020	developing countries	not studied	1/1000 to 1.57/1000
Cowgill et al. [6]	2015	Africa, South Asia	0-4.09/1000	0-81/1000

The consequences of OF include divorce (16-92%), social isolation, worsening poverty, malnutrition, sexual dysfunction and mental illness (including anxiety/depression), insomnia, general ill health and thoughts of worthlessness and suicide. [12, 13]

There are few detailed reports documenting these women's obstructed labours. The time of onset of labour is rarely recorded and reports from delivery locations may disregard the fact that the woman has laboured at home for days prior to attending the delivery location. The reason for the woman not receiving help rarely differentiates between the absence of health-seeking behaviour and the lack of services. A study in Mali and Niger looked at the pathway these patients followed. The mean duration of the fistula was 4 years and the entire care process took up to 2.7 years, of which 7 months were spent at the repair centre.[14, 15] Treatment seeking behaviour is poorly understood. A study in sub-Saharan Africa showed that only 60.3% of women experiencing fistula related symptoms actually sought treatment and that only 28.5% underwent surgical treatment. The leading reasons for not seeking treatment were: unaware that it can be repaired (21.4%), do not know where to get the treatment (17.4%), economic constraints (11.9%), the fistula healed by itself (11.9%) and feeling of embarrassment (7.9%). The regression analysis indicated, teenagers as compared to adults 35 years or older [16]; and women without formal education compared to women with formal education [16], had reduced odds of treatment-seeking.[16]

Recommendations

Community-based epidemiological studies using standardised and validated collection tools with acceptable sensitivity and specificity are highly recommended.	A
Observational and longitudinal studies are needed, utilising advanced epidemiological analyses for risk factors (multivariate analysis controlling potential biases), the impacts and consequences of vesicovaginal fistula (VVF) and for factors determining health-seeking behaviour.	A
Community health workers play a major role in detecting and managing women at risk of OF. Training and resources should be invested to allow for early detection and referral programs.	A

1.2. Iatrogenic Fistulae

While in the developing world poor obstetric care is usually at the origin of VVF, gynaecological or pelvic surgery is the main causes of VVF in the industrialised world. In some developing countries, as caesarean sections and gynaecological procedures to treat benign and malignant conditions of the female reproductive tract are more commonly performed, the rate of iatrogenic fistulae is increasing (e.g. Pakistan, Bangladesh). [17, 18]

1.2.1. Post-gynaecological surgery

A recent study by Dallas et al. on nearly 300000 women undergoing hysterectomy for benign indications, there were 2,817 (1.0%) ureteric injuries, 2,058 (0.7%) bladder injuries and 834 (0.3%) genitourinary fistulae (80/834 of which developed after an injury repair). Diagnosis was delayed in 18.6% and 5.5% of ureteral and bladder injuries, respectively. Subsequent genitourinary fistula development was lower if the injury was identified immediately (compared with delayed) for both ureteric (0.7% vs 3.4% odds ratio [19] 0.28; 95% CI 0.14–0.57) and bladder injuries (2.5% vs 6.5% OR 0.37; 95% CI 0.16–0.83). Indwelling ureteral stent placement alone was more successful in decreasing the risk of a second ureteral repair for immediately recognized ureteric injuries (99.0% vs 39.8% for delayed injuries). With multivariate adjustment, prolapse repair (OR 1.44, 95% CI 1.30–1.58), an incontinence procedure (OR 1.40, 95% CI 1.21–1.61), mesh augmented prolapse repair (OR 1.55, 95% CI 1.31–1.83), diagnosis of endometriosis (OR 1.46, 95% CI 1.36–1.56), and surgery at a facility in the bottom quartile of hysterectomy volume (OR 1.37, 95% CI 1.01–1.89) were all associated with an increased likelihood of a genitourinary injury. An exclusively vaginal (OR 0.56, 95% CI 0.53–0.64) or laparoscopic (OR 0.80, 95% CI 0.75–0.86) approach was associated with lower risk of a genitourinary injury as compared with an abdominal approach. [20] They concluded that genitourinary injury occurs in 1.8% of hysterectomies for benign indications and that immediate identification and repair is associated with a reduced risk of subsequent genitourinary fistula formation.

The types of fistulae associated with gynaecological procedures may include communication between any reproductive organ (uterus, cervix, Fallopian tube, vagina), intestinal tract (colon, rectum), genitourinary organ (bladder, ureter, urethra), and cutaneous system (abdominal wall, perineum). In general, VVF are the most common type. The most common causes of VVF as a consequence of surgery, in developed countries is an injury to the urinary tract during hysterectomy for benign conditions (60-75%), followed by hysterectomy for malignant conditions (30%), caesarean section (6%), and obstetric injuries (1%). [21] [22] Overall, the risk of pelvic organ fistula following hysterectomy has been reported to be between 0.1 and 4%. [23]. It is important to recognise that most urinary tract injuries do not result in a fistula.

The prevalence of genitourinary injury and fistulae vary slightly from centre to centre. In one US retrospective study from the Mayo clinic, gynaecological surgery was responsible for 82% of the fistulae, obstetric procedures for 8%, and various forms of irradiation for 6%, and trauma or fulguration for 4%. The majority of fistulae followed treatment for benign conditions. [24] The relative proportions of the types of urinary fistula have changed with urethral fistulae having increased from 6 to 13%, while ureteric, bladder and/ or urethral fistulae having dropped from 20 to 16 and 11 to 7%. (2)

Given the various indications for, and types of hysterectomies, it is important to have an understanding of the type of hysterectomy since genitourinary or colonic fistula is reported with all of these procedures. The overall incidence of hysterectomy complications is estimated to be <2%, with bladder injury (1.3%) and ureteric injury (<1%) being most commonly reported. [25] Traditionally, the most common route used to remove the uterus for benign and malignant gynaecological conditions is abdominal (open incision, laparotomy); referred to commonly as total abdominal hysterectomy (TAH). The types of hysterectomies also include total vaginal (TVH), laparoscopically-assisted vaginal (LAVH), total laparoscopic (TLH), and subtotal or supracervical abdominal (SCH) or laparoscopic (LSH). Laparoscopic procedures may be done using traditional laparoscopic techniques, robotic assistance, and more recently, the single-site umbilical technique or through Vaginal Natural Orifice Transluminal Endoscopic Surgery (vNOTES). [26]

Benign and malignant conditions confined to the uterus are usually treated with a simple hysterectomy using any of the methods mentioned above. More advanced malignant conditions are usually treated with a radical hysterectomy in which parametrial and/ or vaginal dissection and removal may be involved. In rarer cases, exenterative procedures to remove the bladder or colon may be required if malignant extension to these organs is found. In some centres, robotic radical hysterectomies have been more commonly employed to treat gynaecological malignancies. The rate of urogenital fistula associated with simple abdominal hysterectomy for

benign disease is often reported as being of the order of 1 in 1000. In a national study from Sweden the rate of women undergoing any fistula surgery was reported as 0.26% in women having had a hysterectomy compared to 0.0007% in those not exposed to hysterectomy, with the 'number needed to harm' being estimated at 5700.[27] From Finland the rate of VVF was reported to be 1 in 1250 after all hysterectomies, 1 in 455 after laparoscopic, 1 in 1000 after total abdominal, and 1 in 5000 after vaginal hysterectomy.[28] The publicly available tables from the national hospital database in England give similar figures of 1 in 600 after total abdominal hysterectomy, and 1 in 5000 after vaginal hysterectomy.[29, 30] More detailed longitudinal analysis of patient-level information from the same dataset suggests a rate of 1 in 788 for all types of hysterectomy, 1 in 540 for abdominal hysterectomy for benign disease, 1 in 896 following vaginal hysterectomy for benign disease (excluding prolapse), and 1 in 3861 following vaginal hysterectomy for prolapse.[31]

Caesarean hysterectomy is a recognised cause of fistula, [32] and, with the increase in the number of caesarean deliveries there have been more fistulae related to obstetric surgical trauma.

The degree of bladder injury appears to be a major factor in iatrogenic fistula formation. In one study, 1,317 benign hysterectomies were reviewed (46% abdominal, 48% vaginal, and 6% laparoscopically assisted vaginal) with reference to risk factors for VVF following intraoperative injury to the urinary tract. In all, 34 cystotomies occurred with 4 (11.7%) developing a VVF. Patients who developed a VVF were more likely to have a large cystotomy and these individuals trended toward greater tobacco use, larger uterine size, and more operative blood loss. [33] Another study involving 3,076 vaginal hysterectomies with or without additional gynaecological procedures, one ureteric injury and 54 bladder lacerations were noted yielding a total of 4 VVF. The bladder lacerations occurred during the hysterectomy portion of the surgery in 61% of cases and during the additional procedures in 39%. [34] Also in developing countries iatrogenic fistulae occur. Raassen et al. found 805 iatrogenic fistulae in a series of 5959 (13.5%) patients in 11 countries. Most fistulae occurred as a consequence of caesarean section, intervention or hysterectomy for ruptured uterus.[35]

VVFs associated with hysterectomy may require ureteric reimplantation in as many as one-third of the cases. [36] Ureteric trauma should be considered in any hysterectomy or operative obstetric procedure regardless of the difficulty but certainly in more difficult cases.[37] Iatrogenic ureteric injury may occur after less common procedures such as ureteroscopy, lumbar sympathectomy, abdominal trauma, and iliac vessel ligation. [38]

1.2.2. Oncological fistulae

The literature relating to fistulae of oncological aetiology is limited both in quantity and quality. Seventy-six papers of possible relevance were identified, of which only 52 contained any relevant material. Only one randomised trial was directly identified from the literature searches,[39] although one non-systematic review of relevance,[40] and two systematic reviews were found;[41, 42] each of the latter contained only one further randomised trial. One national cohort study, and one non-randomised cohort study, are included,[31, 43] but all other identified material comprised case series or case reports, and represent level 3 or lower evidence. Two cases of duplicate publication (*i.e.* the same paper in two journals) were found.

In the oncological context, fistulae may occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.

In one study, 536 women underwent a radical hysterectomy for invasive cervical cancer. More advanced stage of disease, obesity, diabetes, and postoperative surgical infection were predisposing factors to urinary tract complications. In this study, ureteric injury occurred in 1.32%, bladder injury in 1.49% with VVF forming in 2.61% and ureterovaginal fistulae in 2.43% of cases, respectively. [44] In a similar report, 1,092 women with cervical cancer underwent a radical hysterectomy with obligatory pelvic lymphadenectomy. A VVF occurred in 0.3% and a ureterovaginal fistula occurred in 1.4%. [45] The rate of GU injury likely varies between centres. For example, in one report of 479 women undergoing different methods of radical hysterectomy for cervical cancer over a 15 year period, 52 (10.8 per cent) had urological complications (17 bladder and ureter injuries, 35 fistulae and strictures). [46] In contrast, one institution reported that , with modifications and careful dissection, ureteric and bladder injury have almost been eliminated.[47]

In two recently published case series, one of fistulae specifically associated with gynaecological cancers,[40] and one of urogenital fistula from all causes,[30] those relating directly to primary cancer were uncommon, (2/20=10%)[40] and (2/348=0.6% - *2/66=3% of the oncological cases in this series*),[30] respectively. Fistulae associated with cancer surgery (3/20=15% and 30/348=8.6% - *30/66=45% of the oncological cases in this series*) or radiotherapy (15/20=75% and 34/348=9.8% - *34/66=52% of the oncological cases in this series*) made up a much larger proportion of both series.

Immune-deficiency may be a further contributory factor, and enterovesical fistula has previously been reported in association with non-Hodgkin's lymphoma in HIV-AIDS,[48] and VVF has been seen in association with classical Hodgkin's affecting the vagina in a long-term pessary user.[49]

1.2.2.1. Cancer surgery

It is likely that all operations carried out in the pelvis can be complicated by genital tract fistula in some circumstances.[30] Operations carried out with the intention of curing malignant disease will inevitably carry a higher risk of subsequent fistula formation, as compared to those undertaken with less radical intent.

Following radical hysterectomy for cervical cancer (Wertheim-Meigs procedure) the rate of fistula formation reported from case series is between 0.6% and 4.4%.[44, 50, 51, 52, 53, 54, 55] It should be noted that these data are very heterogeneous, some reporting all types of fistula together. Where they are reported separately, the rates of vesicovaginal and ureterovaginal fistula appear to be of the same magnitude with both being reported in between 0.9% and 2.5%. of cases [44, 56, 57] The data from UK cited above suggest a urogenital fistula rate of 1 in 95 following radical abdominal hysterectomy in women with malignant disease as compared to 1 in 540 for TAH for benign disease, and one in 2041 for TVH for all benign disease (including prolapse).[31] Overall, the rate of urogenital fistula appears to be approximately 9 times higher following radical hysterectomy in women with malignant disease as compared to that following simple hysterectomy (abdominal or vaginal) in women with benign conditions.[31]

The risk of visceral injury or subsequent fistula formation following radical hysterectomy undertaken in pregnancy, or immediately following Caesarean section is not obviously increased over those carried out electively in non-pregnant individuals; Monk & Montz described inadvertent cystotomy followed by vesicovaginal fistula

in one of 21 women operated on during or immediately after pregnancy.[58]

Several modifications to the conventional Wertheim-Meig's procedure of radical hysterectomy have been described in an effort to reduce the associated morbidity. None of them seems to offer a benefit regarding fistula formation. [46, 50, 59]

Given the increased risk associated with radical surgery for malignancy, it is intuitive that the risks would increase with the stage of disease and with the extent of the surgery undertaken. There are few published reports of fistula following exenterative surgery. One study noted a 16% VVF rate in 19 women following exenteration for vulval carcinoma;[60] while another describes a 15% bowel fistula rate and an 8% urinary fistula rate from a series of 75 exenterations for recurrent cervical cancer.[61] In contrast, Ungar et al. describe only one ureterovaginal fistula and one pouch–vaginal fistula in 212 women undergoing exenteration out of a total of 2540 women treated for cervix cancer in one centre over a 13 year period (0.9%).[62]

Bladder sparing techniques during pelvic exenteration can carry a risk for fistula formation.[63] Also when the bladder has been removed and a neo-bladder has been constructed, fistulae between the neo-bladder and the vagina may occur.[64, 65]

The introduction of laparoscopic surgery within oncology is seen to have considerable advantages in terms of patient recovery; the risk of operative injury to bowel and the urinary tract, and subsequent fistula formation may however remain a concern in such cases. Although some studies, both case series and non-randomised cohorts, describe similar rates of injury to those described following open radical surgery,[43, 56, 57, 66, 67] others have reported injury or fistula rates several times higher following laparoscopic radical hysterectomy.[51, 68]

The risk of urinary tract injury from minor surgical interventions is in general low, although the use of repeat procedures may confer a significant increase in risk. VVF has been reported following repeated use of CO_2 laser for vaporisation of vaginal condylomata,[69] and following cone biopsy of the cervix.[70] In one personal series of 370 urogenital fistulae, 4 were associated with large loop excision of the transformation zone (LLETZ) of cervix, 3 of which followed a second LLETZ procedure (*Hilton, personal communication*).

Rarely, localised malignancies have been associated with VVF. One example is a primary mixed mullerian vaginal tumour reported in a 48-year female. [71] The mechanism for fistula formation is likely to be direct invasion into the bladder.

Genitourinary injuries during colorectal surgery are rare. Eswara et al. described 75 GU injuries in 42570 colorectal surgeries: cystotomy (35%), incomplete ureteric transection (29%), ureteric injuries (15%). Pre-operative external beam radiotherapy or chemotherapy and delayed repair were associated with worse outcome.[72]

1.2.2.2. Radiation fistulae

Pelvic irradiation can be delivered by external beam as well as locally (intracavitary/brachytherapy). Fistula formation appears to be slightly higher for postoperative external radiation (1.9%) compared to intravaginal brachytherapy (0.8%). [73] It does not appear that pre-treatment factors accurately predict those who will develop fistula related to radiotherapy. [74]

The literature in this area is particularly heterogeneous in nature, with wide variation in (and some lack of clarity over) the tumour type and stage being treated, the form of radiation and the site and dose delivered. In a series of urogenital fistulae from the UK, 34/348 or 9.8% were associated with previous radiotherapy; of those related to gynaecological cancer, 34/66 or 52% had undergone radiotherapy.[30] In a further series of cases specifically related to gynaecological malignancy, 15/20 or 75% had undergone previous radiotherapy.[40] In both series most cases followed radiation used for the treatment of cervical cancer, although, 5/34 or 15% followed treatment of endometrial cancer, and 1/34 or 3% followed treatment of a multifocal gynaecological cancer in one series.[30] Amongst a series of 216 radiation-induced fistulae, the time to diagnosis of the fistula was made between 3 months and 10 years (mean 21 months) following radiation.[75] In other series fistulae have been reported to develop or present up to 30 years after the 'causative' influence.[30, 76] (Figure 1a and 1b)

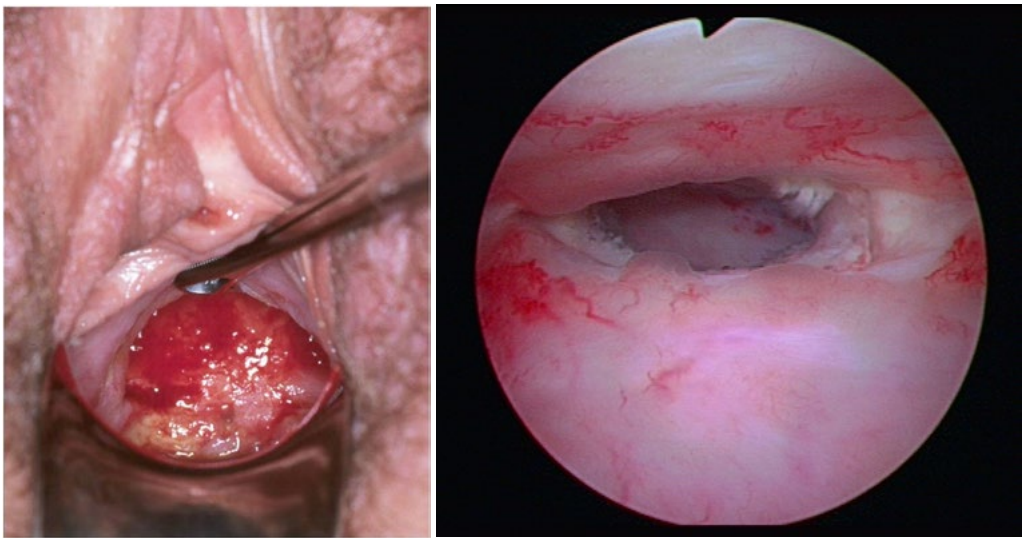

Figure 1a. Left: Acute radiation fistula; Right: fistula 20 years after radiotherapy, both for cervixcarcinoma

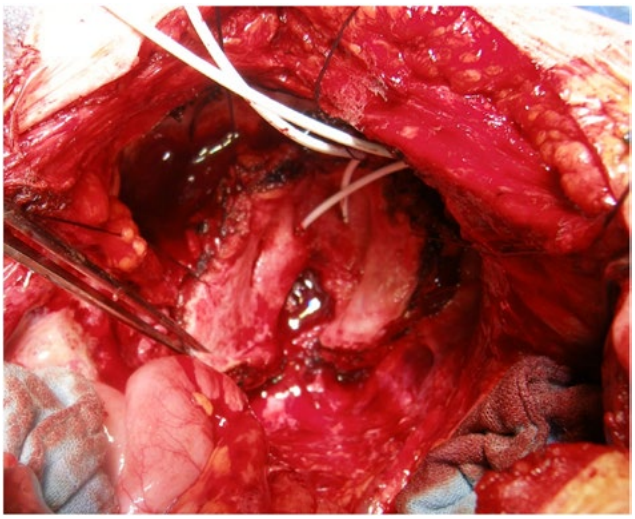

Fig 1b.Supratrigonal vesico-perineal radiation fistula in a small contracted bladder that occurred 22 years after cobalt irradiation for a gynaecological tumour.

The incidence of any deleterious clinical impact on the gastrointestinal and urinary tracts following radiation varies in the literature between 1% and 12%,[42, 77, 78, 79, 80, 81, 82, 83] with fistula rates of 1% to 5%.[40, 84]. In a retrospective review of 2096 patients treated for cervical cancer over a 10-year period using unspecified regimen/s of radiotherapy, 38 patients (1.8%) were found to have developed fistulae, all of whom had stage IIIa/b or IV disease at presentation.[80] Of these cases, approximately 3/4 involved the rectum, with 1/3 being combined rectovaginal and VVF; 1/4 were vesicovaginal only.[80]

Following a clearly defined regimen of external beam radiation plus brachytherapy for the treatment of primary squamous cell carcinoma of vagina in 91 women, de Crevoisier et al. reported 10.0% grade 2-3 urinary tract toxicity (using the Franco-Italian glossary) [85] and 12.1% grade 2-3 gastrointestinal toxicity.[78] Unsurprisingly, they found anterior tumour location to be correlated with increased risk of bladder toxicity and decreased rectal toxicity. Two women in this series developed rectovaginal fistulae (2%), and one ureterovaginal fistula (1%).[78]

In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynaecological cancers in one centre over a 22 year period, 133 (1.2%) developed urological complications of which 35 (0.3%) developed fistulae.[82]

In a series of 28 women treated by brachytherapy for recurrent corpus or cervix cancer, four patients developed chronic morbidities related to treatment. Three fistulae were reported in two patients (7.1%): one combined rectovaginal and VVF and one ureterointestinal fistula; a further patient developed a ureteric stricture and small bowel obstruction requiring resection.[83]

These data tend to suggest a higher rate of fistulae formation following the application of radiotherapy in locally recurrent disease than in primary disease. From a small series of urological complications following radiotherapy for gynaecological cancers, 14 had developed vesicovaginal fistula; of these 4 (29%) had evidence of tumour recurrence.[81] In the series reported by Jones at al. 326/1161 (28%) developed urological complications over a 20 year period; 46 developed fistulae (4%), of whom 33 (72%) had evidence of active malignant disease.[53]

In prostate cancer patients, recto-urethral fistula are described after cryotherapy (0.1-4%)[86], HIFU (0.7%)[87], brachytherapy (2%) [88].

When a fistula occurs after radiotherapy, it is considered good clinical practice to exclude tumour recurrence before attempting a fistula closure. Feddock et al. found 27 fistula in 325 patients after post-radiation biopsies for cervical cancer.[89] The fistula were toxicity related in 51.9%, a consequence of primary disease in 22.2% and of recurrent disease in 25.9%. The residual or recurrent cancer found in the biopsies was only 31.5%. Elevated radiotherapy doses to the rectum, advanced tumour stage and post-radiotherapy biopsy were considered risk factors for fistula formation.

1.2.2.3. Chemotherapy

There are few reports of fistula formation in association with the use of chemotherapy. One case report described a patient who developed a VVF having undergone TAH for atypical endometrial hyperplasia whilst taking *tamoxifen* following a previous modified radical mastectomy. Surgical repair of the fistula was initially unsuccessful, although after discontinuing the *tamoxifen* and continued bladder drainage, healing occurred.[90] It was hypothesised that the impaired healing was a result of the administration of the hormone therapy.

1.2.2.4. Combination therapies

Adjuvant or neoadjuvant therapies are used to increase the efficacy of the primary treatment, compared to its use in isolation. It might be anticipated that this would also increase the range and magnitude of adverse effects.

In a case control study examining the urinary tract complications of radical hysterectomy only a single VVF was seen in 50 patients (2%) – in a patient receiving preoperative irradiation (45-50 Gy). [91] A small case series found 2/20 or a 20% rate of urinary fistulae following preoperative irradiation and radical hysterectomy in a heterogeneous group of 'high risk' cervix cancers.[92] A further case series described the impact of combined external whole pelvic irradiation (50 Gy) and intravaginal cone boost (20-26 Gy) following radical hysterectomy in 108 women. The overall rate of fistula formation was 3.7%, 2.2% following 'prophylactic' radiation, and 10.5% in 'salvage' cases where recurrent disease was present.[93]

Modarress et al. reported a randomised comparison of preoperative combined chemoradiation (cisplatin plus external beam therapy) and neoadjuvant chemotherapy (cisplatin plus vincristine) followed by radical hysterectomy in stage IB-IIB bulky cervical cancer.[39] Four patients developed hydronephrosis (3 in the chemoradiation group – 13.3%) and two vesicovaginal fistula (both in the chemoradiation group – 6.7%).[39] Two further case series reported 2/36 or a 5.6% rate of fistulae following preoperative chemoradiation (cisplatin plus brachytherapy) followed by radical hysterectomy,[94] and 4/46 or 8.7% rate of fistulae following the use of neoadjuvant and postoperative chemotherapy using irinotecan, cisplatin and nedaplatin.[95]

1.3. Rare causes of VVF

Foreign bodies such as pessaries, sex toys, herbs, cups etc… can be a cause of VVF. [96, 97, 98, 99] Often the presentation is delayed (up to 15 months). Also ketamine abuse can not only lead to severe changes in the bladder wall structure, but also to fistu-

la formation, as was shown in 14.8% of 27 patients undergoing a CT-urography. [100]

2. UTEROVESICAL FISTULAE

Uterovesical fistulae classically present as a triad of cyclical hematuria and amenorrhea without urinary incontinence. This clinical entity was first described in the literature by Burkland in 1949 and by Nourse in 1953 but is referred to as Youssef's syndrome since his publication in 1957[101, 102, 103]. Menouria and amenorrhea are the most common symptoms.

Uterovesical fistulae can have several causes. The mechanism through which the abnormal connection between bladder and uterine cavity arises can be acute (e.g. traumatic during caesarean section), progressive (e.g. migration of foreign body) or congenital. [104]

The most common cause is an iatrogenic injury during caesarean section (83-93% of cases) [105]An increased number of caesarean sections leads to an increase in abnormally invasive placentae. Placenta praevia and percreta can lead to dramatic obstetric situations, necessitating an emergency caesarean section. The uterovesical fistulae can form afterwards when the bladder and the uterus and the bladder are not well separated or sutured. [106]

In a study by Rao on 14 patient's, an emergency caesarean section was at the origin of the fistula and in 58% the fistula was formed after the second caesarean section.[107] The mean duration between the caesarean and the diagnosis of the uterovesical fistula was 7 months. These findings have also been confirmed by Washington et al. looking at 34 patient's with cervicovesical or uterovesical fistulae of whom 29% had caesarean section compared to 9% who delivered vaginally.[108]

Congenital forms of uterovesical fistulae – often associated to more complex urogenital malformations -have been described as well, but are very rare.[109]

The diagnosis can be made clinically or by performing cystoscopy during the episodes of menouria. Hysterography, ultrasound, CT scan and MRI scan can be helpful in establishing the location and the size of the fistula. Early detection of abnormally invasive placentas by ultrasound has a good diagnostic accuracy (overall sensitivity of 100% (95% CI 96.5-100) and overall specificity of 61.9 (95% CI 51.9-71.2) for all types of abnormally invasive placenta.[Cali, 2018, Diagnostic accuracy of ultrasound in detecting the depth of invasion in women at risk of abnormally invasive placenta: A prospective longitudinal study] There is a correlation between the ultrasound staging of the placenta accreta spectrum and the peri-operative complications. This is important for counseling patients and for optimizing the care at the time of the delivery.[110]

The treatment is surgical, although there is one case report of a successful conservative treatment as well.[111] Classically a trans-peritoneum approach will be used, where the plane between bladder and uterus will be developed, the fistula closed and eventually interposition material will be used. Laparoscopic and robotic approaches (even early after caesarean section) have been described.[19, 112] The outcome of the surgery is very good. A multidisciplinary approach is advocated to prevent infertility.[113]

3. URETERIC FISTULAE

The real incidence and prevalence of ureteric fistulae is difficult to assess, because the literature only consists of retrospective case series. Studies on large databases suffer from the lack of detail on the type of ureteric fistulae, studies on smaller, mostly institutional, databases suffer from selection bias. However, some of the more recent studies shed some light on the occurrence of ureteric fistulae and the impact of the fistulae on some of the outcomes.

Post gynecological surgery

Genitourinary tract fistulae have an occurrence rate of approximately 1–2% for all major gynecological surgeries. [114] Among these injuries, 75% occur during hysterectomy, which leads to an average of 5,000 injuries annually in the United States. [115]

Blackwell et al. performed a study on 223872 patients, undergoing a hysterectomy between 2007 and 2011, using the Healthcare Cost and Utilization Project California State Inpatient Database. They made a distinction between ureteric injuries that were recognized and diagnosed during the surgery and those that were not recognized and thus repaired in a secondary surgery. Ureteric injury occurred in 1,753 of 223,872 patients (0.78%) and it was unrecognized in 1,094 (62.4%). The 90-day readmission rate increased from a baseline of 5.7% to 13.4% and 67.3% after recognized and unrecognized injury, respectively. Nephrostomy tubes were required in 2.3% of recognized and 23.4% of unrecognized ureteral injury cases. Recognized and unrecognized ureteric injuries independently increased the risk of sepsis (aOR 2.0, 95% CI 1.2e3.5 and 11.9, 95% CI 9.9e14.3) and urinary fistula (aOR 5.9, 95% CI 2.2e16 and 124, 95% CI 95.7e160, respectively). During follow up unrecognized ureteral injury increased the odds of acute renal insufficiency (aOR 23.8, 95% CI 20.1e28.2) and death (1.4, 95% CI 1.03e1.9, p ¼ 0032).[116]

Hwang et al. performed a meta-analysis comparing the risk for urological complications between laparoscopic radical hysterectomy (LRH) and abdominal radical hysterectomy(ARH).[117] The odd ratios (OR) of LRH for the risk of intraoperative urological complications compared to abdominal radical hysterectomy (ARH) was 1.40 [95% confidence interval (CI) 1.05-1.87]. The OR of LRH for postoperative complication risk compared to ARH was 1.35 [95% CI 1.01-1.80]. The incidence of bladder injury was statistically higher than that of ureter injury (p = 0.001). In subgroup analysis, obesity and laparoscopic assisted vaginal radical hysterectomy were associated with intraoperative urologic complications

The urinary bladder is often injured when the prevesical plane is dissected, especially during formation of a bladder flap during abdominal or laparoscopic hysterectomy. These injuries tend to be noticed at the time of surgery except for serosal injuries that do not create a full-thickness defect in the bladder wall, which can lead to delayed cystotomy and vesicovaginal fistula formation during the postoperative period. Factors that increase the risk of cystotomy during hysterectomy include cesarean delivery, endometriosis, pelvic adhesions disease, and cancer.[118] Ureteric injuries tend to be less frequent than bladder injuries, but possibly because their incidence is grossly underestimated. Studies demonstrate that about 66% of ureteric injuries go unrecognized at the time of surgery. Injuries tend to occur during dissection along the pelvic sidewall, especially when dissecting along the infundibular-pelvic ligament. Less common sites of injury include the lower uterine segment during ligation of the uterine vessels and the base of the bladder during ligation of the cardinal and uterosacral ligaments.[114] Several factors predispose the patient to ureteric injury and these include

former pelvic surgeries, hemorrhage, endometriosis, cancer, and compromised exposure secondary to large pelvic masses (leiomyomas) or obesity. [115]

Prevention of genitourinary tract injury. It is vital to identify the bladder and ureters accurately during dissection to preclude injury to these structures during a hysterectomy. Clarke-Pearson and Geller (2013) recommend insertion of a Foley catheter at the start of the case, and confirming drainage will reduce the rate of bladder injury regardless of the surgical route taken. As with the urinary bladder, identification principles help to prevent injury to the ureters. The ureters pass over the bifurcation of the common iliac vessels before coursing below the uterine artery and passing anterior and lateral to the cervix. It is important to pinpoint the ureter on the medial aspect of the broad ligament when operating in the pelvis. Using a retroperitoneal approach by opening the pararectal space can help to identify the ureter in this region. If hemorrhage obscures the surgical field, it is vital to apply pressure rather than clamping and ligating. There is no evidence that preoperative ureteral stenting decreases the rate of ureteric injury during hysterectomy, but intraoperative stenting in cases in which the ureters cannot otherwise be identified can help (Clarke-Pearson and Geller, 2013).

Wallis et al. performed a retrospective cohort study of patients undergoing hysterectomy for benign disease from 2010 to 2014 using the American College of Surgeons National Surgical Quality Improvement Program.[119] They identified 101,021 patients treated with hysterectomy for benign disease: 18,610 (18.4%), 27,427(27.2%), and 54,984 (54.4%) underwent vaginal, open, and laparoscopic hysterectomy, respectively. Cystoscopy was performed in 16,493 cases (16.3%). There were 2427 patients (2.4%) who underwent a concomitant urological intervention. Patients undergoing laparoscopic hysterectomy had increased occurrence of urological intervention, excluding cystoscopy (adjusted odds ratio 1.47, 95% confidence interval 1.29-1.69), compared to vaginal hysterectomy; no differences were found between open and vaginal hysterectomy or laparoscopic and open hysterectomy. Larger uteri, a postoperative diagnosis of endometriosis, increasing comorbidity, and African American race were associated with increased odds of urological intervention whereas concomitant cystoscopy was associated with a decreased chance

Among the whole cohort, 2427 patients (2.4%) underwent a concomitant urologic procedure other than cystoscopy: 1447(1.4%) had endoscopic stent insertion, 375 (0.4%) had a ureteric repair, 717 (0.7%) had a bladder repair, 6 (0.01%)underwent total cystectomy, and 1 underwent urinary diversion without cystectomy.

Sometimes the ureteric injury can be associated to a vesicovaginal fistula. Seth, Jimenez=Romero et al. reviewed their case series of 116 patients retrospectively and found that 3.4% of their patients had an associated ureteric injury. [120]

Prevention

As mentioned above, two thirds of the ureteric injuries are not recognized during surgery. Therefor prevention is very important. The use of cystoscopy is advocated by some authors, while others doubt about the added value. Barber et al. (2019) did retrospective study on 39529 women undergoing a hysterectomy and looked at the rate of delayed 30-day lower urinary tract injury. There was no difference in delayed lower genitourinary tract injury between patients who underwent cystoscopy at time of hysterectomy compared with those who did not undergo cystoscopy (0.27% vs 0.24%, P=.64). Patients who underwent cystoscopy were more likely to be diagnosed with a urinary tract infection (2.6% vs 2.0%, RR 1.27 95% CI 1.09-1.47). Median operative time was increased by 17 minutes in cases where cystoscopy was performed (132 vs 115 minutes, P<.001). [121]

Patton et al. (2019) performed an RCT comparing the use of 10mg Furosemide to saline intravenously during cystoscopy to confirm ureteral patency.[122] Furosemide 10 mg in a routine cystoscopy resulted in a shorter time to confirmation compared with the administration of the placebo (86.5 seconds, IQR 55.0-137.0 vs 165.0 seconds, IQR 77.0-280.0; P<.05). Furthermore, at any given time period, patients receiving intravenous administration of furosemide 10 mg were 2.3 times more likely to have ureteric patency confirmed compared with patients receiving normal saline (95% CI 1.59-3.23). There were no adverse events related to administration of intravenous furosemide and no delayed diagnoses of ureteric injury. Espiallat-Rijo and collegues (2019) also performed a randomized controlled trial comparing saline, 10% dextrose solutio, oral phenazopyridine or intravenous sodium fluorescein. Compared with saline, 10% dextrose and sodium fluorescein resulted in improved visibility and provided significantly more satisfaction in the evaluation for ureteric patency with no considerable increase in operative time or morbidity.[123]Oliveira et al. (2019) used CO2 cystoscopy and could visualise ureteric jetting at 145 seconds (range, 80-300 seconds).[124]

Although the beneficial effects of PUC on IUI incidence remain controversial, when a ureteric injury occurs during pelvic surgery, the presence of prophylactic ureteric catheters can significantly reduce both diagnostic delay and postoperative morbidity. By promoting an immediate repair, ureteric catheterization reduces need for further diagnostics and secondary interventions. [125]

Uretero-arterial fistulae

The obvious symptom of an arterial-ureteric fistula is gross haematuria, that can be pulsatile. Most of the time it is intermittent haematuria. Some predisposing factors have been described: inflammation after ureteric surgery, retroperitoneal fibrosis after (mostly vascular) surgery or radiotherapy. Most of the fistulae occur after placement of ureteric stents. The time to fistulae from the initial stent can be between 1-8 years. [126] This type of fistula also has been found after endovascular repair of a ruptured abdominal aortic aneurysm (rEVAR) [127] The mortality rate has decreased from 69% in 1980 to 7-23% in 2018. [128]

In case of gross hematuria during ureteric stent change in female patients with history of previous pelvic surgery and radiation, UIAF must be suspected and immediately treated, since it represents a urological emergency. Angiography can be useful to confirm the diagnosis and endovascular treatment with vascular endoprosthesis is the best therapeutic option.[129]

Uretero-Cutaneous And Uretero-Intestinal Fistulae

Ureterocutaneous fistulae have been described as complications of obstructed uteric stones, [130] colorectal surgery, [131] and as complication of an arterial iliac graft. [132] Uretero intestinal fistulae can present as ureterocolic or uretero-ileal fistulae. [133, 134]

4. URETHRO-VAGINAL FISTULAE

An obstetric urethrovaginal fistula may occur as a result of obstructed labour with or without associated VVF. It is more common when the obstructed labour occurs in primiparous rather than multiparous women.[135] In high resource communities urethrovaginal fistula in adults are mostly iatrogenic.

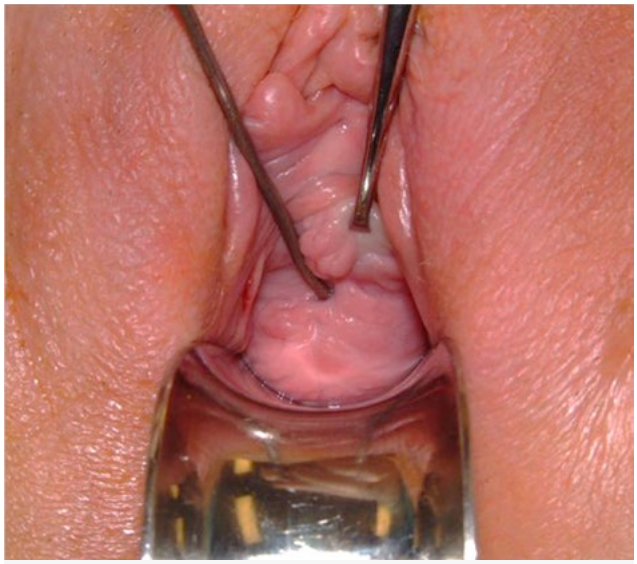

Fig 2: Urethro-vaginal fistula following mid-urethral tape procedure for SUI

In feminising genital reconstructions in children with disorders of sexual differentiation and surgical repairs of cloacal malformations, urethrovaginal fistulae can occur as early or late complications. [136] [137, 138] [139, 140] Urethrovaginal fistulae have been reported in gender reassignment procedures. [141, 142]

In the surgical treatment of stress incontinence in women with bulking agents [143, 144]or synthetic slings several cases of urethrovaginal fistulae have been reported.[145, 146, 147, 148] [149, 150, 151, 152] (see Fig. 2) Even conservative treatment of prolapse with pessaries can lead to the formation of fistulae, if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described.[31, 153]

Trauma – including inappropriate catheterisation- and foreign bodies are obvious cause of fistulae. [154, 155, 156, 157, 158, 159, 160] Urethral diverticula and their surgical repair may also lead to urethrovaginal fistulae.[161, 162, 163]

Urethrovaginal fistula have also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum. [164, 165] Irradiation complications can also result in the formation of urethrovaginal fistula.[166]

5. FISTULAE INVOLVING THE GI TRACT

The literature relating to non-obstetric fistulae involving the gastro-intestinal tract is sparse and of poor quality. It should be recognised that, whilst in most papers the term 'enterovesical' is used to describe fistulae between small bowel and bladder, and 'colo/recto-vesical/vaginal' to describe those between large bowel and bladder/vagina, in some reports 'enterovesical' appears to be employed generically to include all fistulae involving the gastrointestinal tract. In this chapter, the term 'intestino-vesical' will be used in circumstances where the generic term is clearly more appropriate.

Whilst occasionally reported congenitally,[167] the most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn's disease, and malignant disease or its treatment. There are few data on the incidence of fistula formation in these conditions, although published estimates are in the range 2-6% in Crohn's disease,[168, 169, 170] and 20% in diverticular disease.[171]

Intestinal fistulae in Crohn's disease most typically involve the small bowel, although communication with urinary tract and large bowel are also found; involvement of the bladder was reported in 27% and of the colon in 14% in one series.[172] Two large series examining the urological complications in association with Crohn's disease reported that whilst a majority of patients were female, the most serious complications were seen in males; most significantly, 13/14 or 93% of the ileo-vesical fistulae described in these series were in men.[168, 173]

Whilst clearly diverticular disease involves the large bowel primarily in all cases, diverticular fistulae have been reported to communicate with the bladder in 65% of cases, the vagina or uterus in 28% and small bowel in 7%.[171] Diverticular disease is the most common cause of colovesical fistulae in most reports, accounting for up to 75% of cases,[174, 175, 176, 177, 178, 179, 180, 181] with colon cancer, bladder cancer, radiotherapy and Crohn's disease accounting for the remainder.

Although there are no direct comparisons between racial groups, the distribution of these causes may vary between populations. Malignancy and/or previous radiotherapy account for 53-93% of cases of colovesical fistula reported from China,[182, 183] presumably reflecting the previously low prevalence of inflammatory bowel disease.[184]

Previous hysterectomy appears to be a significant factor in the incidence of fistulae associated with diverticular disease.[185] In a national case controlled study from Sweden, involving a total of 783,245 women over a 30 year period, the risk of undergoing fistula surgery increased four-fold in hysterectomised women without diverticulitis (hazard ratio (HR) 4.0 (95% confidence interval (CI) 3.5 to 4.7)), seven-fold in women with diverticulitis without hysterectomy (HR 7.6 (95% CI 4.8 to 12.1)) and 25-fold in hysterectomised women with diverticulitis (HR 25.2 (95% CI 15.5 to 41.2)). [186] Another study described previous hysterectomy in 50% of colovesical and 83% of colovaginal fistulae associated with diverticular disease.[171]

6. EVIDENCE STATEMENTS

The risk of injury to the bowel or urinary tract and of subsequent fistula formation is higher in women with malignant disease undergoing radical surgery than in women with benign disease undergoing simple surgical procedures	2
Several modifications to conventional radical hysterectomy have been described, although they have not consistently been shown to mitigate the risk of urinary fistula postoperatively.	3
Data on exenterative surgery are inconsistent, although the risk of fistula formation may be higher following exenteration for recurrent disease as compared to that following radical hysterectomy for the primary treatment of malignancy	3

The rate of visceral injury and fistula formation is inconsistently reported following laparoscopically assisted radical hysterectomy, but may be somewhat higher than following open surgery	3
Local ablative treatments applied in gynaecological oncology, whilst apparently relatively low risk as single treatments, may carry considerable risk for fistula formation when repeated.	3
The rate of fistula formation following radiotherapy for gynaecological cancer appears to be of the same order as that following surgical treatment	4
The risk of fistula formation following radiotherapy for locally recurrent malignancy is higher than following its use in primary disease	2
The use of neoadjuvant or adjuvant therapies is likely to be associated with a greater risk of fistula development than the primary treatment alone	2
The most common non-obstetric causes of fistula involving the gastro-intestinal tract are diverticular disease, Crohn's disease, malignancy and radiotherapy.	2
The causative factors may vary in different populations, with malignancy being more commonly reported in association with enterovesical fistula in China than in other countries	3

7. RECOMMENDATIONS

The development of fistula following radiotherapy for primary treatment should trigger a search for evidence of tumour recurrence	D
Vaginal urinary leakage after pelvic surgery, local ablative treatments or radiotherapy should trigger an investigation for the eventual presence of a fistula	B

III. CLASSIFICATION OF FISTULAE

The Consultation believes that fistula audit research is considerably hampered by the plethora of VVF classification systems, of which we believe there are 32. The Consultation feels that the fistula system that is able to relate its classification to outcome is the classification that should be used in the next few years. The Waaldijk and Goh classifications are the only ones that have been used to document sufficient numbers of patients from diagnosis to follow-up (Fig 2). The Goh Classication has also shown inter – and intra-observer concordance. [187]Figure 2 shows the Waaldijk Classification assessing mainly the extent of the urethral involvement and whether the injury to the urethra is circumferential or not. Fistulae are classified into types I (distance between the distal edge of the fistula and the urethral meatus > 4cm with no involvement of the urethral closure mechanism), II (distance between the distal edge of the fistula and the urethral meatus 1-4cm (type IIA) or 0.5-1cm (type IIB) with involvement of the urethral closing mechanism at the bladder neck and mid-urethral level)and III. Type III fistulae are those fistulae other than vesico-vaginal fistulae and include recto-vaginal fistulae and uretero-vaginal fistulae.

Similarly, the Goh classification included three of the four proven variables known to affect the outcome for obstetric fistula repair. These are the location of the fistula (assessing the extent of urethral involvement), the size of the fistula and the amount of scarring (including whether or not it is circumferential).[188, 189, 190] Also

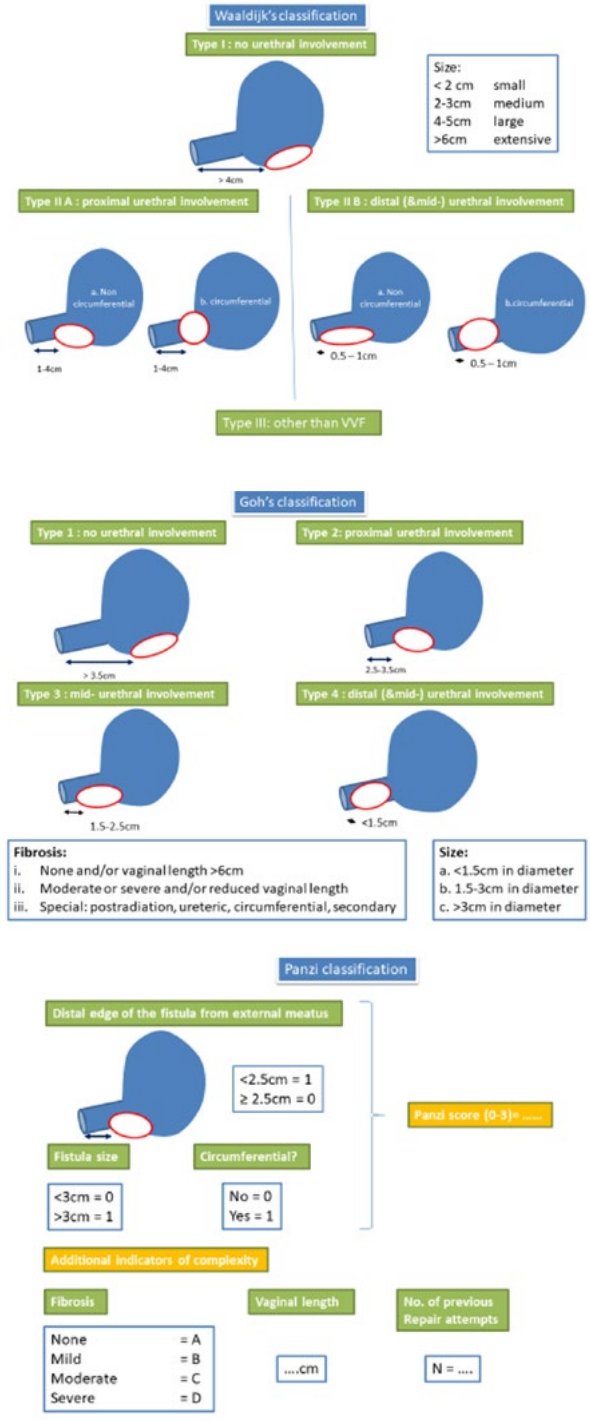

Fig. 3. Classification systems according to Waaldijk, Goh and Mukwege

bladder capacity or size is known to affect outcome, but since this is difficult or even impossible to measure pre-operatively, it has not been included in the Goh classification. (Fig 3)

There has been one comparative study showing that the Goh system is superior to the Waaldijk in terms of predicting closure. [191] Frajzyngier et al, in a prospective cohort study compared the classification systems of Lawson, Tafesse, Goh, Waaldijk and the

WHO.[192] They included 1274 patients in 11 centres. The predictive accuracy for fistula closure was 0.63 for the WHO score, 0.62 for Goh and 0.60 for the Tafesse score. The Waaldijk and Lawson systems fared worse. They propose a new empirical and simplified scoring system. They also suggested including other items in a prognostic scoring systems such as HIV status, malnutrition, malaria and genital cutting. A more recent study demonstrated that the Tafesse system has low predictive value for fistula closure. [193]

The Panzi score was developed following a retrospective analysis of features associated with surgical failure utilising the Goh and Waaldijk systems. [194] The fistula characteristics utilised in the score are location of the fistula, size of fistula and whether or not the fistula was circumferential in nature.

Classification systems have been developed for an obstetric fistula population. (Fig. 3) For iatrogenic fistula the classification is highly variable. The OF classification systems are not always applicable for iatrogenic fistulae. [195]

1. RECOMMENDATIONS

The use of a classification system is recommended. The Goh classification has shown good inter- and intraobserver reliability and is predictive for fistula surgery outcome.	A
Long-term follow up of fistula patients is recommended in order to study the outcome of both conservative and surgical management and, in particular, to determine its effect on quality of life.	C
When reporting the outcome after fistula repair, authors should make a clear distinction between fistula closure rates and post-operative incontinence rates, specifying the time at which follow-up was carried out.	B
A routine post-operative assessment of obstetric fistula needs to be developed to accurately determine the incidence and severity of any ongoing incontinence.	B

IV. DIAGNOSIS OF FISTULAE

1. CLINICAL DIAGNOSIS

Leakage of stool, urine, or possibly both is the hallmark sign of a fistula. The leakage is usually painless, may be intermittent if it is position dependent, or may be constant. Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula. [196]In one study, 36% of VVF presented within one week of a laparoscopic hysterectomy and 50% in the second week. Most of the patients after TAH had leakage in the second week (90%). [197] As discussed above, more extensive dissection is a factor when lower urinary tract injury results in a fistula. However, other than a frank injury such as ureteric transection, not all injuries result in the formation of a fistula. With laparoscopic or abdominal dissection, ureteric injury may occur anywhere along the retroperitoneal ureter usually below the pelvic brim. Since the injury may not be recognised during surgery, post-operative pain is a key symptom.

The cause of VVF after hysterectomy varies with the extent of surgery and the amount of injury that has occurred. Several risk factors for bladder injury during surgery have been documented including the presence of endometriosis, pelvic adhesions, distended bladder and infection[198]. When there are adhesions in the uterovesical pouch, blunt dissection may tear the bladder and/or devascularise the area. The commonest sites for ureteric injuries during gynaecological surgeries are at the level of the uterine artery and at the pelvic brim. Ureteric injuries may result from crush or thermal injury, transection and devascularisation. Common presenting symptoms of post-operative ureteric injuries include abdominal pain, ileus, peritonitis, fever, haematuria, flank pain and raised white blood cell count. The time from surgery to diagnosis of ureteric injury is usually within 7 days post-operatively.

The clinical course observed in many of the patients with VVF suggests that the patient has an unrecognised or recognised injury to the bladder resulting in urinary extravasation. [199] It may be possible to abort the development of many VVF by early recognition and treatment of an unsuspected bladder injury. It is suggested that patients with severe abdominal pain, distension, paralytic ileus, haematuria or symptoms of severe irritability of the bladder after TAH should be investigated early for a possible genitourinary injury.

Another possible aetiology of VVF in the setting of laparoscopic procedures is trocar insertion injury. To prevent this the bladder should be emptied by intermittent or continuous bladder drainage prior to inserting the abdominal and pelvic trocars. During the laparoscopic procedure, gaseous distention of the urinary drainage bag may become evident indicating a hole in the bladder.This intraoperative sign however, has not been associated with fistula formation. [200]

The diagnosis of VVF is almost always made on clinical examination with or without an office dye test[142]. Imaging is required to

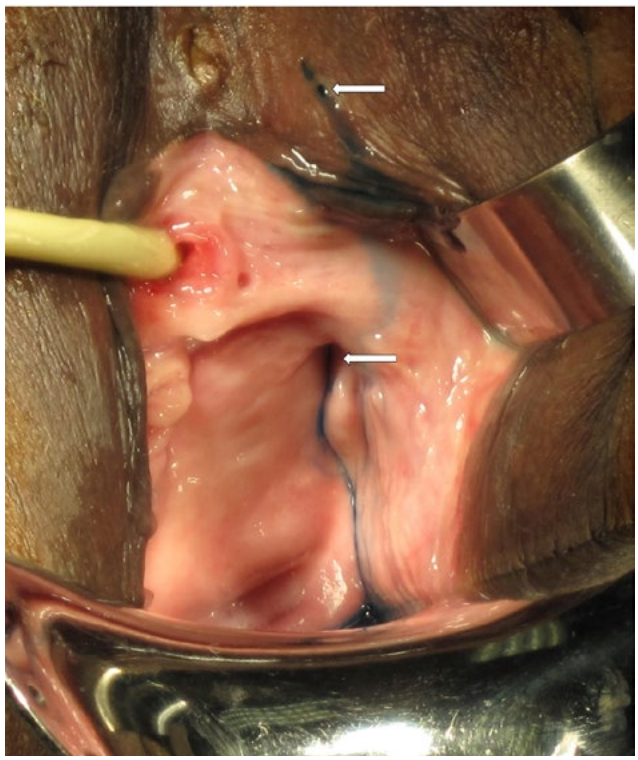

Fig. 4. Methylene blue introduced intravesically, demonstrating complex vesico-vagino-vulval fistula following pelvic fracture (arrows indicate external openings)

diagnose a ureteric fistula. Imaging has been demonstrated to have a high false negative rates for the diagnosis of VVF. Inspection of the vagina via a speculum usually reveals a defect in the anterior vaginal wall but a very small fistula may be more difficult to locate. The dye test for VVF involves retrograde filling of the bladder with dilute dye fluid (such as methylene blue) via a catheter inserted into the bladder. Ensure that the bladder is adequately filled. A speculum into the vagina is usually used and the dye test is positive when dye is observed leaking in the vagina. (Fig. 4) Alternatively, a tampon or swabs may be inserted into the vagina and the woman is asked to mobilise. If there is blue seen on the tampon/swab, the dye test is considered positive. Be careful that the tampon/swab is not positive due to leakage per urethram during the test. If there is urine in the vagina or tampon is wet but is not coloured (dye), then a ureteric fistula needs to be excluded.

A number of studies have investigated the role of routine cystoscopy in avoiding/detecting urinary tract injury at pelvic surgery; Indraratna et al. have recently reviewed these.[201]

Gilmour et al. undertook a systematic review of urinary tract injuries at benign gynaecological surgery including all studies of >500 patients reported between 1966 and 1998. [202] The overall rate of ureteric injury from 17 studies where cystoscopy was not undertaken (mostly hysterectomy) was 168⁄107,068=0.16%. In 10 studies where cystoscopy was undertaken routinely (mainly colposuspension or pelvic floor reconstruction), the rate of ureteric injury was 20/3235=0.62%. The corresponding rates of bladder injury were 0.26% (without cystoscopy) and 1.04% (with cystoscopy). Although the rates of detected urinary tract injury were approximately fourfold higher in those studies where cystoscopy was undertaken as a routine, it should be noted that none of these studies was randomised, and routine cystoscopy was undertaken predominantly during those procedures with intuitively the highest risk of injury.

Cystourethroscopy may provide direct visualisation of the fistula and its location relative to the ureteric orifices. In several series using cystoscopy (mostly with IV indigo-carmine) the sensitivity and specificity in detecting ureteric injury intra-operatively were >95%.

Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fisula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared to serum levels. [203]

A recent trend to use a flexible scope in the vagina, vaginoscopy, can provide magnification, and direct visualisation with minimal discomfort to the patient, particulary in high fistulae.

2. IMAGING

Depending upon availability, radiological studies (cystography, urography, intravenous urography, and CT urography) may be useful. Ultrasonography and colour Doppler have been used by some, although their use in routine practice remains to be established. [204] [205] Imaging has been found to be associated with a high false negative rate for the diagnosis of VVF [142]. An unstructured review by Narayanan et al. suggested that magnetic resonance imaging, particularly with T2 weighting, provided optimal diagnostic information regarding fistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative.[206] These newer modalities were considered to be superior to other X-ray contrast techniques and ultrasound. Ureteroenteric fistula have been diagnosed using 99mTc-DTPA renal scans.[207]

3. DIAGNOSIS OF GI FISTULAE

Pneumaturia, dysuria and/or recurrent UTI's are symptoms of a colovesical fistula but may be due to other causes as well. Accepting the limitations of small case series in this regard, a number of studies have investigated the value of a range of investigative techniques in the detection and evaluation of enterovesical or colovesical fistulae.[176, 178, 179, 183, 208, 209, 210, 211, 212] No test was shown to have consistent reliability; excluding those investigations for which only a single report was identified, CT (53%), cystoscopy (48%), and in the case of colovesical fistula, barium enema (38%) were perhaps the most useful; intravenous urography and sigmoidoscopy or colonoscopy appear to have limited utility in the diagnosis of GI fistula.

4. RECOMMENDATIONS

CT and cystoscopy appear more consistent in the confirmation and location of possible intestino-vesical fistulae, than other investigations	C
Level 3 evidence indicates that the routine use of cystoscopy with dye testing at gynaecological surgery has high sensitivity, specificity and negative predictive value in the detection of ureteric injury, although false positive tests do occur. The clinical and cost-effectiveness of routine cystoscopy remains to be established	C

V. MANAGEMENT OF VESICOVAGINAL FISTULAE

1. CONSERVATIVE MANAGEMENT

1.1. Immediate management by catheterisation

The goal of conservative management of VVF is rapid cessation of urinary leakage with return of normal urinary and genital function. The following are the indications listed below:

- Fistula onset is less than 3 weeks
- Progressively decreasing urine leakage with bladder drainage
- Fistula tract is long and narrow
- Width of fistula less than 1 cm
- Patient is compliant, co-operative and understanding
- Some of the contra-indications to conservative treatment are:
- Radiation induced VVF
- Scarring around fistula site
- Fistula onset is more than 6 weeks
- Fistula size more than 3 cm

Conservative management involves catheter drainage, anti-muscarinic and antibiotic therapy. In addition, it is wise to do a cystogram before removal of the catheter. The duration of catheter is debatable (2 weeks to 12 weeks). Bazi (2007) reported a non-systematic review of papers including information on the spontaneous fistula closure of vesicovaginal fistulae; whilst the data quality of all was poor, he identified 30 studies from which 12 could be included; these included cases that were almost exclusively of surgical etiol-

ogy; it should be noted that in 9 of these 12 studies the sample size was less than 5 patients.[213]

The time of fistula formation and the start of catheterization varies widely, most of them were less than 3 weeks duration. The success rates also vary from 0-100%. In obstetric fistula, spontaneous healing of fistula is reported to be 28% by Waaldijk in 1994, 1997 and 2004. [214, 215] Hilton reported a 6.9% spontaneous closure rate. [216] Oakley in 2014 reported 60 of 226 patients were treated conservatively with catheter drainage, antimuscarinic and antibiotics for 12 weeks. Only 11.7% resolved spontaneously.[217]

Davits et al. reported in 1991, 4 cases of VVF (2 post abdominal hysterectomy and 2 post vaginal hysterectomy for benign indication) between 40-48 years of age. All of them underwent catheter drainage, antimuscarinic and antibiotics for a duration of 18 to 54 days and had longterm follow up for 14 years.[218]

Elkins et al. reported 6 cases of conservative treatment in benign condition. 2 out of 6 were successful (unpredictable result with success rate of 12-80%).[219]

De Ridder et al. reported 13% success rate. The principle was introduction of catheter before epithelization is complete leading to healing of abnormal passage by urinary diversion. [220]

Zimmern PE et al. reported closure of VVF with success rate of 10.8% by catheterization alone. [221]

A systematic review by Hillary et al. described 6 studies on conservative treatment (2 in low resource and 4 in well-resourced countries). Duration of catheterization varied from 3 to 12 weeks. The inference derived was conservative management is likely to be successful, provided fistula was less than 3 mm, non-oblique tract, non-radiation induced or malignant fistula. The success rates were less than 13%. [222]

In 264 of 1716 cases, success rate of 15.4% was reported by Waaldijk.[223] In a more recent update, Waaldijk reported on catheter treatment in 1962 fresh OF. 1332 of them or 68% healed by catheter treatment only (minimum 4 weeks of catheterization). [224] (Fig. 5)

A success rate of 11% was reported by Taylor and Smith in 4 of 35 cases of obstetric fistula.[225]

A rare case of endoscopic closure of a radiation fistula was reported by Tatsuo with conservative management aided by endoscopic fibrin glue.[226] Bodner-Adler et al. reported conservative management in 239 out of 1430 cases (16%) of VVF with a success rate of 8% (12/239).[227]

1.2. Minimally invasive treatment

Due to the unpredictable result of only catheter drainage, minimally invasive techniques are used in an attempt to achieve better results. Several studies (mostly case series) describe non-surgical strategies as the sole treatment option consisting of: Transvaginal injection of fibrin sealant, Nd:YAG laser welding, Cystoscopic electrofulguration followed by fibrin sealant, Endo-vaginal cyanoacrylate glue , Platelet Rich Plasma with or without fibrin glue , Curettage of fistula tract and Rubber/ metal ball placement. The success rates were definitely high from 67-100%, but most fistula were small (<1cm). [228, 229, 230, 231, 232, 233, 234, 235, 236, 237]

Marin Sanchez described 2 cases, where after embolization in PPH, partial bladder necrosis with VVF were treated conservatively with good results.[238]

Cystoscopic fulguration using a small cautery electrode is possible by pushing it fully inside the VVF until the edges are blanched. In patients with fistula less than 3.5mm, the treatment was successful in 11 out of 15 cases.[232]

Dogra and Saini tried laser welding of VVF for less than 3 mm fistulae, however if more than 6mm, this method failed.[228]

In patients with thin VVF septum, large VVF and non-oblique tract, fulguration may be more damaging. Devascularisation of tissue will ultimately lead to a bigger and more complex fistula.

Fibrin sealant (fibrinogen + thrombin) can be injected directly into the fistula tract, after fulguration, followed by prolonged bladder drainage. It facilitates healing by recruiting macrophages and providing a semisolid support structure rich in growth and angiogenic factors which supports the fibroblast to connective tissue transition. [229, 239, 240, 241]

1.3. Pharmacotherapy to assist fistula closure

No medical therapy is available for the management of vesicovaginal and ureterovaginal fistulae. However, multiple therapies are used along with the management to assist and expedite fistula closure and improve closure rates.

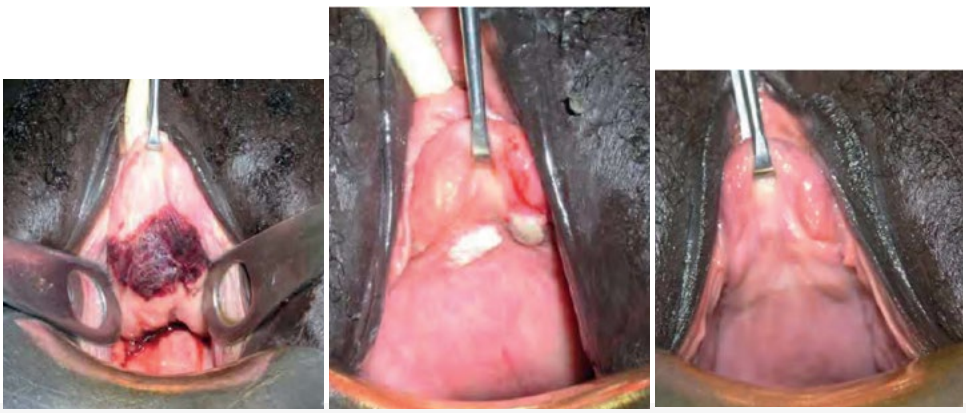

Figure 5: Spontaneous healing of a postpartal fistula by catheter drainage (Courtesy of. K. Waaldijk 2022) [1]

Pre-operative: During the waiting period, indwelling catheters were discouraged, and vaginal estrogen therapy can be used in post-menopausal women. A 4- to 6-week treatment regimen prior to surgery is commonly recommended. It may be used alone or in combination with oral HRT/ERT.[242]

Acidification of urine to diminish risks of cystitis, mucus production, and formation of bladder calculi may be a consideration, particularly in the interval between the diagnosis and surgical repair of VVF. Vitamin C at 500 mg orally 3 times per day may be used to acidify urine. Alternatively, methenamine mandelate at 550 mg plus sodium acid phosphate at 500 mg 1-4 times per day also can be administered to achieve urine acidification.[243]

Intra-operative: Antibiotic prophylaxis for VVF repair was studied in a paper from the Benin Republic by Tomlinson and Thorton. In their series of 79 patients who underwent repair of a VVF by a single surgeon, they found intraoperative ampicillin did not reduce the odds of failed repair. However, patients given prophylactic antibiotic therapy did have fewer urinary infections and required less antibiotic therapy postoperatively.[244]

Anticholinergic drugs are used to prevent early suture tension by causing a relaxation of detrusor smooth muscle hence preventing bladder spasms.[243] Urised which is a combination of antiseptics (methenamine, methylene blue, phenyl salicylate, and benzoic acid) and parasympatholytic (atropine sulfate, and hyoscyamine sulfate) can be used if available. Other antimuscarinics such as oxybutynin, solifenacin, darifenacin, tolterodin, fesoterodine etc.. can be used as well, although no specific data exist on fistula.

The use of antibiotic therapy postoperatively is controversial. Many physicians administer oral antibiotic prophylaxis to patients with VVF postoperatively until the Foley catheter is discontinued. Others check closely for the development of a urinary tract infection and administer antibiotic therapy when urine cultures are positive for bacterial growth. Close follow-up and prompt evaluation for any urinary tract infections and antibiotic therapy, when indicated, are mandatory.

Other measures include minimizing an increase in abdominal pressure, the use of laxatives and a high fiber diet, minimal pelvic examination, and pelvic rest (by avoiding using tampons, or coitus) for 6 weeks.

1.4. Palliation and skin care

This is essential as there is always a waiting period between diagnosis and therapy. Incontinence pads, help to reduce odor, reduce social stigma, and help the patient to continue routine work and allows them to be socially active.

Ammoniacal dermatitis, is a devastating complication characterized by local rashes, skin excoriation around the vulva and the medial side of the thigh due to the continuously wet environment. Silicon barrier creams and zinc oxide ointments have been shown to be effective to some extent. Other conservative measures viz. washing with water, avoiding irritants, drying thoroughly, avoiding rubbing with dry toilet paper, moisture barrier creams, talcum powder or cornstarch and wearing loose clothing and cotton underwear with frequent change of wet pads can be advised with proper counseling and assistance if needed.

Local estrogen cream is only useful in fistulae in post menopausal women (some OF may be diagnosed only at that age) . It increases the vascularity, helps vaginal tissues become softer and more pliable for the subsequent repair in terms of tissue healing.[242]

For personal hygiene and skin care, sit baths with a solution of permanganate or baking soda douches may be helpful. Keeping the perineum and vulva as dry as possible is comfortable for the patient. Inventive collection systems have been described for this purpose.[245] Hyperbaric oxygen treatment has also been described as an adjuvant treatment in radiation-induced fistulae.[246]

The evidence for all of the above 3 is level 3B.

1.5. Nutrition

Malnutirtion is common in surgical patients and is often unrecognized, untreated and worsens in hospital. A 1994 study reported that 40% of 500 patients sequentially admitted across five sub-specialties (including general and orthopedic surgery) were at least mildly undernourished (body mass index < 20, TSF or MAMC < 15th percentile). [247]There are clear prospective associations between inadequate nutritional status and the risk of poorer outcomes for surgical patients, including infection, complications and length of stay. Positive outcomes depend heavily on adequate immune defense and wound healing. Both rely on enhanced synthesis of new proteins, which is significantly limited by negative nitrogen and energy balance. Those patients who received 1,500–2,000 calories per day had a lower mortality rate and a higher fistula closure rate compared with the patients who received <1,000 calories per day. [248]

There is little evidence that parenteral is more effective than enteral nutrition, but it is certainly costlier and associated with higher risks of serious complications, particularly infection. There is evidence that early (within 24 hours) enteral feeding has significant benefits over late enteral and parenteral feeding.[249] Also Early Recovery programs have been shown to be beneficial, although they have not been studied for fistula repair specifically.[250]

1.6. Role of physiotherapy

Pre- and post-surgical VVF and physiotherapy is multifaceted. Most of the women need general rehabilitation, based upon obstructed labor and its subsequent care. All affected women benefit from pelvic floor assessment, education and muscle exercise to optimize the outcome of surgery.

A multi-disciplinary team, including an active physiotherapy team should become an integral part of best care in fistula management. [251]

The Paula exercise method (PEM) has been tested in post-VVF repair management and showed beneficial effects in reducing urine leakage, improving pelvic floor muscles strength, quality of life and sexual function. [252, 253, 254]

2. SURGICAL MANAGEMENT

Fistula surgery is not easy. One of the most important aspects of the unmet needs in fistula surgery training has been the lack of standardization A global competency-based fistula surgical training manual has been created by the International Federation for Gynaecology and Obstetrics (FIGO) with International Society of Fistula Surgeons (ISOFS). The purpose of this manual is to enable health care providers to acquire the required knowledge, skill and professionalism to prevent fistula and provide holistic care to fistula patients that includes medical, psychosocial and surgical care. A

multi-disciplinary team-based approach is encouraged in the training of each doctor and his/her team nurses, physiotherapists and other health professionals. The course is structured at three levels: standard, advanced and expert levels of fistula training.[255]

In the developed world, fistula incidence is much lower. Most results of fistula repair in literature are extremely positive. Since there is no systematic reporting of fistulae and the complications or outcome of the repairs, underreporting, selection bias can be possible confounding factors leading to these positive reports.

If catheter drainage fails, then fistula repair will be necessary. There are certain surgical principles to observe during fistula repair:
- Necrotic tissue must be removed prior to fistula repair.
- Fistula repair must only be undertaken by a properly trained surgeons.
- Adequate post-operative care is essential.
- Proper follow-up should be arranged.

2.1. Timing of surgery

The most appropriate timing for repair of vesico-vaginal fistulae remains one of the more contentious issues in this area. The debate continues between the advocates of early intervention, in order to minimise the distress to the patient from continuousurinary leakage, vs. those in favour of delaying intervention until local inflammatory change has resolved, necrotic tissues have sloughed, and the patient's recovery from the causative event completed, so as to optimise results.

There is no consensus in the literature regarding the definition of 'early' in this context, with different studies either failing to specify at all, or giving a broad range of definitions. Although some studies have used the terms 'immediate',[256] 'less than two weeks',[257] or 'less than 30 days',[258] most reports have considered either less than 6 weeks,[259, 260, 261] or less than 3 months,[257, 262, 263, 264] as their definition of early intervention. Giusti et al. reported a 100% success rate in 16 patients who were treated at a mean of 9d (4-17d) after a hysterectomy for a laparoscopic transperitoneal extravesical fistula repair with Tachosil™ interposition. [265] Although relatively few studies have reported their outcomes for both early and late approaches to management, overall the results do not appear to be significantly different. The overall results for early management are estimated at 91%±6% and for later management (where provided) 90%±27% (p=1.00; Fisher's Exact test).

2.2. Surgical approaches

2.2.1. Vaginal procedures

There are two main types of closure technique applied to the repair of urinary fistulae, the classical saucerisation technique described by Sims,[266] and subsequently modified as a partial colpocleisis by Latzko,[267] and the more commonly used dissection and repair in layers or 'flap-splitting' technique (variously attributed to Hayward, Collis & Lawson Tait).[268] Individual surgeons inevitably employ these techniques somewhat variably, and in different situations, and there are no data comparing their outcomes.

The conventional dissection and repair in layers is entirely appropriate for the majority of post-surgical fistulae, although modifications may be necessary in specific circumstances. In juxta-cervical fistulae in the anterior fornix, vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilisation of the bladder from the cervix, and the repair should usually be undertaken in such a manner (usually transversely) to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulae, particularly those following hysterectomy, can again usually be managed vaginally. The vault is incised transversely and mobilisation of the fistula is often aided by deliberate opening of the Pouch of Douglas.[269] The peritoneal opening does not need to be closed separately, but is incorporated into the vaginal closure.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by Chassar Moir[270] or Hamlin & Nicholson.[271] A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if any prospect for continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but may also provide additional bladder neck support and improves continence by reducing scarring between bladder neck and vagina. These are technically demanding procedures and outcomes of such complex repairs using robust measures regarding continence or sexual function are lacking.

With very large fistulae extending from bladder neck to vault, the extensive dissection required may produce considerable bleeding. The main surgical difficulty is to avoid injuring the ureters. They are usually situated close to the supero-lateral angles of the fistula, and if they can be identified endoscopically, they should be catheterised. Straight ureteric catheters passed transurethrally, or double pigtail catheters may both be useful in directing the intramural portion of the ureters internally; nevertheless great care must be taken during dissection. In such cases where the ureters cannot be visualised cystoscopically, interventional radiological techniques may be utilised to place antegrade ureteric stents from a percutaneous nephrostomy access tract.

2.2.2. Abdominal procedures

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are inaccessible through the vagina; most typically this might be following hysterectomy in nulliparous women, in endometriosis, or in those who have not delivered vaginally. Other indications for transabdominal repair are the need for simultaneous augmentation cystoplasty, or in the setting of a ureteric injury requiring reimplantation or simultaneous VVF and ureterovaginal fistula.

A transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack. The ureters should be catheterised under direct vision either endoscopically prior to skin incision, or following opening of the bladder. The technique of closure is similar to that of the transvaginal flap-splitting repair except that for purposes of haemostasis the bladder urothelium is usually closed with a continuous suture.

A simple transperitoneal repair is relatively uncommonly employed (although this technique does seem to be favoured by some using the laparoscopic approach – see below), although a combined transperitoneal and transvesical procedure is favoured by many urologists and is particularly useful for fistula repair following Caesarean section. A midline incision is made in the vault of the bladder; this is extended downwards in a racquet shape around the fistula. The fistulous track is excised and the vaginal or cervical defect closed in a single layer. The bladder is then closed in two layers.

There are no randomised studies comparing abdominal and vaginal approaches; given that those surgeons undertaking both routes for repair would usually see specific indications for the two such

a comparison is most unlikely ever to be seen as feasible, ethical or appropriate. Nine non-randomised cohort studies reporting results from both abdominal and vaginal procedures were identified in the current review.[22, 30, 261, 272, 273, 274, 275, 276, 277] In all, these series included 388 vaginal repairs and 345 abdominal repairs with overall closure rates at first operation of 89% and 87% respectively (p=0.367; Fisher's exact test). The same reports included 255 transvesical repairs with a 93% cure rate, and 399 transperitoneal repairs with an 89% success rate (p=0.130; Fisher's exact test).

Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previously unsuccessful procedures. In a series of 2484 largely obstetric fistulae, the success rate fell from 81% for first procedures to 65% for those requiring two or more procedures.[278] Series of surgical cases are rarely large enough for this effect to be evident, although the series published by Hilton found successful fistula closure was significantly more likely in the women who had not had attempts at closure before referral (98.2%) than in those who had one or more previous unsuccessful procedures (88.2%) (p=0.003; Fisher's exact test).[30]

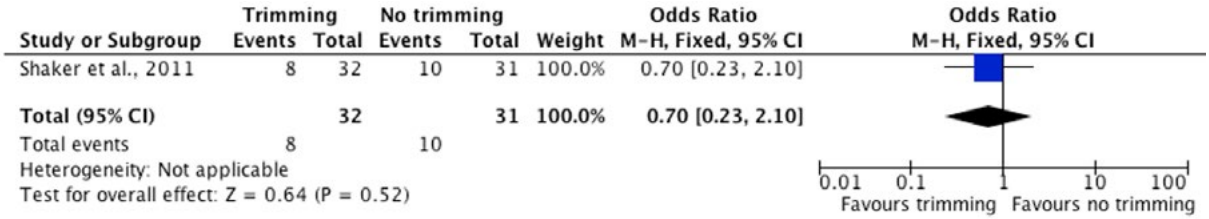
There is only a single randomised trial comparing aspects of surgical technique; Shaker et al. report an RCT comparing trimming of the fistula edge with no trimming.[279] Although there was no statistical difference in success rates between the two groups, in those cases where repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas those where there was no trimming were more likely to be smaller upon recurrence (figure 6).[279]

2.2.2.1. Laparoscopic

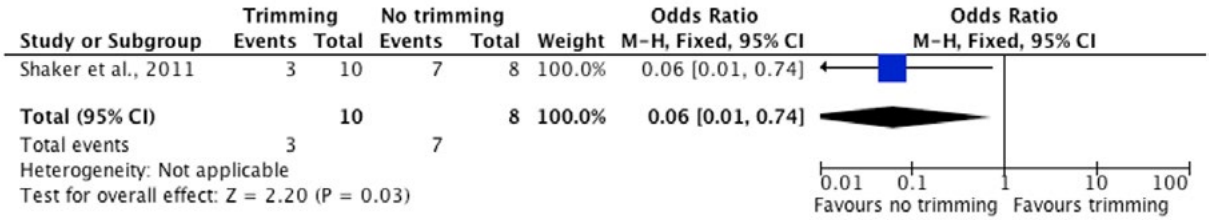
Laparoscopic repair of a VVF was first reported by Nezat et al., in 1994.[280] Fifteen series were identified in the current review,[256, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293] (plus an additional series in which 2 laparoscopic procedures were undertaken amongst a small series of vaginal and open abdominal operations).[277] All reported series are quite small (1-25 cases, median 6 cases), and in total only 119 patients were included, with an overall cure rate of 92% (confidence interval 4%) (See table 4). It is not clear from these series whether they include all fistula repairs undertaken in the reporting centres, or whether they were selected in some way; if the latter, it is not clear what selection criteria were used. It is possible that there may be both selection and reporting biases that make it difficult to fully evaluate laparoscopic procedures against alternative surgical approaches.

A combined vesicoscopic, laparoscopic and vaginal approach has been used successfully by some groups, but the experience remains limited.[294, 295]

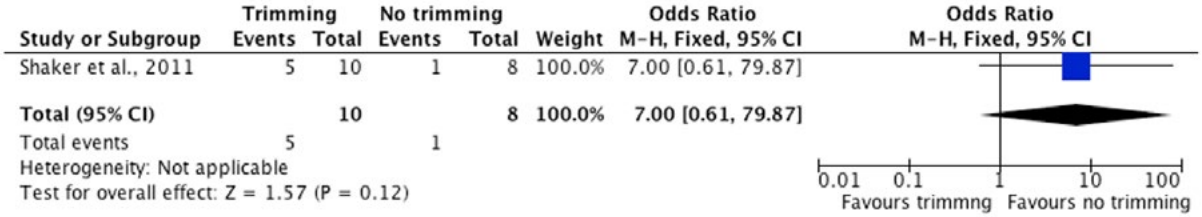
What about the veiscoscopic approach?



(i) Forest plot of comparison: 1 Trimming vs. no trimming of fistula edge, outcome: 1.1 Failure of fistula closure



(ii) Forest plot of comparison: 1 Trimming vs. no trimming of fistula edge, outcome: 1.2 Recurrence smaller than original



(iii) Forest plot of comparison: 1 Trimming vs. no trimming of fistula edge, outcome: 1.3 Recurrence larger than original

Figure 6: Forest plots relating trimming of edges at fistula surgery

2.2.2.2. Robotic

The first report of a robotically-assisted repair of vesico-vaginal fistula was from Melamud et al. in 2005.[296] Since that time four additional reports have been identified,[297, 298, 299, 300] including a total of 17 cases (see table 4). The reported cure rate is 100% in all series, although the same comments as above, in relation to possible selection and reporting biases, apply equally here. At this stage, whilst one could state that fistula repair with robotic-assistance appears to be feasible, it is not possible to indicate what its place or potential advantages are over alternative approaches.

Some of advantages to the robotic technique include three-dimensional visualisation, increased dexterity with wristed instrumentation improving on the severe angulation required for laparoscopic or open VVF repair, and easier intracorporeal knot tying. The retrovesical approach through the vagina can reduce the time for bladder healing significantly and allow the procedure to be done as a single day procedure. Currently, there are no direct comparisons between the classical transabdominal VVF repair, transvaginal VVF repair, and the minimally invasive robotic/laparoscopic techniques

Miklos JR et al. performed a systematic review on laparoscopic and robotic fistula repairs. They included 44 studies: 9 articles of robotic-assisted approach, 3 laparoscopic single-site surgeries, and 32 conventional laparoscopic approaches. A literature review revealed a balanced number of reports for both transvesical and extravesical approaches. The overall success rate of laparoscopic VVF repair was 80% to 100% with a follow-up period of 1 to 74 months. The success rate of transvesical and extravesical techniques were 95.89% and 98.04% (relative risk, .98; 95% confidence interval, .94-1.02). There was no statistical difference in success rates of VVF repair with different number of layers in the fistula closure or with use of interposition flaps, but there was a small increase in success in the cases that documented intraoperative bladder filling to test the integrity of the bladder closure. In conclusion, transperitoneal extravesical VVF repair has cure rates similar to the traditional transvesical approach. Laparoscopic extravesical VVF repair is a safe, effective, minimally invasive technique with excellent cure rates similar to those of the conventional transvesical approach in experienced surgeons' hands.[301]

Sharma et al. reviewed 15 studies on 75 patients who were treated robotically with a 90% successrate. [302]

Gellhaus PP et al. published a series of robotic repair either concomitantly with gynaecological surgery or as a salvage procedure after an previous attempted repair, showing good results for both approaches. [303]

2.2.2.3. Fibrin glue

The use of fibrin glue in urological indications was reviewed by Shekarriz and Stoller;[304] they identified nine reports (eight in human subjects) of the use of fibrin glue in fistula repair, including a total of 16 patients.[226, 305, 306, 307, 308, 309, 310, 311] A further six more recent reports were identified in the current review, where fibrin glue was used either by endoscopic injection or direct application, making a total of now 53 patients with fistulae of various aetiologies.[226, 229, 312, 313, 314, 315, 316] Several of these publications were individual case reports, although there was also one randomised trial comparing fibrin glue (20 patients) with a Martius graft (20 patients) in obstetric fistula patients.[315] All of the case reports described successful repair (1/1=100% cure); the RCT reported 13/20=65% cure; the overall success rate therefore for the 53 reported patients was 77.4% (confidence interval 7.3%) (See table 5). In one case successful closure of a radiation induced fistula was reported from the combined use of bovine collagen and fibrin glue.[226] Overall, the indications for, and optimal patient selection for this approach are not defined.

2.2.2.4. Endoscopic repair

Mackay described a technique for transurethral endoscopic suture repair of vesico-vaginal fistula in 1997.[317]; there have been three further papers using a similar technique on between one and four patients (total 10 cases).[273, 317, 318, 319] Although in three of these series the reported cure rate was 100%, overall, fistula closure was found in 80% (confidence interval 24%).

2.2.2.5. Adjuvant Techniques in the Repair of VVF: Tissue Interposition

Tissue flaps are often added as an additional layer of repair during VVF surgery. [320, 321, 322, 323, 324] Most commonly, such flaps are utilised in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischemic or obstetrical fistula, large fistula, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high level evidence for the use of such flaps in any of these situations. Furthermore, there is no high level evidence that the use of such flaps improves outcomes in the setting of an uncomplicated VVF.

For those VVF repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap can easily be mobilised. From a transabdominal approach, greater omentum can be used as an interposition flap.

A variety of other flaps including gracilis muscle flaps, labial myocutaneous flaps, seromuscular intestinal flaps, and rectus abdominis flaps as well as free grafts of bladder urothelium have been utilized as adjunctive measures in the repair of complex VVF.[325, 326, 327, 328, 329, 330, 331, 332]

There is no evidence that a Martius or any other interposition graft improves the outcome in primary fistula repair.

3. POST-OPERATIVE MANAGEMENT

3.1. Catheter type

No studies were identified comparing different catheter types or duration of drainage following fistula repair. Most reports do not describe their catheterisation practices in any detail; in those that do, the majority have employed urethral catheterisation, with a small number preferring suprapubic drainage or a combination of both. The reason for catheterisation is to ensure free urine drainage until such time as the repair is soundly healed; for this reason some have advocated both suprapubic and urethral drainage, arguing that whilst one catheter might easily become blocked, two are unlikely to do so simultaneously.[30] Bladder spasm are very common and could have a negative effect on the repair. [333]

3.2. Duration

There appears to be no consensus over the duration of catheterisation recommended following fistula repair of various types and aetiologies. In a retrospective study of obstetric fistula patients in Ethiopia, approximately equal numbers of patients were catheterised for 10, 12 or 14 days. There was no significant difference in outcome in terms of the rate of repair breakdown, and the authors therefore suggested that postoperative catheterisation for 10 days

may be sufficient in the management of less complicated obstetric VVF.[334]

In a recent review of practices amongst obstetric fistula surgeons, Arrowsmith reported a considerable range of practice. For 'simple' fistulae, the average duration of bladder drainage used was 12 days (range 5-21 days); for 'large' fistula the average was 17 days (range 0-30 days); and for 'difficult' fistulae, the average was 21 days (range 14-42 days).[335]

Torloni et al. reported on 2 non-inferiority trials including 684 patients, that showed no difference between short and longterm (> 10d) catetherisation regarding length of stay, fistula repair, incontince or the occurrence of UTI.[336]

The WHO published new guidelines for catheterisation after simple fistula repair and concluded that short term catheterisation defined as 7 tot 10 days, was sufficient for simple fistula repairs. [337]

Studies of non-obstetric fistula management are no more consistent in their description of duration of catheterisation. Most report periods of between seven and 21 days drainage; most typically 10-14 days for surgical fistulae and 14-21 days for radiotherapy-associated fistulae. There is no more than level 3/4 evidence to support any particular practice in these aspects of fistula management.

The summary of the surgical management of VVF can be found in Figure 7-9.

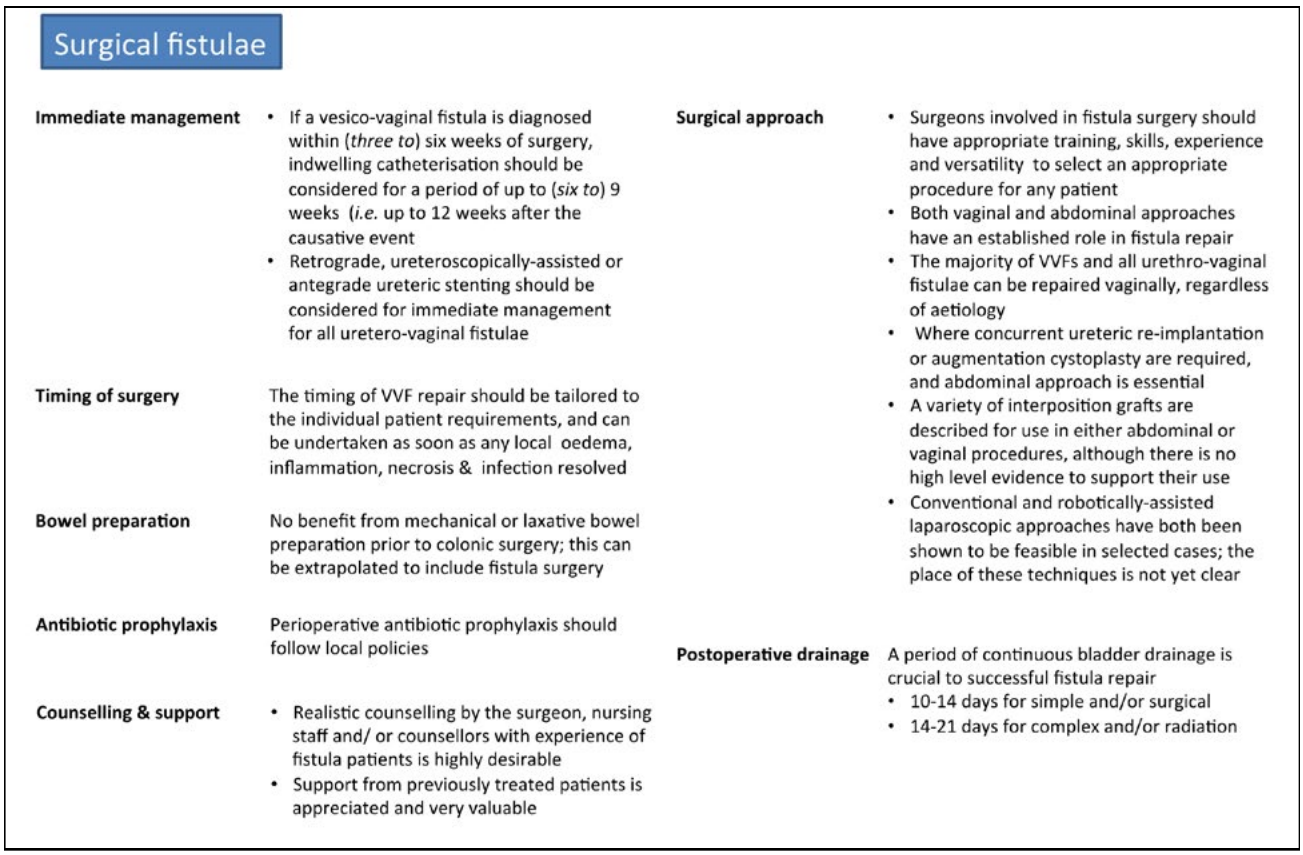


Figure 7. Treatment recommendations for vesicovaginal fistula

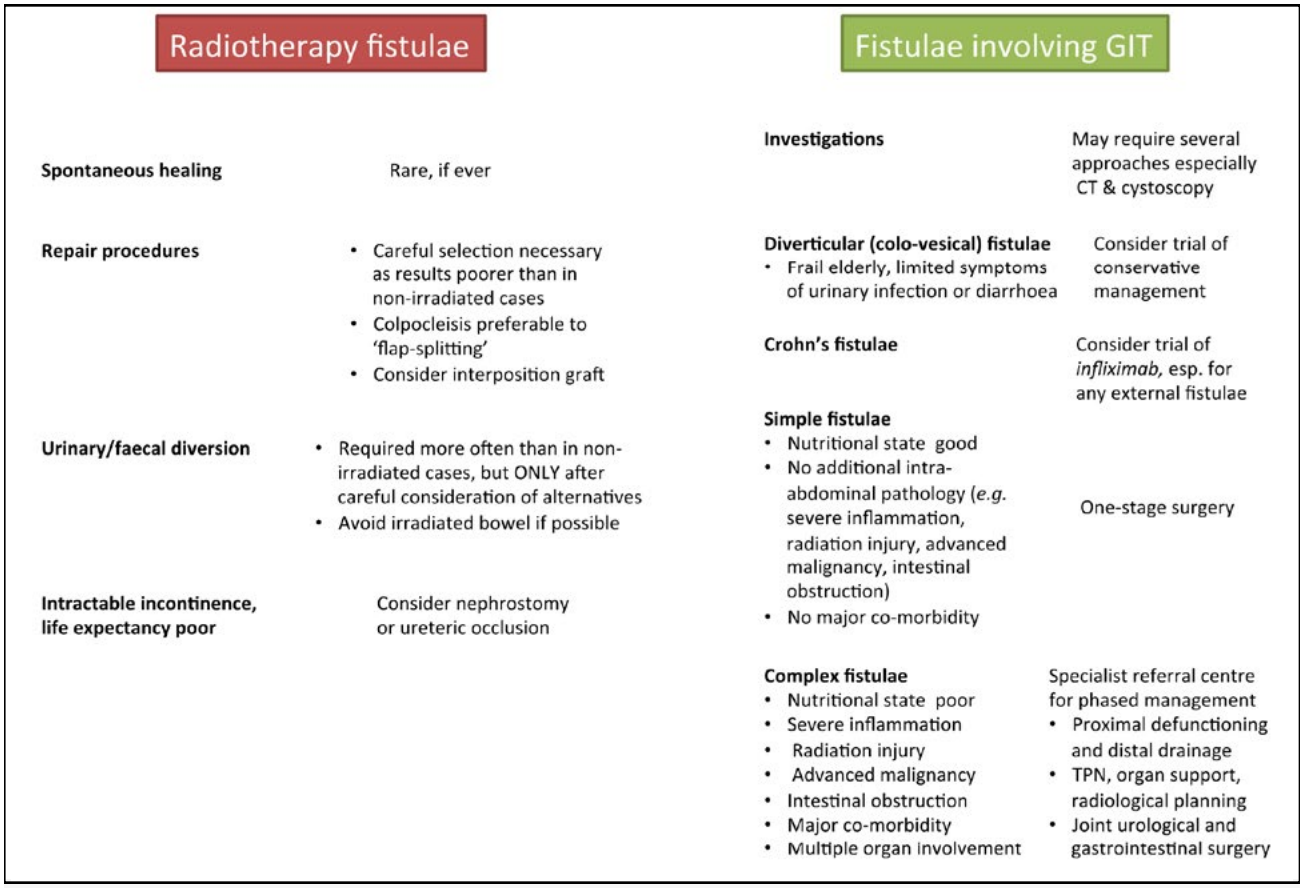

Fig 8. Treatment recommendations for radiation fistula and fistula involving the gastro-intestinal tract

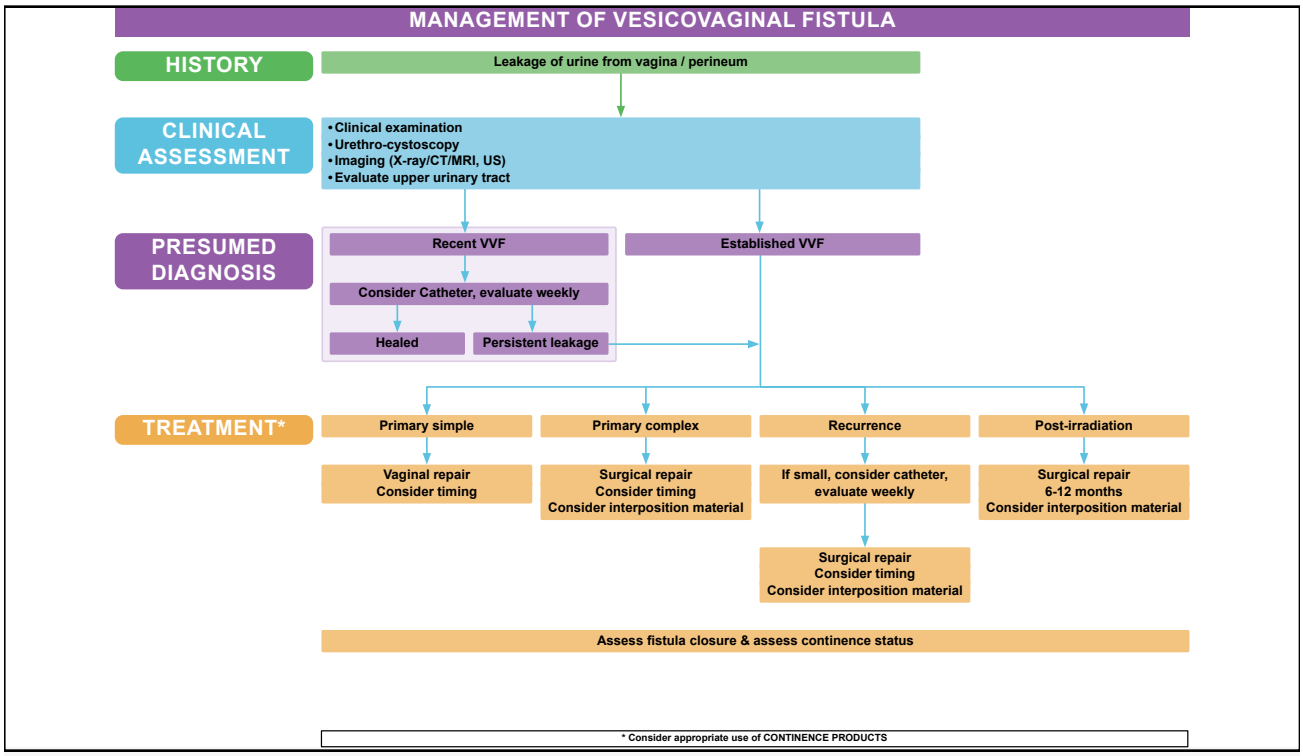

Figure 9. Algorithm for iatrogenic vesicovaginal fistula

4. OUTCOMES FROM TREATMENT AND FOLLOW-UP

In the developing world longterm follow-up of patients is difficult to organise, so most papers only report on shortterm outcomes. But also in the developed world data on longterm outcome of fistula repair are scarce Comparing the outcomes of treatment between different reports and different methods is made difficult by the inconsistent and relatively inefficient outcome measures used. These have ranged from the apparent achievement of a water-tight repair based on dye-testing in the operating theatre, to patient reported symptoms at the time of discharge from hospital. Follow-up in obstetric fistula patients is inevitably difficult in many developing world centres, but even amongst surgical or radiotherapy cases in the developed world, relatively few reports describe examination findings or symptoms at later postoperative review. Long-term outcomes and quality of life measures have only rarely been reported. [338, 339]

Reporting on fistula repair outcomes should always include the fistula closure rate, urethral continence status and sexual function. Next to that attention needs to be given to aspects of social reintegration. [340, 341]

Bengston et al. published an incontinence prediction calculator based on age, the number of prior surgeries, the fistula size, the circumferential nature of the fistula, scarring and the urethral length. [342] A prospective validation of this tool is awaited. The assessment of post-repair continence can be done with a 1-hour pad test. A 1.5gr cut off will identiy 94% of women who will remain continent. [343]

5. MANAGEMENT OF COMPLICATIONS OF VVF

The complications of obstetric fistulae and/or the complications of fistula repair are many and these include:

- Recurrent Fistula:
  - Success rate of uncomplicated vesicovaginal fistula (VVF) 70-80%
  - Success rate of complicated VVF 50-60%
- Stress incontinence after successful fistula closure: 16_33%
- Infections: wound, urinary tract infections (UTI) and pyelonephritis and urosepsis
- Voiding Dysfunction (overactive bladder – incomplete micturition – dysuria)
- Ureteric obstruction (ligation – fibrosis – injury)
- Outlet obstruction (meatal stenosis, urethral stricture, bladder neck obstruction (BNO))
- Bladder contracture
- Vaginal stenosis (overcorrection – fibrosis)
- Sexual dysfunction (vaginismus – dysparunia)
- Rare complications (granulomas – diverticulum formation)
- Neurological complications (foot drop – neurogenic bladder)
- Complex neuropathic bladder dysfunction and urethral sphincter incompetency often result, even if the fistula can be repaired successfully
- Psychological trauma (social isolation – divorce)

While fistula complications might be more manageable in the developed world due to the availability of reconstructive surgery and a multidisciplinary approach, the same complications might have severe consequences for patients in developing countries due to the lack of the appropriate skills, experience or equipment. It is important to realise that HIV is not a prognostic factor for complications.[344]

VI. RECURRENT FISTULA (PERSISTENT INCONTINENCE)

Fistulae can be closed successfully in around 72% to 92% of cases. The definition of success, however, is often different when the perspectives of the patient and the surgeon are compared. “Success” to a fistula patient means complete restoration of urinary continence and control, whereas many surgeons define “success” as simply closing the fistula. [220]

It is essential to establish defined criteria that will allow meaningful comparison of treatment outcomes. The patient-oriented criterion of continence restoration should be the goal when the outcomes of various fistula treatments are compared. Persistent incontinence despite successful closure of the fistula has been termed “the continence gap”.[345]

A patient whose fistula is closed but who remains incontinent may be just as wet as a patient whose fistula closure operation failed. The estimates of persistent urinary incontinence after a successful closure of the fistula come from case series, ranging from 16.3% in a large retrospective review of patients by Wall et al. to 33% in a small series of complex fistulae in which the proximal urethra was lost.[346, 347] Adequate epidemiologic studies on the prevalence of fistulae and its sequelae are scarce, and because long-term data on surgical outcomes are difficult to obtain, the prevalence of persistent incontinence after surgery appears to be severely underestimated.

Persistent urinary incontinence in patients after fistula repair is due to multiple factors including scarring, location of the fistula/s and surgical experience of the operator as well as failure to perform a sling operation or urethral reconstruction at the time of repair in patients likely to require such intervention. The goal of fistula surgery should be restoration of continence and resumption of a full and active life on the part of the patient, not just closing the fistula.

1. PATHOPHYSIOLOGY OF PERSISTENT URINARY INCONTINENCE AFTER FISTULA REPAIR

Several possible etiological factors can be postulated in women who remain incontinent after successful fistula closure: loss of bladder tissues, massive damage to the mid-urethral continence mechanism, damage to attachments of the urethra, fibrosis and loss of compliance, neuropathy, etc. . . .

Loss of bladder tissue is one of the main reasons why obstetric fistula repair is technically difficult. The loss of bladder tissue from pelvic ischemia during obstructed labour affects both the technique needed for, as well as the functional outcome of, fistula repair.

Although there are as yet no basic histological studies of the tissue surrounding obstetric fistulae, it seems clear that these tissue have themselves sustained significant damage during obstructed labour. The fistula itself develops in an area which becomes necrotic; but the tissues surrounding the fistula have also suffered varying degrees of ischemia. In some cases pressure necrosis may destroy virtually the entire bladder, so that if the defect can be closed at all, the afflicted woman is left with a remarkably small (30 - 50 ml) bladder. Also the compliance may be altered by the extensive fibrotic changes that often take place. To date there have been few urodynamic studies reported on patients who have undergone successful fistula closure.[348]

In the study by Carey et al., of 22 women with severe urinary incontinence after fistula closure, 9 had urodynamic stress incontinence with normal bladder compliance, 3 had urodynamic stress incontinence with poor bladder compliance, 9 had mixed incontinence, and one had voiding difficulty with incomplete bladder emptying and overflow[202]. Limited data from urodynamic studies by Hilton and by Carey, Goh et al. suggest that detrusor overactivity and changes in bladder compliance are frequent causes of urinary incontinence in fistula patients with post-repair incontinence, in addition to the leakage resulting from successful closure but persistent intrinsic sphincter deficiency. [348, 349] There is a great need for further investigation of these issues; unfortunately, those hospitals most likely to see large numbers of patients with obstetric fistulae also usually lack the resources for more advanced urological investigation.

A number of patients with vesicovaginal fistulae develop vesical calculi. [350, 351] Often these bladder stones develop in association with a foreign body in the vagina. After stone removal, the bladder should be allowed to heal prior to attempted fistula closure. If this is not done, there is substantial risk of post-operative infection and breakdown of the repair.

The ischemic changes produced by obstructed labour often have a devastating impact on urethral function. Complete urethral loss occurs in about 5% of fistula patients, with about 30% of fistula patients sustaining partial urethral injury. Goh et al. found that up to 63% of fistula patient have sustained some injury to the urethra. [352]

Depending on the amount of tissue that is lost at the bladder base, the ureteric orifices can be found in bizarre locations, ranging from the lateral vaginal walls all the way up to the level of the vesico-urethral junction and the pubic arch. Aberrant ureteric locations of this kind can easily be missed on clinical examination and are one cause of persistent incontinence after otherwise “successful” fistula closure. Standard urological tools such as ureteric stents are usually not available in hospitals in the developing world, and most of the surgeons who work in such hospitals are not trained in “urological” techniques such as ureteric reimplantation.

The impaction of the fetal head is sometimes serious enough to cause ischemic injury to the bladder will also cause ischemic injury to the vagina, which is likewise trapped between the two bony surfaces. These injured areas heal with varying degrees of scarring. Adetiloye and Dare detected fibrotic changes in 32% of fistula patients and minor vaginal wall fibrosis in another 36% in their sonographic study of a small number of patients. [353]

The presence of vaginal scarring appears to be an important prognostic factor in determining the likelihood both of successful fistula closure, and also for the development of debilitating urinary stress incontinence after otherwise successful fistula repair. Kelly and Kwast reported worsening surgical outcome in fistula patients who have vaginal scarring. [354]

2. MANAGEMENT OF RECURRENT FISTULA

The most important concept is the recognition of the differences between simple and complex fistulae.

Vaginal surgery for small fistulae can be attempted under local anaesthesia. [355] Larger or more complex fistulae can be treated under spinal anaesthesia, which is preferred over epidural or general anaesthesia by many authors. [356]

Operating by the abdominal route increases the cost and time of the operation, but is still often performed for some high fistulae where surgical access is problematic. Experienced fistula surgeons may be able to repair such defects vaginally. A retrospective study by Chigbu compared the outcome of juxtacervical fistula through the vaginal or abdominal approach. [357] Both approaches had similar cure rates and hospital stays, but the abdominal route was associated with a significantly higher need for blood transfusion.

General anaesthesia is also more expensive, more complicated to administer, carries more risks, and should therefore be reserved for those patients who need an abdominal approach.

2.1. The Complex Fistula

A complex obstetric fistula can be described being larger than 3 cm, involving the urethra, and associated with reduced vaginal capacity from significant scarring and/or a reduced bladder volume. Sometimes the defect may be urethrovaginal, but more commonly both the urethra and bladder are involved and therefore the fistula is called an urethrovesicovaginal fistula.[188]

Most of authors with extensive experience in the management of obstetric fistulae comment on the great difficulty in achieving postoperative continence in patients who have had extensive damage to the urethra, even if the defect itself has been closed successfully. Rates of postoperative urethral incontinence range between 6-50%.[348, 354] Often the diagnosis of postoperative incontinence is given only if the patient suffers from severe incontinence while walking. If rigorous questioning is used to exclude any leakage with coughing or other exertion, the rate of postoperative incontinence increases dramatically.

The four risk factors that lead to a high rate of incontinence following fistula repair are:

- ***Urethral involvement***. Odds Ratio 8.4 for developing urethral incontinence post operatively.
- ***Large size of the fistula***. Odds ratio 1.34 for each cm increase in size of the defect.
- ***Severe vaginal scarring***. Odds Ratio 2.4 if the scarring is significant enough to prevent the introduction of a Sims speculum without relaxing episiotomies.
- ***Small bladder size***. Odds ratio 4.1 if the bladder capacity is less than 120 ml.[188]

In repairing complex obstetric fistulae, the principles for simple fistula repair still apply, but with the following additions:

Exposure is more difficult. In complex cases the fistula may be obscured from view due to the presence of severe vaginal scarring.

Such scaring often consists of a thick band of scar tissue on the posterior vaginal wall. Occasionally, the vagina has been completely occluded. Wide bilateral episiotomies may be required and where possible the scar should be released from the lateral pelvic sidewalls. This will enable the fistula to be seen more clearly.

The ureters should be identified and protected against possible injury, as in the case of a simple repair.

The bladder and urethra should again be carefully mobilized. The tissues are often thin, scarred, and fragile in such cases. The mobilization often has to be extended along the lateral pelvic side walls and even on to the posterior aspect of the pubic symphysis in order to free the lateral and anterior bladder.

The mobilization of tissues should be wide to ensure a tension-free closure.

The utility of tissue flaps remains controversial. In some cases the use of tissue transposition techniques such as the Martius graft and various forms of sling operations are the mainstays of treatment.

Using the fibrin glue could be useful in many cases especially the recurrent cases with tissue damage. The use of fibrin glue as an interpositioning layer during the vaginal anatomical repair of complicated vaginal fistulae appears to be of great value as an alternative to the use of Martius flaps interpositioning. Decreasing the operative time and adding simplicity to the already complicated procedure are additional values of using this procedure. [358]

Often destruction to the vagina has been so extensive that rotational skin or myocutaneous flaps are required in order to cover the defect. [359]

If these principles are applied, the success rate in fistula closure is high, but many women remain incontinent despite successful closure. In patients in whom all of the risk factors mentioned above are present, the postoperative incontinence rate may approach 100%. [360, 361]

In light of this dismal successrate, some surgeons now suggest that two further principles of repair be maintained:

Maintain the urethral length;
A shortened urethra has been noted in post-repair fistula patients returning for furthertreatment of persistent urinary incontinence. An unpublished series of72 patients with post fistula repair incontinence foundan average urethral length of 1.4 cm in these women. This suggests that continence might be improved if normal urethral length can be restored at the time of fistula closure. Vertical (as opposed to horizontal) repair of urethrovaginal fistulae has therefore been suggested. This appears to be possible in approximately 20% of such cases. In cases in which there is an urethrovesicovaginal defect, vertical repair of the urethral defect may improve success, while the vesical defect can be repaired either vertically or horizontally. [362]

Support the urethra;
For all urethral defects larger than 4 mm with a urethral remnant less than 2.5 cm, many fistula surgeons use an ‘anti-incontinence’ procedure during the initial repair. Currently there are two widely used procedures. The first sutures the urethra/bladder neck to the periosteum of the pubic ramus in a type of suspension operation. The fascia or muscle of the bladder is sutured on either side of the bladder neck area to the posterior aspect of the symphysis pubis or the arcus tendineus. [363]

The second procedure creates a sling of tissue to support the urethra. A pedicle of tissue is created on either side of the urethra from the lateral pelvic side wall. In theory this involves use of the pubococcygeus muscle, but more often it is simply a pedicle of fibromuscular tissue or scar that can be harvested. The pedicles created on either side are then sutured together in the midline. If either of these two extra steps are used, the incontinence rate after closure of complex fistulae can be reduced from 100% to 50%. [361]

Pope et al. compared the outcome of this type of pubococcygeal sling with refixation of the bladder neck in a retrospective series of 185 slings and 50 refixations and 32 combined cases. Approximately 49% of patients remained incontinent in all groups and no redommendation on a preferred technique could be made. [364, 365]

Various authors have described neourethral reconstruction using bladder flaps. All of these operations are based upon transabdominal techniques such as that described by Elkins et al.[366] In this technique, a neo-urethra is created by mobilizing a flap from the anterior bladder, which is then rolled into a tube. The anterior surface of the neourethra is then sutured in two layers and the posterior edge of the fistula is closed transversely, also in two layers. The neourethra is reattached to the posterior edge of the pubic symphysis, and a Martius graft is placed before reapproximating the vaginal epithelium. In 18 of 20 cases, this technique resulted in fistula closure, but four women had severe stress incontinence postoperatively. Other authors have described various urethral reconstruction techniques, used for various indications. Most series are small and follow-up is limited. [367, 368, 369]

It is not known how many had mild incontinence. Neither of these surgical methods is ideal. Although they may create an anatomical urethra, often that urethra does not function normally. A further option in such cases is to create a ‘tube’ using either technique and then attempt to render the patient continent with the use of a urethral plug. [370]

Advanced Surgical Techniques
A transabdominal approach could be used for large, supratrigonalvesicovaginal fistulae, associated ureterovaginalfistulae or if bladder augmentation and bladderneck reconstruction was required. The transvaginal route was preferred for small sub-trigonal fistulae. A combined abdominal and vaginal approach was used for large fistulae involving the trigone or the bladderneck. The surgical approach varied in each patient.

Interposition grafts or flaps were used when required. [371]The overall surgical failure rate was 4.3%. The average operative time for layered closure was 72 minutes (45-130 minutes) and that for graft or interposition tissue repair 100 minutes (90-165 minutes). The mean hospital stay was 9 days (6-17 days). There were no reported intra-operative complications. Postoperative complications were urinary tract infection, haematuria, wound infection and fever. None of the patients required blood transfusion. For the repair of small fistulae, surgeons did not use interpositional flaps but rather used the layered closure technique with a success rate of 97.1%. Complicated fistulae required repair by graft or tissue interposition and had a success rate of 94.8% which is similar to the experience of other Indian centres. [372] Risk factors for the failure of vesicovaginal surgery included previous failed repair, large-sized fistulae, fistulae involving the trigone or ureteric orifices, a small bladder capacity and unhealthy vesical aurothelium at the time of surgery.

The majority of the large-sized fistulae were successfully repaired using the transabdominal technique described by O'Connor, with interposition of an omental flap. This technique works well except when the fistula extends up to the bladder neck or when its transverse diameter is too large to allow tension-free approximation.

Combined abdominal and vaginal approach
This technique may be required in complicated fistulae involving the bladder neck. In cases where urethral continuity is disrupted due to a fistula, a combined approach may be preferable. The fistula is repaired by the abdominal route and continuity of the urethra is established by anastomosing the urethra through the vaginal route.

Urinary diversion
Urinary diversion in developing countries is usually not a viable option since stoma appliances and catheters (in the case of continent urinary diversions) are often unavailable or are too expensive. [373] In such cases performing a diversion procedure merely moves the fistula to another part of the body and the end result of such surgery may be more stigmatizing in the local culture than the original injury.

Uretero-sigmoidostomy has been used as a surgical option in developing countries for many years. Many data show that both short- and long-term complications will arise and that surgeons must face this and treat them. On the other hand a series of 9 Tanzanian patients undergoing diversion found that results were acceptable and that patients had a marked improvement in their quality of life. Even pregnancies after ureterosigmoidostomy have been described. [274, 374, 375, 376, 377]

Urinary diversion with the creation of a sigmoid or rectal pouch is feasible in selected patients. Longterm data on outcome are not yet available. The risk of complications is rather high and managing complications adequately often requires diagnostic capabilities that are absent in developing countries.

Recommendations:

A care programme for failed repairs with persisting incontinence after a successful repair, needs to be in place.	D
It is recommended that surgical treatment of post-operative stress incontinence should only be considered six months after fistula repair.	D
Autologous material should be used when a graft or sling is required and there is no place for synthetic sling material.	C
In recurrent identifiable fistula make sure of the size and number as this kind of fistula is better repaired by a well experienced fistula surgeon. It is important to use tissue interpositioning like a Martius flap or fibrin glue.	A

3. OVERACTIVE BLADDER AFTER VAGINAL FISTULA REPAIR

The successful repair of a vesicovaginal fistula can correct the anatomical defect, but it might not render the patient dry. Failure to store urine is another problem that may occur after vaginal fistula repair.

Although persistent incontinence after fistula repair tends to be blamed on urethral dysfunction, a few urodynamic studies suggest that bladder dysfunction may play a role. [254] [378]

In the Addis Ababa Fistula Hospital, 144 patients were urodynamically assessed post fistula claosure: Forty-nine percent had urodynamic stress incontinence only, 3 % had detrusor overactivity only and 43 % had both urodynamic stress incontinence and detrusor overactivity. Five percent of women had neither detrusor overactivity nor urodynamic stress incontinence. Seven percent had postvoid residual volume of 150 ml or more.[254]

There are no specific reports on the use of antimuscarinics in fistula patients. Oxybutinin is not always available in low resource setting.

In cases where there has been extensive loss of bladder tissue or marked reduction in bladder compliance due to fibrosis, augmentation cystoplasty can be performed, usually using by interposing a segment of bowel. In some case, urinary diversion may be indicated, but only after careful discussion of the issues involved with the patient.

Recommendations:
Patients complaining of persistent leakage due to urgency incontinence or those ended up with contracted bladder may try antimuscarinics, Botulinum A toxin injection or even augmentation cystoplasty in small poorly compliant bladders. (Grade C)

4. CONTRACTED BLADDER AS A COMPLICATION OF VVF REPAIR

Although contracted bladder is a recognized complication of vesico-vaginal fistula, there is very little if any mention of this of vesico-vaginal fistula in the literature. Nardos and colleagues mentioned that among 1045 who were subjected for repair of obstetric vesico-vaginal fistula, 17% suffered from small bladder capacity post-operatively. They also realized small bladder capacity is a risk factor for failure of repair of vesicovaginal fistula.[379]

It is wiser to post-pone treatment until successful repair of the fistula is achieved. Nevertheless, a group in India attempted to repair complex vesico-vaginal fistula and to augment bladder with ileum during the same procedure. Their repairs were successful in all the 4 cases they treated. [380]

It has to be mentioned that in 3 of these cases the origin of the fistula were obstetric and one secondary to genital tuberculosis. Eilber and colleagues suggested that abdominal approach to repair the fistula can be utilized if bladder augmentation is planned simultaneously. [381]

Treatment should follow the same principles and indications of treating contracted bladder of other etiologies. The only treatment option available is augmentation cystoplasty since pharmacological manipulation, detrusor botulinum toxin injection, and neuromodulationis unlikely to work since the problem is primarily myogenic.

Recommendations:

Contracted bladder is a recognized complication of vesico-vaginal fistula and it is a risk factor of repair failure.	EL4
Contracted bladder can be a cause persistent incontinence after successful closure of the fistula.	EL4
Augmentation cystoplasty may be the only reasonable option in extreme cases.	EL4
Every effort should be made during the repair of the fistula to preserve bladder tissue.	EL4
Diagnosis should rely on urodynamics.what are eyeball UDS?	EL4
Further research on this topic is required.	EL4

5. URINARY TRACT INFECTION

Urogenital fistulae may occur due to infective pathologies (e.g. lymphogranuloma venereum, schistosomiasis, tuberculosis, actinomycosis, measles or gangrene). [382]

Although urinary tract infection (UTI) is relatively uncommon in women with fistula, it may be seen as a complication of surgical repair of fistula or of the prolonged catheter drainage that usually follows such procedures.

No systematic reviews or meta-analyses were identified from the literature search. Only two randomised controlled trial (RCT) were identified.[244, 383] The majority of papers were uncontrolled retrospective case series, looking primarily at surgical techniques and outcomes in terms of continence.

Wondimeneh et al. reported gram negative bacteria to be the most prevalent cultured strains in north Ethiopian post fistula surgery women (Citrobacter 24.5% and E. Coli 11,3%). More worrying was the antibiotic resistance pattern: Enterobacter, E.coli and Proteus mirabilis were 100% resistant to tetracycline. Enterobacter, Proteus mirabilis, Klebsella pneumonia, Klebsella ozenae and Staphylococcus aureus were also 100% resistant to ceftriaxone.[384]

Concerning antibiotic prophylaxis, Muleta et al. showed that a single dose of Gentamycin (80 mg IV) given preoperatively at the administration of spinal anesthesia appears to be equally effective as the extended use of either of or combination of Amoxicillin, Chloramphenicol and Cotrimexazole.[383]

Ayed et al. reported on the basis of a multivariate analysis of a retrospective cohort that UTI prior to repair was an adverse prognostic factor for successful surgery (p=0.03); the OR however was not significant (OR 2.72; 95%CI 0.69, 12.1) making the conclusions of the study of limited significance. [272] In a small series of post-hysterectomy fistulae, managed by laparoscopic, open abdominal, or vaginal repair, Ou et al. reported only a single episode of UTI following a vaginal procedure (1 out of 6 cases), and none following the alternative approaches. [277]

Chigbu et al reported no difference in the rate of successful fistula closure, nor of postoperative UTI between abdominal and vaginal repair procedures in women with juxtacervical fistulae. [357] The numbers of patients included, and the methodology used in these reports makes conclusions on the relative rate of UTI following different repair procedures inappropriate.

Conclusions:
The literature on this topic is limited, and the majority is of inadequate scientific value to allow meaningful evidence statements and recommendations.

There is limited evidence from a single study that UTI prior to fistula repair may be a poor prognostic factor.	EL4
The use of intra-operative antibiotic prophylaxis has been shown to reduce the rate of UTI and of antibiotic use postoperatively following fistula repair, but has not been shown to influence the rate of successful fistula closure.	EL2
There is no evidence available to adequately determine whether the rate of UTI postoperatively varies between different surgical approaches nor non-surgical management techniques.	EL4

6. CONTRACTED VAGINA, DYSPAREUNIA & SEXUAL DYSFUNCTION

The extent of scarring has been considered an important predictor of surgical success and has been incorporated into fistula classification systems. [191, 192, 194] [385]

Muleta and colleagues reported severe vaginal scarring or obliteration in 14.9% of 14,373 women undergoing obstetric fistula repair in Ethiopia. [386]

It is common that some women report sexual symptoms following pelvic surgery; this is particularly problematic following vaginal surgery, including that for urinary incontinence and pelvic organ prolapse. In a study of quality of life after anatomically successful repair, both urinary and sexual symptoms were found to be common, and were reported with approximately twice the prevalence of the local population of comparable age.[387, 388] The persistent sexual symptoms were reported as ‘quite a problem’ or ‘a serious problem’ by 27%. No comparable prevalence data for sexual dysfunction in obstetric fistula patients has been identified from the literature.

The literature searches identified 5488 papers related to urogenital fistula, 1961 of which related to surgery; 272,261 related to dyspareunia, sexual dysfunction, vaginal constriction, scarring, cicatrisation, or obliteration, of which only 88 related to these problems following fistula surgery, after removal of duplicates. Additional hand searching of 2010 journals and conference abstracts identified a further 25 studies of which only 2 were of relevance. Overall, only 7 references were identified which contained any information of any relevance to the topic of this review; of these none were RCTs and only one included any comparative data.

Both systematic reviews identified interventions for the physical aspects of sexual dysfunction in women following pelvic radiotherapy.[42, 389] Only 7 useful studies were identified in these reviews, investigating the effects of vaginal dilators (or stents or specula), [390, 391, 392, 393] (390-393) (390-393) [387, 388, 389, 390] [385, 386, 387, 388] [384, 385, 386, 387] intravaginal estrogen, and benzydamine douches. The latter compound is an anti-inflammatory, which acts directly on inflamed tissues by stabilising cells and lys-

osomal membranes and by inhibiting the synthesis of prostaglandins.

It is used topically and is well absorbed through the vaginal skin reaching higher concentrations in the underlying inflamed tissue than after oral administration; it also has analgesic, local anaesthetic and antimicrobial effects. Each of these interventions might therefore be of potential value in the face of sexual dysfunction following fistula repair surgery.

Two studies (both from the same unit) investigated the effects of a programme of psychoeducational support along with the use of vaginal dilators.[391, 394] Both reported an increase in compliance with the use of dilators (see figure 5), although no difference in sexual function scores was found. [391] Two RCTs investigated the use of benzydamine, and one intravaginal estrogen to reduce vaginal symptoms and sexual dysfunction following radiotherapy. [395, 396, 397] Each of these reports found improvements in vaginal symptoms, although both were underpowered, and of limited quality.

Secondary amenorrhea is commonly seen in obstetric fistula patients. Whether this reflects the tissue loss within the pelvis or a hypothalamic influence as a result of the physical and emotional effects of a traumatic labor, stillbirth and fistula development is not clear. The live-birth rate has been reported to be no more than 10% in obstetric fistula patients, so estrogen deficiency as a result of lactation is unlikely to be a significant factor. [386]

Conclusions:

Vaginal scarring is a common finding in obstetric fistula patients, and has been commonly (but inconsistently) linked to poor prognosis for surgical outcome.	EL3
There is no evidence on the use of vaginal dilators in the management of scarring associated with obstetric vesicovaginal fistula. Extrapolated data from post-radiotherapy vaginal stenosis may or may not be appropriate. Compliance is likely to be a problem with this approach to management, although there is evidence that additional psychoeducational support may improve compliance; data on effectiveness are inconsistent.	EL3
Persistent symptoms of sexual dysfunction are common following fistula repair surgery, and have a significant impact of the quality of a significant number of women.	EL3
Data on alternative non-surgical modalities of treatment for vaginal and sexual symptoms following obstetric fistula repair are also limited. Extrapolation from post-radiotherapy vaginal stenosis using intravaginal estrogen or benzydamine douches are encouraging, but supported by only limited RCT data.	EL2

7. URETHRAL COMPLICATIONS OF VAGINAL FISTULA REPAIR

Apart from urethral involvement in genitourinary fistula, urethral injury can be of iatrogenic origin during the repair of genito-urinary fistula: urethral injury occurred in 2% of the patients during the repair of the genitourinary fistula. Urethral stenosis was reported in 5.63% of patients after repair of urethrovaginal fistula. [398]

The exact incidence of different urethral complications of VVF is very difficult to determine. In one report from Sierra Leone examination of 505 patients with genito-urinary fistula showed that only 56% of these patients were judged to have a normal urethra. [399] Similarly, Raassen and others found that urethral involvement occurred in 5% of patients with obstetric urogenital fistulae. [400]

Presentation is dependent on the site of the fistula along the urethra and the involvement of the bladder neck and the bladder. If theurethro-vaginal fistula is large or if there is involvement of the bladder neck and the bladder, continuous incontinence occurs as in cases of vesico-vaginal fistula.

On the other hand, if the fistula is proximal in position, patient may present with stress urinary incontinence. Distal fistula can be completely asymptomatic or may be associated with splayed urinary stream. Positional wetting, which is incontinence on rising after voiding due to filling of the vagina with urine during voiding may also occur in proximal fistulae.

Pushkar and colleagues suggested repairing a urethrovaginal fistula by circumferential incision involving the fistula. The urethra is then mobilized and closed transversely to avoid constriction of the urethra. They advised against extensive trimming of the fistula edges since there is usually minimal tissues left for repair. They tested the urethra for any residual opening using a metal sound inserted into the urethra. A second layer from the periurethral tissues was placed before closing the vagina. A urethral catheter was placed for 6-9 days. Using this technique obtained a success rate of 90.14%. Recurrent fistulae were re-repaired and were successful in all but one patient. [398]

The use of interposition tissue layer is always advisable. The Martius labial fat pad flap is the most easily accessible and the most widely used flap.[401, 402] Others have described the use of peritoneal flaps with similar success to that of Martius flap although most of the fistulae in that report were non-obstetric. They have shown as well that the use of full thickness labial flaps is feasible. Nevertheless, they used that particular technique in only three patients. [381]

Bruce and colleagues have described the use of rectus abdominis muscle flap as intervening layer between the urethral and the vaginal layers.[403] The use of autologous fibrin glue has been shown to function equally to the use Martius graft in complex genitourinary fistula. The clear advantage of this was shown in the form of decreasing the complexity of already complex procedure and decreasing operative time. Additionally in does not preclude the use of Martius graft simultaneously. [233, 358]

Stress urinary incontinence that develops after urethrovaginal fistula repair can be treated with suburethral sling whether autologous or synthetic. Most of the patients in one study (59.46%) were objectively cured, while (32.43%) expressed they were satisfied, and (8.11%) of the patients remained incontinent.[398]

Hilton and colleagues reported their preliminary experience of treating sphincter incontinence following repair of urethrovaginal fistula in six patients with autologous fat injection. Two patients were cured, two improved and two did not benefit from the procedure. [404] The committee felt that it is safer to use autologous pubo-vaginal sling to treat stress urinary incontinence in these patients whether simultaneously with the original repair or later on.

Conclusion

The level of evidence in the literature regarding urethral complications of VVF is quite low. It appears that most urethral complications of VVF are preventable. These complications are urethrovaginal

fistula, urinary incontinence, and urethral obstruction. Diagnosis of urethrovaginal fistula is mainly dependent on vaginal examination and can be facilitated by the use of methylene-blue and a urethral sound. Persistent urinary incontinence after successful repair of vesicovaginal fistula is mostly due to ISD but can be secondary to overactive bladder.

Treatment of urethrovaginal fistula is always surgical not true using anatomical closure with the use of tissue interpositioning. The use of fibrin glue can improve the results. Stress urinary incontinence is best treated with pubovaginal sling using autologous material such as rectus sheath or fascia lata.

Recommendation:

Involvement of the urethra in the original fistula may worsen the outcome of the repair and is associated with higher incidence of postoperative stress urinary incontinence.	EL3
Treatment of urethrovaginal fistula is always surgical fistula not causing symptoms don't need to be treated and needs special surgical techniques and tissue interpositioning.	EL3
Treatment of stress urinary incontinence following repair of urogenital fistula can be performed by autologous pubovaginal slings.	EL4
Urethrovaginal fistula are preferably treated by a vaginal approach	EL3
A variety of autologous tissue interposition techniques have been described, but their value remains uncertain	EL3
Urethrovaginal fistula repair may be complicated by stress incontinence, urethral stricture and urethral shortening necessitating long-term follow-up	EL3

8. URETERIC LIGATION / INJURY DUE TO VVF REPAIR

Injury to pelvic ureter is one of the most serious operative complications of gynaecological surgery. Vesico vaginal fistula (VVF) repairs lead to 10-15% of ureteric injuries.[215] Ureteric injuries can be either expected or unexpected, and they may be the result of carelessness or due to a technically challenging procedure.

We refer to the section in ureteric fistula for further reading.

9. NEUROLOGICAL COMPLICATIONS OF VVF

Prolonged obstructed labor results in pressure induced ischemia and necrosis of the vagina, bladder,(occasionally)ureters, urethra and rectum, often provoking profound genitourinary fistula formation. These injuries may be part of a syndrome called the obstetric labor injury complex, which can include damage to the urological, gynecological, gastrointestinal, neurological and musculoskeletal systems. [405]

Neurological complications of VVF can involve peripheral (peroneal) or perineal nerves. Peripheral nerve injury is estimated to occur in 5% of women exposed to obstructed labor and vesico-vaginal fistulae in Sierra Leone. Since most women in Sierra Leone do not deliver in hospitals, urgent medical attention such as cesarean section for prolonged obstructed labor is often substantially delayed or completely unavailable.[219] This incidence can be underestimated.

In a study in northern Nigeria, when the charts of vesicovaginal fistulae patients were reviewed, only 5.3% of 470 patients were noted to have peroneal nerve injury. In contrast, when patients were asked and examined specifically for symptoms and signs of peroneal nerve injury prospectively, 75.9% of them had either symptoms of signs of peroneal nerve injury. [215] This may reflect the importance for a focused neurological examination on receiving a patient with vesico-vaginal fistula. Etiology of this lesion is most probably related to compression of the lumbosacral trunk of the peroneal nerve in the pelvis or due to direct injury of the peroneal nerve due to prolonged squatting and pushing in the 2nd stage of labor. [406, 407]

Peroneal nerve injury is mostly unilateral and occurs more often on the right side. Neverthless, it can still occur on the left side and can be bilateral. In the study of Waaldijk and Elkins peroneal nerve injury occurred bilaterally in 47, on the right side in 211, and on the left in 146 out of 311 patients with peroneal nerve injury. Most of these injuries resolve spontaneously. Only 13.3% persisted beyond 2 years after the occurrence of VVF. [215]

Neuropathy associated with vesico-vaginal fistula can also involve the perineum. In a study, 68.18% of fistula patients presented with a clinical neuropathy in the perineum. When these patients underwent electromyography, all fistula patients with vesicovaginal fistula in this study showed a degree of denervation. In contrast, there was no detectable lesion either clinically or by electromyography.

The severity of this lesion ranged from moderate (36.37%) to severe (63.63%). The severity is related to age at presentation since it is more severe in younger women. Furthermore, it is more severe in primiparous woman. Interesting, it appears from that study that the success of repair is affected by the severity of the lesion since severely denervated cases are usually associated with repair failure or at least persistent vesicosphincter dysfunction. [405]

Complex neuropathic bladder disorder can occur as a result of obstetric vesicovaginal fistula. This has been discussed else where in this chapter.

10. INFERTILITY AS A COMPLICATION OF VVF

Vesico-uterine fistulae can present in different ways, depending on their location, size, and the degree of patency of the endocervical canal. The least troublesome vesicouterine fistulae do not result in incontinence, but are characterized by the absence of vaginal menstruation in the presence of cyclic haematuria ("menouria" or "Youssef's syndrome"), whereby the menstrual flow exits exclusively through the urinary tract .[103, 107]

Other vesico-uterine fistulae may be associated with various combinations of altered menstruation and either periodic or continuous incontinence. The finding most characteristic of an uterovesical fis-

tula is demonstrable loss of urine through the cervix (a finding that also occurs with vesicocervical fistulae).

Many patients sustain severe cervical damage as well as vaginal injury during the course of obstructed labour. It is rare to see a completely normal cervix when examining a fistula patient. In the worst cases, prolonged obstructed labour may result in complete cervical destruction, leaving the patient with no identifiable cervical tissue at all.

Unfortunately, detailed descriptions of the condition of the cervix have not been included in the case series of fistulae published to date. Since cervical competence is such an important factor in future reproductive performance, this is yet another clinical area that demands further study. Other studies have shown amenorrhea rates from 25% to 44% . [408]

Many of these patients undoubtedly have hypothalamic or pituitary dysfunction. [409] A follow up study by Browning et al. showed that while the amenorrhea rate was 58% pre-operatively, this rate improved to 29% at 6 months after surgery, suggesting a recovery of ovulation in a proportion of operated women. [410] While the high incidence of amenorrhea in vesicovaginal fistula patients is widely recognized, only one unpublished study has been done to date looking specifically at uterine pathology in the vesicovaginal fistula population.

Dosu Ojengbede of the University of Ibadan (personal communication) performed hysteroscopy on fistula patients in Nigeria and found that intrauterine scarring and Asherman's syndrome were common in these women. The combination of widespread amenorrhea, vaginal scarring, and cervical destruction leads to a tremendous problem of secondary infertility among these patients. To date, there have been no serious scientific efforts to explore treatment of cervical and uterine damage in vesicovaginal fistula patients.

Subsequent reproductive performance of women who have had an obstetric vesicovaginal fistula has been analyzed in a few articles. [408]Emembolu analyzed the subsequent reproductive performance of 155 fistula patients delivered at Ahmadu Bello University Teaching Hospital in Zaria, Nigeria, between January 1986 and December, 1990. [411] This series included pregnancies in 75 women who became pregnant after successful fistula closure and 80 women who became pregnant while still afflicted with an unrepaired fistula that had occurred in a previous pregnancy. In women with pre-existing, unrepaired fistulae who became pregnant but who did not register for antenatal care in the subsequent pregnancy, maternal mortality and morbidity in those pregnancies was high, reflecting continuation of the conditions that led to fistula formation in the first place.The commonest maternal morbidity, excluding recurrence of vesicovaginal fistulae, was haemorrhage requiring blood transfusion in 35 patients (27.3%). Others included ruptured uterus in 3 unbooked patients whose fistula had not been repaired, bladder injury at caesarean section in 1.6% and acute renal failure in 0.8%.

Maternal complications occurred more frequently in the patients whose fistula had not been repaired and who were also unbooked. The largest series is that of Aimakhu, who analyze a subsequent reproductive performance in 246 women who underwent successful fistula closure at University College Hospital in Ibadan, Nigeria, between 1957 and 1966. [408] Only 48 patients became pregnant following fistula repair with a total of 65 pregnancies. All but 6 of these were managed at University College Hospital. Five patients aborted prior to the 16th week of gestation, leaving only 60 viable pregnancies. The plan was to perform an elective caesarean section on all patients who became pregnant after fistula repair, but only 49 caesarean operations were carried out. The results of the vaginal deliveries were not encouraging.

Patients who underwent caesarean delivery fared better. There were 49 babies delivered and 47 survived. There was no recurrent fistula among women previously repaired who became pregnant and had a subsequent caesarean section. There was one maternal death from pulmonary embolism in a woman who underwent an emergency delivery at 32 weeks gestation due to a prolapsed fetal umbilical cord.

11. PSYCHOLOGICAL COMPLICATIONS

Women with urinary or fecal incontinence suffer from depression, anxiety, and abnormal levels of situational life stresses. It is likely that psychological changes are related to the symptom and related disability and distress than to specific urogynecological conditions. Feeling of insecurity, anger, apathy, dependence, guilt, indignity, feeling of abandonment, shame, embarrassment, depression and denial are also common. Women feel loss of self-confidence and self-esteem.

In addition to these physical problems, fistulae cause acute social problems. As a result of the continuous leakage of urine and/or feces into the vagina, affected women often have an offensive odor, leading them to be ostracized by their husbands, families, and community. For example, families do not want fistula survivors preparing food or participating in family events. Commuting in public transport and engaging in social activities such as weddings and naming ceremonies becomes difficult. Women tend to get socially disengaged and socially isolated. Psychological and functional decline prevails and the potential for institutionalization occurs. [412]

VII. MANAGEMENT OF RADIATION FISTULAE

In the oncological context, fistulae may occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.[413]

1. DIVERSION PROCEDURES

Because of the tissue changes surrounding radiotherapy-associated fistulae, several authors have suggested that urinary and/or fecal diversion should be seen as the treatment of choice in such cases. [275, 414, 415] Some authors use a routine policy of preliminary urinary and fecal diversion, with later undiversion in selected cases [416]. In a non-randomized cohort of rectourethral fistula repairs, Vanni and colleagues reported 100% closure at first operation in 35 non-irradiated patients, compared with 84% in 39 irradiated patients.[416] In addition, 97% of the non-irradiated patients subsequently underwent undiversion, whereas 31% of the irradiated patients required permanent fecal diversion because of a noncompliant rectum or severe sphincter dysfunction.[416]

Some authors have emphasized the place of repair in carefully selected cases of radiotherapy-associated fistulae.[417] Of 36 radia-

tion-associated or malignant fistulae in the series reported by Hilton, although 11 patients declined surgery or died before treatment and 6 underwent primary diversion, of the 19 (53%) who underwent repair, closure was achieved in 18 (95%) at first operation. Finally, some authors seem to take the view that diversion has little or no place in the management of radiation-induced VVF in particular [75]. Of 216 radiation-induced fistulae managed over a 47-year period by Pushkar and colleagues, 210 patients underwent a vaginal and 6 an abdominal repair procedure (it should be noted that this is a retrospective case series, and although not stated in the paper, it is possible that other patients not included in this review actually underwent diversion) (Pushkar et al, 2009). It should be noted, however, that with this almost exclusive use of the vaginal repair procedure, although a cumulative closure rate of 80% was eventually achieved after four or more operations, closure was achieved in only 48% after first repair, in 40% after a second operation, in 52% after a third operation, and in 35% after a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favored over ileum as a conduit in this context, to avoid the risk of employing irradiated bowel and distal ureter [418]. Although these benefits seem clear, it should be noted that high perioperative morbidity (37%) and reoperation rates (20%) have been reported from this procedure [419].

As an alternative, where both urinary and fecal diversion are proposed, Hampson and colleagues described the technique of left colic urinary diversion with distal transverse end colostomy.[420] This technique allows a shorter operative time and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active after such procedures, the residual bladder or rectal wall may be used to augment the vagina [421]. Where VVF coexists with significant bladder contracture after surgery or radiation, an abdominal (transperitoneal) repair might be considered, along with simultaneous ileocystoplasty or coloplasty [422, 423, 424]. Fistula repair performed concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaeys and colleagues [425]. Although one might anticipate very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

2. REPAIR TECHNIQUES

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of flap-splitting or dissection and repair in layers [269, 426] and partial colpocleisis [267] have been the most widely advocated in radiation-associated fistulae. [75] When patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect.[417] In a nonrandomized cohort study, Hilton reported anatomic closure by colpocleisis in 94.7% of patients with radiation-associated fistulae, compared with 96.1% for a range of repair procedures in fistulae of surgical cause.[216]

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colovesical or enterovesical and colovaginal or enterovaginal fistulae[427]. Although the results have generally been good, with the avoidance of a permanent urinary or fecal stoma, Levenback and colleagues reported poorer results than after resection of the affected bowel, largely related to bleeding from the isolated segment and bacterial infection. [427]

The interpositional grafts mentioned earlier are particularly useful in radiation-induced fistulae.

3. OTHER MANAGEMENT APPROACHES

In patients with intractable urinary incontinence from radiation-associated fistulae, percutaneous nephrostomy or ureterostomy might be considered [81]. This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteric occlusion might be more appropriate. Several methods have been described, including the insertion of coils [428] and other devices [429, 430, 431] These were reviewed by Avritscher and colleagues with success rates ranging from 50% to 100% for the different methods, and with an overall success rate of 77% in 150 cases from nine papers reviewed [432].

4. RECOMMENDATIONS

Although diversion is used more widely in radiation-associated fistulae of all types as compared with non-irradiated fistulae, there is low-level evidence that repair procedures can achieve successful fistula closure and continence in appropriately selected cases.	C
There is low-level evidence to support the use of interpositional grafts when repair of radiation-associated fistula is undertaken.	C
Where urinary and/or fecal diversions are required, attempts should be made to avoid using irradiated tissues whenever possible and to minimize the potential for anastomotic complications.	C
In patients with intractable urinary incontinence from radiation-associated fistula in whom life expectancy is very short, ureteric occlusion might be considered; there is insufficient evidence to recommend any particular technique.	C
Individuals with nonhealing urocutaneous fistulae caused by chronic infection should be evaluated for an occult source of the infection, and also undergo a nutritional evaluation because these individuals may be catabolic, immunosuppressed, and unable to mobilize adequate metabolic reserves to initiate wound closure. Other considerations in individuals with nonhealing urocutaneous fistulae include occult malignancy or an undiscovered foreign body.	C

C is level of evidence not recommendation

VIII. MANAGEMENT OF GI FISTULAE

1. LITERATURE REVIEW

The literature relating to the management of urinary fistula involving the gastro-intestinal tract is limited in quantity and quality. Recent systematic reviews on surgical and non-surgical management demonstrated lack of randomised and prospective trials. [433, 434, 435] Most fistulae involve the sigmoid to the bladder dome. [436]

2. NON-SURGICAL MANAGEMENT

In the context of colo-vesical fistulae associated with diverticular disease, a surgical approach is most commonly advocated. One non-randomised cohort of 30 patients included six who did not undergo surgery, four of whom remained well for periods of up to 14 years; of the 24 who underwent surgical treatment, five (21%) died in the postoperative period.[437]

Ileo-vesical fistula in Crohn's disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents; in a non-systematic review of the management of internal fistulae in Crohn's disease, Levy & Tremaine describe the drugs that have been reported to close internal fistulae partially or completely including *azathioprine*, *6-mercaptopurine*, *mycophenolate mofetil*, *cyclosporine A*, *tacrolimus*, and *infliximab*.[438]

One case series of 500 patients with Crohn's disease included 17 with entero-vesical fistulae; all received *sulfasalazine*, and most were treated with corticosteroids and antibiotics intermittently, and eight in addition received *6-mercaptopurine*. Although it is not clear that their fistulae closed completely, six continued on medical treatment alone for several years.[170]

Present et al. reported a placebo controlled randomised trial of the tumour necrosis factor α (TNFα) neutralising agent *infliximab,* a murine/human chimeric monoclonal antibody that binds both the soluble subunit and the membrane-bound precursor of TNFα, in patients with externally draining fistulae associated with Crohn's disease.[439] Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5mg *infliximab.* This latter study did not include intestino-vesical fistulae, although a case of successful use of *infliximab* in an ileo-vesical fistula has been reported.[440]

A systematic review on the medical treatment for fistula from Crohn's disease demonstrated a 65.9% fistula closure for enterovesical fistula. [434]However, prospective studies are lacking.

3. SURGICAL MANAGEMENT

A systematic review on entero- and colo-vesical fistulae, with 961 patients, indicated that surgical management, for the majority of case was performed as a one-stage procedure, that is, primary resection of the affected area with anastomosis and closure of the urinary tract defect. [435] The review also demonstrated significant heterogeneity in the studies with a lack of consensus on patient selection criteria for surgery, timing of surgery and techniques for repair of the fistula.

There was no statistically significant difference in the risk of recurrence of the fistula when comparing one-stage to multistage surgery to treat the fistula. [436] This study also showed a higher risk of recurrence of the colovesical fistula in patients with a history of radiation treatment and more complex bladder repairs including bladder resection and omental or other interpositional flaps. Laparoscopic repairs are becoming more common. [435] [441]

A systematic review on open versus laparoscopic surgery for the treatment of diverticular colovesical fistulae demonstrated no significant differences in stoma rates, rates of anastomotic leaks, surgical site infection and mortality rates. [433] As the results were obtained from non-randomised studies, the authors concluded that further studies are required before recommending laparoscopy over the traditional open approach.

Case reports of novel endoscopic approaches have been reported, including simultaneous procedures via cystoscopy and colonoscopy. [442]

4. LEVELS OF EVIDENCE

There is limited evidence to support a non-surgical or conservative surgical approach in colo-vesical fistulae where there are minimal symptoms or evidence of limited bowel involvement	EL 3
There is only limited level evidence to support a non-surgical approach in colo-vesical fistula associated with diverticular disease; nevertheless, in the frail elderly, or in patients who have limited symptoms of urinary infection or urinary diarrhoea it is reasonable to consider a trial of conservative management	EL 3
There is evidence that infliximab is efficacious in the treatment of external fistulae, but only very limited low level evidence of efficacy in urinary fistulae in association with Crohn's disease	EL 4
A one-stage approach to surgery for intestino-vesical fistulae is appropriate in many cases.	EL 2
A laparoscopic approach to one-stage management has been shown to be feasible, although there is no high level evidence to allow comparison of outcomes with open surgery	EL 3

IX. MANAGEMENT OF URETERIC FISTULAE

1. GENERAL PRINCIPLES

The relevant clinical principles are related to prevention, diagnosis, management, and after care. [443] Patients at higher risk of ureteric injury such as those undergoing complicated childbirth, radical or repeated pelvic surgery, or surgery following pelvic radiotherapy require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and also recognise injury promptly when it occurs. Immediate repair of any intraoperative injury should be performed observing the principles of debridement, adequate blood supply and tension free anastomosis with internal drainage using stents.[444] Delayed presentation of upper tract injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvi-calyceal system. Fluid should be sent for creatinine determination to differentiate serous from urinary leak. Repair of such cases should be undertaken by an experienced team and may consist of conservative management with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< 3 months) or delayed (> 6 months) surgical repair when required.[445] Surgery should again adhere to the standard principles of tissue repair and safe anastomosis. Functional and anatomical imaging should be used to follow up patients after repair to guard against late deterioration in function of the affected renal unit. These general aspects of care of patients with trauma to the upper

tract and subsequent fistula formation are covered in standard textbooks of urology and guideline documents.[444, 445]

2. URINARY LEAK AFTER RENAL PRESERVATION SURGERY

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days post-operatively, in 4% (45/1118) of patients undergoing partial nephrectomy.[446] This was associated with larger tumours, higher blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic *versus* open). The majority resolved without intervention but 30% required ureteric stent insertion or percutaneous drainage. Another large series of 752 patients showed that 21 (2.8%) experienced urinary leakage.[447] four of the 21 patients with urinary leakage had spontaneous resolution, one patient underwent nephrectomy, and 16 patients were treated by retrograde ureteral stents insertion On univariate analysis, hilar renal masses ($p < 0.04$) and higher preoperative creatinine levels ($p < 0.01$) were found to be associated with higher rates of urinary leakage. None of these variables was significant on a multivariate analysis. Review of the urinary leakage rate over time revealed it has been constantly decreasing over time, from 4% in early cases to 1.3% among the most recent ones, suggesting that the decrease in incidence is related to the improved surgical skills, rather than to differences in tumours' or patients' characteristics. A poor quality quasi-randomised study involving 16 patients with persistent leakage after pelvi-calyceal surgery despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared to control.[448]

3. URINARY LEAK AFTER RENAL TRANSPLANTATION

A case series from Brazil observed a fistula rate of 2.9% (31/1046) presenting at a mean of 28 (1-131) days following transplantation predominantly due to distal ureteric necrosis and with most cases requiring open repair.[449] Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and two deaths from sepsis. A case series from China observed fistula development in 3.5% (43/1223) of patients presenting at a mean (range) of 6 (3-20) days following transplantation again primarily due to necrosis of the distal transplanted ureter.[450] Open intervention with re-implantation of the ureter into the bladder or native ureter was required in 34 patients, with one other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series form Serbia found a fistula rate following renal transplantation of 2.2% (5/224) and all required open repair.[451]

4. URO-ENTERAL FISTULAE FOLLOWING PERCUTANEOUS RENAL SURGERY

Case reports of ureterocolic fistulae occurring after renal cryotherapy, and gunshot trauma all resolved with insertion of ureteric stent. [452, 453] This is in line with previous accounts of this complication following percutaneous nephrolithotomy.[454]

5. URETERO-ARTERIAL FISTULAE

A systematic literature review found reports of 139 cases of uretero-arterial fistula published between 1999 and 2008.[455] All patients presented with haematuria with 25% also having other urinary symptoms or back pain. Virtually all cases had a relevant past surgical history particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The great majority affected the iliac segment and pre-operative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent case series of 20 patients also showed a high mortality of 10 – 20% but did not find any difference in outcome between open or endovascular graft insertion techniques.[456] Kibrik et al. reported on endoureteral coil embolisation after failed endovascular coiling, resulted in successful closure of the uretero-arterial fistula. [457]

6. URETEROVAGINAL FISTULAE

Ureterovaginal fistulae occurring in the early post-operative phase predominantly after hysterectomy is the most frequent presentation to urologists of upper urinary tract fistula.

The use of ureteric stenting in patients with uretero-vaginal fistulae was reported in 11 studies, including 126 patients in total;[458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468] this resulted in closure in 63 cases altogether. Success rates were between 6% and 100%, although the overall closure rate across all series is calculated at 50% ± 18% (Fig. 10).

Li et al. reported on 46 patients with an ureterovaginal fistula who were treated with delayed ureteric stenting. Success was achieved in 45 cases, and urinary leakage was stopped 48 h after surgery. Of the 45 patients operated on, 16 had their double-J stents removed after 3-6 months, and 29 needed replacement every 6-12 months. In a postoperative follow-up of 6-36 months, 10 patients had recurrent stenosis needing ureteroscopic endoureterotomy or reexpansion with a balloon. No other complications occurred. [469]

Where retrograde stenting proves impossible, percutaneous nephrostomy and antegrade stenting might be considered if there is some degree of pelvicalyceal dilatation. Ureteroscopy may also be helpful,[463, 467] and a technique for combined antegrade and retrograde ureteroscopic cannulation has been reported.[460] In one report all cases of uretero-vaginal fistula were managed by temporary diversion using a percutaneous nephrostomy followed by delayed repair 4-6 weeks later,[470] and a similar approach was taken in the management of one uretero-uterine fistula.[471]

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if the relevant skills and facilities are available.[472, 473, 474] A recent case report has sug-

Fig 10. Conservative management of bilateral lower ureteric injury. Retrograde ureterogram showing successful cannulation of left ureter by guide wire and successful placement of right ureteric stent.

gested that open repair through the vagina is possible if abdominal access is problematic.[475]

7. URETERIC FISTULA ASSOCIATED THE TERMINAL PHASE OF PELVIC MALIGNANCY

Urinary leakage is very distressing for people dying of advanced pelvic malignancy but palliation by open diversion may be associated with a high rate of complications. Recent case series have described the technique of occlusion of the distal ureter with coils or other devices using an antegrade approach combined with chronic urinary diversion using nephrostomy tubes.[476, 477, 478] Natarajan et al reported successful management of five patients with two requiring repeat embolization but all achieving good palliation until death without adverse effects.[476] Shindel et al reported on 29 patients with bothersome urinary fistula despite chronic nephrostomy drainage, and poor performance status.[477] In all cases palliation of the urinary leakage was achieved. The majority of patients (23/29) died of their underlying cancer at a mean of eight months after the procedure. Three patients with benign disease subsequently underwent definitive surgical diversion with the remaining two lost to follow up. Coil migration was seen in one patient without serious consequence and there were no other complications specific to the embolisation. Kim et al used the technique to temporally palliate five women with ureterovaginal fistula prior to delayed definitive repair.[478] Jalaeian et al. performed 15 transrenal ureteral occlusions in 9 patients as palliation for refractory fistulae or leaks in the setting of malignancy not responding to percutaneous nephrostomy or uretericl stent. [479]

The algorithm for uretero-vaginal fistula can be found in figure 11.

8. LEVELS OF EVIDENCE

Prophylactic ureteric stent insertion does not reduce the risk of ureteric injury during gynaecological surgery	2
The use of desmopressin may hasten resolution of urinary leak after pelvi-calyceal surgery	3
Uretero-arterial fistula is associated with a high mortality rate	3
Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase	4

9. RECOMMENDATIONS

Surgeons undertaking complex pelvic surgery should be competent at identifying, preserving and repairing the ureter	D
Ureteric stents are not required as prophylaxis against injury during routine gynaecological surgery, while their role in more extensive surgery remains to be established.	B
Ureteric injury or fistula may be suspected in patients following pelvic surgery if a fluid leak or pelvi-calyceal dilatation occurs postoperatively	D
Uretero-arterial fistula may be suspected in patients presenting with haematuria with a history of relevant pelvic surgery and indwelling ureteric stent.	D
Elevated levels of creatinine in drainage fluid following pelvic surgery are suggestive of a urinary tract injury.	D
Most upper urinary tract fistula should be initially managed by conservative or endoluminal techniques where such expertise and facilities exist	B
Persistent ureterovaginal fistula should be repaired by an abdominal approach using open, laparoscopic or robotic techniques according to availability and competence	D
For patients with ureteric fistula associated with advanced pelvic cancer and poor performance status, palliation by nephrostomy tude diversion and endoluminal distal ureteric occlusion is an option.	C

X. GENERAL CONCLUSION

Fistulae can have a devastating impact on the quality of life of women. In developing countries the number of obstetric fistulae is still unacceptably high, due to poor peri-natal care in many countries. The experience and skill of several fistula surgeons should become available and transferable to many other surgeons, interested in this field. But more importantly major efforts are necessary to prevent fistula in those circumstances.

In the developed world, fistulae are less common and the outcome of fistula repairs seems to be reasonable. More prospective research is needed in this field.

REFERENCES **1538**

I. INTRODUCTION

Older adults have the highest known prevalence of urinary incontinence (UI) of any group, other than those with specific neurological disease (e.g., spinal cord injury). As the proportion of older people in the populations of the developed world increases, so will the absolute numbers of those with either urinary (UI) or faecal incontinence (FI) or lower urinary tract symptoms [1]. The ageing of populations and the failure to increase the number of healthy years at the end of life means that the impact on future health care and long-term care costs will be profound [2].

No matter how those in later life, conventionally defined as those of 65 years and older, are described, this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally and cognitively impaired adults in their late 60's. Because the healthier group is closer in phenotype and physiology to middle aged adults than frail older adults, information relating to the management of urinary and faecal incontinence in this group is integrated into the other ICI chapters. This chapter focuses on frail older adults, emphasizing not only the different aetiologies and treatment of UI and FI, but the additional issues of disease burden, disability, altered responses to drug therapy and the role of caregivers.

The committee took the view that where there is a paucity of data reflecting the effectiveness or utility of approaches to the treatment of UI or FI in frail older adults, interventions aimed at community dwelling older adults should be employed with due regard to the likely benefits, harms, feasibility, expectations and outcomes of treatment, rather than not be attempted at all. In line with the recent ICS white paper on the ethical treatment of older adults, due recognition should also be given the burden that might be placed on an older adult when any treatment regimen is recommended [3]. The committee recognized that frail older people may be "victims" of therapeutic nihilism and may receive standards of care below those received by younger persons [4, 5].

The pathophysiology of UI in frail older adults requires a broader conception of "disease," centring on patient-level factors rather than just the bladder or bowel and its neurological control. UI and FI in frail older adults is normally a result of multiple interacting risk factors including age-related physiological changes, comorbidity, polypharmacy, functional and cognitive impairments and common pathways between them (Figure 1). Furthermore, the impact of UI or FI in frail older adults extends beyond the affected individual to their caregivers, leading to caregiver stress and an increased likelihood of institutionalisation [6]. Therefore, assessment requires a broader scope than that employed in the care of younger individuals. Failure to address the multifactorial nature of disease and treatment limits not only clinical care and research, but also important opportunities to improve function and quality of life [7]. Management of incontinence in frail older adults is necessarily multicomponent, and must address the many associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining physical exercise with prompted voiding) [8]. Drug therapy must be placed in the context of altered pharmacology, pre-existing polypharmacy and an increased susceptibility to adverse events. The continuing challenge in this Consultation has been the relative dearth of Level 1 evidence for interventions. Research in frail older adults (and older people in general is hampered by substantial difficulty in recruiting to clinical trials due to either overt or covert exclusion and the additional challenge of intervening illness and death) [9]. Despite the oldest-old (those of 80 years of age and above) forming the fastest growing group of affected individuals, intervention studies continue to be rare. Moreover, trial outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique & meaningful to this population [10].

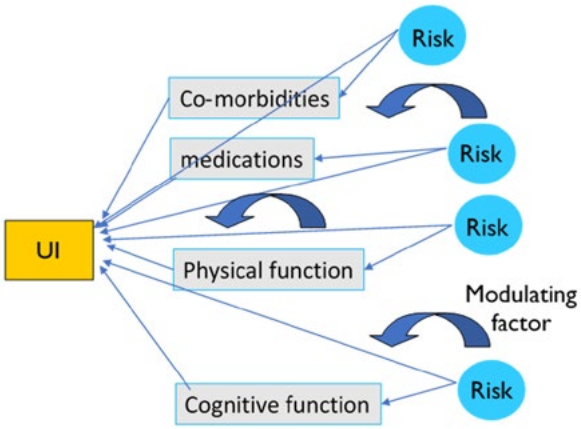

Figure 1. Incontinence as a geriatric syndrome

1. SEARCH STRATEGIES

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS, frail, FRAIL ELDERLY, FRAILTY, function, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL; and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URETHRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGYNECOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION , nocturia OR nocturia OR "night-time voiding" OR "night- time voiding" OR "nocturnal voiding" OR "night- time voids" OR "night-time voids" OR "nocturnal voids" OR "night-time frequency" OR "night-time frequency" OR "nocturnal frequency" OR "night- time urination" OR "night-time urination" OR "nocturnal urination" OR "night-time micturition" OR "night-time micturition" OR "nocturnal micturition" OR "night-time polyuria" OR "night-time polyuria" OR "nocturnal polyuria" OR nocturia) OR ((noctur* OR night*) AND (void* OR urination OR micturition OR polyuria OR pollakiuria OR "LUTS" OR "lower urinary tract symptoms" OR "BPH" OR "benign prostatic hyperplasia")) AND ("aged, 80 or over" OR ageing OR elderly OR older OR "very old" OR senior OR "all aged" OR geriatric OR frail OR aged) AND ("double blind method" OR "double blind" OR placebos OR placebo OR "controlled clinical trial" OR "randomized controlled trial" OR "random allocation" OR "single blind method" OR "research design" OR "exp clinical trials" OR "clinical trial" OR "single blind" OR "double blind" or "triple blind" OR "single mask*" OR "double mask*" or "triple mask*") (longitudinal OR "natural history" OR cohort OR incidence OR remission OR progression OR prospective OR "community-based" OR "population-based" OR epidemiol* OR "follow-up"); TOLTERODINE; OXYBUTYNIN; SOLIFENACIN; PROPIVERINE; TROSPIUM, IMIDAFENACIN; DARIFENACIN; FESOTERODINE; MIRABEGRON; faecal incontinence OR, constipation, OR anal incontinence. Ovid Expert Search

Filter; Publication years 2015-20. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations. A research librarian aided this process.

2. FRAILTY

The proportion of older persons in the population is increasing in almost every country around the world. By 2050, approximately 2000 million people will be aged 60 years or over, and 400 million will be over the age of 80. Frailty is essentially a state of vulnerability to insult, which may be in the form of a relatively minor stressor, from which the individual does not fully recover. The Consultation has defined "frail older adults" as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion). This is consistent with the Fried phenotypic approach to frailty in which there is a clear distinction between frailty and disability, and with the accumulation of diseases (deficits) model of Mitnitski and Rockwood [11]. Among those meeting strict phenotypic criteria for frailty, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability without comorbidity, and 27% had neither comorbidity nor disability [12, 13]. Frail individuals do however usually have multiple chronic medical conditions, take multiple medications, require care from others and assistance to perform some or all of the activities of daily living (ADLs) (e.g., bathing, dressing, toileting, and mobility), are often homebound or institutionalised. They have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1]. In the United Kingdom, an examination of 5,450 people aged 60 and over from the English Longitudinal Study of Ageing using Fried criteria found the overall weighted prevalence of frailty to be 14%. Prevalence rose with increasing age, from 6.5% in those aged 60–69 years to 65% in those aged 90 or over. Frailty was more common in women than in men (16% versus 12%). 93% of frail individuals had difficulties with mobility compared to 58% of non-frail individuals [14]. In the United States, using the Fried model of frailty applied to 7,439 participants in the 2011 baseline of the National Health and Ageing Trends Study of persons aged 65 and older, 15% (95% CI: 14%, 16%) of the older non-nursing home population was frail, and 45% were prefrail (95% CI: 44%, 47%). Frailty was more prevalent at older ages, amongst women, racial and ethnic minorities, those in supportive residential settings, and persons of lower income. Chronic disease and disability prevalence increased steeply with frailty [15]. In Latin America and the Caribbean, a meta-analysis of 29 studies including 43,083 people, of mean age of approximately 60 years, using a variety of frailty assessment scores, identified a prevalence of frailty of 19.6% (95% CI: 15.4-24.3%) with a range of 7.7% to 42.6% [16]. Likewise there have been an increasing number of epidemiological studies assessing the point prevalence of frailty, using a variety of definitions, across a number of countries such as Russia [17], China [18], South Korea [19] and Brazil [20] amongst others [21].

2.1. Frailty and incontinence

Several studies demonstrate a strong association between urinary incontinence and frailty. Incident UI in those over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [6]. In a Taiwanese study of 440 men aged 80 years and older, the rate of frailty was determined to be 19.1% based on the clinical frailty scale. Frailty was more common among subjects with UI than those without (60.7% vs 32.3%). Men with UI also had increased rates of comorbidity, poorer physical function, were more likely to have depressive symptoms, impaired cognitive function, poorer nutritional status, polypharmacy and a higher likelihood of faecal incontinence compared to men who were not frail [22]. In a population-based study of older Mexican Americans, incident, but not prevalent, UI was independently associated with functional decline in ADLs, IADLs, and physical performance [23]. Another population-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [2]. A Portuguese study found that older adults who presented with either "slowness" or "exhaustion" had a risk of UI almost five times greater than those without [24]. Among women ages >/=65 presenting to a urogynaecology practice in the United States, 16% were found to be frail and 31% reported functional difficulty in at least one ADL.[25]

2.2. Cognitive Frailty

Frailty is considered to be a *syndrome* that has both physical and cognitive components. Cognitive frailty is a heterogeneous clinical manifestation characterised by the simultaneous presence of both physical frailty and cognitive impairment. The key factors defining such a condition include the presence of physical frailty and mild cognitive impairment and excluding concurrent dementia, reflecting reduced cognitive reserve [26]. The exclusion of the dementias may not be useful in that the two features are often intimately intertwined. Conceptually, however, the definition may have clinical utility in terms of continence management, where the application of treatment options may vary depending upon the predominant factor influencing frailty. To be able to distinguish those with a vulnerability to cognitive decline amongst persons either with or without physical frailty may be of use, but again, the pathophysiological mechanisms leading to both entities are common and probably shared.

2.3. Dementia

The proportion of people living with dementia, a group of conditions also associated with an impairment in quality of life and physical function increases with age; prevalence estimates suggest that globally in 2010 35.6 million people lived with dementia with numbers expected to almost double every 20 years, to 65.7 million in 2030 [27][28]. In addition to the morbidity associated with urinary incontinence in older people, its presence with co-existent dementia increases the likelihood of institutionalisation [29]. Unfortunately, once there, there is evidence of institutional practices, such as *en masse* toileting, making incontinence more likely [30]. Likewise, caregivers identify looking after an older adult with dementia and incontinence as being burdensome [31, 32]. Management guidelines for urinary incontinence and lower urinary tract symptoms seldom consider the implications for management in those patients with co-existing medical conditions [33-35]; few discuss management in those with a dementia diagnosis [36]. The likelihood of incontinence increases in association with the severity of dementia but until recently longitudinal studies did not identify an association with incident cases [37, 38]. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by a modified mini mental status exam (MMSE) was not associated with increased frequency of urinary incontinence over 6 years but did predict a greater impact [39]. Despite strong associations with baseline incontinence in the Canadian Study of Health

and Ageing, moderate or severe cognitive impairment, measured by the same modified MMSE, was not associated with incident UI over 10 years [40]. However, in a longitudinal study of 12,432 women aged between 70-75 years with a 3 year follow up there was a strong association with a dementia diagnosis (OR 2.34) [41]. Similarly, over 9 years follow up of 1,453 women aged 65, dementia was strongly associated with incident urinary incontinence (RR 3.0) [6]. Likewise, in a Scottish study, the prevalence of urinary incontinence increased with decreasing mini-mental state scores and was notably more common in those with impairments of attention and orientation, verbal fluency, agitation and disinhibition [42]. In a United Kingdom General Practitioner database, when compared with those without a dementia diagnosis, dementia was associated with approximately three times the rate of diagnosis of urinary incontinence. The incidence rates of first diagnosis per 1,000 person-years at risk (95% confidence interval) for urinary incontinence in the dementia cohort, among men and women respectively, were 42.3 (40.9-43.8) and 33.5 (32.6-34.5) [43]. When assessed urodynamically, most incontinence associated with dementia appears to be related to detrusor overactivity, resulting in urgency incontinence [44, 45].

Incontinence in dementia adds to caregiver burden [46], and influences decisions to relocate people to care homes [6]. Whether successful management of incontinence reduces either this associated burden or alters decisions to institutionalise these people is unknown, evidence is limited to case reports and anecdotal evidence. Family physicians identify dealing with incontinence in dementia as a significant challenge [47]. Likewise there is the concern regarding the influence of antimuscarinic medications on cognition, where there is increasing evidence of cognitive impairment and higher rates of incident dementia diagnosis associated with high antimuscarinic load and long exposure in older persons in epidemiological studies [48, 49], although data in those with pre-existing dementia are less consistent [50]. Data suggest that the majority of older adults with dementia living at home receive inadequate toileting assistance [51].

Once institutionalised, urinary incontinence becomes a major factor in those with dementia, In a study in Austrian nursing homes, urinary incontinence was present in 84.2% of residents with dementia versus 53.2 % of those without and was highly prevalent even in those with early dementia, affecting 64% of the 277 residents studied [52]. Once admitted to a nursing home, the presence of a dementia diagnosis is associated with a hastening of loss of continence, compared to those residents without. Incontinence is associated with a reduced quality of life and impaired nutrition and mobility in older people with dementia [53, 54], but is sadly neglected in terms of the amount of attention paid to it despite the acknowledged adverse effect on quality of life and the associated costs of management [55].

2.4. Managing incontinence in dementia

Most people with a dementia diagnosis living in the community can potentially be managed in a similar way to any other community dwelling adult, in line with current guidelines. As noted in the 6th International Consultation on Incontinence, the expectations of both patient and caregiver, the nature of the proposed treatments and likelihood of benefits, harms and burden should be taken into account [56].

Successful and safe management of incontinence in people with more advanced dementia presents additional challenges. For the most part, successful delivery of conservative or behavioural therapies in late life requires the ability for the individual to learn or change behaviour; the active engagement of a caregiver is also required [56]. A dementia diagnosis should not preclude an attempt to manage incontinence with behavioural methods, but for those with a compromised ability to retain behavioural change this is clearly inappropriate. A stepwise approach to initiating interventions and assessing the results seems like a reasonable first step in management, recognising that older people do appear to be more likely to need drug therapy for urgency incontinence than younger persons [57]. For prompted voiding to be successful, a three day trial should result in either a 20% reduction in wet episodes or an increase in spontaneous requests to use the toilet [58]. If this is not successful then the mainstay of management is a strategy of check and change of appropriately assessed containment products [36, 59]. The remaining option is to introduce a fixed voiding schedule, which requires no behavioural change, but this too may be impractical in circumstances where there is limited caregiver support or availability. Even in adequately staffed institutions, evidence suggests that for those who need toileting, the average number of toilet assists per resident is around two per day, sadly short of that which might be needed [60, 61]. The maintenance of mobility is paramount, and exercise interventions designed to maintain mobility led to a reduced burden of care for care partners and an improved quality of life for residents of congregate living. Unfortunately, once hospitalised, there is a statistically significantly increased change of a person living with dementia returning home incontinent [62]. A systematic review examining the evidence for conservative management approaches for those with dementia living at home concluded, unsurprisingly that there was insufficient evidence to make any recommendation; little, if any, specific guidance for practice in the community exists [63, 64]. Since the last ICI there has been little research into evidence informed interventions for those with dementia except a single study which examined the effect of an educational intervention followed by case conferences aimed at improving quality of life for frail older adults living with dementia. Sessions included dementia education (e.g., dementia symptoms, interaction with people with dementia and challenging behaviour) and incontinence education comprising presentations, group work and discussions. The trial resulted in no difference in incontinence, perhaps a success in the face of a deteriorating progressive condition but an improvement in QoL for most homes participating in the project [65].

Evidence on pharmacological treatment for UI in those with dementia is lacking; that which does exist is discussed in the pharmacological treatment section.

II. URINARY INCONTINENCE

1. AETIOLOGY & ASSESSMENT

1.1. Background

The aetiology of UI in frail older adults is grounded in the concept of a classical geriatric syndrome, involving multiple interacting risk factors, including age-related changes, comorbidity, and potentially common pathways between them. This section addresses these components.

1.2. Quality of the data

The data on aetiology of UI in frail older adults remain limited, and observational studies of varying quality constitute much of this literature. Additionally, longitudinal studies of large numbers of frail individuals are difficult to carry out because of paucity in

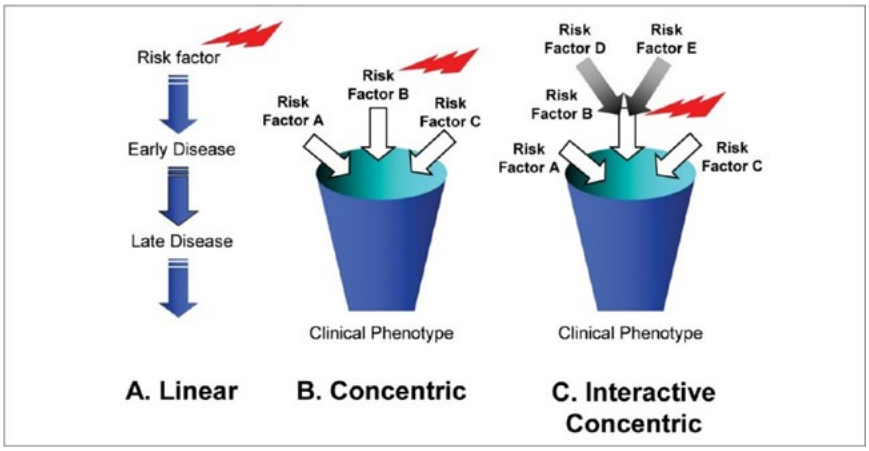

Figure 2. The mechanistic geriatric syndrome

recruitment and the high rate of natural attrition. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

1.3. UI as a geriatric syndrome

In older adults, especially those who are frail, UI forms a classical geriatric syndrome, many of its risk factors are not directly related to the genitourinary tract [66, 67]. Geriatric syndromes have been defined as ‘‘multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges” [66]. Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges. This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes [66]. **Figure 2**

Nevertheless, because common risk factors (e.g. arm and leg weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence) [68], they may represent particularly attractive sites for the development of interventions [66]. For example, the presence of brain white matter hyperintensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI [69]. F unctional magnetic resonance imaging (fMRI) studies have identified central nervous system areas that are particularly relevant to urinary storage symptoms and urgency [70, 71]. Therefore, failure of activation within orbitofrontal regions may contribute to an older individuals’ decreased ability to suppress urgency [72]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role in maintaining continence supporting the concept that decline in connectivity [72] and coordination between different brain regions represent early critical events in ageing. These findings suggest the possibility that interventions to prevent the development of white matter hyperintensities, such as control of vascular risk factors, could also prevent UI.

2. AGE RELATED CHANGES RELEVANT TO UI IN FRAIL OLDER ADULTS

2.1. Introduction

Age-related changes in the lower urinary tract (LUT) can function as risk factors for the development, continuation, and worsening of UI in frail older adults (**Table 1**). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on “normal” LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate “normal LUT ageing” from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe “age-related” associations, as opposed to normal ageing. Other limitations include derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; “age-effects” derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as “normal” controls. Even the definition of “normal” can be difficult: is it continence?, absence of LUTS?, lack of comorbid disease, or normal physiological testing [73]? The following sections focus on findings from more robust and, where possible, confirmatory studies. Moreover, the influence of sex on changes in the biology and physiology of the lower urinary tract with ageing extends beyond obvious anatomical differences [74].

2.2. Bladder

Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of “normal,” and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral nervous system innervation, and reflex patterns as determinants of bladder function in older persons. The research focus has been urodynamic function, neurohumoural responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciat-

Table 1. Age related changes in the lower urinary tract

Age-Related Change	Potential Effects on Continence
Bladder ultrastructure on electron microscopy Dysjunction pattern Muscle and axon degeneration	Bladder overactivity and urgency UI Impaired bladder contractility, increased residual urine, and decreased functional bladder capacity
Bladder function Decreased capacity Decrease sensation of filling Increased detrusor overactivity Decreased bladder contractile function Increased residual urine	 Increased likelihood of urinary symptoms and UI
Urethra Decreased closure pressure in women	 Increased likelihood of stress and urgency UI
Prostate Increased incidence of benign prostatic obstruction Increased incidence of prostate cancer	 Increased likelihood of urinary symptoms and UI
Decreased oestrogen (women)	Increased incidence of urogenital atrophy related symptoms Increased incidence of recurrent urinary tract infections
Increased night-time urine production	Increased likelihood of nocturia and night-time UI
Altered central and peripheral neurotransmitter concentrations and actions	Increased likelihood of lower urinary tract dysfunction
Altered immune function	Increased likelihood of recurrent urinary tract infections
Increased prevalence of white matter hyperintensities in brain	Increased prevalence of severe urge / urgency, link to cognitive impairment and impaired mobility

ed (See Committee 2, Cell Biology; Committee and Committee 3, Pathophysiology), there are only limited human data on urothelial changes with age. Urodynamic changes associated with age have typically included smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity (DO)). Correlations with age are often small, suggesting that other factors are at least as important [75]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy adults over age 55, DO was found in 42% of continent women, one-third of whom were totally free of LUTS [73]. In another study, charts of 53 consecutive females over age 80 undergoing multichannel urodynamics according to ICS standards were retrospectively analysed. These older patients presented with LUTS, yet in 11% urodynamic studies were reported as being normal, with considerable other discordance between symptoms and urodynamic findings [76]. Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [77].

The ability of the bladder to empty efficiently also declines in healthy older men and women who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [73, 78]. A variety of different risk factors associated both with ageing and common comorbid conditions may contribute to age-related declines in detrusor contractile function, which may ultimately lead to detrusor underactivity [79, 80]. Decreased contractile function during voiding in older persons is associated with lower urine flow rates and a small increase in post voiding residual volume (PVR) (generally to < 50 ml) [79]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractile function rather than obstructed voiding [80]. A large cross-sectional study revealed that maximum detrusor contraction power was lower in older as compared to younger individuals and that these differences with ageing were greater in women than men [81]**.** While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischaemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Pathophysiology). More recently, Smith highlighted the potential contribution of age and disease-related declines in bladder afferent sensory activity in contributing to impaired voiding performance seen with detrusor underactivity [82]. Incomplete bladder emptying from all such causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [79]. The development of a model allowing continuous uroflow in mice has led to studies evaluating the impact of normal ageing on overall LUT performance [83, 84]. While ageing did not influence measures of detrusor expulsive strength, pre-contraction pressures, intervoid intervals, per-void volumes and voiding flow rates all increased with ageing [83]. Moreover, aged animals demonstrated a decreased homeostatic capacity to respond to the challenge of continuous bladder filling, with indirect measures suggesting a role for decreased bladder volume sensitivity [83, 85].

In human studies, the observation that bladder volume at the initial desire to void declines with age may be confounded by comorbid conditions and concurrent medications [86]. Furthermore, unlike the positive association between detrusor contraction strength and DO found in younger subjects, older adults demonstrate a decline in DO-associated detrusor contractile function [77] and detrusor contractility [87] . Moreover, many frail older adults with UI present with a combination of DO on filling and poor emptying during voiding, an association termed detrusor hyperactivity with impaired contractile function (DHIC) [44, 79, 88]. In such cases, the bladder contraction does not empty the bladder fully, leaving a large PVR otherwise not explained by BOO. Because DHIC symptoms can include urgency UI, stress and mixed UI, dribbling, frequency, and nocturia, they may be mistaken for other conditions. At the same time, DHIC may be mistaken for DO with normal contractility function because significant detrusor underactivity may be present in the absence of any relevant symptoms. Thus, while it is not possible to speak of precise cutoffs when differentiating between “normal” and “abnormal” PVR values, PVR assessments do provide crucial information into age- and disease-related alterations in overall LUT performance [89].

A study of older women with an elevated PVR (> 100 ml) revealed on average a higher detrusor pressure at Qmax and greater bladder capacity than women with a normal PVR (PMID: 25400112). Also, with higher PVRs (> 200 mL) history of back surgery or injury (odds ratio (OR) = 4.30, 95% confidence interval (CI) = 1.16-15.91) and pelvic surgery (OR = 4.42, 95% CI = 1.51-12.95) were significantly associated with incomplete bladder emptying in multivariate analysis [90]. All of these considerations highlight the importance of an approach to older patients with elevated PVR that is systems-based and grounded in physiological principles [89]. One of

the major clinical challenges arises from the fact that while impaired bladder emptying is a well-recognized cause of lower urinary tract symptoms, many different terms are used to describe these issues plus the symptoms produced do not always relate to voiding, and may include frequency, urgency and incontinence. Ultrastructural studies demonstrate cellular changes associated with age-related changes in detrusor function. One series of such studies involved symptomatic and asymptomatic persons aged 65 - 96, using urodynamic testing and electron microscopy of bladder biopsy specimens, which were read in a blinded fashion using explicit protocols [91-94]. A consistent, one-to-one correlation between specific urodynamic findings and bladder ultrastructure was observed, although there has been considerable debate about the veracity of these findings and they have not been reproduced and have been disputed by the findings of a later study which found the ultrastructural changes described evenly distributed between normal women (n = 15) and women with detrusor overactivity (n = 22) [95]. In the small number of asymptomatic patients with no DO, normal contractility, and no obstruction, detrusor muscle fascicles were largely intact, with two distinctive ultrastructural findings that may be related to ageing alone: muscle cell membranes characterized by numerous “dense bands” and markedly depleted caveolae, and slightly widened spaces between muscle cells with limited content of collagen and elastin. Depletion of caveolae may be related to de-differentiation of muscle cells, which could eventually result in the reversion of actively contractile cells to inactive, synthetically immature cells. A similar phenomenon has been reported in atherosclerotic blood vessels and postmenopausal myometrium and may be related to reports of increased collagen in bladders from older women [91, 96]. Moreover, lack of oestrogen contributes to, and oestrogen replacement reverses, both caveolar depletion and detrusor fibrosis [97, 98]. Thus, both ageing and post-menopausal decline in oestrogen levels may contribute to bladder muscle cell differentiation and contractile function [79].

The natural history of these ultrastructural changes remains largely unknown. From the ultrastructural studies described above, a subset of 23 patients was followed longitudinally [99]. The previously observed one-to-one correlation between ultrastructure and function was maintained, but it was unclear whether urodynamic or ultrastructural changes occurred first in subjects who developed or had a change in LUTS. The pattern of dense-bands and non-disruptive muscle cell degeneration varied over time: the DO with dysjunction pattern developed in some subjects, and impaired detrusor contractility and the corresponding degeneration pattern was observed to progress in severity or develop. Other investigators have found similar results but without the one-to-one correlation (e.g., see Brierly *et al* [100, 101]). Clearly, further work is needed understand the associations between changes in ultrastructure, urodynamic features and clinical syndromes.

In addition to such alterations in ultrastructure, a variety of changes involving relevant nerve fibres, receptors and signalling pathways have also been described in bladder tissues from aged animals, and to lesser extent human biopsies. For example, with ageing overall, sympathetic nerve fibre density may decrease [102, 103]. Bladder biopsies from older subjects with normal urodynamic profiles typically show little or no evidence of axonal degeneration and the density of some CGRP-positive sensory nerves is maintained in old age, yet the impact of ageing on other categories of sensory fibres or on motor fibres remains unknown [91, 102]. Examples of other changes include decreased contractility and calcium fluxes in response to cholinergic agonists or depolarization [104]; increased responsiveness to adrenergic agonists with increased expression of the alpha 1D-adrenergic receptor [103]; declines in phosphodiesterase 5 (PDE5) levels and possibly signalling [105]; as well as decreased P_{2X1} purinergic receptor expression [106]. Unfortunately, the interpretation and generalisability of these findings is often limited by a failure to include intermediate age-points which would allow investigators to distinguish changes attributable to ageing as opposed to maturational processes [107, 108].

More recent studies have suggested a role for decreased A_2B receptor expression in lower ability of adenosine to relax the detrusor [109]. Also, use of permeabilised bladder muscle strips suggested that IP_3-induced calcium release is primarily responsible for the contractions in older rats, thus ageing-related decline in carbachol contractions may result from decreased calcium-induced calcium release rather than carbachol-induced calcium sensitisation [110]. The use oxidative stressors has shown that mechanisms possible related to the TRPM8 (cold sensing TRP melastatin 8) ion channel may compromise urothelial function in aged bladders [111]. Studies conducted with human bladder muscle strips suggested an age-related increase in carbachol-mediated contraction via Rho Kinase pathways [112], associated with lower MLCK expression [113]. Finally, studies conducted in aged mice from a systems-based perspective demonstrated that an increase in neurogenic power during filling accompanies augmented centrally mediated compliance enhancement with ageing, thus suggesting the existence of a bladder control model in which brain processes related to micturition may compensate for age-associated changes [114].

2.3. Urethra

Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes like the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls. Urethral closure pressure decreases with age [115, 116]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH_2O per decade [117]. A number of anatomical and physiological changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [118]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [119]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen [120]. Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [121-123]. However, age explained only 9% of the variability in vascular density in one study [121], and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [124, 125]. Both oestrogen receptor alpha ($ER\alpha$) and oestrogen receptor beta ($ER\beta$) are present in paraurethral tissues [126]. Although there were no apparent differences in the expression of these genes between women with stress urinary incontinence (SUI) versus controls, levels of $ER\alpha$ and $ER\beta$ mRNA were lower with the menopause and ageing, respectively [126].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral

wall of the proximal urethra [127, 128]. These authors estimated that striated fibres decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [129]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra. Moreover, a recent study raised the possibility that TNF-alpha may contribute to age-related rhabdosphincter satellite cell death and muscle loss with ageing [130]. Urethral sensation, measured as current perception thresholds, was significantly higher in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI [131], and another in asymptomatic women [119]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity [131], and the "asymptomatic" older women may have had urodynamic DO [119].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles, benign violaceous soft swellings, often appear at the meatus and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [132]. Diverticula should be considered in women who have repeatedly failed "conventional" UI treatment. Diagnosis requires imaging by voiding cystourethrography, ultrasound, or magnetic resonance scans. Urethral obstruction is relatively uncommon in older women and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or is iatrogenic (from LUT/pelvic surgery or radiation. In men, age-related decrease in striated sphincter muscle cell density also occurs, [133, 134] and has been associated with increased muscle cell apoptosis [133]. While some investigations describe an increase in resting prostatic urethral pressure with age, [135] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [136]. These discrepancies may reflect differences in prostate volume and morphology.

2.4. Pelvic floor

Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity [137]. A number of studies are cross sectional rather than longitudinal and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI, after adjustment for obesity, birth history, menopause, and hormone use [138]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [139]. In contrast, a study combining an interview, physical exam and transperineal ultrasound identified age as a weak (r = -0.25) but statistically significant predictor of pelvic muscle weakness and levator ani morphometry even after controlling for obvious confounders [140]. A recent MRI study was able to distinguish distinct patterns of change in pelvic support in women with stress as opposed to mixed urinary incontinence[141]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2,Neural Control & Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [142]. A histomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (</> age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [143]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [144] but this association does not imply a direct causative effect of "ageing." Constipation may independently contribute to pelvic floor dysfunction in older women [145, 146]. Finally, while vaginal atrophy was as expected more intense in women aged >60 years, no difference was found in pelvic floor muscle strength with ageing in continent women [147]

2.5. Vagina

The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [148]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamentum rotundum [149]. Yet, as the Women's Health Initiative trial has shown, one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms [150, 151]. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [120].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail older women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4 [152]. These changes can lead to loss of normal adherent flora (lactobacilli), colonisation with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [153].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age. Whether this is oestrogen related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases and may be accompanied by invasion by lymphocytes and plasma cells [153]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [149]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [154]. Vaginal shape also may be altered by POP. Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symptoms/LUTS

should not be automatically assumed. Very few randomised trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [155]. There are insufficient data to provide an evidence-based approach to symptomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring). The validation of vaginal self-swab collection specimen collection offers new opportunities for extending relevant questions to epidemiological studies of older women living in the community [156]. Nevertheless, despite all reported biological changes, ageing did not interfere with the ability of fibroblasts obtained from older women with prolapse to be successfully reprogrammed [157].

2.6. Prostate

Histological benign prostatic hyperplasia (BPH) is strongly age-related [158], and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5-α reduction of testosterone. Dihydrotesterone levels decrease with age, while oestradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the oestradiol/dihydrotesterone ratio and promoting stromal proliferation [159, 160]. Epithelial hyperplasia in turn is mediated by an array of stromal factors [161].

Histological BPH occurs in nearly 80% of men by age eighty [158]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate specific antigen level of >1.4-2 ng/mL [162]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [163]. Natural history studies and randomized intervention trials, however, consistently demonstrate that symptomatic progression of benign prostate disease is not inevitable. LUTS remit in about one-third of symptomatic men without treatment [164]. Approximately one-third to one-half of affected men develops DO. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate related LUTS in older men a diagnosis of exclusion. Nevertheless, age-stratified normative values for prostate volume, PSA level, as well as indicators of clinical symptoms, quality of life measures and urodynamic parameters may help in such decisions [165].

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail older men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men is contradictory. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [166]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infarction and AUR [167]. Nevertheless, a recent study demonstrated phenotypic changes and an increased differential expression of a variety of genes involved in inflammation and oxidative stress within glandular adjacent stroma microdissected from young and aged mouse prostates [168]. Such changes may play a role in promoting the development of BPH, BPE and cancer in aged prostates [169]. However, recent studies conducted using both human tissues and animal models support the hypothesis that senescence-associated inflammatory pathways contribute to the pathogenesis of BPH [170].

2.7. Other changes

The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee 2, Cell Biology & neural control). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older adults.

The prevalence of both asymptomatic bacteriuria and UTIs increase with age [171], and the two are often found together in frail older adults. Age-related changes in immune function, vaginal epithelium, faecal incontinence, and insufficient hygiene related to disability, cognitive impairment, and/or lack of caretakers may predispose the frail older adult to bacteriuria and recurrent UTIs. However, the role of otherwise asymptomatic bacteriuria (often found in association with pyuria) [172], in the aetiology of UI in frail older adults remains unclear [173]. Treating otherwise asymptomatic bacteriuria in frail older patients with chronic, stable UI does not, in general, reduce UI severity [174]. UTI symptoms may be subtle and non-specific in this population, and include worsening of UI, delirium in patients with dementia, or a minor but important decline in functional ability [174]. At the same time, current consensus criteria for UTI are poorly sensitive and only moderately specific for UTI in older adults. In a prospective cohort of 340 nursing home residents, in which UTI was defined as pyuria (>10 white cells) with >100,000 colony forming units on culture, the McGeer, Loeb, and revised Loeb UTI criteria had sensitivities of only 19-30% and specificities of 79-89% [175, 176]. [177]

2.8. Role of biological ageing

In recent years, there has been a tremendous growth in our knowledge in the basic biological mechanisms that drive ageing processes at the level of organisms, systems, organs and individual cells [178-180]. This has led to the emergence of two major concepts within the recently established field of Geroscience [178-180]. First, it has been proposed that interventions designed to target multiple mechanisms which are known to contribute to biological ageing, would have the capacity to prevent or slow the impact of ageing on clinically relevant physiological mechanisms. To that end, the recent observation that dietary restriction in rats reduces ageing-related declines in LUT function together with increases in inflammatory mechanisms, suggests that such interventions could represent a promising direction for future research. Conversely, a number of ageing changes involving the LUT appear to be augmented in a mouse model of accelerated senescence [181].

Second, the concept of Geroscience suggests that since ageing represents the predominant risk factor for many chronic diseases such as atherosclerosis, cancer, dementia and others, such chronic diseases are also likely to share common mechanisms with both ageing and each other; and therefore strategies designed to target such pathways would have the potential to delay the onset of such chronic diseases, thus enhancing function, independence and health span in older adults [178-180]. Although there is growing evidence that atherosclerosis and other forms of ageing-related cardiovascular dysfunction [182, 183], contribute to declines in LUT function and symptoms in old age, from the perspective of mechanisms this hypothesis remains to be explored in the context of

genitourinary ageing. Although much still remains to be defined and understood, evidence that lower urinary tract symptoms are associated with physical performance [184] [184], frailty [185] and adiposity [186] raise the possibility that inflammation, cellular senescence and other biological hallmarks of ageing represent potentially modifiable targets for geroscience-guided therapies [187].

III. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO URINARY INCONTINENCE

A hallmark of UI in the frail older adult population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to urinary leakage **(Table 2).**

Table 2. Comorbid conditions that can cause or contribute to UI in frail elderly persons

Conditions	Comments	Implications for Management
Comorbid medical illnesses		
Diabetes mellitus	Poor control can cause polyuria and precipitate or exacerbate incontinence; also associated with increased likelihood of urgency incontinence and diabetic neuropathic bladder	Better control of diabetes can reduce osmotic diuresis and associated polyuria, and improve incontinence
Degenerative joint disease	Can impair mobility and precipitate urgency UI	Optimal pharmacological and non-pharmacological pain management can improve mobility and toileting ability
Chronic pulmonary disease	Associated cough can worsen stress UI	Cough suppression can reduce stress incontinence and cough-induced urgency UI
Congestive heart failure Lower extremity venous insufficiency	Increased night-time urine production at night can contribute to nocturia and UI	Optimizing pharmacological management of congestive heart failure, sodium restriction, support stockings, leg elevation, and a late afternoon dose of a rapid acting diuretic may reduce nocturnal polyuria and associated nocturia and night-time UI
Sleep apnoea	May increase night-time urine production by increasing production of atrial natriuretic peptide	Diagnosis and treatment of sleep apnoea, usually with continuous positive airway pressure devices, may improve the condition and reduce nocturnal polyuria and associated nocturia and UI
Severe constipation and faecal impaction	Associated with double incontinence (urine and faecal)	Appropriate use of stool softeners Adequate fluid intake and exercise Disimpaction if necessary
Neurological and psychiatric conditions		
Stroke	Can precipitate urgency UI and less often urinary retention; also impairs mobility	UI after an acute stroke often resolves with rehabilitation; persistent UI should be further evaluated Regular toileting assistance essential for those with persistent mobility impairment Optimizing management may improve mobility and improve UI
Parkinson's disease	Associated with urgency UI; also causes impaired mobility and cognition in late stages	Regular toileting assistance is essential for those with mobility and cognitive impairments in late stages
Normal pressure hydrocephalus	Presents with UI, along with gait and cognitive impairments	Patients presenting with all three symptoms should be considered for brain imaging to rule out this condition, as it may improve a ventricular-peritoneal shunt
Dementia (Alzheimer's, multi- infarct, others)	Associated with urgency UI; impaired cognition and apraxia interferes with toileting and hygiene	Regular toileting assistance essential for those with mobility and cognitive impairment in late stages
Depression	May impair motivation to be continent; may also be a consequence of incontinence	Optimizing and phamacological management of depression may improve UI
Medications	See Table 3	Discontinuation or modification of drug regimen
Functional impairments Impaired mobility Impaired cognition	Impaired mobility and/or cognition due to a variety of conditions listed above and others can interfere with the ability to toilet independently and precipitate UI	Regular toileting assistance essential for those with severe mobility and/or cognitive impairment
Environmental factors Inaccessible toilets Unsafe toilet facilities Unavailable caregivers for toileting assistance	Frail, functionally impaired persons require accessible, safe toilet facilities, and in many cases human assistance in order to be continent	Environmental alterations may be helpful; supportive measures such as pads may be necessary if caregiver assistance is not regularly available

2.1. Medications

The risk of difficulty controlling urination in community dwelling older women taking medications with LUTS effects was about 30% higher compared to those who did not take such medications (OR 1.31 CI 1.05-1.62). This did not occur in men (OR, 1.08; 95% CI, 0.97-1.21) [188]. Overall, 20.5% of these women reported incident incontinence at Year 4 (3 years from baseline) [194]. Several studies have implicated alpha blockers as causing UI in women with an adjusted OR of 4.98 (95% CI, 1.96-12.64) [189, 190] and increasing to OR 8.81 (95% CI, 1.78-43.53) in conjunction with loop diuretics [191]. Oestrogens have been shown to increase risk of incontinence in women OR 1.6 to 2.0. [190, 192] A wide range of medications have been implicated in causing UI with varying degrees of evidence [193]. There has even been a case report of hydroxychloroquine causing UI [194]. A retrospective analysis of drug dispensing data in a Japanese cohort found that polypharmacy was associated with the use of medications known to contribute to urgency [195]. Similarly, a Canadian cross-sectional study identified a strong association (OR, 4.9; 95% CI, 3.1-7.9) between polypharmacy, defined as 5 or more medications, and the prescription of a medication known to cause LUTS [196]. In an acute care hospital setting in Korea, polypharmacy was one of the predictors of UI in both sexes (OR, 3.35; 95% CI, 1.89-5.92) [197]. However, there is little evidence that polypharmacy in the absence of drugs that cause incontinence has an impact on the lower urinary tract, and it is likely that the association between polypharmacy and urgency relates to the fact that the more drugs an individual is prescribed, the higher the odds that one of them will be a drug known to induce urgency. Older patients commenced on new treatments should be monitored for changes in urinary symptoms. Many classes of medications commonly prescribed for frail older adults can cause or contribute to the development of UI **(Table 3).**

2.2. Prevalence, incidence & impact

Not only UI but also faecal incontinence (FI) is more prevalent in frail older adults, and both are associated with cognitive impairment, decreased mobility and decreased levels of physical activity and reduced quality of life. The prevalence of UI varies by the study settings. In a single large University hospital setting (n = 1,556), 29.8% of geriatric patients had UI and poorer health literacy and cognitive impairment were independently associated with an increased likelihood of nursing-reported UI [198]. Among the elderly receiving home hospice care (n = 15,432), the prevalence of UI was 32% and female sex (Hazard ratio (HR) 1.30, P<0.001), age (HR 1.02, P<0.001), dementia (HR 1.68, P<0.001), and stroke (HR 1.72, P<0.001) were associated with a greater risk of UI.[199]. Among the community care recipients in New Zealand (n = 93,462), prevalence of UI, FI, and double incontinence (DI) was 36.6%, 9.9%, and 13.2%, respectively. Epidemiological surveys of continence status among older individuals living in nursing homes had been conducted in the US (n = 2,416,700), Norway (n = 898) and Japan (n = 2,517) [200-202]. The prevalence of UI, FI, and DI were 49.6%, 43.4%, and 35.5% in the US; 72.0%, 42.8%, and 40.2% in Norway; 66.9%, 42.8%, and 41.1% in Japan, respectively. Physical and cognitive impairments were significant predictors of both UI, FI, and DI [202].

In a group of subjects with Medigap insurance advancing age has been associated with an increase in the prevalence of UI (37.5% in 5,530 subjects). Comorbidities associated with UI including arthritis of the hip or knee (Relative Risk Ratio (RRR) = 1.21, P<0.001), arthritis of the hand or wrist (RRR = 1.15, P = 0.001), stroke (RRR = 1.18, P = 0.078), other heart conditions (RRR = 1.19, P<0.001), and having any cancer (RRR = 1.13, P = 0.0020). Obesity and being overweight increased the likelihood of having UI (RRR = 1.32, P≤0.001 and RRR = 1.14, P = 0.0013, respectively),

Table 3. Medications that can cause or contribute to UI in frail elderly persons

Medications	Effects on Continence
Alpha adrenergic agonists	Increase smooth muscle tone in urethra and prostatic capsule and may precipitate obstruction, urinary retention, and related symptoms
Alpha adrenergic antagonists (Alpha blockers)	Decrease smooth muscle tone in the urethra and may precipitate stress UI in women
Angiotensin converting enzyme inhibitors	Cause cough that can exacerbate UI
Anticholinergics	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause cognitive impairment and reduce effective toileting ability.
Calcium channel blockers	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause dependent oedema which can contribute to nocturnal polyuria
Cholinesterase inhibitors	Increase bladder contractility and may precipitate urgency UI
Diuretics	Cause diuresis and precipitate UI
Lithium	Polyuria due to diabetes insipidus
Opioid analgesics	May cause urinary retention, constipation, confusion, and immobility, all of which can contribute to UI
Psychotropic drugs Sedatives Hypnotics Antipsychotics Histamine (H1) receptor antagonists	May cause confusion and impaired mobility and precipitate UI Anticholinergic effects Confusion
Selective serotonin re-uptake inhibitors	Increase cholinergic transmission and may lead to urinary UI
Sodium-glucose cotransporter 2 (SGLT2) inhibitor	Glycosuria and polyuria, increased propensity to urinary tract infection
Others Gabapentin Glitazones Non-steroidal anti-inflammatory agents	Can cause oedema, which can lead to nocturnal polyuria and cause nocturia and night-time UI

compared with being at normal weight. Incontinence remained a significant predictor of lower quality of life [203].

Frailty is associated with UI, and predicts incident UI and/or death, even up to 12 months following hospitalization. A prospective cohort study conducted in a large teaching hospital in Singapore to address whether ability of frailty could predict incident UI. Frailty predicted incident UI over time (at discharge, OR 2.98, P = 0.050; at 6 months, OR 2.86, P = 0.027; at 12 months, OR 2.67, P = 0.025), after adjusting for age, sex, and severity of illness. Greater emphasis should be given to identifying and managing UI during hospitalization and after discharge, especially among frail older adults [204-210].

Moreover, the prevalence of UI is increased in the presence of frailty. The older individuals are prone to frailty and commonly have co-morbid medical illnesses. In a large population-based observation study UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29% and three or more in 13% [211]. Older subjects with UI had a 2.9-fold greater chance of becoming more frail over a 12-month period than those without (p=0.007) [212]. In a cross-sectional survey conducted in Taiwan (n = 1,014), presence of UI was a predictor for frailty among older adults living in rural communities (OR 1.951, P = 0.037) [213].

In a sample of 572 older Latinos participating in a programme to increase walking, medical comorbidity was independently associated with higher rates of UI (OR, 1.66; 95% CI, 1.30-2.12). More physical activity was independently associated with lower UI (OR, 0.77; 95% CI, 0.60-0.98). Hypertension, congestive heart failure, arthritis, depression and anxiety were associated with a higher prevalence of UI. A linear correlation was found between prevalence of UI and the number of comorbid conditions (correlation coefficient = 0.81) [214]. In an observational study of 6,361 community dwelling women, aged 65 and older, participating in the study of Osteoporotic Fractures, after adjusting for confounders, women with recent physical function decline (a worsening of 1 standard deviation from baseline) were more likely to report weekly incontinence (OR, 1.31; 95% CI, 1.09-1.56) for decline in walking speed over 6 metres and (OR, 1.40; 1.19-1.64) for decline to stand from sitting [215]. The Nurses' Health Study found that moderate-intensity low impact physical activity, including walking, resulted in a 20-25% reduction in the risk of developing UI in older women particularly stress rather than urgency UI [216]. Factors associated with persistent UI were similar to those associated with increasing incidence including lower physical activity levels. The strongest factors for persistent UI were older age, white race and obesity [217]. Likewise, impaired cognition is associated with an increased likelihood of UI. For example in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (Mini Mental State Exam score <= 23, prevalence 18%) were significantly more likely to have UI (adjusted OR 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7) have had at least two falls in the previous six months (OR 1.4), and report poorer health (OR 1.9) [218].

The Jerusalem Cohort Longitudinal study assessed the same community dwelling subjects at age 70, 78 and age 85. UI increased from 14.1% to 31.3% and to 42.5% at age 85. This was associated with an increase in comorbidity and Charlson's comorbidity index of 7.3, 11.7 and 21.7 respectively and an increase in geriatric syndromes [219].

A study of 6903 participants (mean age 82.2) in Europe and Ontario receiving home care services identified an increase in Geriatric syndromes (GS) in the presence of associated diseases. Participants presented with an average of 2.6 diseases and 2 GS. UI was present in 47% [220]. A study of 270 subjects aged 65 to 89 reported 26.3% moderate or severe UI in the preceding 12 months in 3 groups: frailty (7.4%), pre-frail (45.9%) and non-frail (46.7%). In a second sample of 300 frail subjects aged 90 to 107, 37.4% reported moderate or severe incontinence. Incontinent subjects were 6.5 times more likely to be in the frail group and 2.3 times in the pre-frail with respect to continent subjects. The authors concluded that UI was a marker of frailty [221]. In a cross-sectional study of 521 community Brazilian adults > 60 years were assessed for the association between frailty and geriatric syndromes. Subjects were classified as frail (≥ 3 criteria), pre-frail (1 or 2 criteria) or robust elderly. Urinary/faecal incontinence occurred in 23.7%,12.8% and 9.2% respectively. The commonest Geriatric syndrome was cognitive impairment (54.7%). In this study, there was no association between incontinence and frailty (OR, 0.76; 95% CI, 0.16-3.57) [222]. A study of 447 community dwelling nursing home eligible elderly with diabetes found a prevalence of UI of 44%. Older age, dependence on others for ambulation or transferring and cognitive impairment were associated with UI [223].

Comorbid conditions can affect incontinence through multiple mechanisms e.g., diabetes mellitus, present in approximately 15-20% of older adults may cause UI by diabetes associated lower urinary tract dysfunction (DO, OAB, cystopathy and incomplete bladder emptying) or by poor diabetic control (hyperglycaemia causing osmotic diuresis and polyuria). The Nurses Health Studies, NHS and NHS II [224] showed an increase in weekly urgency incontinence (OR 1.4) in women with type 2 diabetes compared to those without. Findings from the NHANES 2001- 2002 Survey showed that prevalence of UI was significantly higher in women with impaired fasting glucose and diabetes mellitus compared to those with normal fasting glucose. Two microvascular complications caused by diabetes, peripheral neuropathic pain and macroalbuminuria were positively, but not statistically, significantly associated with weekly UI [225]. In diabetic women, peripheral neuropathy has been significantly associated with LUTS and metabolic syndrome has been associated with OAB [226]. In a younger population of mean age 59 years, the Diabetes and Ageing Study found the prevalence of occasional UI to be over 65%. HbA1c level was not associated with the presence or absence of UI. Women with HbA1c .≥9% had more limitations in daily activity due to incontinence, defined as self-reported "quite a bit" or "extremely" in the preceding 12 months compared to women with HbA1c <6% [227]. Higher glycated haemoglobin levels have been associated with increased symptoms of OAB [228]. From the findings of the SABE study (Health, Well-being, and Ageing) including the older people living in seven countries in Latin America and the Caribbean, the risk of UI was greater among the older women aged ≥60 years with past history of cancer (other than skin) (incidence relative risk, 2.66; 95% CI, 1.33-5.31; P = 0.006) and those with diabetes (incidence relative risk, 1.70; 95% CI, 1.03-2.80; P = 0.037) [229].

Incontinence impairs quality of life (QOL) in older adults [230]. In a cross-sectional study of 1,124 subjects over 70 (mean age 79.5 years), prevalence of UI was 18% and the severity of UI increased with age. UI was more common in women and was associated with worse self-reported health. Incontinent subjects were more likely to require assistance with ADLs, had more depressive symptoms and worse physical performance. Increasing severity of incontinence was negatively associated with QOL as measured by the Short Form-36 [231].

UI affects mortality, a population-based cohort study with 1,580 participants aged ≥65 years living in Fukushima, Japan, urgency UI was substantially associated with the occurrence of death (HR, 2.29; 95% CI, 1.22-4.31). The risk of death was further exacerbated in older adults with severe urgency UI (HR, 4.18; 95% CI, 1.78-9.79) [232]. A population-based cohort study with 2,282 community dwelling individuals aged ≥50 years in Canada, frailty individuals with UI were at higher risk for death (HR, 1.39; 95% CI, 1.13-1.72); however, after adjustments for the frailty index, the association between UI and mortality was no longer significant (HR, 1.10; 95% CI, 0.89-1.36) [233]. In a nursing home setting with 267 residents aged ≥65 years in Korea, a multivariate logistic regression analysis revealed that UI was associated with risk of death (OR, 2.04; 95% CI, 1.16-3.61) [234].

2.3. Neurological & psychiatric disorders

A more detailed summary of neurological disorders and their impact on UI is covered in the Chapter on Specific Neurological Diseases. Neurological and psychiatric disorders are highly prevalent in frail older people. Neurological conditions in the elderly commonly associated with UI include stroke, Alzheimer's dementia (AD), multi-infarct dementia or mixed AD and vascular dementia, Diffuse Lewy body (DLB) disease and Parkinson's disease. Less common conditions include normal pressure hydrocephalus (NPH), progressive supranuclear palsy (PSP) and multiple system atrophy (MSA). Each of these conditions are associated with the development of brain lesions that can interfere with the micturition pathway and interfere with the normal ability to inhibit voiding as well as affecting cognition. These conditions are associated with impaired mobility and can interfere with the ability to toilet independently.

In Alzheimer's disease, UI is often associated with severe cognitive decline whereas in DLB it usually precedes severe cognitive impairment. Occurrence of UI was significantly earlier 3.2y in DLB compared with 5.9y in AD [235]. NPH should be a diagnostic consideration in any frail older patient who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefits from surgical implantation of a cerebrospinal fluid shunt [236, 237].

LUTS, UI and urodynamic DO are common in older adults with Parkinson's disease. A logistic regression analysis of 3,414 Parkinson's disease patients found a significant correlation of orthostatic hypotension and UI with age and duration of the disease. The presence of UI in persons with Parkinson's disease may in turn increase their risk for disability: in one series of patients with Parkinson's disease, UI increased the risk of falling by nearly six-fold. Urinary symptoms are often non-responsive to L-dopa therapy [238]. The efficacy of behavioural therapy, including pelvic floor muscle training, bladder training, fluid and constipation management was limited in improving OAB symptoms; however, it could significantly improve quality of life and ICIQ-OAB bother [239]. MSA presents with a combination of impaired autonomic function, parkinsonism (MSA-P) or cerebellar ataxia (MSA-C) or both [240]. It frequently begins with bladder dysfunction and erectile dysfunction in males and is associated with bladder symptoms of DO, often progressing to incomplete emptying and urinary retention [241]**.** High post-void residual (PVR) may help in pointing to a diagnosis of MSA-P rather than Parkinson's disease [242]. Recently, several studies revealed neuromodulation therapies including deep brain stimulation (DBS) and tibial nerve stimulation (TNS) were effective in improving of UI Witte *et al.* performed a *post-hoc* analysis of a randomized clinical trial with 128 advanced Parkinson's disease patients (NSTAPS study). UI and urinary frequency significantly improved after subthalamic nucleus DBS treatment in male and female patients. Nocturia and night-time incontinence due to parkinsonism did not improve after DBS, irrespective of sex [243]. Scelzo *et al.* reported the efficacy of DBS therapy for Parkinson's disease. Of note, the rates of mild cognitive impairment, UI, nocturia and falls were lower in the surgical cohort than the group of medically treated patients [244]. A prospective cohort study including 416 patients with Parkinson's disease, DBS surgery is effective in improving urinary function in patients, primarily reflected by the alleviation of urinary frequency, urgency, and incontinence. Female patients with Parkinson's disease displayed better urinary function outcomes from DBS treatment than did males [245]. A retrospective study with a cohort of 17 patients with Parkinson's disease who have used TNS, efficiency was seen in 10 patients (59%), on nocturia and/or UI for 9 patients. Three patients found TNS was not effective, and four patients did not use it long enough to evaluate [246].

With the introduction of magnetic resonance brain imaging into routine clinical practice, radiology reports in older patients have increasingly emphasised the presence of structural abnormalities involving the white matter [247]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (Binswanger's disease, a specific and relatively rare form of dementia), towards leukoaraiosis [248] and, most recently, to the concept of white matter signal abnormalities (WMSA) [247, 249]. Brain MRI identified subjects with leukoaraiosis as more likely to have urinary dysfunction which may precede cognitive impairment particularly in grade 1 disease [250]. White matter hyperintensities (WMH) have been linked to severity of incontinence rather than to its presence [251]. The disorder of bladder control resulting from white matter disease (WMD) has been termed vascular incontinence [252]. WMH load appears to progress in association with ageing and the amount of frontal WMH are predictive of UI in amnestic mild cognitive impairment and AD [253].

White matter lesions were found to be a more significant contributor to OAB and incontinence than AD in older adults [254].

2.4. Depression

As in younger persons, frail older adults with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and under treated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [255]. UI may add to the burden of depression by decreasing life satisfaction [256] and self-rated health, [257] and by its association in frail older adults with comorbidity [258].

Studies of the association of depression and UI in older adults are consistent across several depression measures. The validated Center for Epidemiologic Studies-Depression was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based persons found an adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55]), [259]. A large community-based study of older Mexican Americans reported UI was predictive of high levels of depressive symptoms (adjusted OR for depression, 1.94; 95% CI, 1.46-2.59) [260]. The emotional disturbances and social isolation subscales of the Nottingham Health Profile Questionnaire was associated with urgency but not stress incontinence [261] and have included studies in Asia [262]. Although no association between UI and depression was found in a Korean study of 135 community living older adults greater than 85 years, it used a higher cut-off (>7) on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility [263]. Self-report of depression or sadness has [264] and has not been associated with

UI [265]. In another Korean study of 444 inpatients aged 65 and older, patients with depression were more likely to have poor UI-related QOL (OR, 8.54; 95% CI, 1.43–51.15) [0001]. In the Korean Study of Women's Health Related Issues with 3,000 female subjects between 65 and 75 years, the prevalence of stress UI, urgency UI, and mixed UI were 45.7%, 39.6%, and 33.1%, respectively. Depression and stress levels were significantly higher in women with UI than those without UI ($p<0.001$).

2.5. Psychological distress and quality of life

Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR, 5.60;95% CI, 1.88–16.67), but not in whites, in a cross-sectional study of community based older persons with mean age 67y. However, a longitudinal analysis of the same population over 13 years found that persons with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR, 6.55;95% CI, 1.94-22.12). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR, 3.66;95% CI, 1.61–8.33) [266, 267].

The EpiLUTS study, a large cross-sectional internet study showed significant impairments in mental health and HRQOL when different urinary symptoms were combined [268, 269]. The US sample of the EpiLUTS study involving 2,485 men and 2,877 women aged 65 and older found OAB was associated with significant impairment in HRQOL. Rates of Anxiety of ≥8 on the Hospital Anxiety and Depression Scale-Anxiety (HADS-A) were 16.4% for men and 23.6% for women with OAB compared to 3.3% and 8.6% with minimal or no symptoms. Similarly rates for depression on the HADS-Depression (HADS-D) were 17.3% and 15.7% for OAB compared to 4% and 6.4% in those with no or minimal symptoms. A case-controlled study of 100 older men attending a Urology outpatients matched with 100 age matched controls from the community and Geriatric outpatient clinics found those with moderate to severe LUTS had worse HRQOL. This was evident in a number of symptoms including depression, decline in feelings of general well-being, decreased sexual performance, decreased muscle strength [270].

The direction of the causal relationship between UI and depression in frail older adults is unclear, as nearly all studies were cross-sectional. The results of the one longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most closely associated with psychological distress, even after controlling for important covariates [255].

2.6. Falls

Urinary urgency and UI, urinary frequency, and nocturia have been identified repeatedly as risk factors for falls among community-dwelling older adults [271-277]. Mixed incontinence (a combination of urgency and stress incontinence) has also been associated with falls risk in women 70 years and older [278]. Brown and colleagues [277] performed a secondary analysis of data from an osteoporosis cohort study, examining a group of 6049 community-dwelling older women using regular self-completed questionnaires sent to all participants every four months. In this cohort, followed for an average of three years, those with at least one weekly UUI episode were more likely to fall (OR 1.26, 95%CI 1.14-1.40) than those without. Weekly UUI was also associated with higher odds of sustaining a non-spinal fracture (hazard ratio 1.34 95%CI 1.06-1.69). In this study, stress incontinence was not associated with higher odds of falling (adjusted OR, 1.06; 95% CI, 0.95-1.19) or sustaining a fracture (relative hazard, 0.98; 95% CI, 0.75-1.28). In a national population study conducted in New Zealand involving 57,781 females and 35,681 males aged 65 and older, high falls risk was common, found among 8.8% of women and 12.4% of men; and 43.7% of women and 33.7% of men reported some incontinence. For women, the adjusted odds ratio of increasing falls risk was 1.24 (95% CI, 1.18-1.30) for those with occasional UI, 1.36 (95% CI, 1.29-1.43) for those with frequent UI, and 1.19 (95% CI, 1.13-1.26) for those with any FI compared with their continent counterparts. Among men, the adjusted odds were 1.49 (95% CI, 1.41-1.58) for any UI and 1.18 (95% CI, 1.10-1.27) for any FI.

Analysis of the Concord Health and Ageing in Men Project, a longitudinal study of community-dwelling men in Australia followed 1090 men over a period of 2 years. Here, the presence of urgency incontinence, defined as weekly episodes of UUI, was associated with a higher incidence of falls (OR 2.57 95%CI 1.51 – 4.3) and men with a higher International Prostate Symptom Score storage sub-score, defined as a score of 19 and above, had a higher incident rate of falls (incident rate ratio 1.72 (95%CI 1.24-2.38) [279]. A Japanese study of patients with Parkinson's disease found that increased micturition frequency either by day or night was not associated with falls, but that the presence of urinary urgency was strongly associated with a large increase in the odds of falling (OR 5.14 95%CI 1.51-17.48). Only 14% of the falls reported in this study occurred on the way to or from the toilet [280].

A systematic review of the association between falls and LUTS in community-dwelling men aged 60 years and over identified six cross-sectional studies and three prospective cohort studies. The identified data were only suitable for qualitative synthesis, but UI and storage LUTS were consistently shown to have a weak to moderate association with an increased likelihood of falls. None of the identified studies examined potential causes for these associations; the categorisation of continence or not and degree of accounting for confounding variables was inconsistent across the included studies [281]. A small cross-sectional analysis of community dwelling women aged 65 and over in the US examined the association between nocturia, nocturnal enuresis and falls. Neither severity of UI nor severity of nocturia was associated with an increased risk of falls, but there was a statistically significant association between nocturnal enuresis, impairment of physical function and the presence of frailty. However, in the multivariable regression model, which included age, physical function, and the frequency of nocturnal enuresis episodes, only physical function remained as significant risk factor for falls [282]. One study, a prospective cohort study of older men in the USA, identified a statistically significant association between straining to void and falls, with a 60% increase in falls risk for those reporting the need to push or strain to initiate urination at least half the time [283]. In hospital, UI is associated with an increased propensity to fall in older inpatients [284, 285]. UI is also associated with falls in institutionalised older adults [286, 287]. The underlying reason for the association is not yet clear, although several and multiple mechanisms are most likely. A UK case control study in older community dwelling women presenting to an urban Emergency Department found that only 6% of those with a fall attributed this to their LUTS [288].

2.7. Stroke

Conservative interventions (e.g., bladder training, pelvic floor muscle training and prompted voiding) have been shown to have some effect in Cochrane systematic reviews but have not had their effectiveness demonstrated with stroke patients. UI may have worse prognostic implications after stroke, being associated with greater mortality, a poorer functional recovery and an increased likelihood of institutionalisation than those following strokes who regain continence [289]. Of 1,187 patients aged 60–96 with stroke, those with

low bladder maintenance scores (more dysfunction) fared worse with rehabilitation than those with higher scores [290]. There has been little advance in care since the 6th International Consultation. A survey of stroke unit practice in Australia showed that less than half had a formal plan for continence care and in the UK, as part of the national sentinel audits of stroke, there was little advance in continence care [291, 292]. A comparative study of stroke nursing found a dearth of evidence and treatment focused on containment and social continence, highlighting the need for systematic assessment and management [293]. The burden on caregivers of those with incontinence following stroke has been acknowledged [294]. Thomas *et al.* reviewed randomised or quasi-randomised controlled 20 trials with 1,338 participants after stroke. Five trials assessed complementary therapy using traditional acupuncture, electroacupuncture and ginger-salt-partitioned moxibustion plus routine acupuncture. Low-quality evidence from these trials suggested that complementary therapy may increase the number of participants continent after treatment; participants in the treatment group were approximately three times more likely to be continent (RR, 2.82; 95% CI, 1.57-5.07). Adverse events were reported narratively in one study of electroacupuncture, reporting on bruising and post-acupuncture abdominal pain in the interventional group. The authors concluded that there was insufficient evidence to guide continence care of adults in the rehabilitative phase after stroke. As few trials tested the same intervention, conclusions are drawn from few, usually small, trials. Confidential intervals were wide, making it difficult to ascertain if there were clinically important differences. Only four trials had adequate allocation concealment, and many were limited by poor reporting, making it impossible to judge the extent to which they were prone to bias. More appropriately powered, multicentre trials of interventions are required to provide robust evidence for interventions to improve UI after stroke [295].

Recommendations for research

Further research is required to:

- Examine the effect of treatment for UI in older adults with Parkinson's disease
- Examine the temporal association and mechanism underlying falls and LUTS/UI in frail older adults
- Determine the effect of structured treatment for UI in older adults following stroke.
- Examine the impact of interventions comorbid disease on the experience and outcomes of UI in frail older adults

Recommendations for practice

Clinicians need to assess and manage coexisting comorbid conditions which are known to have an impact on continence status or the ability to successfully toilet.

1. ENVIRONMENTAL FACTORS

This section addresses factors unrelated to underlying pathophysiology that can affect the UI status of frail older adults in organisational settings such as nursing homes and hospitals. These key factors are conceptualised here as either related to: (i) the physical environment or (ii) organisational processes of care. We define organisational processes of care as organisational practices and procedures that can increase a frail older adult's risk of UI. They include:

- A lack of assessment
- A lack of knowledge about UI among healthcare practitioners and/or formal caregivers
- Practices that reduce/restrict the frail older adult's mobility and functional abilities
- Limited or inconsistent access to toileting assistance
- A lack of privacy and attention to the frail older person's dignity
- Reduced staffing
- The overuse and misuse of continence products

The following information describes the potential influence of the physical environment on frail older adults' UI status, followed by organisational processes of care.

In this section, we define processes of care as the instrumental procedures involved in the assessment and management of incontinence relating to frail older persons.

Although the physical environment is considered a risk factor for incontinence in frail older adults, there continues to be limited research on this topic.

1.1. The nursing home physical environment

Previously described research about the potential influence of the nursing home physical environment on residents' risk of developing UI was conducted over 40 years ago [277, 278] prior to the establishment of internationally agreed standards for reporting trial data. Three were published from a series of projects conducted in the USA to examine the impact of the physical environment on specific problems of people with Alzheimer's disease and related disorders [279-281]. One qualitative study was identified that employed an ethnographic design [282].

Attempts to evaluate the effects of enhancing the physical environment on rates of incontinence in nursing homes were reported by Chanfreau-Rona [296, 297]. In both studies, the intervention involved enhancing visual access to the toilet by painting toilet doors in bright colours and strategically locating pictorial signs and other visual cues. In addition, staff were asked to accompany residents to the toilet at predetermined 'peak times' and to employ operant conditioning techniques to reinforce residents' appropriate toileting behaviour. In the first of these trials, 24 older female residents, most of whom had cognitive impairment, were purposively assigned to either the intervention, or to usual care for seven weeks [297]. The same procedures were repeated in a subsequent trial [296]. Although reductions in incontinence were noted for residents in the experimental groups compared to the control groups, the extent to which these reductions were related to the intervention is difficult to determine as both studies lacked power and did not control for confounding factors. Nonetheless, these studies represent an early, multifaceted intervention that involved evaluating the effect of changes to the physical environment to reduce incontinence among frail older adults in long-term care.

According to the first of a series of projects conducted by Namazi and colleagues, the overall physical environment has a considerable impact on the well-being and quality of life of individuals with Alzheimer's' Disease (AD), affecting their ability to function in the face of incontinence, distraction and disorientation [298]. One of the projects focused on the clinical utility of using environmental cues (i.e. signage, colour differentiation and images) in a dementia-specific unit to assist compensate for resident' visuo-perceptual deficits

[299]. The most effective environmental cue in terms of orienting individuals with AD to the toilet was a combination of using a sign with the word “toilet”, together with “wayfinding” arrows on the floor. No single strategy was suitable for all individuals with AD due to the variability in the ability of individuals with AD to perform all of the tasks associated with successful toileting. The researchers therefore recommended “to maximize the remaining strengths of those who are afflicted with AD, each component of the morphology which creates difficulties for AD patients must be identified and treated individually”. In essence, individuals with AD may need individually targeted cues that address identified specific deficits.

In a second project, Namazi and colleagues [300] systematically examined toilet use in a dementia- specific unit under two conditions: with the toilet highly visible to residents, and with the toilet concealed. The frequency of toilet use increased when toilets were visually accessible during the 45 hours of observation. Visibility and accessibility of toilets may be an important factor in supporting frail older adults to maintain continence.

Toilet accessibility also featured highly in a qualitative study conducted by Sacco-Peterson and Borell [301]. Using ethnographic methods, the researchers collected over 200 hours of field observational data and conducted in-depth interviews with nine nursing home residents. They reported that different aspects of the physical and socio-cultural environment of the home influenced residents’ abilities to maintain autonomy in self-care. For example, there was an inadequate number of toilets, inadequate privacy for toileting, inappropriate toilet heights, excessive distances to the toilet, and a lack of call light, toilet paper, soap, paper towels, lighting and commodes. Despite the challenges of negotiating this ‘defeating ward geography’, many residents attempted to participate autonomously in toileting, whilst others were deterred because of a fear of falling.

1.2. The hospital physical environment

A recent study addressed the physical environment of hospitals to ensure they are elder friendly. Aranda *et al.*, (2019) and Arenas *et al.*, (2019) described a cross-sectional observational study that focused on changes to the physical environment of a hospital to better meet the needs of hospitalised older adults with dementia. The implemented measures were: (1) Informative Posters for delirium prevention and stimulation of early mobilisation. (2) Triptychs with information for families: dementia and terminally ill patient. (3) Bedside magnetic codes for: Mobility, Risk of delirium, Dysphagia, Continence and Sensory Deprivation. (4) Door signs for private interviews and terminally ill patients. At 3 months, compliance with the use of bedside codes up to 90% of patients, with an average use of >60% [302].

2. ORGANISATIONAL PROCESSES OF CARE IN THE NURSING HOME

2.1. Introduction

Continence in nursing home residents declines over time [303] and those with a diagnosis of dementia lose continence at a more rapid rate than those without dementia [304]. Incontinence in this setting is likely to be multifactorial in aetiology. For example, in a systematic review of the prevalence and risk factors for urinary incontinence in long-term aged care homes, Offerman and colleagues [305] identified 46 risk factors for urinary incontinence. The researchers grouped these factors into 1) locomotion, 2) cognitive function and 3) drugs. However, in addition to these risk factors, the reviewers stated, “differences in the care process and quality of care can also influence urinary incontinence prevalence; reasons for a less-than-optimal approach in long-term care homes may include, for example, inadequate knowledge of and skills for urinary incontinence in general, inability to use guidelines for urinary incontinence care, insufficient staff and poor communication among healthcare professionals” (p.291). They recommended that risk factors related to care processes be further investigated. Two studies offer qualitative data on how processes of care in nursing homes may represent a risk factor for incontinence. For example, descriptive information derived from semi-structured interviews with six elderly women from two nursing homes in Canada, suggests that some residents experience an environment characterised by rituals and routines, limited assistance with pad changing, restrictions on the number and type of continence products available, set times for toileting and pad changes, ageism, and a lack of recognition of residents’ attempts to maintain continence [306]. Sacco-Peterson and Borell [301] also found that ‘toileting assistance was provided at set times, and ‘if residents required more assistance other than at set times, pads were used‘. Pad use also correlated with residents’ mobility level, rather than their cognitive or continence status. Additionally, night-time use of pads often started following a fall at night. Residents did not divulge their difficulties to staff and were reluctant to ask for help and thus staff members were unaware of residents ‘difficulties and efforts. Residents valued the capacity to exercise some power and autonomy with regard to self-care, and didn’t want to be ‘a bother to the nurse ‘. Thus, their attempts to maintain continence may be undermined by care processes that unintentionally diminish an individual’s independent toileting [301].

Ostaszkiewicz [307-309], conducted a grounded theory study to describe and explain the context that affects continence care in nursing homes. The findings suggest a basic social problem that is characterised by multiple constraints to residents’ overall care. Factors that contribute to this problem include: (i) a highly regulated work environment; (ii) ethically challenging care; (iii) highly dependent residents; and (iv) a devalued role. Staff responses to this problem include accommodating strategies such as acquiescing, concealing, protecting, adapting, prioritising, normalising, compromising, and ritualising, as well as self-protective distancing strategies such as blanking out, using distancing language, and reframing care. The researcher called for a comprehensive multifaceted research-based strategy that addresses the social, regulatory, organisational, and personal constraints to evidence-based, ethical, resident-centred care, including continence care. There is a need to counter the pervasive belief that quality continence care for frail older adults is a function of cleaning and containing incontinence. In countries that rely on education about incontinence from the continence product manufacturing industry, the strategy should also counter the dominance of industry-based education. Although independent quality performance standards have been developed for disposable absorbent products there is an absence of standards to promote ethical relationships between healthcare consumers and the continence product manufacturing industry [310].

2.2. A lack of assessment in nursing homes

A comprehensive assessment to determine type and causes of UI is an essential precursor to appropriate management. However, evidence suggests many frail older people with UI in nursing homes do not have access to this assessment and are therefore at risk of remaining incontinent (Table 4).

Since the last Consultation, two further studies were identified that support previous research indicating a lack of assessment of UI in nursing homes. They include a descriptive, correlational study using primary data from 1,560 randomly selected residents from

815 different nursing homes in the USA and a large observational cross-sectional study of 42,693 older adults in the USA who were continent on admission to a nursing home [311, 312]. Harrison *et al.*, (2019) investigated care and staff skill factors that predicted quality continence care. They found an overall UI rate of 48.4% (n = 755) and the risk of developing UI over a ten-year-period in a nursing home was 6%. Forty-six percent of residents with UI had no care plan for their incontinence. Moreover, the majority of UI care plans (65%) were not based on that resident's voiding pattern and needs. Bliss *et al.,* (2017) conducted a large observational cross-sectional study of 42,693 older adults in the USA who were continent on admission to a nursing home to determine the prevalence of older continent adults who received primary prevention of incontinence at admission, assess whether there were racial or ethnic disparities in incontinence prevention, and describe factors associated with any disparities. Only 12% resident admissions received incontinence prevention and there was a significant disparity (2%) in incontinence prevention for Blacks (P < 0.05) compared to Whites (10.6%).

2.3. A lack of knowledge about UI among healthcare practitioners and/or formal caregivers in nursing homes

A number of studies reveal gaps in nurses' and nursing aides' knowledge about, and attitudes toward older people with incontinence in nursing homes [313-332]. This lack of knowledge about UI and its management could operate as an antecedent to care processes that inadvertently promote incontinence. Specifically, a lack of knowledge that incontinence is a symptom of a potentially treatable condition, may have the unintended effect of hindering access to diagnosis and treatment.

2.4. Practices that reduce/restrict the frail older adult's mobility and functional abilities in nursing homes

The role that mobility and functional status play in a frail older adult's ability to maintain continence cannot be underestimated. Impaired mobility and ability to perform activities of daily living (ADLs), such a toileting ability, can cause or contribute to UI in frail older adults in any setting.

UI is associated with severe impairment in ADLs in nursing homes, [333,334,335] and subsequent research confirms this association [336,337,338]. A structural equation modelling examined the relationships between UI in institutional older adults with dementia and a range of factors, including agitated behaviours, depression, cognitive function and activities of daily living. Li *et al.* (2019) recruited 226 older adults with dementia from 15 long-term care facilities in southern Taiwan. Activities of daily living performance was found to be significantly associated with UI; however, age, cognitive function, depression and agitated behaviours were not significantly related. Age did not have effects on any of the variables tested in this model. However, activities of daily living performance was significantly associated with cognitive function and depression. Results further showed that cognitive function and depression were mediators between activities of daily living and agitated behaviours. In nursing home settings, a decline in functional status is correlated with a decline in continence status. According to an a analysis of longitudinal data conducted with 196 older adults from one of 10 nursing homes in the city of Natal-RN (Brazil), the cumulative probability of maintaining continence is 82.6% at six months (confidence interval [CI], 95%: 76.5%-87.3%); 74.7% at 12 months (CI, 95%: 67.8%-80.4%); 66.9% at 18 months (CI, 95%: 59.4%-73.2%); and 49.3% at 24 months (CI, 95%: 40.1%-57.9%). Among the cohort, 105 (53%) older people maintained their continence status during the period, 21 (10.7% improved at one or more assessment and 76 (38.8%) declined. Factors that predicted a decline in continence status were disability (hazard ration [HR] = 4.03;P<0.001), functional decline (HR=3.02; P=0.001), and potentially inappropriate medication (HR-1.84; P=0.008). In the same cohort, the cumulative probability of maintaining functional capacity was 78.2% (CI 95%: 72.8±82.7%), 65.1% (CI 95%: 58.9±70.5%), 53.5% (CI 95%: 47.2±59.5%) and 44.0% (CI 95%: 37.7± 50.2%) at 6, 12, 18 and 24 months, respectively [339]. Continence decline was one of sev-

Table 4. Evaluative studies on assessment of UI in frail older adults in nursing homes

Study	Objective	Sample	Method	Findings
Bliss *et al.*, 2017	To determine the prevalence of older continent adults who received primary prevention of incontinence at NH admission, assess whether there were racial or ethnic disparities in incontinence prevention, and describe factors associated with any disparities.	42,693 older adults free of incontinence at NH admission	An observational cross-sectional study of a nation-wide cohort	There was a significant disparity (2%) in incontinence prevention for Blacks (P < 0.05): Fewer Black admissions (8.6%) were observed to receive incontinence prevention than was expected had they been part of the White group (10.6%). The percentage of White admissions receiving incontinence prevention was 10.6%.
Harrison *et al.*, 2019	To explore the associations between interpersonal and skill measures that may predict quality measures in nursing facilities.	1,560 residents from 815 nursing facilities in the USA	A descriptive correlational study using primary data	Overall, of the 1,560 residents, 48.4% (n = 755) experienced UI. The risk of developing UI over a ten-year-period in a nursing facility was 6%. Only 54% of residents with UI had a care plan for their incontinence. For those with a UI plan in their chart, 143 (35%) had a person entered UI plan developed based on that resident's voiding pattern and needs. The more satisfied the resident was with the response to their calls for help with voiding the more satisfied with the nursing facility

Study	Objective	Sample	Method	Findings
Georgiou *et al.*, 2001	To evaluate the recommended outcome measures in clinical practice	1125 residents in 17 residential homes, 14 nursing homes and 5 long-stay wards in UK.	Analysis of data on the UI section of the Royal College of Physicians Continuous Assessment Review and Evaluation Scheme audit tool	Rates of full clinical assessment were 48% for people in residential homes 24% for people in nursing homes 36% for people in long- stay wards
Rodriguez *et al.*, 2007	To explore continence prevalence, knowledge and care	66 care homes in Birmingham, UK	Survey completed by managers or other senior staff	Only two respondents gave information indicative of a full assessment. Most respondents had difficulty identifying the process of assessment.
Pringle-Specht *et al.*, 2002	To determine patterns and treatment of urinary incontinence	145 residents with dementia (mean age 83.3yrs) from 13 special care units in long-term care facilities in USA	Retrospective audit of residents' medical histories using 'Incontinence Patterns Tool' (IPT)	55% of residents with UI and dementia had a documented care plan for treatment of UI 2.1% (n=3) had a current medical diagnosis of bladder incontinence
Wagg *et al.*, 2008	To assess the quality of continence care for older people	Patients from 138 primary care trusts, 195 secondary care trusts, and 27 care homes in UK	Audit of patients' clinical records	Poorly documented aspects of a clinical assessment across all settings: rectal examinations and post-void residual urine volumes. In secondary care trusts, 919/3509 (25%) of histories had documentation of an assessment to determine UI type or cause
Watson *et al.*, 2003	To assess the use of the Agency for Healthcare Policy and Research Guideline for managing UI in nursing homes	200 residents with new UI or newly admitted with UI from 52 nursing homes in upstate New York, USA	Retrospective chart review and Nursing Assistants screening interviews	4 new cases of UI per 100 beds over 12 weeks UI Guideline standards met 20% of cases (0-45%). Aspects of assessment rarely performed rectal examination (15%) digital examination of prostate (15%) pelvic examination (2%)

eral predictors of functional decline in this setting (HR = 1.85; p = 0.002). The others being severe cognitive impairment (HR = 1.96; p = 0.001) and incidence of hospitalizations (HR = 1.62; p = 0.020), adjusted by the incidence of depression, age, education level, presence of chronic diseases and low weight.

According to the findings of a multicentre descriptive cross-sectional prevalence study of 2,044 people from 30 nursing homes throughout Germany, UI is not only strongly associated with impaired mobility, but can also negatively affect residents' health-related quality of life. Using the International Consultation of Incontinence Questionnaire Short Form (ICIQ-SF), the researchers found chronic, severe UI exerted the greatest impact on health-related quality of life [340]. Given these findings, greater emphasis should be given to interventions that reduce the risk of functional decline that may subsequently prevent or delay the onset of incontinence and, thus, increase their health-related quality of life.

Moreover, practices that restrict or minimise a person's mobility and ability to function hinder their ability to reach and use the toilet autonomously are likely to cause disability incontinence. The use of physical restraints is one such practice. Although restraint-free care has been recommended as standard, restraints remain widely used in long-term aged care homes, ranging from 12-47% internationally [341]. In a multivariate analysis of data from 2,014 residents from 270 USA Medicaid-certified nursing homes, Brandeis and colleagues [334] identified that UI was independently associated with a number of factors, including the use of restraints of the trunk (OR = 1.7; CI = 1.5,2.0), restrained to a chair (OR = 1.4; CI = 1.2,1.6), and bedrails (OR = 1.3; CI = 1.1,1.5).

Another important consideration is the potential unintended negative effects of interventions designed to reduce the risk of falls in frail older people. Several studies identify UI as a risk factor for falls among older adults [342].[343] [281] [344]. Schluter reported 'older people with urinary urgency or UUI are significantly more likely to fall and sustain injury compared to age-matched controls, with estimates of the odds ratio for falls ranging from 1.5 to 2.3. A Cochrane review of interventions for preventing falls in older people in care facilities and hospitals [286] categorised interventions as: exercise, medication (drug target) interventions which include interventions targeting vitamin D and medication reviews, environment or assistive technologies including bed/chair alarms or the use of low/low beds, social environment interventions which target staff members and changes in the organisational system, knowledge interventions and multifactorial interventions. Although UI was not identified as an adverse event, it is likely that interventions such as low/low beds that restrict a person's movement or hip protectors that are difficult to remove, could cause disability associated incontinence. Further research on strategies to promote continence among frail older adults who are at risk of falling are required.

2.5. Limited or inconsistent access to toileting assistance in nursing homes

Interview data with family members of nursing home residents suggests timely assistance to use the toilet is an important indicator of the quality of care. Ostaszkiewicz and colleagues (2016) conducted qualitative interviews with relatives of five residents in Australian residential aged care homes in order to explore their understandings and expectations about the concept of 'quality continence care'. The family members placed a high value on staff being able

to interpret the behaviours of cognitively impaired residents regarding their need for help to use the toilet and provide them with timely assistance to use the toilet and equated this practice with protecting a resident's autonomy and dignity [345]. A more recent quantitative study reinforces the importance of timely assistance to use the toilet. In their investigation of factors that predicted quality continence care, Harrison *et al.*, (2019) found residents' satisfaction with the nursing home correlated with their satisfaction with staff response to their calls for help with voiding [311]. This is an important finding that should inform efforts to improve the quality of continence care in nursing homes.

Despite the importance resident and family members' place on being access to access timely toileting assistance little is known about the actual care needs of nursing home residents who require assistance to use the toilet; a condition hereafter referred to as 'toileting disability'. Consistent with the disablement process model (WHO 2001), and as proposed by Yeung *et al.*, (2019), we define 'toileting disability' as practices, procedures, or disease conditions that result in an individual requiring physical assistance using the washroom [toilet] to urinate and/or defaecate in a timely manner. According to the findings of a scoping review led by Yeung *et al.*, (2019) about toileting disability in older people residing in long-term care or assisted living facilities, 15% of older adults without dementia living in this setting (a subgroup that comprised 34% of all residents), have a toileting disability [346]. This finding was based on a cross-sectional analysis data from 2,395 adults aged 65 years or older, without dementia and residing in a residential aged care facility [333]. In addition to identifying toileting disability rates, a logistic regression model identified an association with fair or poor health, living in a facility with four or less residents, living in a for-profit facility; having bowel incontinence, UI, an increased number of physical impairments, visual and hearing impairments; and needing assistance with bathing, dressing, and transferring.

Based on a cross-sectional nationwide point prevalence study nursing home residents from 969 (41.4%) facilities in Japan, 44.2% (2,144) of residents were offered toileting assistance – most commonly, timed voiding (59.3%) followed by prompted voiding (26.6%) [202]. Reasons for not providing toileting assistance to the 2,707 (55.8%) residents were:

- (24.4%) were able to ambulate to the toilet independently,
- (45.1%) usually voided in diapers or pads,
- (2.2%) refused toileting assistance
- (28.3%) unknown.

The 41.4% of residents offered toileting assistance in Japan compares with 8% reported by Jerez-Roig *et al.*, (2016) who conducted a cross sectional study of 321 elderly, mostly female aged care residents from 10 nursing homes in Brazil. The prevalence of UI was 58.88% (CI 95%: 53.42–64.13) and the final model revealed a statistically significant association between UI and white race, physical inactivity, stroke, mobility impairment, and cognitive decline. The most frequent UI type was functional UI [347].

Several trials describe an intervention designed to improve rates of toileting assistance in nursing homes. Most are now over 20 years old. However, one recent trial reported improvements in rates of UI following a toileting assistance programme [202] and the other reported increases in the number of UI assessments conducted, increased toileting assistance rates and improvements in residents' quality of life [348] (see section on interventions).

In an effort to support staff to make informed decisions about toileting assistance programmes *vis-à-vis* a containment programme at an individual level, van Houten *et al.*, (2020) designed a Toileting and Containment Decision Support Tool. The tool was developed by a multidisciplinary group of experts following a review of literature and was validated by continence specialists in 8 countries. The tool is designed to guide the non-specialist health care professional in carrying out a rapid and focused incontinence assessment resulting in a person-centred management strategy tailored to individual characteristics and circumstances [349]. Further validation of the tool is required to determine its effects on practice and patient outcomes.

2.6. A lack of privacy and attention to the dignity of frail older adults in nursing homes

Privacy to void or defaecate are important social factors unrelated to underlying pathophysiology which may affect the continence status of frail older adults. It is possible a lack of toileting privacy may cause a person to defer or ignore the urge to void or defaecate. According to the findings of a cross sectional survey of 120 adults with faecal incontinence aged 65 and over and living in either their own homes, a nursing home, or an acute or rehabilitation, privacy to defaecate is usually attainable in one's home, but not in a nursing home. Privacy to defaecate was reported by 23% of respondents in a nursing home, 53% of those in rehabilitation wards, and 50% of those in acute wards [350]. Further research is required to explore the relationship between a lack of toileting privacy and incontinence in frail older adults.

Since the last ICI, there has been an increased interest in the privacy and dignity of individuals with continence care needs, part due to widespread concerns about a lack of attention to the dignity of older people who need assistance with toileting, incontinence or bladder or bowel care in health or social care settings that provide long-term care. A lack of dignity in the personal care needs of care dependent older people is a recurrent theme within a number of reviews and enquiries, including The Francis Report of the mid- Staffordshire NHS Foundation in the UK and the Royal Commission into Aged Care Quality and Safety in Australia (2021) [351] [352].

In 2009, Billings *et al.*, undertook a mixed methods study involving non-participant observations and interviews to: (i) identify and validate person-centred attributes of dignity in relation to continence; (ii) develop reflective guidelines for dignified care; and (iii) produce recommendations for best practice. The researchers concluded that the definition of dignity was a complex, shifting concept, dependent upon individual context and interpretation and whilst aspects of dignity were directly related to continence, such as privacy and hygiene, in general it interrelates to all aspects of care and cannot be separated, and thus, was not measurable [353].

In 2020, Ostaszkiewicz *et al.,* conducted a concept analysis of dignity-protective continence care for this population group. The researchers identified 50 individual attributes which were categorised in 6 domains (respect, empathy, trust, privacy, autonomy and communication). A further 15 attributes were identified that related to the environment (6 physical and 9 social). Key consequences of undignified continence care were also identified and categorised into 3 levels of impact (resident/family member, staff or organisation). This conceptual understanding of dignity protective continence care can be used as a value or guiding principle in an ethic of care for older people who require continence care. It could also inform the development of education programmes for nursing home staff, and methods to evaluate whether continence care is delivered in a way that protects a person's dignity [354].

2.7. Reduced staffing levels in long term care

Estimating and achieving the optimal level and skill mix of any workforce is a challenge. In long-term aged care homes where residents' have chronic health problems and complex health needs, maintaining sufficient staffing levels is exacerbated by a high staff turnover. Nurses consistently cite inadequate staffing levels as a major barrier to providing optimal continence care [355-359]. The extent to which patients and residents' continence care needs are considered in formulae designed to establish the right staffing level and skill mix is unclear. The time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management to prevent and/or manage incontinent episodes require consideration in service planning.

Over 150 studies have been documented that confirm a 'strong positive impact of nurse staffing on both care process and outcome measures' [360]. These studies have mainly been conducted in the U.S, Canada, United Kingdom, Germany, Norway, and Sweden. They highlight the contribution of organisational factors to care quality, such as having a high professional staff mix (ratios of RN to total staffing levels), low staff turnover rates and use of agency staff, and consistency in staffing. The strongest positive relationships are found between RNs (with two to four years of training) and quality, which is stronger than the relationship between licensed vocational/practical nurses (LVNs/LPNs; who have less training than RNs) and quality. Total nurse staffing levels (which includes RNs, LVNs/LPNs, and certified nursing assistants [CNAs; with about two weeks of training]) are also related to quality.

Evidence presented in the last ICI highlighted the importance of considering the number of staff, their skill mix and how they work and the association with the quality of UI care in nursing homes. Temkin-Greener *et al.*, [361] analysed data from 46,044 residents in 162 nursing homes in New York State, for June 2006–July 2007, and survey responses from 7,418 workers in the same homes. They reported an association between incontinence and nursing home work environment attributes such as teams, consistent assignment and staff cohesion. After adjusting for other factors, they found residents in homes with stronger staff cohesion had a significantly lower odds of incontinence (OR = 0.924; p < .001). A one standard deviation (0.23) increases in the staff cohesion score resulted in 7.6 percent lower odds of incontinence. Likewise, in a longitudinal correlational study, Yoon *et al.* [362] examined the impact of organizational factors on the quality of UI care (i.e. defined as improvement in UI status or maintenance of continence) post admission to Korean long-term care hospitals. After controlling for other factors, they found higher Registered Nurse to patient ratios was significantly associated with better resident UI outcomes.

Two further studies further reinforce the need to consider the influence of staffing on the quality of continence care in nursing homes. Harrison *et al.*, (2019) investigated care and staff skill factors that predicted quality continence care. After controlling for gender, and age, there was an association between the creation of a UI plan of care by a Registered Nurse for a resident with UI and the resident's self-rated health [311.] Boscart *et al.*, (2018) explored the relationship between staffing characteristics and residents' quality of care indicators. Staff and resident characteristics were examined and data on 13 practice sensitive RAI-MDS 2.0 quality indicators, including indwelling catheter use and urinary tract infections were collected. Most direct care (76%) was provided by the NAs. The number of hours of care a resident receives from Nursing Assistants (NAs) is significantly associated with higher quality of resident care (p = < 0.01).

2.8. The overuse and misuse of continence products in nursing homes

For many people, continence products represent a means by which they can achieve effective and discrete containment of incontinence, minimise physical discomfort and optimise psychological and social function [363]. At the same time, their overuse and misuse may represent a risk factor for incontinence and, for pads, urinary tract infection. Although continence products have an important place in the containment of incontinence, their use in the general community, in hospital settings, and in nursing homes is widespread (see Table 5). For example, in the largest and widest audit of continence care conducted in the UK and involving over 6,000 patients across primary and secondary care trusts, and care homes, containment strategies (i.e., the use of continence products) far exceeded all other forms of documented continence management [364].

We located eight studies that provide data about the use of continence products in nursing homes. These were conducted in the UK [365, 366], the USA [334, 367], and in Norway [368]. Wagg and colleagues reported that of 488 residents from 27 care homes included in the national audit of continence care in the UK, 307 (63%) used a containment strategy to manage their incontinence [364]. Rodriguez and colleagues reported similar rates based on interview data from managers of 66 care homes in Birmingham [366]. An international comparison of the dependence levels of 90,000 nursing home residents from four countries (including UK, Spain, New Zealand and Australia) reported 87-94% of residents used incontinence pads (1998-2009) [369]. A cross-sectional survey of 810 older people in long-term care facilities in Taiwan reported 639 (78.9%) of the total residents wore diapers, and of these, the most common form of diaper was an adhesive-tape diaper (74.3%). Of those residents using diapers, 99 (12.2%) were able to ambulate independently and 247(51.5%) were able to stand for 30 seconds [370].

In the USA, Brandeis and colleagues reported a high rate of pad use (84%) in their sample of 2,014 residents from 270 Medicaid-certified nursing homes [334]. Eighty-four percent were managed with pads/briefs, and more than one third of incontinent patients were managed with two modalities. An evaluation of the use of urinary collection devices by 57,302 residents from skilled nursing facilities found that pad use remained relatively stable over a 12 month period [371]. Pad use among a sample of 11,549 newly admitted 75–84-year-old residents was 58.7% at admission and 61.1% twelve months later. This rate was higher for residents aged 85 years of age and older (i.e., 60.3% at admission and 62.6% one year later). In a survey of patterns and treatments of urinary incontinence in 13 special care units in the USA, Specht and colleagues (2002) reported that 72% (n=105) of residents used a continence product: the most common type of product being a continence brief or pad (n=93) [367].

According to Omli and colleagues, who estimated the daily pad usage of 153 elderly residents from six nursing homes in Norway, 77% of residents use pads [368]. They also found that residents' pads were changed infrequently (i.e., an average of 2.3 times a day (range 0.5-8.0) for female residents and 3.1 times a day for male residents (range 1.0-9.0). Moreover, urinary tract infections were associated with pad use (41 vs. 11%; P= 0.001): but not with fluid intake or number of pad changes. Residents pad usage did not correlate well with the volume of their incontinence:

As inappropriate use of continence products may contribute to the onset, or continuation of, UI, it is important that clinicians who ad-

vocate or authorise their use, are familiar with evidence-based guidelines that advocate an active approach to diagnosis, prevention and treatment.

Table 5: Evaluative studies on the use of continence products (pads and briefs) in nursing homes

Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes				
Study	**Objective**	**Sample**	**Method**	**Results**
Brandeis *et al.*, 1997	To describe the frequency and correlatessnip of potentially treatable causes of urinary incontinence	2014 residents (mean age 84.3 ± 8.7) from 270 Medicaid-certified nursing homes in USA	Review of MDS data / Interview with the nursing home staff, and interaction and observation of residents	990/2014 (49%) of residents were incontinent. Of these, 84.0% were managed by pads/briefs. More than one-third (n = 350) of the incontinent residents were managed with two modalities
Boyd *et al.*, 2012	To describe an international comparison of dependency of long-term care residents	90,000 nursing home residents from Spain, New Zealand, Australia and the UK.	A descriptive correlational study	Prevalence of dependent mobility ranged from 27 to 47%; chronic confusion, 46 to 75%; and double incontinence, 29 to 49%. Continence trends over time were mixed, chronic confusion increased, and challenging behaviour decreased.
Omli *et al.*, 2010	To determine daily pad usage & association with UTI, and fluid intake	153 residents (mean age 83 ± 8.2 yrs) from 6 nursing homes in Norway	Number and weight of pads per/resident calculated over 2 days	118/153 (77%) used pads 36/48(75%) men 82/105(78%) women Average number of pad changes p/day-2.7 UTI correlated with pad use but not fluid intake or number of pad changes
Specht *et al.*, 2002	To describe the prevalence, patterns and complications of UI in older adults residing on dementia special care units	145 residents with dementia from one Special Care Unit	Descriptive correlational survey	48% had UI compared to 6% on admission. 72% of resident used incontinence aids, the most common being incontinence briefs and padding
Roderiguez *et al.*, 2007	To explore incontinence prevalence, knowledge and care	66 care homes in Birmingham, UK	Questionnaire to care home managers	Several methods to manage incontinence were cited however briefs and pads accounted for over 50% of responses
Rogers *et al.*, 2008.	To assess use of urinary collection devices (external, intermittent, and indwelling catheters; pads or briefs) and examine predictors of indwelling catheters in skilled nursing facilities	57,302 patients admitted to skilled nursing facilities in five states in the USA in 2003 who remained there for 1 year	Retrospective cohort study	The prevalence of indwelling catheterization was 12.6% at admission and 4.5% at the annual assessment (P<.001). Intermittent and external catheterization were infrequently used (<1% at admission and annual assessment). Paraplegia, quadriplegia, multiple sclerosis, and comatose state were strongly associated with indwelling catheterization. Male residents were more likely to use an indwelling catheter at every assessment, as were obese patients; individuals with diabetes mellitus, renal failure, skin conditions, deep vein thrombosis, aphasia, or end-stage disease; and those who were taking more medications.

Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes				
Study	**Objective**	**Sample**	**Method**	**Results**
Tsai *et al.*, 2018	To investigate the prevalence and continence care strategies among elderly population living in the long-term care institution.	810 residents from long-term care institutions in Eastern Taiwan	A cross-sectional survey	Prevalence of UI was 40%, and 7.8% for fecal incontinence and 29% with double incontinence. Inability to stand or hip lifting had significantly higher risks of wearing diapers, (OR 29.86, p <.0001). In addition, unable to stand but able to lift hip for 30 seconds still obtain a higher risk on diaper use (OR 6.77, p <.001). In related to diaper use, 639 (78.9%) of the total participants wore diaper, and use of adhesive-tape diaper is 475 (74.3%). For the people using diapers, 99 (12.2%) of them could ambulate independently without assistance but still wearing diapers. And 247(51.5%) of the subjects who wear adhesive-tape diaper were able to stand for 30 seconds.
Wagg *et al.*, 2008	To assess the quality of continence care for older people	2717 patients from 138 primary care trusts in UK	Audit of patients' clinical records	Containment strategies were used by 1294/2717 (48%) of patients

Table 6: Evaluative studies on assessment of UI in frail older adults in hospitals

Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes				
Study	**Objective**	**Sample**	**Method**	**Results**
Artero-Lopez *et al.* (2018)	To assess the existence of therapeutic inertia in the nursing care of patients with UI during the patient's time in hospital, together with the sociodemographic and professional variables involved	600 medical records reviewed	A prospective observational study with nonparticipative observation of medical practice units and review of patients' medical records.	In 50% (n = 301), the use of a rating scale was not reflected. In over 90% (n = 560) of cases, the type of incontinence was not recorded. In no continuity of care report were recommendations regarding incontinence included, nor was the type of continence products recommended indicated
Mulrooney *et al.* (2017)	To examine whether incontinence was assessed by admitting doctors and nurses in an acute medical assessment unit	40 patients from an acute medical unit. Average age 72.25 (SD=16.3264) years, of whom 17 were females.	A cross sectional analysis of medical admission notes and nursing patient assessment sheets	In 50% of cases, incontinence was not documented on the admission note by doctors. Duration, frequency, management and cause of incontinence were documented in 8.3% of patients. In contrast the nursing pro-forma patient assessment sheet had 95% documentation rate of bladder and bowel continence in both the continent and incontinent patients.
Randles *et al.* (2019)	To determine whether appropriate assessments of continence in older adults presenting to the hospital setting were completed and documented.	31 medical records	A one day audit of patient's medical records in a general medical ward and a specialist geriatric medicine ward	42% UI of whom 40% had completed documentation Six of the patients with documented incontinence had their symptoms/ type of incontinence documented
Redley & Barker (2019)	To test the mnemonic Have you SCAND MMe Please? as a framework to audit nursing care to prevent harms common to older inpatients	A random selection of 400 medical records of inpatients over 65 years of age with an unplanned admission of longer than 72 hr in acute medical wards from four hospitals in Victoria, Australia	Retrospective audit of medical records	The most often documented assessments were skin integrity (94%-97%), mobility (95%-98%) and pain (93%-97%), however only 4%-31% were assessed gaps in assessment of continence (4%-31%), nutrition (9%-49%), cognition (delirium, depression and dementia) (10%-24%) were most common. No patient record had evidence of all eight factors being assessed. Almost 80% of records had interventions documented for one or more factors that contribute to preventable harms. In almost 20% of patient records, a new preventable harm was documented during hospitalisation.
Redley & Raggatt (2017)	To scope the preventable harms addressed by standard forms used to screen and assess older people and how standard forms are operationalised in hospitals across Victoria, Australia	152 standard assessment forms to assess older people at 11 health services in Victoria, Australia in 2015	Mixed methods study: (1) cross-sectional audit of standard risk screening and assessment forms (2) 9 focus groups with a purposive sample of 69 participants at 9 health services.	Assessments of skin integrity and mobility loss (including falls) were consistently included in forms; however, nutrition, cognitive state, pain and medication risks were inconsistent; and continence, venous thromboembolism risk and hospital acquired infection from invasive devices were infrequent. Qualitative analyses revealed five themes explaining issues associated with current use of assessment forms: (1) comprehensive assessment of preventable harms; (2) burden on staff and the older person, (3) interprofessional collaboration, (4) flexibility to individualise care and (5) information management.

Table 7: Evaluative studies on the use of continence products (pads and briefs) in acute/hospital/secondary care

Acute care / hospital / secondary care				
Study	**Objective**	**Sample**	**Method**	**Results**
Condon *et al.*, 2018	To explore the appropriateness of using continence containment products (CCP) in hospitals	435 inpatients (>=18) in a large university hospital in Galway, Ireland	A point prevalence study with assessment of pre-admission and current use of CCP, function based on the Barthel Index (BI) and frailty according to the Clinical Frailty Scale (CFS). Baseline characteristics and the Charlson Co-morbidity Index	CCP usage was 39.8% of inpatients aged >=18 and increased to 57% >=70. All-in-one pads (69% of all CCP) were the most common type used. In all, 62/435 (14%) inpatients used a urinary catheter. There was a 21% increase in all-in- one pad usage compared to premorbid levels (27% versus 6%, p < 0.001). Inappropriate use of all-in-one pads was 64% and was significantly more common in patients with established frailty (p = 0.02) and those with functional impairment as judged by the BI, currently on review (p < 0.001) or at baseline (p = 0.001). Age was independently associated with use of
Fernandez *et al.*, 2017a, 2017b;	To establish views on wait times and hypothesized that they may vary depending upon perspective, circumstance, and incontinence type.	Eligible patients were inpatients, 65 years and older, in a single tertiary acute care hospital.	Cross-sectional, descriptive survey	There was patient-provider mismatch for daytime urinary incontinence: 90% of patients but only 44% of DCPs reported urinary soiling more than 1 hour in the daytime as unacceptable (38.0 vs 85.0 minutes; P <.0001). A significant majority (80%-90%) of both groups reported short acceptable wait times for fecal incontinence (<15 minutes). The odds of being tolerant to any soiling were significantly higher in patients who were prior residents of care facilities (odds ratio [OR] = 6.2; 95% confidence interval [CI], 1.3-28.1; P =.019), previously used incontinence products (OR = 2.0; 95% CI, 1.0-3.8; P =.036), or used walking aids (OR = 4.0; 95% CI, 1.1-14.7; P =.039). Actual wait times were significantly longer than deemed acceptable by either patients or DCPs.
Goes *et al.*, 2020	To identify reasons for the indiscriminate use of diapers and bladder catheters in hospitalized elderly	10 professionals from the nursing team of a hospital in northeastern Brazil	Qualitative methods using the focus group as the collection technique	Factors such as shame (modesty), fear of getting wet and the greater need for help from the team for support at this time, influenced this practice. The majority of the team didn't assess patients' previous states of continence when it is was not related to the reason for the admission
Kadir, 2004	To determine the incidence and appropriateness of incontinence aid use	333 elderly patients in an acute hospital (Singapore)	Survey – patient self-report	200/333 (60%) - using some form of aid 101 (50.1%) could have been managed with alternatives

Acute care / hospital / secondary care				
Study	**Objective**	**Sample**	**Method**	**Results**
Murphy *et al.*, 2015	To explore why clinicians, decide to place indwelling urethral catheters in acute medical care.	in the emergency department and acute medical wards of a 1200+ bed hospital, undertaking 30 retrospective think aloud and 20 semi-structured interviews with nurses and physicians who made the decision to place an IUC. A purposive sample and thematic analysis were used.	Qualitative interviews	Opinions on when an IUC was warranted varied considerably. Inconsistency in decision-making was caused by differing beliefs on when an IUC was appropriate for each clinical indication. Numerous patient and non-patient factors, including clinical setting, resources, patient age and gender and staff workload, also impacted on each decision. Assessing when the benefit of an IUC outweighed the risk could be problematic due to conflicting goals
Ostaszkiewicz, *et al.*, 2008	To determine the prevalence of UI & FI + pad use + documentation of incontinence	447 inpatients (mean age 70 ± 18.7yrs) admitted to 3 acute and 1 subacute care hospitals in Australia	Point prevalence survey + an audit of medical records	266/446 (60%)- using a continence product/ device 50/121 (41%) of patients using pads had no UI or FI in the preceding 24 hrs. 18/113 (16%) patient with UI or FI in preceding 24hrs had no continence product/device
Palese *et al.*, 2007	To evaluate the incidence of pad use and explore appropriateness and reasons for use	396 patients (mean age 76.8 ± 11.8yrs) admitted to medical units in 2 acute care units in Italy	Survey – interview + clinical assessment 3 x day each day during hospitalization	Inpatient use of pads – 218/396 (55.1%). Of this cohort, 120/396 (30.3%) had incontinence prior to admission. Rationale for pad use: urinary incontinence associated with acute confusion or dementia
Percival *et al.*, 2021	To identify factors that help or hinder good continence care for patients aged 65 years and over in hospital medical ward settings	27 nursing, medical and allied health practitioners in three hospitals.	Qualitative interviews	Good continence care was said to be advanced through person-centred care, robust assessment and monitoring, and a proactive approach to encouraging patient independence. Barriers to quality care centred on lack of oversight, automatic use of incontinence products and staffing pressures. Suggested improvements centred on participatory care, open communication and care planning with a higher bladder and bowel health profile.
Wagg *et al.*, 2008	To assess the quality of continence care for older people	3683 patients from 195 secondary care trusts (hospitals) in UK	Audit of patients' clinical records	2070/3683 (56%) patients used containment strategies
Zisberg 2011	To determine incidence of incontinence brief [pad] use	465 older patients (mean age 78.6 ± 5.8 yrs) who were not using incontinence briefs prior to admission to medical acute care units in a 900-bed teaching hospital in Israel	Admission interview and then every day after first 48 hrs	65/465(14%) used incontinence briefs during most of their hospitalisation. Brief use was associated with low mobility

3. ORGANISATIONAL PROCESSES OF CARE IN HOSPITALS

There has been an increased interest in research on incontinence in hospitals since the last ICI, identifying hospitals as an organisational setting that potentially increases the risk of a frail older person developing UI. According to a retrospective review of 182 medical records, there is a significant relationship between hospitalisation and new onset UI (p = .007), and an increased length of stay increases the likelihood of developing a form of incontinence [62]. Similarly, in a prospective cohort study of 282 hospitalised adults aged 70 and older who were admitted for a non-disabling problem, Zisberg *et al.* [372] found in-hospital continence care was directly and indirectly (through its relationship with mobility) related to functional decline at discharge. This important finding may indicate that low mobility and use of continence products form a "double jeopardy" and should be addressed simultaneously in-hospital.

3.1. A lack of assessment in hospitals

A study on nursing practices for patient with UI in hospital noted what the authors called inertia in continence care. The researchers analysed 600 records from 132 nurses and found little documentation of assessment or diagnosis of UI in hospital inpatients [373]. Similar findings were reported by Mulrooney *et al.* (2017) who examined whether admitting doctors and nurses in an acute medical assessment unit assessed and documented patients' incontinence. The researchers found in 50% of cases, incontinence was not documented on the admission notes by doctors and only 8.3% of patients' records contained information about the duration, frequency, management and cause of incontinence. Randles *et al* (2019) also reported low rates of documentation of patients' continence status in a sample of 31 patients over 65 years of age in a general medical ward and a specialist geriatric medicine ward in Ireland. Only 6 of the patients with documented incontinence had their symptoms/type of incontinence documented [374].

In Australia, Redley and Raggatt (2017) reviewed 152 standard assessment forms from 11 Victorian acute care health services and found the forms rarely included a prompt for healthcare practitioners to screen patients' continence status. Whilst assessments of skin integrity and mobility loss (including falls) were consistently included in forms; nutrition, cognitive state, pain and medication risks were inconsistent; and continence, venous thromboembolism risk and hospital acquired infection from invasive devices were infrequent [375]. Roggeman *et al.* (2020) reported similar gaps in the quality of screening and assessment processes to identify falls associated with lower urinary tract symptoms (LUTS). Their review of literature found a total of 23 fall risk scales, from which 11 were applicable for in-hospital patients and 12 were applicable for community-dwelling older people. In nine of the 11 scales for in-hospital patients, a LUTS or LUTS-related parameter was included. There were no LUTS included in the risk assessment tools for community-dwelling older people [376].

Having identified gaps in the quality of screening/assessment tools for hospital-acquired conditions/harms, Redley and Barker (2019) also developed and tested the mnemonic *Have you SCAND MMe Please?* as a framework to audit nursing care to prevent harms common to older inpatients. The mnemonic brings together eight factors known to contribute to preventable harms common in older hospitalised patients, including incontinence. The researchers reviewed a random selection of 400 medical records of inpatients over 65 years of age with an unplanned admission of longer than 72 hr in acute medical wards from four hospitals in Victoria, Australia for the frequency of documented evidence of assessments, interventions or new problems related to the eight factors. The most often documented assessments were skin integrity (94%-97%), mobility (95%-98%) and pain (93%-97%), however only 4%-31% were assessed for incontinence [377].

3.2. A lack of knowledge about UI among healthcare practitioners and/or formal caregivers in hospitals

Several studies reveal gaps in hospital based nurses' knowledge about incontinence and its management [329, 378-383]. A new integrative review of nine studies reported nurses lack knowledge or motivation to thoroughly assess UI in hospitalised older adults, often focusing on containment strategies, rather than conducting an assessment and promoting continence [384].

3.3. Practices that reduce/restrict the frail older adult's mobility and functional abilities in hospitals

Urinary incontinence is associated with severe impairment in ADLs for frail older people in acute and sub-acute care settings. Hence, care processes or practices that reduce or restrict a frail older person's mobility and functional status requires attention. Chong *et al.*, (2018) found frailty in hospitalised older adults predicted incident UI and/or death over time (at discharge: OR 2.98, 95% CI 1.00-8.91, P = .050; 6 months: OR 2.86, 95% CI 1.13-7.24, P = .027; 12 months: OR 2.67, 95% CI 1.13-6.27, P = .025), adjusting for age, sex, and severity of illness [210]. Similarly, Mallinson *et al.*, (2017) conducted a retrospective, cohort study of 425,547 Medicare patients discharged from inpatient rehabilitation facilities in 2005 and found 26.6% of men and 22.2% of women were incontinent on admission and their continence status was significantly associated with discharge to institutional care, particularly among orthopaedic patients [385]. According to the findings of a co-design study that aimed to improve service delivery for hospitalised frail older people, continence care is one of five areas of care that needs to improve; the other areas being improved mobility; improved access to food and hydration, improved patient information and improved collaboration along the integrated care continuum [386].

3.4. Limited or inconsistent access to toileting assistance in hospitals

The last ICI reported on a large mixed methods study led by Thomas *et al.*, [387] that explored the organisational context for embedding a systematic voiding programme for patients with UI after stroke in secondary care settings. The researchers concluded there was a focus on containment of UI that was not conducive to therapeutic continence management [388]. They also found toileting dependence to be the most problematic aspect for patients after a stroke. The researchers conducted a cross-sectional correlation study of 107 adult inpatients, hospitalized for a stroke. Boltzmann sigmoid modelling revealed that the total scores required to obtain a response at 50% of the maximal value for the required components of toileting ranged between 2.691 and 34.962 points, for the components of "wearing pants" and "cutting the toilet paper," respectively. A generalized linear model showed that the Berg Balance Scale score was a significant predictor for independent performance on most component activities of toileting. The component of toileting that was easiest to carry out was cutting the toilet paper, and the most difficult was wearing pants. Balance impairment was an independent predictor of independent toileting after stroke. Further research is required to assess the motor and process skills required for independent toileting among different groups of hospitalised older people.

3.5. A lack of privacy and attention to the dignity of frail older adults in hospitals

The lack of attention to the privacy and dignity of frail older people in nursing homes also extends to frail older people in hospital settings. Using an ethnographic design Boddington and Featherstone (2018). examined the complex systems of dominance, hierarchy, and the social and institutional routines in five hospitals in England and Wales. The aim was to examine the ways in which the recognition of personhood is negotiated, achieved, and threatened among hospitalised older adults with incontinence and dementia.

The researcher reported routines and prioritisation dilemmas pose barriers to patients' control over their elimination needs and disrupt the presence of the patient in the social life of the ward. They described the way in which that which was private becomes open to control by others, i.e., people no longer have control over how others see them, and it is no longer unusual for people to be viewed during intimate moments, or for their continence care needs to be delayed or interrupted by the competing priorities of others. Importantly, the researchers stated 'the coexistence of a diagnosis of dementia and needing continence care creates a double jeopardy not only for the dignity and moral status of the patient, but also for those involved in their most intimate care, who must complete the pressing routines and timetables of medication rounds, personal care and continence care etc. throughout a shift. This sets the conditions within which the loss of personhood and dehumanization of people living with dementia can flourish' [389]. According to the findings of a qualitative descriptive exploratory study about patients' end of life preferences for continence care, dignity is often threatened as a result of having to receive continence care, with most patients acquiescing to staff recommendations for management approaches as being easiest [390]. Moreover, as patients approached end of life, they were willing to give up dignity if it was required to address symptoms causing them more distress, like pain.

3.6. Reduced staffing in hospitals

The relationship between nurse staffing and quality of care is much debated. We found no studies that specifically describe the association between staffing and the quality of continence care in hospitals or UI rates among frail older persons in hospitals. At the same time, there are several large studies that reveal an association between the number of nurses, their education, length of stay, cost and hospital mortality. The most recent of these is a study of 231,902 patients from 27 hospitals in Queensland, Australia. 142,986 patients in intervention hospitals and 88 916 in comparison hospitals were assessed at baseline (2016) and 257,253 patients (160,167 in intervention hospitals and 97,086 in comparison hospitals) were assessed in the post-implementation. After implementation, mortality rates were significantly lower than at baseline in intervention hospitals (0·89, 0·84–0·95, p=0·0003) [391-393].

3.7. The overuse and misuse of continence products in hospitals

Rates of continence product use in elderly patients in acute care across several countries are similar and range from 55.1% in Italy [394], 56% in the UK [365] to 60% in Singapore [395] and Australia [396]. Not only are they widely used but they are often used indiscriminately. One of the earliest studies to draw attention to an overreliance on continence products was conducted by Starer and Libow [397] who found more residents using pads than those with incontinence. More recently, Ostaszkiewicz and colleagues found that in the inpatient care setting, pads were inappropriately used for some patients, and were underused for others [396]. Of 121 patients who were using pads at the times of the survey, 50(41%) reported no UI or FI in the preceding 24-hours. However, 18% of patients who had no pad did report such an episode. This mismatch between incontinence and pad use has been noted in other research [394, 398].

The last consultation reported that in-hospital use of continence products was associated with new onset UI at discharge, according to a prospective cohort study of 684 hospitalised older adults admitted for a non-disabling problem [398] based on a mixed-methods study that explored the organisational context for embedding a systematic voiding programme for patients with UI after stroke in a secondary care setting, in the UK. It also reported that the focus of UI care is on containment of UI rather than therapeutic continence management [387]. Since then, five new research studies have been identified that examined the use of continence products in hospital settings (see Table 7).

Timely changing of incontinence products is important since patients are at risk of developing incontinence-associated dermatitis. A cross-sectional survey of hospitalised older adults who required continence products and their direct care providers investigated the length of time they thought was acceptable for patients to spend in a soiled pad during the day and the night [399]. Data on patients' previous continence status, pad use, use of mobility aids and place of residence (community, institution) were also collected. The researchers reported a mismatch between patients and provider in their tolerance for waiting related to daytime pad change related to UI. Specifically, 90% of patients but only 44% of direct care providers reported urinary soiling more than one hour in the daytime as unacceptable (38.0 vs 85.0 minutes; P <.0001). A significant majority (80%-90%) of both groups reported short acceptable wait times for faecal incontinence (<15 minutes). The odds of tolerating any soiling were significantly higher in patients who were prior residents of nursing homes (odds ratio [OR] = 6.2; 95% confidence interval [CI], 1.3-28.1; P =.019), previously used incontinence products (OR = 2.0; 95% CI, 1.0-3.8; P =.036), or used walking aids (OR = 4.0; 95% CI, 1.1-14.7; P =.039). Actual wait times were significantly longer than deemed acceptable by either patients or direct care providers. The actual wait times patients and direct care providers reported were also markedly different, with patients reporting generally shorter wait times than direct care providers during the day (74.6 vs. 148.8 min; p<0.0001). The majority of direct care providers (86%) reporting wait times of 91-120 minutes at night vs. a range of times by patients (155.4 vs. 128.4 min for patients and direct care providers, respectively; p=0.024).

Concerted efforts are required to tackle the inappropriate use of continence products in hospital settings according to the findings of a point prevalence survey of 435 inpatients, median age 72 +/- 23 years. Based on hospital policy and NICE guidelines (2015), the researchers deemed the use of all-in-one pads appropriate for patients who scored zero on the bowel section of the Barthel Index, indicating faecal incontinence and/or zero on the transfer section indicating major assistance or a hoist to transfer from bed to chair [400]. Inappropriate use of all-in-one pads was 64% and was significantly more common in patients with established frailty (p = 0.02) and those with functional impairment as judged by the Barthel Index, currently on review (p < 0.001) or at baseline (p = 0.001). Age was independently associated with use of any product, including pads and urinary catheters (p < 0.001).

Qualitative interviews with health care professionals from a hospital in north-eastern Brazil suggest patients' impaired mobility was the main reason for promoting the use of continence products in a hospital setting [401]. Other factors included the anticipation of shame and fear for the resident, and the lack of team support to promote

the patient's continence. Qualitative interviews with 27 nursing, medical and allied health practitioners in three hospitals study from the UK also found a high reliance on the use of incontinence products that staff reported was due to staffing pressures [402].

According to the findings of a qualitative study in the emergency department and acute medical wards of a 1200+ bed hospital, decision-making regarding the use of indwelling urinary catheters is also arbitrary and influenced by multiple factors [403]. These included patient and non-patient factors, including clinical setting, resources, patient age, sex and staff workload, also effected each decision. The researchers advocate for greater understanding of the complexity and lack of clarity clinicians face when making the decision to insert a catheter.

4. ORGANISATIONAL INTERVENTIONS

4.1. Assessment and communication interventions

Since the last consultation, four peer reviewed publications were identified that describe an organisational intervention designed to improve the assessment and communication of UI in organisational settings. Grainger *et al.*, (2019) describe an intervention focusing on communication between the acute hospital and community teams responsible for care home residents after discharge from acute care. The team designed a discharge summary template that addressed 8 core domains, including continence. The introduction of the template resulted in 90% of discharge summaries being completed [404]. Similarly, Tazeen *et al.*, (2017) described the development and evaluation of a new continence assessment form for completion by ward nurses. Supported by regular ward visits and education sessions from the continence team, ward staff were encouraged to refer appropriate patients to the continence out-patient service. A follow up audit of 36 patients found 100% compliance with completing the screening and assessment form and 7 new cases were identified and referred to the continence team for further assessment [405]. Improving the assessment and documentation of UI in nursing homes was also the focus of a randomised controlled trial led by Gencbas *et al.*, (2018) in Turkey. Thirty-two female residents were randomised to the 12-week intervention and 30 to a control usual care group. The intervention consisted of education to staff about three Standard Nursing Languages (Nursing Diagnosis: Definitions and Classification; NIC: Nursing Interventions Classification; NOC: Nursing Outcomes Classification) and their application to residents' continence care plans. The researchers reported statistically significant improvement in all NOC scales in the intervention group compared to the control group (i.e., assessment and documentation about urinary elimination, urinary continence, tissue integrity, self-care toileting and medication response). They also reported significant and positive differences in the ISI (P = 0.001), UDI-6 (P = 0.001), and I-QOL (P = 0.001) scale scores for the IG group post-intervention [406]. A similar approach was taken by Hödl *et al.*, (2019) who evaluated the effects of introducing 29 evidence-based nursing recommendations about the conservative management of UI in 12 Austrian nursing homes. The intervention group (n=216) received conservative UI management strategies for 12 weeks and the control group (n=165) received usual care. The intervention group had a lower risk of daily UI (P = 0.02), were less likely to receive absorbent products (P = 0.01) and were five times more likely to receive recommended interventions (P = 0.001) than residents in the usual care group [407]. Finally, Trad *et al.*, (2019) reported using the Joanna Briggs Institute Practical Application of Clinical Evidence System and the Getting Research into Practice tools to review the nursing assessment and management of adult patients with urinary and faecal incontinence, and to develop local resources to assist nursing staff to assess and manage incontinence in a large hospital in Australia. Nursing staff received education about 10-best practice criteria for incontinence assessment and management. A pre–post audit revealed notable improvements in the nursing documentation, and in assessment and management.

4.2. Exercise programmes

The last ICI reported on two trials in a nursing home setting [408, 409] that revealed reductions in the frequency and severity of incontinence from exercise programmes that aim to improve frail older person's functional status. No further trials have been identified.

4.3. Technological interventions

A new technological intervention designed to augment and enhance the assessment of UI in frail older adults offers promise. Electronic monitoring systems designed to detect moisture in incontinence pads can augment existing assessment processes for aged care residents with complex conditions in long-term care homes or geriatric hospitals. A health technology report that examined the effectiveness of budget impact of, and patient values and preferences about the technology reported the system would cost $6.4 million in the first year of implementation and $1.6 million in subsequent years. As only one observational was identified, the authors concluded that the effectiveness of using the electronic monitoring system to assess UI was uncertain because of the very low quality of the evidence and introducing it would result in incremental costs, and there would be savings only if the systems substantially reduced incontinence [410]. Further trials on this technology are required.

4.4. Night-time continence care practices

According to a recent study, 80% of hospitalised older patients experience nocturnal LUTS during sub-acute hospitalisation [411] which may affect the quality and duration of their sleep and increase their risk of falling at night. It is unclear if the symptoms relate to physiological function or to disruptions caused by care practices. According to an evaluation of a night time intervention for 21 nursing home residents with dementia in Japan, continence care routines are common practice. Mizaguchi *et al.*, (2017) examined the effects on sleep and activity following an intervention designed to manage UI during the night for 21 nursing home residents with dementia in Japan. The intervention involved changing diapers immediately after urination and taking residents to the bathroom according to their individual needs, rather than leaving them in a wet diaper. The researchers reported the number of times per night that residents received continence care during the control period was 1.35 (+/- 1.40) compared with 4.47 (+/- 1.39) during the intervention. The volume of UI during the control period was reportedly 271.78 (+/- 393.50) ml while during the intervention period it was 242.22 (+/- 211.46) ml showing residents were less likely to develop UI during the intervention period. The researchers reported improvements in residents' total sleep time at night and improvements in daytime activeness, particularly among residents with milder cognitive impairment [412].

4.5. Toileting assistance programmes

There were three new trials that describe an evaluation of a toileting assistance programme in a nursing home setting. Lai and Wan (2017) examined the effectiveness of the use of prompted voiding by nursing home staff to manage UI among residents over a 6-month period in a randomised controlled trial conducted with 52 nursing home residents from five nursing homes in Hong Kong.

The intervention was delivered by usual care staff who were trained in the protocol. At six months both groups had improved, but there were significant differences between the two groups in the number of UI episodes per day, UI rate per day, and total continent toileting per day. A decrease of 9.1% was observed in the incontinence rate of the intervention group [413]. According to the findings of a randomised trial conducted in 13 nursing homes in Japan, prompted voiding that is augmented with ultrasound technology to identify residents' individual urine volumes, is more effective than prompted voiding alone [414]. The ultrasound-assisted prompted voiding intervention was characterised by caregivers regularly evaluating each resident's bladder urine volume using an ultrasound device and prompting them to void when the volume reached close to the individually optimized bladder capacity. The researchers reported statistically significant reduction in the volume of daytime UI in the intervention group (median, −80.0 g) compared to the usual care group (median, −9.0 g; P =.018) and a reduction in the proportion of elderly individuals with daytime urine loss compared to residents who received prompted voiding alone. Resident's quality-of-life scores and caregivers care burden scale scores did not differ between groups. However, the care burden scale score of caregivers was significantly worse in the usual care group (P =.010) after the intervention.

The other study, conducted in residential care facilities in Sweden, focused on a person-centred approach to incontinence care for older adults with cognitive decline [348]. The study involved 79 residents from 3 facilities and 20 health care workers (including nurses and nurse aides). The ten-month intervention consisted of five education sessions for the health care workers about a person-centred approach to continence care and to take the lead in coaching and supporting their colleagues in implementing the intervention. The training comprised how to approach and interview residents using a person-centred approach, how to transform significant elements of residents' narratives into a tailored care plan and evaluate the effect of individualised actions. They additionally received training in incontinence assessment, planning, caring actions, and outcome follow up. A usual care control group facility was matched by resident case-mix and geographic region. Introduction of a person-centred approach showed an increase in residents' quality of life in the intervention group compared to baseline and the control group. A positive effect was found on the number of UI assessments conducted ($p < 0.05$). In addition, the number of person-centred caring actions (e.g., toilet assistance) was significantly higher during and 6 months after implementation.

4.6. Education

Improvements in knowledge about UI among healthcare professionals among are possible. Szonyi and Millard [415] reported a significant improvement in GPs knowledge about incontinence following receipt of an education package. Likewise, Mathis *et al* [416] and Ehlman *et al.* [417] demonstrated improvements in knowledge among nursing home staff following an educational intervention as did Kholer *et al*., [65] and Wijk *et al.*, [348] in more recent research. A subsequent systematic review of 19 studies that included the studies by Mathis *et al.* [416] Ehlman *et al.*, [417] and Kholer *et al.*, [65] found educational interventions about UI improved nurses' and nursing assistants' knowledge, but the effects on practice and patient outcomes were mixed. Uncontrolled trials reported improvements in nursing home residents' and community-dwelling patients' continence status, but this effect was not observed in a large, controlled trial. Similarly, two studies set in inpatient rehabilitation found no significant differences in patient continence outcomes following an educational intervention targeted to nurses [418]. Martin-Losada *et al.* (2019) reported on an organisational intervention that included education for hospital staff about the management of UI in hospitalised older patients in Spain. The Joanna Briggs Institute's Practical Application of Clinical Evidence System and Getting Research into Practice audit tools were used to promote staff compliance with best practice recommendations related to assessment of UI, type of UI, documented plans, appropriate management, changing of continence products, staff education, and discharge assessment. Local champions delivered 10 short educational sessions about the definitions and types of UI prevalence, associated problems, evaluation and treatment, and areas for improvement. In a 6-month follow-up, the researchers reported rates of adherence of 82-100% [419]. There is a need to better understand strategies that successfully facilitate knowledge implementation about evidence-based approaches to UI in organisational settings such as hospital. A multidisciplinary team of nurses and physiotherapists or occupational therapists were appointed to facilitate the implementation of an evidence-based protocol for UI in patients aged 65 or older undergoing hip surgery in two hospitals in Sweden. The teams were supported by external facilitators who shared knowledge about UI and implementation science. The intervention raised the internal facilitators' awareness of UI risks associated with hip surgery, which in turn increased staff awareness. More time and managerial support were required to implement evidence-based UI care [383, 420]. Blachman *et al.* (2017) reported that a programme that addressed UI management for older adults enhanced learners' communication, collaboration, and comprehensive primary care to vulnerable older adults [421]. A similar interdisciplinary programme was described by Jonsson *et al.*, (2018) who reported participants' satisfaction [422]. Wilkinson *et al.* (2017) described a novel podcast as a means of educating multi-disciplinary teams about ageing. With over 7,000 downloads for the first 10 episodes, the researchers claimed the rapid accumulation of a large audience (including non-geriatric specialists) demonstrates that podcasts are an effective way to deliver geriatric education across disciplinary and locational boundaries [423]. DuFour & Northwood (2017) used a Delphi technique to gain consensus among an expert group of 12 panellist on the connection between falls and UI into action and to develop a preliminary set of consensus-based practice principles related to falls prevention and UI for relevant stakeholders in community-based primary health care. There is a need for better reporting of educational interventions about UI. [424] . This would allow comparisons between programmes and to address the key question of what works best in terms of the educational duration, delivery mode, content, expected learning outcomes, assessment methods, and extent to which the teaching methods accommodate different cultural, literacy, and contextual learning needs. The review revealed existing content emphasis is on a biomedical construction of UI that has cure as the underlying aim, rather than care or on strategies to help people adjust to changes in bodily function that affect their identity, autonomy, control, and independence. As such, researchers should evaluate measures of care as well as cure.

4.7. Facilitation

Since the last ICI, a large randomised controlled trial was published which evaluated the effects of different methods of facilitation to promote the uptake of evidence-based recommendations for UI management in nursing homes. The trial was conducted in four European countries across 24 long-term nursing care sites for people aged 60 years or more with documented UI. The primary outcome was the documented percentage compliance with the continence recommendations, from reviews of 2,313 records assessed at baseline, then at 6, 12, 18, and 24 months after the intervention. The quantitative analysis revealed no statistically significant differences in compliance with continence recommendations between the groups and hence, it was not possible to identify whether different

types and "doses" of facilitation were influential within very diverse contextual conditions.no significant differences in the primary outcome (documented compliance with continence recommendations) between study arms and all study arms improved over time [425].

The research team also conducted a realist process evaluation to answer the question of what worked (and did not work), for whom, how, why and in what circumstances during the process of implementing the facilitation interventions in practice. The researchers reported 'the success of intervention implementation was largely dependent on whether sites prioritised their involvement in both the study and the facilitation programme'. The personal characteristics and abilities of Internal facilitator, including personal and formal authority combined the managerial support facilitated the potential for learning over time [426].

4.8. Advanced Practice Nursing Care

One study was identified that examined the effects of employing advanced practice nurses to drive organisational changes in the management of UI in nursing homes [427]. Residents received tailored, conservative continence treatment from a Nurse Continence Specialist for 12 weeks. Interventions included pelvic floor muscle exercises and bladder retraining with a focus on deferment strategies, on fluid intake, on optimising bowel function and increased physical activity, and life-style changes. Prompted voiding, techniques to improve bladder emptying, prescription of anticholinergics and oestrogen cream were also recommended to some residents. Mean urine loss fell significantly by 60 ml per day (P = 0.024) and there was a significant reduction in pad changes per week by a mean of 4.3 (P = <0.0005). Scores on the ICIQ-SF improved statistically by 2.84 (P = <0.0005) but there was no significant improvement in any other quality of life or activities scales. The number of pads used per week reduced by a mean of 4.3 with a significant reduction of pad costs per week (mean NZ$2.43/16%). There was no significant different in carers' cost or additional laundry costs. The total cost of providing the intervention for 12 weeks (NZ$247.75 minus cost-savings NZ$12.48), was NZ$235.27 per participant.

5. INSTRUMENTS TO EVALUATE THE QUALITY OF CONTINENCE CARE FOR FRAIL OLDER ADULTS IN ORGANISATIONAL SETTINGS

Although there are several instruments that measure the incidence and prevalence of UI and quality of life, to the best of our knowledge, few instruments specifically address the quality of continence care in organisational settings. We identified two new instruments:

- Instrument for Structural Assessment of Wards for the Preservation of Urinary Continence in Older Adults which consists of 27 items, distributed in three dimensions: "physical structure", "human resources", and "material resources". It requires clinical validation [428]
- The ICIQ-Cog - a 12-item scale measuring disease-specific bother (ICIQ-Cog-P) and a four-item scale assessing efforts associated with care of people with incontinence and cognitive [429].

Three other instruments are in development. They include:

- The ICF-Incontinence Assessment Form [430, 431]
- The Dignity in Continence Care Scales (self-report version)
- The Dignity in Continence Care Scales (staff version) [432]

Although there are several instruments that measure the incidence and prevalence of UI and quality of life, to the best of our knowledge, few instruments specifically address the quality of continence care in organisational settings. We identified two new instruments:

- Instrument for Structural Assessment of Wards for the Preservation of Urinary Continence in Older Adults which consists of 27 items, distributed in three dimensions: "physical structure", "human resources", and "material resources". It requires clinical validation [428]
- The ICIQ-Cog - a 12-item scale measuring disease-specific bother (ICIQ-Cog-P) and a four-item scale assessing efforts associated with care of people with incontinence and cognitive impairment [429]

Three other instruments are in development. They include:

- The ICF-Incontinence Assessment Form [430, 431, 433]
- The Dignity in Continence Care Scales (self-report version) [432]
- The Dignity in Continence Care Scales (staff version) [432]

IV. ASSESSMENT OF THE FRAIL OLDER ADULT WITH URINARY INCONTINENCE

Recommendations for the basic assessment of frail older adults with UI are summarised in the algorithm (see Summary Document). Because UI in the frail older adult is almost always multifactorial, a comprehensive assessment should be conducted wherever possible. Collaboration between primary care physicians, geriatricians, surgical specialists, nurses, other health professionals and caregivers, both formal and informal, may be necessary for optimal assessment and management.

The number of guidelines in the area of urinary incontinence has proliferated since the 6th Consultation, the majority of these are consistent in their approach. For example, the European Association of Urology has developed its published guidelines on UI which bear relevance for frail older men and women. These remain largely based on the findings of the 5th ICI but now include consideration of anticholinergic load when prescribing for older people. Other than this guideline, the impact of associated comorbidity is seldom considered; there remains a need for consideration of this area in both robust and frail multimorbid older adults

1. IDENTIFICATION OF FRAIL OLDER ADULTS.

Health care providers can case find in older patients with UI for frailty using the Vulnerable Elders Survey, which can be administered in person or by phone [434]. Persons with a score of 3 or greater have four-fold increase in the risk of death and functional decline compared with persons with lower scores. A patient self-reported scale in which those people classified as either frail or pre-frail had higher frequency of hospitalisation, a higher probability of co-morbidity and higher mortality than those classified as non-frail has also been reported [435]. There has also been increasing interest in the detection of frailty in patients undergoing surgery (see later), as its presence predicts poorer outcomes from hospitalisation and surgery. The use of the Clinical Frailty Scale has increased since the last ICI. It has proven utility in the prediction of outcomes following surgical treatment in terms of complications and needs for addition-

al care. It has a close relationship to the Frailty Index, initially derived from the 78 items of the Comprehensive Geriatric Assessment [436]. However, caution still needs to be exercised when classifying an older individual as frail as there is considerable heterogeneity within this group [437]. There may also be a clear distinction between cognitive and physical frailty.

2. PRIMARY CARE ASSESSMENT

Physician education using a modified version of the ACOVE model to reach a large group of primary care physicians resulted in between 80% and 92% of them planning to make a change in their practice behaviour [438], although no formal assessment of carry through was undertaken. Geriatricians' and primary care physicians' (PCPs) UI assessments were compared in a randomised multicentre study involving 364 subjects, 42% of whom self-reported UI to the investigators. Geriatricians were significantly more likely to detect UI (59% of cases vs. 16%), regardless of the severity of UI, and were more likely to refer to Continence Programmes (25%); all referrals by PCPs were to urologists [439]. An assessment strategy based on clinical evaluation, simple cystometry, and several criteria for referral was compared with urodynamic diagnosis. Approximately 25% of patients met criteria for referral, half of patients accepted urodynamic evaluation, yet urodynamics changed the treatment plan in only 12% of the patients who did not meet the a priori criteria for referral [440].

Practice patterns and adherence to US UI guidelines were evaluated by retrospective chart review of 300 consecutive patients aged >65y, seen by either an internist or geriatrician for UI at a tertiary care centre. Geriatricians ordered more testing, such as urodynamics, before referring patients to a surgical specialist [441]. Over-all, primary care practitioners rarely follow the US Agency for Healthcare Research and Quality UI guidelines, [442] and nursing home practitioners rarely follow the Federal guidance for UI care regarding recommended physical examination, PVR testing, urinalysis, and identification of potentially reversible causes [443]. Okamura and colleagues investigated the diagnosis and treatment of lower urinary tract symptoms (LUTS) by general practitioners (GPs) according to the "Practical manual for LUTS evaluation and treatment in the elderly for GPs (Japanese)" and found adherence to the manual, reinforced by educational and promotional activities resulted better treatment outcomes [444, 445]. A randomised trial of an electronic screening tool was useful in improving conversations about urinary incontinence in older women (not frail) [446].

A systematic review of articles identified only 5 studies meeting eligibility criteria, and all were in women. None of studies found sufficient diagnostic evidence (for different types of UI. The best was a general population study reporting the utility of history and examination for the diagnosis of SUI (positive and negative likelihood ratios 3.23 and 0.40, respectively) [447]. Adding a nurse practitioner to general practitioner care for adult patients with UI can reduce the impact of UI and has been proposed as a cost-effective model using the Netherlands as an example [448, 449].

3. COUGH STRESS TEST

We have found no additional evidence on the utility of the cough stress test since the 4th consultation. Utility of the cough stress test was studied in 97 incontinent female long-term care residents using blinded comparison with single channel cystometry. Of the 77% in whom single channel cystometry diagnosis was congruent with the stress test (i.e., urodynamic DO with negative cough test, no DO and positive cough test), all were correctly classified. No woman with SUI was missed nor were any with DO misclassified [450]. An analysis of 200 older women with UI found that provocative full-bladder cough test was as effective as radiographic or urodynamic pressure measurement in detecting SUI. Clinical diagnosis incorporating the cough test with leakage symptoms was 78% accurate, with only 6% false negatives for SUI, but was only 44% accurate with 45% false negatives for urgency UI [451].

4. POSTVOID RESIDUAL MEASUREMENT

We identified no new studies evaluating the impact of PVR measurement on clinical diagnosis and treatment outcomes. Readers are referred to previous consultations regarding the associated frailty state of older adults with raised PVR. Largely, the committee concurs with recommendations from the Urodynamic committee of the 7th ICI.

- PVR measurement is recommended in the evaluation of UUI in frail older adults with symptomatic voiding difficulty or a history of urinary retention. Assessment of prostate size and assessment of prolapse as well as of current use of all medications should be taken into account while considering PVR.
- PVR measurement is recommended before initiation of antimuscarinics in the frail older adult patient with UUI
- PVR measurement is recommended in the frail older adult patient with urgency UI prior to invasive therapy.

5. URODYNAMIC TESTING

Urodynamic testing is feasible and safe, even in frail nursing home residents [44]. There is no evidence, however, that urodynamic diagnosis changes the outcome of treatment. Expert guidelines, including those from this consultation, recommend urodynamic testing before surgical or minimally invasive UI treatment in women, but there remains debate about the utility of this approach in men.

Summary of evidence

- Active case finding and screening for UI in older adults because many do not spontaneously report their symptoms. **(LoE 1)**.
- Screening for frailty is possible with short screening instruments **(LoE 1)**.
- Current quality of primary care assessment of UI in frail older adults is poor **(LoE 2)**.
- Cough stress test has moderate accuracy in frail institutionalised women **(LoE 2)**.
- No recommendation is possible on the utility of PVR testing **(LoE 4)**.
- Urodynamic testing is feasible in frail older people **(LoE 1)**, but it is unlikely to change management or outcomes except, perhaps, in those considered for surgical treatment of UI **(LoE 4)**.

Recommendations for evaluation

The essential first step is to actively case find in the frail older adults, as both UI and FI are generally under-reported.

The second is to identify treatable, potentially reversible conditions and other factors (medications, environment) that can cause or contribute to incontinence. It is important to evaluate for such contributing factors because their amelioration may improve UI directly, make UI more amenable to other interventions, and overall improve the patient's (and caregiver's) quality of life [452]

The common, treatable, potentially reversible conditions that can contribute to UI in frail older people can be defined by the mnemonic DIPPERS ((Delirium, Infection [urinary tract), Pharmaceuticals, Psychological, Excess fluid (in/out), Restricted mobility, and Stool impaction [and constipation]). This is a useful aid to teach and remember these conditions [453]. Cognisance must be made of the potential to overtreat asymptomatic bacteriuria as apparent infection because of the risk of adverse outcome [454].

V. FACTORS IN MANAGEMENT OF THE FRAIL OLDER PERSON WITH URINARY INCONTINENCE

1. BACKGROUND

This section highlights some of the important issues that distinguish the management of incontinence in frail older adults from that in healthier older adults. Among these critical issues is an understanding of the roles of competing comorbidity, establishing the importance of patient-centred goals, incorporation of knowledge of remaining life expectancy, and the costs and benefits of care, both for the patient and for the caregiver. These factors contextualize continence care and should be incorporated into the management of all incontinent frail older adults, regardless of the choice of specific treatment.

2. ROLE OF COMORBIDITY IN MANAGEMENT DECISIONS

Many frail older adults have coexisting comorbidities, which can influence both the clinical presentation and assessment of UI, as well as responsiveness to interventions. Some examples of comorbidities that can affect the function of the urinary tract include diabetes mellitus, degenerative joint disease (resulting in lower limb weakness and dependency on walking aids), chronic obstructive pulmonary disease, congestive heart failure, lower extremity venous insufficiency, obstructive sleep apnoea, severe constipation and faecal impaction, and neurological and psychiatric conditions such as stroke, Parkinson's disease, dementia, and depression [455]. In part due to the presence of these comorbidities, frail older adults can also be at increased risk for poor treatment-related outcomes, such as fulminant *Clostridium difficile* colitis from antibiotics used to treat otherwise asymptomatic bacteriuria or constipation, dry mouth or even potential cognitive impairment resulting from anticholinergic medications used to treat overactive bladder. Reflexively, sometimes treatment of UI may result in improvement of comorbid conditions [452]. For example, topical oestrogen treatment for urogenital atrophy/genitourinary syndrome of menopause may also reduce risk of recurrent UTI), and a nursing home exercise programme for toileting can also improve physical function [409]. Treatment of comorbidities can also improve UI, as is the case with management of chronic cough from obstructive pulmonary disease, which may benefit stress urinary incontinence.

3. DEFINING OUTCOMES FROM TREATMENT

Outcome measures used in frail older adults must be fundamentally different from those used in healthy older persons. This is because of the heterogeneity of this frail population regarding comorbidity, remaining life expectancy (RLE), patient perceptions, personal values, and the involvement of caretakers and proxy decision makers. Unfortunately, intervention studies in frail older populations remain focused on objective disease related variables, and seldom consider these important factors. Subjective outcome goals and measures may be preferable study outcomes in this patient group. A review of care home residents' views on continence revealed that these individuals valued having independent bowel and bladder function, and that the effects of continence on QoL, self-esteem, and sense of value and autonomy were paramount [456].

Although quality of life (QoL) is a key concern for UI in all persons (see Committee 4, Initial Assessment), and has special relevance in frail older adults with limited RLE, there are few validated QoL outcome measures applicable to this population. Only one validated UI-related QoL measure is derived specifically from patient-based data among persons older than 65, and these subjects were community-dwelling and relatively healthy [457]. Only one ICI-endorsed UI-related QoL measures have been validated in the oldest-old or cognitively and/or functionally impaired persons, currently only available in German [429]. Traditional UI QoL domain—e.g., impact on IADLs, travel, sexual relations—are often not relevant to frail older adults, and there could be significant effects for social and functional domains. One alternative QoL domain for frail older adults is social interaction, especially for nursing home residents; [458] an analysis of cross sectional and longitudinal data from over 100,000 US nursing home residents found that prevalent and especially incident UI had a negative impact on social interactions, particularly among persons with moderate ADL impairment [458]. An analysis of older Medicare beneficiaries over 65 years of age, and including those over 85, found significant impairment of QoL, in accordance with that found in younger people [459].

The profound question when considering UI out- comes in frail older adults is, "Is complete cure possible?" In short, this depends on patient factors, specific treatment(s), and the target outcome. While no geriatrician endorses "ageism" or therapeutic nihilism, research evidence suggests that complete dryness is unlikely for certain frail older adults, particularly frail institutionalised adults with severe cognitive and functional impairment. Even "intractable" UI is amenable to interventions that may improve the individual's urinary and bowel function and QoL. The continence paradigm for frail older adults (Figure 3), which subsequently generalised for all persons with UI [460] remains valid. In this paradigm, people with "dependent continence" are dry due to ongoing assistance, behavioural treatment, and/or medications. UI would return if the interventions ceased, a situation analogous to chronic disease models [461] such as "controlled hypertension" or "controlled diabetes." Persons with "independent continence" are cured without the need for ongoing

treatment (e.g., dry after successful anti-incontinence surgery). For individuals who are unable to achieve independent or dependent continence, “contained incontinence” should be possible by use of appropriate products such pads, catheters, and appliances (See Chapter 19, Management Using Continence Products), thus providing “social continence” [462]. The balance between the degrees of continence achieved may vary as UI severity changes over time, and these states are dependent upon patient and caregiver preferences. outcomes encompass a common need: to be both realistic and hopeful about UI in frail older adults while avoiding nihilism and neglect; maintaining comfort and dignity and preventing avoidable complications of UI. The other consideration is that any comorbidities associated with frailty, e.g., dementia and Parkinsonism, are progressive conditions so that treatment goals may need to be re-evaluated as time progresses.

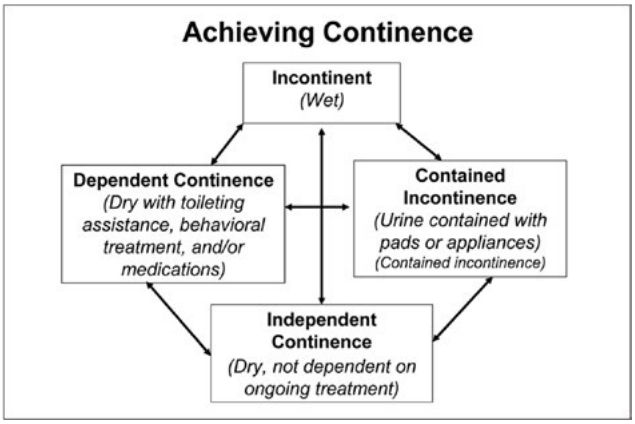

Figure 3. A paradigm for continence

4. ROLE OF REMAINING LIFE EXPECTANCY IN TREATMENT DECISIONS

Remaining life expectancy (RLE) is a key yet often misunderstood concept in treatment decisions for frail older people. RLE is not uniformly short in this population; moreover, there is a demographic trend of increasing RLE, with a smaller proportion of persons spending their remaining years living with disability [463]. Evidence shows that many health care professionals will underestimate life expectancy [464]. Reference to actuarial tables produced for insurance purposes is often enlightening. Comprehensive Geriatric Assessment can help estimate remaining life expectancy and can help predict treatment-related morbidity and mortality in older men with prostate cancer [465].

Walter and Covinsky [466] developed a graphical tool for estimating quintiles of RLE by age. Medical conditions most closely associated with shorter RLE are class III/IV congestive heart failure, end-stage renal disease, and oxygen-dependent chronic obstructive pulmonary disease. Estimates of RLE are significantly affected by frailty and cognitive impairment [467]. Functional status has a dramatic impact on life expectancy. For example, 75-year-old men and women without limitations have life expectancies 5 years longer than those with ADL limitation and more than 1 year longer than those limited in mobility [468]. Alzheimer’s dementia decreases RLE profoundly (by nearly 75%) among older persons who otherwise would be in the top quintile of RLE [469]. Compared to older adults with at most one IADL deficit, those with more deficits have significantly higher 5-year mortality (with two deficit, adjusted RR 1.46 [95% CI 1.20 – 1.78] ; with three or more deficits, adjusted RR 1.64 [1.26 – 2.14]) [466].

5. PREFERENCES FOR CARE

As multiple treatment options are available for frail older adults with UI, and individualised care should be emphasised, obtaining the preferences and goals of frail older adults and their caregivers is essential for quality care planning. This includes those persons living with cognitive impairment. It should not be assumed that persons with cognitive impairment are unable to make their care preferences known or participate in treatment decisions and all reasonable efforts to help them to do so should be made. Few studies have examined frail older adults and caregiver’s preferences. Four studies were identified in earlier editions. In a study of 111 nursing home residents with UI; residents preferred an average of 2 pad changes, 1.5 toilet assists, and 2 walking assists more than they received, yet even these levels were lower than guidelines recommendations, suggesting reduced expectations of residents [470]. In a study of family members of incontinent nursing home residents and facility nursing staff, participants were given definitions of and information about UI treatment options (indwelling catheter, prompted voiding, adult diapers, electrical stimulation, and medications). Residential care residents (n=70), who tend to be more independent and cognitively intact than nursing home residents, were proxy respondents and a small number of cognitively intact nursing home residents (n=9) were also included. [471]. Respondents rated preferences between pairs of treatment options Residents and family members were evenly divided between “definitely” and “probably” preferring prompted voiding versus diapers. Almost 80% of nursing staff, however, preferred prompted voiding to diapers. Families perceived staff members as unwilling to perform prompted voiding, and some thought prompted voiding was degrading and bothersome to the resident. A German study with 117 geriatric hospital patients (mean age 85; 43% with UI), 72 staff members, and 71 family members, found that most patients preferred diapers (79%), medications (78%), and scheduled toileting (79%) over urinary catheters, and 64% preferred scheduled toileting [472]. When choosing between diapers and medication, equal proportions preferred each option. Patients with greater functional dependence were more likely to prefer catheters, and those with experience with diapers were more likely to prefer medications and toileting. Spouses showed moderate to almost perfect agreement with patient preferences, but other family proxies had only slight to fair agreement. In a qualitative study of 25 women with pelvic floor dysfunction living in residential facilities, residents expressed a desire to live with their problem rather than undergo assessment and management, emphasizing the need to include the patient in management decisions at the outset [473].New evidence for preferences among frail older persons is scant. Only one retrospective study of women seeking care at a pelvic medicine clinic for pelvic organ prolapse and urinary incontinence was identified [474]. Women who preferred conservative treatment to surgical treatment at first visit tended to be older (mean age 64.5 ± 13.5 vs 59.0 ± 11.7 years), however no data were collected on cognitive or physical function, so whether they represented a frailer group is unknown.

6. COSTS AND BENEFITS OF TREATMENT OF UI IN FRAIL OLDER ADULTS

An overall discussion regarding UI-related costs is covered by Committee 21, Economics of Incontinence. The following discusses UI cost issues specific to frail older adults.

6.1. Estimating Costs

For most developed countries, the greatest increase in population is occurring in the oldest old, those > age 85. This group has the highest prevalence of UI, and accordingly the increased prevalence of lower urinary tract symptoms will result in higher UI care costs. Such an increase was observed between 1992 and 1998 amongst US women aged > 65 [475]. The costs of care for older persons has been estimated at dou-ble that for people under 65, but care for those older adults living in institutions was less than for community dwelling individuals [476]. Likewise, the cost of OAB in five European countries is estimated to rise by one billion Euros between 2000 and 2020 [477] and in the US it has been estimated that by 2030 the greatest increase in demand for UI care (81%) will be in older women aged 60-89 with OAB symptoms [478]. In one US study using of a community managed care population, the presence of OAB and comorbidity doubled the associated costs of UI care [479]. In South Korea, the estimated cost of treating overactive bladder was 117 billion Korean Won (KRW) in 2006 and 145 billion in 2007. The estimated total cost in treating stress urinary incontinence was 122 billion KRW in 2006 and 59 billion in 2007 [480].

Costs can be expressed as direct costs, indirect costs, and intangible costs [479]. Estimates have focused on diagnostic costs, treatment (including routine care and pads), and consequence costs (skin irritation, urinary tract infection, falls, fractures, additional nursing home and hospital admissions, longer hospital length of stay). Direct healthcare costs are most often estimated but there is a lack of meaningful research into indirect costs and those related to comorbidity in the frail older adults. Intangible costs have not been considered in these estimates because of their subjective nature and the methodological difficulty of collection and estimation. Much of the evidence for the cost of UI in older persons has been gathered from either epidemiological surveys or analyses of claims from insurance databases; these have often involved many assumptions or complicated formulae to calculate financial costs. There is a consistent theme that the cost of caring for older adults with UI will increase, but the estimated magnitude of this increase is variable.

For frail older adults, especially those in long term care, cost calculation is especially complex. The greatest costs for UI care in nursing homes are by far nursing labour costs [481]. Extrapolated costs for nursing home admission due to UI was $6 billion (2000 US dollars), with institutional costs of UI management and consequences of $5 billion (2000 U.S. dollars) [482]. In one small 6-month study, the mean daily cost of UI care, including direct nursing care, indirect nursing overhead, and supplies, was $9.09 (+/- $ 0.52) per resident (2003 U.S. dollars) [483]. The costs for UI pads alone in Dutch long-term care have been estimated at 160 million Euros [484]. In an Australian sub- acute care setting, the costs of daily UI care was AU $49, with most spent on staff wages [485]. In Canada, researchers found that 1% increase in UI prevalence was associated with an 11-12% increase in costs [486]. The extra nursing time needed to maintain toileting programmes contributes to high costs [487]. Routine garment and laundry costs may be lower than estimated because, in practice, residents are not changed as often as needed. In addition, for prompted voiding to remain effective, such things as regular refresher education programmes for staff or wet sensors may be necessary, and thus are rarely considered in cost estimates. Moreover, the time over which the costs and benefit are calculated needs to be explicit because both benefit and costs will change, and patient morbidity and mortality need to be considered. The costs of correcting functional and medical causes of UI are rarely considered. Also, the potential differential in costs across the span of cognitive and functional impairment has seldom been assessed, [204] despite evidence that UI care costs are closely related to the degree of functional impairment [205]. Some surveys suggest that the costs of care for younger community dwelling adults outweighs that associated with older persons, but there are wide variations of estimates depending upon the population studies [206].

Costs related to caregivers of frail persons with UI living in the community include lost wages, decreased productivity (both within and outside of the home), the additional number of caretaking hours when a frail person develops UI, [207] and the cumulative effect of increased strain and burden, along with any resultant illness. A qualitative study in Europe of spousal and adult child caregivers of older persons with incontinence identified effects on caregivers' quality of life, financial cost for products as well as mental and physical exhaustion [488]. Overall, there are still limited data on costs of UI treatment in other residential (such as assisted living or rest homes) and acute care settings [208], costs may vary by access to care. Frail older adults are often homebound or live in institutions without the same access to the UI therapies as other populations. Health care providers may be limited to primary care physicians, community nurses, and care assistants or aides with little to no expertise in UI management, and limited access to specialist consultation leading to a focus on behavioural management and/or containment products. An assessment of a multi-component intervention based upon absorbent products, a structured skin care regimen, and nursing advice on incontinence associated dermatitis revealed that incontinent residents used an average of 5.19 absorbent products, at a mean cost of € 1.79 per day. Following introduction of the intervention, the mean number of absorbent products consumed per day was € 2.02 per incontinent patient, at a mean cost of € 0.97 per day [209].

6.2. New studies identified

One US study using Medicare data for older adults in a single state identified that Lewy body dementia had higher costs that other types of dementia (e.g. Alzheimer's disease), which was explained in part by urinary incontinence or infection, as well as other co-occurring conditions including falls, depression, dehydration and delirium [489]. The authors suggest that dementia subtype may predict health care costs with potential mitigation through early identification and treatment. The influence of dementia type and the role urinary incontinence plays in costs needs further study.

Cost relates strongly to reimbursement, which varies considerably from country to country, depending not only on structure of the health system but special programmes for older persons and persons with UI. Within countries, there may be further variation based on insurance, co-insurance, drug versus procedure cover- age and incentives, access to care, programmes for vulnerable populations, and urban/rural differences.

6.3. Benefits and effectiveness of treatment

The ability to define the benefit of UI treatment in frail older people is highly dependent on the individual, their caregivers, and the health care system. Outcomes research indicates that patients value quality of life, which encompasses many domains beside

reduction in UI (See Committee 4, Symptom and Quality of Life Assessment). Even cognitively impaired people can still express treatment preferences [472, 490], so it is also possible to evaluate domains of quality of life (e.g., social interaction) [458] and assess treatment satisfaction directly or behaviourally. At the same time, we found no data on the value or utilities frail older adults, or their caregivers assign to varying degrees of UI (with or without treatment intervention) versus "dryness." Standard outcomes such as quality adjusted life years (QALYs) may overestimate effectiveness in older people, [491] not just because of potentially different utilities, but because of the altered importance of "years of life saved" in a population with variable and limited remaining life expectancy. However, studies continue to report QALYs. Future scenario cost analysis of implementing was used to assess a previously evaluated primary care continence nurse service in the community for older persons with urinary incontinence in the Netherlands. The authors found that while some costs increased (e.g. treatment costs and containment products paid by the insurer), reductions were found in both health care (formal home care) and social perspectives (informal care by family/friends, private home care costs and other out of pocket expenses) across four scenarios projected from 2014 to 2030 [492]. Overall, implementation was argued to have potential for large health gains and cost savings. A smaller study of nurse provided conservative treatment for older women in New Zealand rest homes reported a cost of $247.75 per participant for advisor time and travel cost, but costutility analysis was undertaken as no significant improvement in outcomes was found [427]. Larger well controlled studies of continence advisor services for older frail individuals that include cost-benefit analysis are needed.

Use of technology may shift the focus of assessment, and eventually outcomes of continence programs for older persons. A Canadian health technology study estimated the cost of a 72 hour continence assessment using an electronic monitoring system for residents in long term care facilities at $291.76 (CAD) resident, including the device, materials and development of a care plan [410]. They concluded that an electronic monitoring system had potential to health care system costs through savings in care workers time if the system improved incontinence care but expressed limited confidence in this due to the lack of certainty regarding how the electronic monitoring system would change management of incontinence. The economic benefits of pharmacological treatment of OAB in older persons is unclear, with few published studies found. A retrospective case-control study using medical and pharmacy claims from a US based healthcare network (mean age 73.32 years) found those with wet OAB had a significantly higher adjusted risk of experiencing falls/fractures and depression/anxiety after starting anticholinergic therapy than those without OAB, with total health total health care costs 33% higher for wet OAB [493] In contrast, Qin *et al.*, using a decision analytic cost model using data from a clinical trial of persons over 65 years with urgency urinary incontinence symptoms and a score ≥3 on the Vulnerable Elders Survey 13. They reported a decrease in healthcare cost in treating vulnerable older persons with the antimuscarinic agent fesoterodine compared to no treatment. Health Healthcare resource use included costs of inpatient hospitalization, outpatient visits, and physician office visits. This is one of the few studies that reported inclusion criteria that screened for frailty [494].

There is a continued need for novel and specific clinical and research outcomes related to care of incontinent frail older persons. Outcomes measured by single item tools of perceived benefit or satisfaction with treatment are unlikely to be generalisable across the heterogeneous older population. Perceived benefit of treatment cannot be measured with the same tools across cultures and health systems unless such tools are sensitive to differences in such things as reimbursement and provision of continence services and supplies. The association between expectations, preferences, and outcomes needs to be prospectively studied in relevant and representative populations. New approaches and tools to assess UI-specific quality of life in cognitively-impaired frail older adults are needed, as well as better understanding of the interaction between functional impairment and the impact of UI [458]. When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analysed by age and health status.

Preferences for Care, Costs and Benefits of Treatment of UI in frail older adults

Summary of evidence

- Evidence for preferences for care among frail older adults is scant.
- There is beginning evidence on the potential cost saving of technology monitoring systems in long term care to support assessment of incontinence in frail older residents, but there remains lack of certainty on the effect of continence management. (**LoE 3**)
- Similarly, there is some evidence nurse led continence services for older adults in the community may be cost effective in term of formal and informal care providers, but treatment and containment costs may increase (**LoE 3**).
- The cost-effectiveness of pharmacological treatment of OAB in older persons in terms of health care system costs is uncertain (**LoE 3**).

Recommendations

- Future research on care preferences and cost benefit of treatments needs to acknowledge the heterogeneity within the population of older persons and differentiate between those older individuals who are robust and those that are frail, both in the community and long-term care.
- Future research studies need to include health system outcomes in cost-benefit analysis of using technology to assess incontinence in long term care residents, nurse led continence services in the community and pharmacological treatment of OAB in frail older persons.
- When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analysed by age and health status.

7. ISSUES IN DRUG TREATMENT

7.1. Age related changes in pharmacology

Specific age-related changes in pharmacokinetics, alteration in drug absorption, distribution, metabolism and clearance, and their potential effect on UI drugs, are shown in Table 8. Age-related pharmacokinetic changes are rarely considered in planning the duration of time off previous UI medications, placebo run in periods, and wash-out periods in UI drug trials in older persons. Typically, a two-week washout from other drugs, three weeks for solifenacin and mirabegron, is planned, regardless of age. The numerous factors potentially affecting drug clearance in older, frail patients,

as well as previous and/or cross-over compounds, may confound observed drug effects. Age-related changes in pharmacodynamics have been described for benzodiazepines, beta-adrenergic agents, and opiates [495, 496] but there are few available data concerning change, even in these, other than for limited numbers of community dwelling older people, often with median age of around 65 years old.

7.1.1. Availability of low dose agents

One effect of the underrepresentation (if not exclusion) of frail older persons in UI drug studies is a lack of knowledge regarding minimal effective drug doses for this population. The age-related changes in pharmacology noted above suggest that some UI drugs may be effective at lower than standard doses in frail older adults with concomitant decreased adverse effects [497]. This issue is especially relevant for extended-release preparations, which cannot be divided into smaller doses. There are some data supporting the effective use of low dose oxybutynin in older adults [498, 499] with few adverse events reported. A single study has assessed low standard doses of trospium chloride and solifenacin in combination in older persons (not frail) of average age 69. 4 years in comparison to higher doses showing higher efficacy of combination lower dose therapy [500].

7.2. Polypharmacy

Accompanying the rise in multimorbidity, unsurprisingly, there has been a concomitant rise in the prevalence of polypharmacy in older adults reported across multiple countries [501-503]. The increase may be precipitated by adherence to disease specific clinical treatment guidelines [504-506]. As the number of prescribed medications increases, so does the risk of drug-drug and drug-disease interactions. Approximately 60% of people over age 65 take at least one prescribed medication, and about one-third take more than five prescribed drugs. There is evidence from some jurisdictions which suggests a reduction in potentially inappropriate medication exposure in older adults [506-509].

However, the rates of polypharmacy are highest in the oldest old, those in their ninth decade of life, frail older adults and those older adults living with dementia [510, 511]. There are also data suggesting under prescription of indicated medications in frail older adults suggesting that there remains a careful need to analyse the relative risks and benefits of disease treatment in this group [512].

Many older adults take over the counter (OTC), naturopathic or herbal agents and dietary supplements, with the rate of use varying across countries and cultures. In a Japanese cross-sectional study 32.5% of 729 patients aged ≥65 years with chronic diseases used such substances, Vitamins were the most commonly used dietary supplements. Female sex, higher education, and good economic status were identified as predictors for use. Concurrent use with more than 5 prescription medications was present in 12.2% of participants and 1:3 people had told their usual physician about their use [513]

In a population representative study of Canadians, females aged ≥71 years had the highest prevalence (67.8%; 95% CI = 64.1-71.5) of vitamin/mineral supplement use. Female gender, older age, higher education level, higher income, living in urban areas, having chronic conditions, having a normal body mass index (BMI), and being non-smoker were independent positive predictors of vitamin/mineral supplement use among adults. In the US, use of dietary supplements is high, with 29% of users regularly taking ≥4 DSs. There is a high concurrent usage with prescription medications. [514] A US study comparing changes in usage of OTC medications and supplements between 2005-2006 and 2010-2011 found increases in use and in 2010-2011, 15.1% of older adult users were at risk for a potential major drug-drug interaction compared with an estimated 8.4% in 2005-2006 [515]. In the Health Ageing and Body Composition Study of 3055 adults aged 70-79, over 1/3 had at least one potential drug-drug and drug-disease interaction [516]. Non-prescription medications (NPM) are also felt to be of low risk. In a Scottish study investigating this, just over half (57%) of the 927 respondents perceived NPM to be associated with low general risk. interestingly, those who judged NPM higher risk were less likely to disclose information during consultations than those with low-risk perception [517]. The likelihood of adverse drug reactions (ADEs) and drug interactions rises exponentially as the number of medications increases. This approach is relevant in geriatric UI, as UI may have been precipitated and/or worsened by medications (see Table 3). Changes to existing drug regimens should be considered in the management of UI in all frail older adults.

7.3. Adverse drug effects (ADE)

ADEs are extremely common in older persons, [518]. Although the prevalence of drug – drug and drug disease interactions in older persons is high, there are limited data on important clinical outcomes, largely due to the varying nature of the reporting of events [519]. In a systematic review of studies that examined drug-related hospital readmission, rates of readmissions due to drugs varied from 3% to 64% (median 21%, interquartile range (IQR) 14-23%) but generally were higher in older adults [520]. In an Australian study, adults aged between 65 and 84 years accounted for nearly half of ADR hospitalisations (45.6%). Over the period of comparison, 2001-2002 to 2012-2013, age-adjusted rates of ADR-related hospitalisations nearly doubled and increased by 5.8% (95% CI: 5.0-6.6%) per annum, with an in-hospital death rate increase of 2.4% (1.6-3.3%).

Table 8. Pharmacokinetic changes in older persons

Parameter	Age-associated Changes	UI Drugs Potentially affected
Absorption	Minimal quantitative change despite ↓ gastric motility, yet little known regarding effect on slow-release agents	Extended-release preparations
	↓ Skin thickness	Transdermal preparations
Distribution	Decrease in lean body mass leads to ↓ Vd / ↓ T½ for hydrophilic drugs and ↑ Vd/↑T½ for lipophilic agents	Lipophilic agents, tricyclic antidepressants
	Decreased protein binding in frail patients with low albumin, leading to higher concentration of free drug	Tolterodine
Hepatic metabolism	↓ Phase I reactions (oxidation/ reduction)	Tricyclic antidepressants
	No change in Phase II reactions (glycosylation)	
	↓ Hepatic blood flow and ↓ hepatic mass, leading to reduced clearance for agents with first-pass metabolism	Oxybutynin Tolterodine Solifenacin Darifenacin
	Stereoselective selectivity in metabolism (hypothetical)	Enantiomers
	Cytochrome P450	Oxybutynin Tolterodine Solifenacin Darifenacin Mirabegron 5HMT, (clearance only)
Clearance	Decrease in renal clearance	Tolterodine Fesoterodine (5-HMT)

Of particular interest are ADE related to antimuscarinic therapy because of age, and comorbidity-related changes in muscarinic receptor number and distribution, blood-brain barrier transport, and drug metabolism [521]. Whereas antimuscarinic ADEs in younger persons are bothersome, in frail older adults, they can result in serious morbidity such as sedation, heat intolerance, prolongation of delirium and use in some retrospective analyses is associated with an increased risk of dementia diagnosis [522].

Since the last consultation, a systematic review has examined the risk for AEs between older and non-older adults with OAB. Of the six included studies that made nine comparisons between older and non-older subjects, the AEs of dry mouth (46.7%), constipation (10.3%), and headache (7.7%) were most frequently reported. Older subjects were more likely to experience dry mouth (relative risk [RR] 1.09; 95% confidence interval [CI] 1.00-1.19), constipation (RR 1.92; 95% CI 1.52-2.43), dizziness (RR 2.37; 95% CI 1.21-4.62), and urinary retention (RR 4.17; 95% CI 1.76-9.89) than were non-older subjects. Treatment discontinuations due to AEs were more likely to occur in the older subjects (RR 1.59; 95% CI 1.20-2.11). In a separate review examining AEs and treatment discontinuations in adults 65 or older taking antimuscarinics for OAB, anticholinergic AEs were more common compared to placebo. Incidence of dizziness, dyspepsia, and urinary retention with fesoterodine, headache with darifenacin, and urinary tract infections with solifenacin were significantly higher compared to placebo. Treatment discontinuation due to AEs and dry mouth were higher in the antimuscarinics when compared to placebo in older adult [523]. No frail older adult data were available.

The evidence relating to individual AE are available in the 6th Consultation and are not repeated here. Readers are referred to the previous chapter.

7.3.1. Anticholinergic medication and cognitive impairment

A major antimuscarinic ADE of concern in frail adults is cognitive decline. There has, since the last consultation been several associative reports linking anticholinergic medication to cognitive impairment, an increase in incident dementia diagnosis and a possible increase in mortality [48, 522, 524, 525].

Medications with anticholinergic properties are commonly used by older adults and older adults living with dementia. For example, in a US retrospective, cross-sectional study of adults aged 65 years and older using 2012 American Geriatrics Society Beers Criteria, 9.56% (7.51 million) older adults used potentially inappropriate anticholinergic medications in 2009-2010; those aged 75-84 or ≥ 85 years did, however, have a decreased likelihood of receiving them [526]. Of 964 older persons attending an Australian memory clinic, potentially inappropriate medications affecting cognition were used by 206 (21.4%) patients. Anticholinergics and sedatives were the most common. One hundred and thirteen (11.7%) patients had a clinically significant anticholinergic burden score (≥3) [527]. As much as there is a reported increase in overall medication prescribing for older persons, temporal trends also reveal an increase in anticholinergic medication prescribing for older adults [528]. Due to the nature of the cohorts of persons studied, data on medications used for overactive bladder and urgency incontinence are limited to identifying immediate release oxybutynin as a consistent significant factor in exposure. In the study of Gray [49], over 10 years, those with the highest cumulative burden of oxybutynin exposure had a significant association with cognitive impairment. In a systematic literature review and meta-analysis aimed to assess the impact of ≥3 months of exposure to anticholinergics on the risk of dementia, mild cognitive impairment, and change in cognitive function, 21 studies underwent qualitative synthesis and 6 reported endpoints relevant for inclusion. The overall rate ratio for incident dementia was 1.46 (95% CI: 1.17-1.81; 95% PI: 0.70-3.04; n = 6). The risk of incident dementia increased with increasing exposure (n = 3). In addition, two studies from the meta-analysis reported an increased risk of dementia with ≥3 months of use of bladder antimuscarinics (adjusted odds ratios ranged from 1.21 to 1.65, depending on exposure category). This relationship was consistent in studies assessing overactive bladder medication [529]. In a retrospective cohort study of 71 688 Medicare claims, there appeared to be no difference in the strength of association between “bladder selective” and non-selective agents according to level of exposure, Odds ratios for non-selective use

were 0.97 (CI: 0.89-1.04) for the lowest quartile of exposure, 0.94 (CI: 0.83-1.06) for the 2nd quartile, 1.00 (CI: 0.87-1.16) for the third and 1.03 (CI: 0.88-1.20) for the highest. [530].

Cognitive effects may be under-detected because they are clinically subtle, neither asked about nor reported by the patient, or mistaken for age-related diseases and ageing [531, 532]. A 2014 systematic review of the effect of medications with anti-cholinergic properties on cognitive function, delirium, physical function and mortality examined 46 studies including 60,944 participants; 77% of included studies evaluating cognitive function (n = 33) reported a significant decline in cognitive ability with increasing anticholinergic load. Four of five included studies reported no association with delirium and increasing anticholinergic drug load (P > 0.05). Five of the eight included studies reported a decline in physical function in users of anticholinergics (P < 0.05) [533]. A recent study investigating the association between anticholinergic medication use and neuroimaging biomarkers of brain metabolism and atrophy in 52 cognitively normal adults, mean [SD] age, 73.3 [6.6] years in the Alzheimer's Disease Neuroimaging Initiative and the Indiana Memory and Ageing Study found showed lower mean scores on Weschler Memory Scale-Revised Logical Memory Immediate Recall, Trail Making Test Part B and a lower executive function composite score in participants taking anticholinergic medications compared to those participants not taking such medications. Reduced total cortical volume, temporal lobe cortical thickness and greater lateral ventricle and inferior lateral ventricle volumes were also seen in the participants taking anticholinergic medications compared to those not taking such medications [534]. It is clear that duration of exposure and extent of exposure to medications with anticholinergic properties are significant factors in the observed associations with cognition. Many scales exist which purport to measure anticholinergic burden, each varies in its utility in identifying anticholinergic load. The clinical results in studies using these scales are different depending on the scale used and upon the different methods used in their development [535]. Persons with pre-existing cognitive impairment (especially from conditions known to affect central cholinergic pathways) may be at greater risk for cognitive impairment although there are also some data to suggest that those with established dementia may not experience cognitive decline following therapy with anticholinergic agents [50]. Additionally, a meta-analysis examined the relationship between serum anticholinergic activity and decline in cognitive performance, delirium, and functional impairment. The review included 4 RCTs, 5 prospective cohort studies, 3 longitudinal cohort studies, 17 cross-sectional studies, and 4 case-control studies. Twenty-four of the retrieved studies examined an association between SAA and cognitive outcomes, 2 studies examined an association with SAA and functional outcomes and 8 studies examined associations between SAA and both cognitive, and functional outcomes. The meta-analysis on 4 RCTs showed no association with higher SAA and cognitive performance however, the pooled data from 4 observational studies showed elevated SAA was associated with reduced cognitive performance (I2 = 0.00%, H2 = 3.37 and p-value = 0.34) [536]. For older adults living with dementia, use of non-selective antimuscarinics was associated with a 50% increase in mortality risk among older adults with dementia and OAB in a propensity matched retrospective new-user cohort study of 16,955 community dwelling Medicare claimants [537]. A related study found no effect on rate of falls or hospitalisation in older adults with dementia and OAB using nonselective and selective antimuscarinics [538].

7.4. Drug interactions

Because frail older adults take higher numbers of drugs and usually have several comorbid conditions, drug interactions are more common [539]. All antimuscarinic agents for UI will have additive side effects when combined with other anticholinergic agents.

Drug-drug interactions for oxybutynin, solifenacin, darifenacin, and tolterodine include potent CYP3A4 inhibitors (azole antifungals, macrolide antibiotics, cyclosporin, and vinblastine). Fesoterodine, a pro- drug that is converted to tolterodine by non-specific esterases, is also dependent upon CY3A4 for its excretion. There is one case report of interaction between tolterodine and warfarin in 2 older patients, which [540] has not been seen in healthy volunteers. Naturopathic/ herbal preparations should also be considered for potential interactions, especially in areas where these agents are frequently used. Potential drug-drug interactions with mirabegron, a beta-3-agonist for the treatment of overactive bladder have been evaluated in younger healthy subjects, between mirabegron and metformin, warfarin, digoxin, or a combination oral contraceptive. Changes in maximum concentration of metformin and digoxin were observed, but no dose adjustment of either drug is required when mirabegron is administered concomitantly with metformin, or warfarin. The authors suggested that patients receiving mirabegron with digoxin may require additional monitoring of digoxin concentrations with dose adjustments where needed [541].

Evidence regarding the co-prescription of bladder antimuscarinic agents and cholinesterase inhibitors (CEIs) used for dementia are of poor to moderate quality. There is evidence CEIs can cause or worsen UI from a case report [542] and also a case series of 216 consecutive patients with probable Alzheimer's disease attending a memory treatment centre [543], but this finding has not been replicated in a large Dutch dataset analysis [544]. In the case series, CEI treatment was overall associated with 7% risk of new UI: the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Further evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [545]. Residents with dementia, newly treated with cholinesterase inhibitors, were more likely to then be prescribed a bladder antimuscarinic than those residents with dementia not given a cholinesterase inhibitor, an example of a geriatric "prescribing cascade", a finding replicated in a 2016 Finnish study. [546, 547]. In a cross-sectional survey to determine the proportion of nursing home residents with overactive bladder or urinary incontinence with potential contraindications to antimuscarinic treatment because of concomitant anticholinergic medications or acetylcholinesterase inhibitors (AChEIs) 71.3% received at least one anticholinergic medication. CEIs and antimuscarinic treatment were prescribed concurrently in 24% [548]. Concomitant use of antimuscarinics (extended-release oxybutynin and tolterodine) and cholinesterase inhibitors in nursing home residents was associated with a decline in ADL function in the most functionally able residents but there was no worsening of cognition, probably because the cognitive measure (MDS-COG) was inadequately sensitive. More importantly, there was no case of delirium observed [549]. In a study in which the primary objective was to assess the cognitive impact of trospium chloride in older people with dementia treated with galantamine over a six-month period, 46 subjects with UI and dementia were enrolled, 10 withdrew from the study. No effect on cognition or activities of daily living was detected over the duration of the study. A within group analysis demonstrated an improvement in nocturia and reduction in pad use in this combination group [550]. A small study reported some positive effect of the treatment of UI with propiverine in subjects with probable AD taking cholinesterase inhibitors [551]. The practice appears to be common in Finland [552]. Although intuitively illogical, given the opposing pharmacological actions, there seems to be no reason

not to use bladder antimuscarinics for older people with dementia, ensuring that the cholinesterase inhibitor is warranted and effective, that the incontinence is sufficiently bothersome to warrant treatment and that the patient (where possible), and the caregiver are fully informed. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living.

7.5. Potentially inappropriate drugs for older adults

Efforts at quality improvement for older populations have led to the development in several countries of expert consensus guidelines regarding inappropriate drugs for older persons, although the continuing relevance of these guidelines has been questioned and alternative systems suggested. A revised Beers criteria was published in 2019 [553] These guidelines focus on drugs with lower risk-benefit ratios and higher potential for drug-drug and drug-disease interactions, and are used for nursing home regulation and quality performance measurement. All bladder antimuscarinics are included with respect to their anticholinergic properties. The Fit fOr The Aged (FORTA) criteria with respect to drugs for lower urinary tract symptoms systematically review available evidence for the use of medications adults >65y with multimorbidity and assign levels of appropriateness according to the available data. A Delphi process is used to assign drugs into A, Absolutely, B, Beneficial, C, Caution and D, Don't criteria. Of all lower urinary tract drugs, fesoterodine achieved a Beneficial grade. Most drugs were placed into the Caution category, reflecting either deficiencies in, or absence of, available data [554].

8. SPECIAL ISSUES IN FRAIL OLDER MEN

Although their ranks thin into the ninth decade, men still comprise a significant portion of frail older adults. The prevalence of UI increases in men after age 80, going from about one-third of the rate in women to become equivalent. At the same time, frail older men are under-represented in UI treatment trials, whether behavioural, pharmacological, or surgical (see also Committee 10: Surgery for Urinary Incontinence in Men). This under representation is unfortunate, because results from treatment trials in frail women cannot be directly extrapolated to men for several reasons:

8.1. Differences in comorbidity

Frail older women have higher rates of functional impairment, chronic disease and geriatric syndromes [555] which may mean that frail older men may be more likely to respond to behavioural intervention. For older adults who become incontinent, a composite measure of physical performance (rising from a chair, walking, balance) is a better predictor of UI incidence in men than in women [556].

8.2. Differences in caregivers

More older men have living spouses who can provide care, with a potential impact on the risk and type of caregiver burden associated with UI management.

8.3. Prostate cancer

Nearly all men in their ninth decade have histological evidence of prostate cancer. However, it is not clear that frail older men have an increased risk of prostate cancer-specific mortality, especially given that their remaining life expectancy (RLE) is primarily affected by comorbid conditions. The need to screen for and treat prostate cancer diminishes with functional status, comorbidity, and RLE [557]. At the same time, more men are living with the sequelae of prostate cancer treatment, particularly stress UI after radical surgery. In several studies and metanalyses different techniques are discussed with a primary focus on a possible improvement through robotic assisted radical prostatectomy (RARP) [558, 559, 560]. None of these studies analyzed specific risk factors for older or frail older. Physicians tend to underestimate the incidence of urinary incontinence following radical prostatectomy and age seems to increase the magnitude of this underestimate [561].

8.4. Benign prostate disease

The prevalence of histological BPH, BPE, and BOO increase with age, and is associated with LUTS, UI, and DO. In a urodynamic study of older adults, 29% of men had BOO and 59% had DO as the predominant cause of UI, versus 4% BOO and 61% DO in [44]. Bortnik *et al.* give an overview of modern best practice in the management of BPE. They state that often medical therapy for BPH has been thought to be both safe and effective, however, newer studies sow a seed of doubt [562]. Antimuscarinics and alpha-blockers are associated with AE which might outweigh the benefit of treating older men with these drugs [554]. That the major trials studying the efficacy of these medications are limited as they did not focus on older men and were not of sufficient duration to make meaningful conclusions regarding long-term side effects. Surgical treatment for BPH might be an alternative. There has been a push for minimally invasive, office-based procedures which can be performed without general anesthesia. However, AUA recommendations on minimally invasive techniques such as the use of Prostatic UroLift®, RezümTM or Aqua Ablation are based on prostate size and not on comorbidities [563, 564]. A systematic review and meta-analysis comparing endoscopic enucleation vs endoscopic vaporization and laser enucleation procedures vs laser vaporization procedures included 16 studies with 4907 patients. Endoscopic enucleation and laser enucleation procedures were favoured regarding perioperative factors, rate of complications, and functional outcome. The authors stated that the clinical significance of their findings remained unclear and did not evaluate data in relation to risk factors common in frail older men. However, photoselective vaporization and enucleation of prostate might be beneficient for frail older men due to the better control of bleeding [565]. European Association of Urology (EAU) guidelines recommend laser vaporization and enucleation for anticoagulated patients while HoLEP, PVP, and ThuLEP are recommended by the American Urology Association (AUA) Guidelines [566, 567]. Prostatic stenting – either temporary or permanent is not mentioned in the AUA guidelines. The EAU recommends the use of prostatic stents as an alternative to catheterization -although the use of prostatic stents is rare due to the associated rate of complications. New types of prostatic stents are in clinical trials and, if approved, might add to the therapeutic armamentarium, especially for frail older men.

8.5. Risk of urinary retention

Because of age-related decrease in detrusor contractile function and increased likelihood of BPE and BOO, it is often assumed that frail older men have a higher prevalence and risk of urinary retention. However, this has never been demonstrated. Among NH residents with UI, the prevalence of underactive detrusor was similar in women and men (38% and 41%, respectively), despite the higher prevalence of BOO in men [44] [44, 88].Ahmadi *et al* demonstrated in a single centre RCT with 172 patients that condom sheet placement to prevent postoperative urinary retention showed no benefit [568].

8.6. Differences in device usage
A nationally representative survey of adults in the US showed that older men were nearly three times less likely than older women to use pads to contain leakage (15% vs. 45%) [569]. Data from Scandinavia, where some countries provide absorptive pads as part of the health care benefit, showed that this gap might be narrowing (22% vs. 48%), and that increased functional impairment was associated with greater pad usage [570]. In a survey of patients recruited from family practice clinics in the Netherlands, the sex difference for pad usage by older adults with UI was even higher, with 4 out of 5 women using pads versus 1 of 9 men using pads [571]. Men are also more likely to be users of indwelling catheters, both in the long-term care setting [371] [572]. There remain few data and little guidance on use in men.

8.7. Differences in medical treatments
There are medications that might be used by only one sex or might have distinct side effect profiles. For example, alpha-adrenergic antagonists, in particular, should be cautiously considered in men due to their potential side effect of causing orthostatic hypotension. The interactions of UI and other conditions with regards to orthostatic hypotension and risk of falls merits attention. In a German registry of 3,414 patients with Parkinson's disease, for those with urinary incontinence (716; 21%), orthostatic hypotension was reported for 14% of the men, yet only 9% of the women [573]. On the other hand, for women and men who had strokes and urinary incontinence, both were equally more likely to sustain a fall after stroke, though women were more likely to sustain an injury (OR 1.5) than were men [574]. The use of tamsulosin has been associated with an increased risk of cognitive impairment in older men a single study [575] although this finding has not been replicated by others [576].

8.8. Differences in surgical treatments
There are gender-specific devices and surgical approaches that do require active management on the part of the patient. In particular, certain frail older men might not be appropriate for placement of an artificial urinary sphincter due to co-morbidity, medications and cognitive and/or functional impairment. This would not allow for the individual to manage the device on his own (Grade C) [577].

Despite these issues, evaluation and management of UI in most frail older men follows the same roadmap as for women (see Algorithm).

Summary of the evidence

Age-related changes in pharmacokinetics affect antimuscarinic drugs for UI and should be incorporated into treatment planning. **(LoE 1-2)**

Drugs may be effective at lower doses in frailer compared with healthier older adults **(Level 3)**

Polypharmacy increases the chance of adverse reactions to drug therapy. **(LoE 1)**

Adverse drug events are more common in frail older adults. **(LoE 2)**

Drug-drug and drug-disease interactions are common in frail older adults **(LoE 1-3).**

Antimuscarinics for treatment of overactive bladder remain as potentially inappropriate medications for frail older adults according to the Beer's criteria **(LoE 3-4)**

Specific guidance for drugs for LUTS in older people exists, this may, with caveats, guide practice **(LoE 3).**

VI. TREATMENT OF URINARY INCONTINENCE IN FRAIL OLDER ADULTS

1. LIFESTYLE INTERVENTIONS

Lifestyle interventions are recommended in clinical practice guidelines to treat UI [578-583], and in the 6th ICI management recommendations for women, men, and frail older adults. New systematic reviews were published on weight loss interventions in overweight and obese women [584]; non-antimuscarinic treatment for overactive bladder in adults [585]; and nonsurgical interventions for UI in women [586]. Trials reported in these reviews and recent studies on individual lifestyle interventions were predominantly conducted in healthier younger and older adults (See Committee 8, Adult Conservative Management. No new studies on lifestyle interventions in frail older adults were published.

Weight loss has the strongest evidence for improving stress UI and overall UI in obese or overweight women and men (See Committee 8, Adult Conservative Management; [584]. However, weight loss interventions may be inappropriate for or impractical to use in frail older adults. Caution should be exercised in recommending fluid restrictions as inadequate fluid intake and dehydration are common in long-term care residents [587, 588], assisted living memory care residents [589], and newly admitted frail older hospitalized patients [590]. Dehydration may increase the risk of UI and its severity in frail older adults because of its significant association with constipation and delirium, both known risk factors for UI [591, 592]. The 6th ICI found limited evidence that increased hydration for incontinent frail older adults may decrease UI.

1.1. Recommendation
In the absence of trials in frail older adults, no recommendation can be made about any individual lifestyle intervention for prevention or treatment of UI. If modifiable lifestyle factors are established as risk factors for UI, these could be targeted for treatment if assessment warrants this. There remains a need for rigorous studies to evaluate lifestyle interventions in the prevention and management of UI in frail older adults.

2. BEHAVIOURAL INTERVENTIONS

2.1. Voiding programmes
Voiding programmes are used predominantly with frail older adults, some who require active caregiver participation. Voiding programmes can be used for older adults with cognitive and physical impairments who have difficulty learning new behaviours or difficulty actively participating in self-care activities, as well as in frail older adults without these impairments. They include:

- **Prompted voiding (PV)**, involving prompts to toilet with contingent social approval, is designed to increase patient requests for toileting and self-initiated toileting, and decrease the number of UI episodes. It has been used for older adults in long-term care settings and homebound older adults [593, 594].

- **Habit training** requires the identification of the incontinent person's individual toileting pattern, including UI episodes, usually by means of a bladder diary. A toileting schedule is then devised to pre-empt UI episodes; no attempt is made to alter an individual's voiding pattern [595].
- **Timed voiding** involves toileting an individual at fixed intervals, such as every 2-3 hours. This is considered a passive toileting programme; no attempts are made at patient education or reinforcement of behaviours, or to re-establish a voiding pattern. Other terms used to describe timed voiding are scheduled toileting, routine toileting, and fixed toileting [595].
- **Bladder training (or bladder retraining)** involves a progressive voiding schedule in combination with patient education that incorporates teaching of strategies for suppressing urgency and delaying voiding. This intervention is used in motivated individuals who do not have cognitive or physical impairments [596].

2.2. Summary

Prior ICI reviews found limited evidence that supported the short-term effectiveness of PV alone or in combination with functional exercise training to improve mobility and toileting skills. Since the last review, three RCTs on PV in nursing home populations were published [Table 9]. A RCT testing a staff-implemented PV protocol in 52 residents from five Hong Kong nursing homes found statistically significant improvements in wet episodes/day, incontinence rate/day, and total continent toileting/day but not self-initiated toiletings at 6 months, suggesting the effects can be sustained [413]. Overall, there was a 9.1% decrease in the incontinence rate. In 28-day trial of a PV protocol conducted by researchers with staff assistance with 12 nursing home residents in Indonesia, there were statistically significant improvements in Incontinence Severity Index scores [597]. In an 8-week cluster RCT, ultrasound-assisted PV resulted in a statistically significant reduction in daytime urine loss measured by pad weights in 80 residents from 13 Japanese nursing homes compared to a conventional PV [414]. There were no differences in residents' generic quality-of-life scores nor staff's burden scores; however, within group staff burden scores were significantly worse in the conventional PV group. This new trial, along with prior evidence, indicates that ultrasound-assisted PV may be superior to conventional PV.

Earlier studies used research staff to implement PV; however, the new studies indicate that it may be feasible when administered by nursing home staff, although this might be country specific. The 6th ICI identified that treatment response could be predicted by a three-day PV trial prior to actual implementation. Predictors included: appropriate toileting rate greater than 66%, a wet check rate less than 20%, ability to pass a simple cognitive screening procedure of a one-step command, and the ability to transfer without human assistance. This approach was not incorporated in recent PV trials and may have affected UI outcomes. PV studies continue to be limited by sample size, methodological weaknesses, including lack of staff adherence measures, and use of different outcome measures making comparisons across studies difficult.

No new studies were published on habit training, timed voiding, or bladder training since the last review. The 6th ICI found bladder training was effective in the short-term for older women, some of whom may be frail.

2.3. Recommendation

PV with and without exercises to improve mobility and toileting results in modest short-term improvements in daytime wetness rates and UI and is recommended for nursing home residents and home care clients (**LoE 1**). Ultrasound-assisted PV may offer greater benefit for nursing home residents than conventional PV (**LoE 2**). A 3-day PV trial is recommended to predict which frail older adults can benefit from PV (**LoE 1**).

Based on limited evidence, no recommendations can be made about the other voiding programmes. Habit training and timed voiding may be effective in frail older adults (**LoE 4**). Bladder training may be effective in motivated frail older women who are cognitively and physically intact (**LoE 4**).

Future research involving rigorous designs are needed to determine the effects of voiding programmes in frail older adults. Trials on voiding programmes in long-term care settings should include care process measures, staff and resident outcomes, and costs.

2.4. Pelvic Floor Muscle Training (PFMT).

PFMT has been extensively studied in adults and some older people, primarily women and men undergoing prostatectomy; however, it has had limited study in frail older adults.

2.5. Summary

Evidence from prior ICIs indicates that PFMT as a stand-alone therapy is effective for improving UI in healthy adults and non-frail older adults, and that biofeedback-assisted PFMT improved UI in homebound older adults. One quasi-experimental, 2-arm study was published that tested a 12-week programme of PFMT in 38 homebound male and female stroke patients in Turkey. Statistically significant within treatment group changes in ICIQ-SF and quality of life scores, reduced pad test weights, UI episodes, and self-efficacy scores were found [598] [Table 9].

2.6. Recommendation

PFMT should be offered to frail older adults with sufficient cognition and motivation to participate (**LoE 1**). Future research is needed to determine the most effective methods of teaching PFMT, the training regimen, and supervision needed to optimize outcomes in frail older populations.

3. MULTICOMPONENT BEHAVIOURAL INTERVENTIONS

An increasing number of trials investigate a combination of one or more behavioural interventions in the prevention and treatment of UI in long-term care and community-residing populations, predominantly in women and non-frail older women.

3.1. Prevention Trials Using Multicomponent Behavioural Interventions

Summary

Prevention trials for UI have tested interventions that combine PFMT with bladder training, the Knack (preventive pelvic muscle contraction), and/or lifestyle modifications and exercise using a variety of teaching formats (Committee 8: Adult Conservative Management). Prior research and two new RCTs [599, 600]. found that these interventions were effective in preventing UI in community-dwelling non-frail older women. There have been no published trials on prevention of UI in frail older adults.

3.2. Recommendation

Given the lack of evidence, no recommendation on multicomponent behavioural interventions to prevent UI in frail older adults can be

made. Evidence in non-frail older women suggests that multicomponent behavioural interventions that include PFMT may be effective in preventing UI in frail older women (**LoE 4**). Future RCTs are needed that test prevention strategies in continent frail older adults.

3.3. Treatment trials using multicomponent interventions

The 6th ICI found limited evidence on the effectiveness of multicomponent behavioural interventions. Five new studies were located, including one RCT in a community setting with non-frail older women [601], two RCTs with frail older adults, one in a long-term care setting with older men [602], and one in a community setting with frail older women [603] and two uncontrolled studies with older women residing in the community [604] and rest homes [427].

A RCT of an 8-week self-care programme (e.g., lifestyle modifications, PFMT, bladder training, balance and strength exercises) involving weekly group-based sessions and individual visits with research staff conducted in 61 male nursing home residents in Iran [602]. Findings indicate statistically significant improvements in ICIQ-SF scores, change in ICIQ-SF severity category (6.7% to 0% very severe, 93.3% to 10% in severe and 0% to 90% in moderate categories), and improvement in self-esteem scores were found 4 weeks post-intervention. A RCT evaluating a 12-week programme involving PFMT and tailored behavioural interventions provided by a gerontological nurse practitioner, along with weekly walking (150 minutes) and group-based strength exercises in 42 community-residing, cognitively intact, frail older women in the United States [603] found a statistically significant reduction in daily UI episodes (50%), and a higher percentage of participants perceiving improvement (81%). Although toileting skills were improved, these changes were not significant. A two-group pretest-posttest study evaluating the long-term effects of a self-management educational programme involving PFMT, lifestyle modifications, and action plans in 26 older women in rural Korea found statistically significant improvements in ICIQ-SF scores at 12-months but no difference in UI knowledge or attitude scores [604]. An uncontrolled study evaluating a 12-week programme of tailored conservative treatment (e.g., lifestyle changes, physical activity, PFMT, bladder training, and urgency suppression techniques) provided by a continence advisor nurse to 68 older female rest home residents in New Zealand found significant reductions in leakage (mean reduction 60 ml/24 hr and 4 less pads/week) and improvements in overall ICIQ-SF and perceived bother item scores, with the mean cost of $247.74 NZ/participant [427]. There was a small, but minimal clinically significant change in function, and no change in daytime frequency, nocturia, or quality of life scores.

There continues to be a lack of evidence on multicomponent behavioural interventions in the prevention UI in frail older populations. There is increasing evidence, although insufficient, that multicomponent behavioural interventions that include PFMT with and without exercise are effective in frail older adults. Studies are limited by small samples; high risk of bias; varied outcome measures; inconsistent definitions and measurement of frailty; limited racial or ethnic diversity or men in samples; little focus on nighttime UI; limited measurement on caregiver burden and intervention costs; and no long-term follow-up. The increasing number of trials incorporating the ICIQ-SF as a primary outcome measure is a positive development in being able to compare outcomes across studies.

3.4. Recommendation

Multicomponent behavioural interventions that incorporate PFMT with and other behavioural interventions should be offered to frail older populations (**LoE 2**).

Future high-quality RCTs with larger samples of frail older adults residing in long-term care and community settings, with evidence on their effectiveness in reducing UI, improving quality of life, impact on caregiver burden, their costs, and long-term benefit are needed.

4. INTERVENTIONS TO MANAGE NIGHT-TIME INCONTINENCE IN LONG-TERM CARE SETTINGS

Nighttime sleep in long-term care residents is often fragmented and disrupted, with much of this sleep disruption caused by noise, light, and incontinence care routines.

The 6th ICI found some evidence on interventions that enhance the quality and duration of sleep for long-term care residents with UI. Interventions tested include a daytime physical activity programme alone or with a night staff behaviour programme aimed at reducing noise, light, and sleep-disruptive care practices; a 2–4-hour PV schedule based on an individualised assessment of each resident's skin health; an individualised UI care routine combined with feedback to staff about methods to reduce noise levels; and 4-8 hourly pad changing regimen based on an individualised assessment of each resident's skin health. The ICI recommended that nighttime continence care in long-term care settings should be individualised based on an assessment of residents' skin health; their ability to spontaneously move in bed; their sleep/wake status, the frequency, severity, and type of the UI, and residents' preferences. Few trials on behavioural interventions in long-term care populations include nighttime frequency as an outcome. Since the last review, no new studies were located on behavioural interventions to improve nighttime UI in long-term care residents.

4.1. Recommendation

Given the limited evidence available, no recommendation can be made on a particular behavioural intervention for nighttime UI in long-term care residents. Nighttime continence care should be individualised to the residents' needs, UI and health status, functional abilities, and preferences (**LoE 4**).

Further research to guide practice is needed on residents' preferences for nighttime continence care, the frequency of nighttime pad changing regimes, as well as their impact on skin health. Well-designed behavioural trials that include outcomes on nighttime urinary frequencies and U are needed.

5. INTERVENTIONS FOR NURSING STAFF IN LONG-TERM AND ACUTE CARE SETTINGS

The 6th ICI found that nurses across all care settings (home care, acute care, and long-term care) provide urine containment interventions rather than promoting continence, and that assessment processes are inconsistently used. Nursing staff preferences for UI management (toileting) often conflict with those of residents and their families' treatment preferences (medications and absorbent products) in long-term care and acute care settings. A recent secondary analysis from the Dutch annual independent Prevalence Measure of Quality of Care found that the most common approach in care homes was a combination of absorbent products and toileting times on a set basis [605].

The previous ICI noted multiple challenges reported in conducting research in long-term care and other practice settings which include staffing ratios, staff turnover, suboptimal staff attendance at trainings, staff adherence to implementing behavioural interventions, administrative and regulatory issues, and resident/patient turnover. Because of the limited RCTs in practice settings, this current ICI review includes evidence from implementation studies that have been conducted in long-term and acute care settings [606].

6. INTERVENTIONS WITH LONG-TERM CARE STAFF

Frail older residents in long-term care settings rely on nursing staff for toileting assistance and personal care. Prior ICIs have noted barriers to implementing voiding programmes in nursing homes which include poor communication, inadequate staffing, staff workload, turnover, absenteeism, lack of UI education programmes, and the need for staff monitoring. Other barriers include the belief by nursing assistants that UI is a normal part of ageing and that nothing could be done for it or that use of incontinence pads protect and dignify residents [309]. The 6th ICI identified the need for changes at resource and policy levels to address the disincentive inherent to toileting assistance programmes that require significantly more staff time than the practice of checking and changing residents' pads.

As reduced mobility is a major risk factor for UI, interventions that can increase residents' functional skills or at the very least, minimise their physical decline may be beneficial in preventing and treating UI. A recent scoping review on toileting disability (i.e., the need for assistance to use the bathroom) in older adults residing in long-term care or assisted living facilities found limited evidence on its epidemiology, contributing factors, and validated instruments for measuring toileting disability [346]. Future research is needed to develop toileting disability measures and test multicomponent and multidisciplinary approaches on the prevention and management of toileting disability which then may result in reduced UI rates. Interventions for continence care in frail older adults should also minimize the incidence of incontinence-associated dermatitis (IAD) (See Committee 19: Management Using Continence Products).

6.1. Summary

The 6th ICI noted that education alone does not change staff behaviour and improve UI rates in care settings. Important factors in optimizing uptake of evidence into continence care practices include managerial support; sufficient resources to implement new learning; the learner's belief in the practicality of training; integration of the learning into ongoing practice; staff feeling valued; on-the-job reinforcement of learning; knowing change of practice is supported; seeing benefits of new approaches; and attitudes toward older people. Interventions tested for increasing staff knowledge of UI and improving continence care delivery in subacute and long-term care settings included a clinical leadership model involving staff empowerment and mentorship for implementing practice-based changes for continence care, and a staff training programme involving distance learning and coaching for motivating nursing home staff to adopt a best practice toileting programme.

One new systematic review was published on the effects of education about UI on nurses' and nursing assistants' knowledge, attitudes, continence care practices and patient outcomes [418]. This review noted that positive effects of education found in non-randomised and pretest-posttest studies were not confirmed in RCTs. Education combined with facilitation and/or audits and feedback did not consistently produce statistically significant differences in patient-related outcomes. Study differences were attributed to variable methodological quality; the strength and quality of the educational interventions; limitations of education in achieving behavioural and organisational change; and limitations in outcome measures that focus on UI cure or reduction. This review noted the importance of evaluating measures of care as well as cure in a population where continence restoration is not possible.

Five new studies on staff interventions in semi-acute and long-term care settings were published [Table 10], including three RCTs [65, 348, 426] and two uncontrolled studies [419, 607]. One study employing a stepped-wedged design with four clusters evaluated the effects of a 4-hour educational session and six unit-based care conferences in seven Switzerland nursing homes [65]. Pad test weights decreased in some clusters or was approximately equal at baseline, and residents had significant improvements in 7 out of 9 quality of life subscale scores. A large, pragmatic clustered 3-arm RCT involving 24 long-term care sites in four European countries investigated different facilitator development programmes that varied in the days allocated to facilitator training, months to work on unit-based implementation and evaluation, self-study, and virtual support (e.g., monthly teleconferences and email communications [426]. All arms received written UI recommendations and a slide presentation on implementation strategies. No differences were found among groups in documented compliance with UI screening recommendations, detailed assessments, individualised treatment plans, and specialist referrals. A 2-arm clustered RCT evaluated an education and training programme along with implementation strategies in three Swedish residential care facilities. The education programme consisted of five sessions that focused on implementing a person-centred approach that involved tailoring UI care plans to individual residents. Statistically significant increases in documented UI assessments and number of person-centred care actions (e.g., toilet assistance) and decreased use of incontinence products were found. Residents' quality of life scores also significantly increased [348]. A one group, pretest-posttest design of a 6-month intervention involving education, unit-based continence champions, team huddles and PV in a Canadian inpatient geriatric rehabilitation unit found significant changes in nurses' attitudes, confidence, with an 80% completion of continence assessments [607]. A 6-month implementation study to improve continence care practices using pretest-posttest chart audits in a Spanish medium-to-long stay rehabilitation ward found 100% compliance in staff documentation of UI including UI type, continence products changed as required, and completed UI discharge assessments. However, there was only a slight increase in use of PV [419].

6.2. Recommendation

Staff education alone is insufficient for improving continence care practices in long-term care. Staff education that incorporates implementation strategies may improve continence care processes (**LoE 3**). Based on limited data and mixed findings, no recommendation can be made on the type and format of staff-based interventions and implementation strategies that are most effective. The specific implementation approach may be unique to each setting. Future well-designed controlled studies are needed that evaluate care processes, staff burden, resident outcomes, and costs. Attention should be given to incorporating residents' treatment preferences into care plans.

7. INTERVENTION STUDIES WITH ACUTE CARE STAFF

Summary
Four new uncontrolled studies were published that evaluated staff-based interventions for older hospitalised patients {Table 10). A study using pretest-posttest chart audits evaluating education workshops and teleconferences for older patients undergoing hip surgery in two orthopaedic units in Swedish hospitals found that only one unit increased their UI documentation [383]. A 14-month quality improvement project in an Australian acute care hospital used pretest-posttest chart audits to evaluate an education session on a formalised continence pathway in combination with continence tools in four medical and surgical units. Increased staff compliance on all audit criteria was found with notable improvements in UI assessments, specialist referrals, and patient receipt of tailored interventions [608]. A large 1-year study with pretest-posttest chart audits implemented in the Spanish National Health Service evaluated education, use of internal facilitators, clinical audits, and feedback on continence care processes [609]. Audits in 17 participating medical, surgical, primary care/outpatient care, and nursing home units found statistically significant increases documentation of UI assessments, with a non-significant increase in care plans and patient education. Staff-based intervention and implementation studies were limited by methodological issues including lack of a comparison group, small samples, no fidelity measures, and lack of patient-based UI outcomes.

7.1. Recommendation

Education in combination with implementation strategies may be effective in improving continence care practices in acute care settings (**LoE 3**). Because of limited studies and inconsistent results, no recommendations can be made on the format and type of implementation strategies that are the most effective.

Future well-controlled studies are needed that can assess different types and formats for education as well as implementation strategies on continence care processes, staff and patient outcomes, and costs.

7.2. Interventions with family caregivers

Family caregivers of frail older adults with UI report a high level of physical and psychological exhaustion, burden, embarrassment, and social isolation [610]. This is particularly so for family caregivers of individuals with UI and dementia, especially if the care recipient has responsive behaviours. A review on qualitative studies on continence care of community-dwelling people with dementia in Europe found that the main difficulties and challenges in caregiving were personal perceptions of incontinence, availability/provision of support and care, financial cost, mobility and the environment, relationships and social inclusion, and emotional issue [611]. This and a recent study on the burdens and educational needs of family caregivers of older adults in the United States [612] indicate that family caregivers need information on UI treatment strategies, resources, and guidance to select appropriate supplies.

7.3. Summary

The 6th ICI identified that limited intervention studies have been conducted with family caregivers of frail older adults with UI. Two systematic reviews of dementia caregiver training programmes indicate these programmes primarily focuses on dementia education, management of behavioural and neuropsychological symptoms, and caregiver support, with content on UI rarely included [613] [614]. Since the last ICI, no RCTs or uncontrolled studies on UI caregiver interventions were located. One small study using a single group, pre-post design was published that described the development and preliminary feasibility testing of a 6-week multicomponent behavioural intervention involving education, PV, and social support delivered by tablet computer and weekly telephone calls with a specialist nurse practitioner [594]. This intervention involved six interactive video modules that focused on UI in frail older adults, practical help to promote toileting, PV techniques, fluid management, and skin care and UI costs, along with a 3-day PV diary. Evidence from an evaluation with three family caregivers indicated the intervention was feasible and acceptable. Technology-based interventions have the potential to increase the reach and access of family caregivers to UI education and support interventions.

7.4. Recommendation

Technology-assisted skill-based education, information, and support may be an effective approach as a family caregiver intervention (**LoE 4**).

There is a major gap in the evidence base related to family caregiver interventions for UI which offers an opportunity for future research. Well-designed RCTs are needed that address caregivers' needs for education, skill training, information on resources and UI products, and support. Intervention studies should include caregiver outcomes on burden, quality of life, and satisfaction as well as care recipients' outcomes related to UI.

7.5. What is new?

1. Several small studies on multicomponent behavioural interventions in frail older adults indicate that these may be effective.
2. Increasing use of the ICIQ-SF as a primary outcome measure in behavioural intervention studies with frail older adults enables the comparison of interventions across studies.
3. The inclusion of implementation studies of staff-based interventions that include education and implementation strategies offer a pragmatic approach for improving the quality of continence care in long-term and acute care settings.
4. The development of a feasible technology-based, educational and social support intervention for family caregivers can increase the reach and improve UI care for frail older adults.

Table 9. Behavioural intervention trials in frail older adults

Author, Year	Intervention	Study Design	Sample	Methods	Results
Voiding Programmes					
Lai *et al.*, 2017	PV	2-arm RCT3	52 male and female residents (mean age 85.4 years) from 5 Hong Kong nursing homes	6-month intervention delivered by nursing home staff with prompting q 2-2.5 hours for 12 hours/day; control group received usual care	• Intervention group had statistically significant improvements in wet episodes/day, incontinence rate/day, and total continent toileting/day • No change in self-initiated voiding
Siswoyo *et al.*, 2020	PV	2-arm RCT	12 residents (mean age 72.7 years) from Indonesian nursing homes	28-day intervention delivered by nursing staff with prompting q 2-2.5 hours over 24 hours; control group received usual care	• Intervention group had statistically significant within group improvement of ISI scores
Suzuki *et al.*, 2018	PV	2-arm RCT	80 residents (median age 85 years) from 13 Japanese nursing homes	8-week intervention delivered by nursing staff; Arm A received prompting q 2-3 hours; Arm B received prompting based on ultrasound-assessed residual urine volume at 75% of individual predetermined bladder capacity q 2-3 hours	• Ultrasound-assisted PV group had statistically significant greater reduction of daytime urine loss compared to conventional PV • No within group differences in generic quality-of-life, depression, or activities of daily living scores • No change in care burden scale scores in ultrasound-assisted PV group, whereas conventional PV scores significantly worsened
Pelvic Floor Muscle Training					
Arkan *et al.*, 2019	PFMT	2-arm quasi-experimental	38 community-residing male and female stroke patients (mean age 65.1 years) in Turkey	12-week intervention of PFMT with 4 home visits; control group received no treatment	• ntervention group had statistically significant within group changes in ICIQ-SF and quality of life scores, reduced pad test weights, UI episodes, and self-efficacy scores, whereas the control group had no significant within group changes
Multicomponent Behavioral Interventions					
Arnold *et al.*, 2016	Tailored behavioural treatments and drug management	One group, pre-test, post-test design	68 older women (mean age 85.3 years) in 26 New Zealand rest homes	12-week intervention with visits by a continence nurse advisor q 2-4 weeks; tailored behavioural interventions (e.g., lifestyle interventions, PFMT, bladder training with urgency suppression, or prompted voiding), drug deprescribing or drug therapy with anticholinergics and/or oestrogen cream)	• Intervention led to statistically significant improvements in overall ICIQ-SF and bother scores, reduced leakage and pad use and costs • Modest improvement in function, but not clinically significant • No change in daytime frequency, nocturia, or EQ-5D scores • Costs were $247.75 (NZ) per participant

Author, Year	Intervention	Study Design	Sample	Methods	Results
Voiding Programmes					
Azizi, *et al.*, 2020	Education, PFMT, bladder training, and strength exercise	2-arm RCT	61 male residents (mean age 68.2 years) in two Iranian nursing homes	8-week self-care education programme with weekly group-based education sessions, lifestyle modifications, PFMT, bladder training, and balance and strength exercises, with visits every other day by researchers; control group received no treatment	• Intervention group had statistically significant improved overall ICIQ-SF and ICIQ-SF severity category scores and improved self-esteem scores at 12-week follow-up compared to control group
Brown *et al.*, 2019	Education, PFMT, fibre and fluid modifications, bladder training	2-arm RCT with wait-list control group	121 community-residing older women with urinary or faecal incontinence, or both (mean age 75 years) in United States	4-month intervention involving small group-based education, behavioural interventions (PFMT, bladder training, lifestyle fibre and fluid modifications), personalized goal setting, and action planning delivered by trained facilitators. Control group: no intervention	• Intervention group had statistically significant improvement in ICIQ-SF, perceived percent improvement, quality of life, and self-efficacy scores • No difference in depression or care-seeking
So *et al.*, 2019	Education, PFMT, action plans	Quasi-experimental, two group, pretest, posttest	26 community-residing older women (mean age 72.7 years) in rural South Korea	5-week intervention with weekly 90 minute education sessions delivered by community health practitioner and investigators, PFMT, daily diary. Comparison group: no intervention	• Intervention group had statistically significant improved ICIQ-SF scores over 12-months • No difference in UI knowledge and attitude scores • Intervention group had statistically significant improved UI attitudes scores at 5-weeks, but scores declined lower than baseline score
Talley *et al.*, 2017	PFMT, tailored behavioural treatments, and exercise	2-arm RCT	42 community-residing, frail older women (mean age 84.9 years) in the United States	12-week intervention with 4 home visits by a gerontological nurse practitioner; PFMT, tailored behavioural interventions (e.g., lifestyle interventions, bladder training, urge suppression, medication education), walking 150 minutes/week of walking and twice weekly strength exercises; control group received no treatment	• Intervention group had statistically significantly reduced daily leaks, reported greater satisfaction and perceived improvement compared to control group • No difference in total ICIQ or quality of life scores • Toileting skills were improved in intervention group but not significantly compared to control group who declined

PMFT= pelvic floor muscle training; PV= prompted voiding

Table 10. Staff-Based Interventions in Long-Term and Acute Care Settings

Author, Year	Intervention	Study Design	Sample	Methods	Results
Systematic Reviews					
Ostaszkiewicz *et al.*, 2020	Education	Systematic review on the effects of UI education on nurses' and nursing assistants' knowledge, attitudes, continence care practices, and patient outcomes	19 studies of UI educational programs to nurses and nursing assistants (N=1301)	Literature review using PRISMA guidelines; included RCTs and uncontrolled studies	• Education improved nurses' and nursing assistants' knowledge, but most effective forms of education are not known • Lack of statistically significant changes in practices and patient-related outcomes in 3 RCTs, whereas 5 uncontrolled studies reported positive outcomes
Individual Studies—Long-Term Care Settings					
Kohler *et al.*, 2018	Education and case conferences	Clustered, stepped-wedge design with 2-arms	140 residents with dementia from 7 Switzerland nursing homes	13-month project involving one 4-hour education session (dementia symptoms and UI care), with 6 unit-based case conferences (1 hour each); control clusters nursing homes in control clusters received no intervention	• UI (pad weights) decreased in some clusters or were approximately equal to initial measurement • Significant improvements in 7 of 9 quality of life subscale scores
Lappen *et al.*, 2016	Education, implementation strategies, and PV	One group, pre-post intervention	21 nurses and 12 interdisciplinary team members on a Canadian inpatient geriatric rehabilitation unit	6-month continence care protocol involving education, unit-based continence champions, team huddles, and prompted voiding	• Significant changes in nurses' attitudes, confidence, and completion of admission continence assessments (80%) • No difference in nurses' responses on sufficient team communication and whether patients and families were informed of discharge continence care plans • No change in interdisciplinary team's responses on use of a multidisciplinary approach for managing continence, sufficient team communication, and whether patients and families were well-informed about discharge continence care plans
Martín-Losada *et al.*, 2020	Education, PV, and implementation strategies	Pre-post implementation chart audit using JBI's PACES and GRIP tools	140 nurses and nursing assistants and 60 patients (mean age74- 80 years) from a medium-to-long stay rehabilitation ward in Spain	6-month implementation involving short educational sessions (20 mins), UI champions, and PV	• Improved compliance on all audit criteria • 100% compliance in documentation of UI assessment including UI type, continence products changed as required, and UI discharge assessment • Slight increase in documented use of PV

Author, Year	Intervention	Study Design	Sample	Methods	Results
Systematic Reviews					
Seers *et al.*, 2018	Education, implementation strategies, and virtual support	Pragmatic clustered 3-arm RCT	346 male and female residents (mean age 82-87 years) from 24 long-term care sites in 4 European countries (England, Sweden, Netherlands, Republic of Ireland)	12-24-month project with dissemination of written UI recommendations and presentation on implementation strategies, facilitator development program with virtual support (monthly telephone group supervision and email communications); Type A arm (12 months): facilitators received a 3-day program, followed by 10 days over 12 months to work locally on implementation and evaluation, 12 half-days for monthly teleconferences and self-study. Type B arm (24 months): facilitators attended a 5-day program, 20 days to work on local implementation and evaluation, 24 half-day learning groups via teleconference and 24-half days for self-directed study	• No significant differences among groups in documented percentage compliance with recommendations for UI screening, detailed assessment, individualized treatment plans, and specialist referrals
Wiljk *et al.*, 2018	Education and implementation strategies	2-arm cluster RCT with matched control	54 residents with cognitive decline and 20 health care workers in three Swedish residential care facilities	10-month project implementing a person-centred approach involving 5 training sessions, staff facilitators, and tailored incontinence care plans; control group received usual care	• Statistically significant increase in UI assessments, person-centered caring actions (e.g., toilet assistance) during and 6 months after implementation • Fewer incontinence products needed to manage UI • Statistically significant increases in residents' quality of life scores
Individual Studies--Acute Care Settings					
Martínez-Gimeno *et al.*, 2021	Education and implementation strategies	Secondary analysis using pre-post implementation chart audit using JBI's GRIP tools	2492 patients from 17 medical, surgical, primary care/outpatient care, maternal care, and nursing homes in Spain	1-year project implementing UI recommendations with training, facilitators, clinical audits, and feedback	• Statistically significant increases in frequency of UI assessments • Increased frequency in care plan, and patient education
Nyman *et al.*, 2017	Education and implementation strategies	Pre-post implementation chart audit	271 nursing and rehabilitation staff in 2 orthopaedic units in Swedish hospitals	3-month intervention consisting of workshops and teleconferences on bladder function, UI, and knowledge translation. Unit-based multidisciplinary teams (nurses, physiotherapists or occupational therapists) supported by external facilitators	• Chart audits indicated increased documentation of UI and urinary problems in one unit
Trad *et al.*, 2019	Education and implementation strategies	Pre-post implementation with chart audits using JBI's PACES and GRIP tools	131 nurses and 100 adult medical and surgical patients from 4 acute care hospital wards in Australia	14-month quality improvement project. Education session (60 minutes) of a formalized continence pathway supported by continence tools (e.g., step-by-step flowchart, assessment and management guides, and pad selection guide); education facilitated by ward nurse unit managers, and clinical nurse educators	• Increased staff compliance with all audit criteria with notable improvements in UI assessments, specialist referrals, and patient receipt of tailored conservative interventions

VII. PHARMACOLOGICAL TREATMENT

1. BACKGROUND

This section deals with the management of frail older adults. The pharmacological management of UI in robust older men and women is discussed in Chapter 9, Pharmacology. Specific treatments for bladder outlet obstruction and associated LUTS in frail older men are outside the scope of this chapter; special matters relevant to the care of frail older men with UI are discussed above. For frail older men and women in nursing homes, urinary incontinence and overactive bladder appears to be associated with an excess of concomitant co-morbid conditions compared to continent residents [615] thus frail older adults with UI should undergo a comprehensive evaluation of remediable causative factors and, if practical, have had a trial of behavioural and lifestyle interventions prior to initiating pharmacological therapy. Drug treatment should not generally be used for persons who make no attempt to toilet when aided, become agitated with toileting, or are so functionally and cognitively impaired that there is no prospect of meaningful benefit.

Data for the use of pharmacotherapy for OAB in frail older people remain sparse. A systematic review in 2015, largely encompassing data published in the period covered by the 6th ICI, concluded that anticholinergics have a small, but significant, effect on urinary leakage in older adults with UUI and that "treatment with drugs for UUI in the frail elderly is not evidence based" [616]. This analysis only considered anticholinergic agents, and the beta-3 agonists mirabegron and vibegron were not included in this analysis. No new trials of pharmacotherapy for OAB in frail older adults were identified during the period of the 7th ICI. Readers are referred to previous editions of the ICI for trial data up until 2016.

2. NEW TRIALS OF SPECIFIC AGENTS IN OLDER ADULTS

2.1. Topical Oestrogens

In a small uncontrolled and unblinded trial, treatment with topical oestrogens in post-menopausal women for 12 weeks was associated with increased lactobacillus levels in the bladder and a small decrease in OAB symptoms, as measured with the 33-point overactive bladder questionnaire, OAB-q [617].

2.2. Mirabegron

The PILLAR trial compared mirabegron to placebo in 888 people aged 65 and over with OAB-wet. The participants were community-dwelling and frailty was not formally assessed. Following placebo run-in, participants were randomised to either placebo or mirabegron 25mg, increasing to 50mg at week 4 or 8 at participant or investigator discretion. At 12 weeks follow up, those in the mirabegron treated group had, on average, 2.3 fever micututions/24 hours, compared to 1.7 fewer with placebo ($p<0.001$) and 2 fewer episodes of incontinence/24 hours, compared to 1.5 fewer in the placebo group ($p<0.001$). Statistically significantly more people in the mirabegron group achieved a 50% decrease in incontinence episodes/24h and complete dryness than the placebo group (72% vs 60% and 38% vs 30% respectively) [618].

Safety and tolerability data in the PILLAR trial were also reported. TEAEs were reported in 39.4% of the placebo treated group and in 44.2% and 49.8% of those receiving mirabegron 25mg and 50mg respectively. There were slightly more TEAEs in those aged over 75 years, and no clinically significant changes to vital signs or cognitive function, measured with the MoCA and reported separately, with the change in adjusted mean (SE) MoCA total score from baseline to end of treatment in the mirabegron group being -0.2 and -0.1 in the placebo group (NS). [619, 620]

A pre-specified subgroup analysis of older people in the BESIDE study, a randomised, blinded trial studying the effects of solifenacin and mirabegron in combination. Patients remaining incontinent following 4 week run in with solifenacin 5mg daily were randomised to receive either solifenacin 5mg, solifenacin 10mg, or solifenacin 5mg with mirabegron 25mg increasing to 50mg at week 4. There were no significant differences in efficacy and safety data in the >65 year and >75-year age groups compared to those <65 years of age. The participants were community-dwelling older people, and no measurement of frailty was performed [621].

3. SAFETY CONCERNS WITH PHARMACOLOGICAL TREATMENT OF OAB IN OLDER ADULTS

A network meta-analysis of 21 RCTs of pharmacotherapy for OAB in older adults (aged ≥65 years) examined five efficacy and five safety endpoints found that mirabegron was not associated with increased odds of dry mouth (OR 0.76 (95%CI 0.26-2.37) or constipation (OR 1.08 (0.39-3.02) relative to placebo, whereas anticholinergics were associated with these anticholinergic effects (95%CI of OR 3.78-7.85 and 2.12-4.66, respectively). The overall rates of treatment emergent adverse events were similar between the groups, with antimuscarinics having slightly higher TEAE rates than mirabegron (OR vs placebo 1.46 [1.05-2.05] and 1.32 [0.78 – 2.27]) respectively [622].

4. ANTIMUSCARINIC TREATMENT AND COGNITION

There has been increasing concern in the literature around the associated risk of receiving a dementia diagnosis and cognitive decline in older people treated with drugs with anticholinergic properties, including those used for treating OAB.

A retrospective cohort study in Canada used propensity- matching to compare rates of dementia diagnoses in those treated with anticholinergic agents, most commonly tolterodine (40%), oxybutynin (29%) and solifenacin (26%) to rates in people prescribed mirabegron. There was an increased risk of dementia among anticholinergic users compared to beta-3 agonist users (hazard ratio 1.23, 95% confidence interval 1.12–1.35). There was a significant effect modification based on both sex and age; men and those aged ≤75 years on anticholinergics had the highest risk of dementia relative to similar beta-3 agonist users [522].

A prospective cohort study assessed cognition in 106 older women. Using the Montreal Cognitive Assessment score (MoCA), the authors compared changes in cognition over 12 months in people with OAB treated with anticholinergics, specifically oxybutynin and tropism chloride, and those attending for "routine gynaecological care" who did not receive anticholinergics. They found no difference between the groups, with the anticholinergic treated group and the

non-anticholinergic group both having changes of less than one point in the MoCA at 12 months [623].

A nested case-control study of 284,343 participants studied 6,864 cases prescribed bladder antimuscarinics with 18,778 controls, finding that those prescribed bladder antimuscarinics had higher odds of incident dementia with OR 1.65 (95%CI 1.56 – 1.75). Anticholinergics for OAB were treated as homogenous group with no distinction made between those anticholinergics with demonstrated cognitive effects and those without [624].

Concerns have been raised around a possible link between the use of anticholinergics for OAB and depression in older people. A retrospective cohort study using the Taiwan Longitudinal Health Insurance Database studied 1952 women with OAB, finding that those treated with antimuscarinics were more likely to be diagnosed with a depressive disorder than those treated with conservative treatment (HR 1.38, 95CI 1.15-1.64) over three years of follow up. However, no control for severity of OAB was in included, and a larger study using administrative data in Ontario, Canada compared rates of depression in older adults with OAB, being treated with antimuscarinics and the β3 agonist mirabegron. 23,622 mirabegron users and 47324 anticholinergic-treated patients. No differences in the rates of depression were found between the groups, HR 1.08, 95% CI 0.92-1.28 [625].

Asparu and colleagues studied the discontinuation of antimuscarinics in older adults living in nursing homes in the USA. In their analysis of 11,912 people, mean age 81.6 years, two thirds of people had their antimuscarinics discontinued during their time in long term care, with solifenacin and fesoterodine the least likely to be discontinued [626].

A small randomised controlled trial of fesoterodine vs placebo in older people with Parkinson's disease, with a mean age of 67, found a reduction in 24-hour micturition frequency, urgency scores, and nocturia over four weeks of placebo control and four weeks of open-label extension, with no deterioration in cognitive function over four weeks, as measured with the mini-mental state examination score [627].

Table 11. evaluable drug trials in frail older adults

Author	Population	Intervention	Outcome measure	Result	PMID
Thomas-White K *et al*	Postmenopausal women with OAB symptoms	Vaginal oestrogen twice weekly for 12 weeks	OAB-q	Improvement in OAB symptoms	32791124 [617]
Wagg A *et al*	Community dwelling older adults with OAB >12 weeks	Mirabegron 25mg, increasing to 50mg at week 4 or 8, vs placebo	Change from baseline to end of treatment (EOT) in the mean numbers of micturitions/24 h and incontinence episodes/24 h. Secondary endpoints: change from baseline to EOT in the mean volume voided/micturition, mean number of urgency episodes/24 h, and mean number of urgency incontinence episodes/24 h.	Statistically significant improvements were observed for mirabegron versus placebo in change from baseline to EOT in the mean number of micturitions/24 h, mean number of incontinence episodes/24 h, mean volume voided/micturition, mean number of urgency episodes/24 h, and mean number of urgency incontinence episodes/24 h.	31733990 [628]
Herschorn *et al*	Community dwelling older adults with OAB >12 weeks	Mirabegron 25mg, increasing to 50mg at week 4 or 8, vs placebo		Treatment-emergent AEs (TEAEs), the majority mild or moderate in severity, were reported in 39.4% of placebo patients and 44.2 and 49.8% of those who received mirabegron 25 mg or 50 mg, respectively. The most common TEAEs in mirabegron-treated patients were urinary tract infection, headache, and diarrhoea. The incidence of TEAEs was slightly higher in mirabegron patients aged ≥ 75 years than in those aged < 75 years. There were no clinically meaningful differences in changes in vital signs from baseline to end of treatment for any treatment group, and no differences were observed between mirabegron and placebo treatment groups. TEAEs tended to occur early post exposure and were not dose related.	32725584 [619]
Griebling *et al*	Community dwelling older adults with OAB >12 weeks	Mirabegron 25mg, increasing to 50mg at week 4 or 8, vs placebo	MoCA scores at baseline and week 12	No statistically significant change in adjusted mean (SE) MoCA total score from baseline to EoT in the mirabegron group (-0.2 [0.1]) or the placebo group (-0.1 [0.1]).	32183741 [620]
Gibson W *et al*	Community dwelling older adults age >65 with OAB, remaining incontinent (≥1 episode during 3-d diary) following 4-week single-blind daily solifenacin 5mg	solifenacin 5mg and mirabegron 25mg, increased to 50mg at week 4, solifenacin 5mg or 10mg for 12 weeks	change from baseline to end of treatment in average daily incontinence (primary) and micturition frequency (key secondary), number of incontinence episodes during the 3-d diary (key secondary) and change from baseline in average daily urgency and urgency incontinence episodes. Safety included treatment-emergent adverse events and vital signs.	Full analysis set included 2110 patients: 30.9% aged ≥65 yr and 8.9% aged ≥75 yr. At the end of treatment, daily, and 3-d incontinence daily micturitions, urgency, and urgency incontinence, were improved in each treatment group and age group; the largest reductions were observed with combination in each age cohort. There were no notable differences in vital signs or the incidence of treatment-emergent adverse events between treatment and age groups, with the exception of dry mouth, which was highest with solifenacin 10mg.	28916436 [621]

Lozano-Ortega, G *et al*	Twenty articles reporting on 21 randomized controlled trials were eligible for data extraction and synthesis. NB – all these trials were in the 6th ICI			Mirabegron was not associated with an increased odds of dry mouth (odds ratio 95% credible interval 0.76 [0.26-2.37]) or constipation (1.08 [0.39-3.02]) relative to placebo, whereas antimuscarinics were strongly associated with these events (odds ratio range 3.78-7.85 and 2.12-4.66, respectively) No increased odds of experiencing overall treatment-emergent adverse events was observed for mirabegron or antimuscarinics (odds ratio range 1.25-1.55), apart from fesoterodine (2.23 [1.37-3.37]) a similar treatment effect was observed across all efficacy endpoints between mirabegron and antimuscarinics in this older population.	32960422 [622]
Welk B, McArthur E	Population-based, retrospective, matched cohort study using linked administrative data from Ontario, Canada from 2010 to 2018.	47324 new users of anticholinergic medications (oxybutynin, tolterodine, solifenacin, darifenacin, fesoterodine, trospium) to 23662 new users of mirabegron		There was an increased risk of dementia among anticholinergic users compared to beta-3 agonist users (hazard ratio 1.23, 95% confidence interval 1.12-1.35). There was a significant effect modification based on both gender and age; men and those aged ≤75 years on anticholinergics had the highest risk of dementia relative to similar beta-3 agonist users.	32167223 [522]
Iyer S *et al*	prospective cohort study assessing changes in cognition in women seen in a referral urogynaecology practice.	Women who started anticholinergic OAB medications with women not on anticholinergic OAB medications (receiving routine gynaecological care so not OAB)	106 women were enrolled, 60 in the OAB medication group (Trospium and oxybutynin) and 46 in the control	Over time there was no difference in change of MOCA score between the OAB and control groups when controlling for age, GDS score, and ACB score (p = 0.78). This association did not change when women with a neurological diagnosis were excluded (n = 6). On average MOCA scores for the OAB group increased by 0.76 over 12 months and the control group increased 0.39, with no difference between the groups (p = 0.53).	31813036 [623]
Coupland *et al*	nested case-control study took place in general practices in England that contributed to the Research primary care database. The study evaluated whether exposure to anticholinergic drugs was associated with dementia risk in 58 769 patients with a diagnosis of dementia and 225 574 controls 55 years or older matched by age, sex, general practice, and calendar time			Increased odd ratio for dementia with exposure to bladder antimuscarinic drugs (AOR, 1.65; 95% CI, 1.56-1.75	31233095 [624]

Chung SD *et al*	retrospective cohort study examined the association between antimuscarinic use and the subsequent risk of depressive disorder using a population-based data set in Taiwan	1952 OAB women who received antimuscarinics as the study cohort and 9760 OAB women who did not receive antimuscarinics as the comparison cohort. Each subject was tracked for 3 years mean ages of the study cohort and comparison cohort were 51.5 ± 16.7 (Rx) and 51.5 ± 16.9 years (no Rx)		Adjusted hazard ratio (HR) for depressive disorder in OAB women who received antimuscarinics was 1.38 (95% confidence interval [CI], 1.15-1.64) compared with those OAB women who did not receive antimuscarinics. In addition, the adjusted HRs for subsequent depressive disorder for OAB women aged 18-39, 40-59, and ≥60 years who received antimuscarinics were 1.83 (95%CI, 1.27-2.64), 1.36 (95%CI, 1.03-1.81), and 1.16 (95%CI, 0.86-1.56), respectively, compared with those OAB women who did not receive antimuscarinics.	28378881 [629]
Welk, B McArthur A	Retrospective cohort study with administrative data	23 622 beta-3 agonist users (mirabegron) to 47 324 anticholinergic users (most commonly tolterodine, oxybutynin, and solifenacin).		The rate of depression was similar among beta-3 agonist users (11.2 per 1000 patient-years) and anticholinergic users (11.9 per 1000 patient-years). In our primary analysis, the risk of depression among anticholinergic users was not significantly different compared to beta-3 agonist users (HR 1.08 [95% CI 0.92-1.28, P = .35])	33015899 [625]
Aparasu R *et al*	Cohort study in long-term care, examining people with LOS >101 in LTC. Mean age 81.6	Discontinuation rates of anticholinergics for OAB		About two-thirds of LTNH residents with OAB discontinued their index antimuscarinic during their nursing home stay. There was significant variation in discontinuation based on the index antimuscarinic agent with lowest risk of discontinuation with solifenacin and fesoterodine.	32638205 [626]
Yonguc *et al*	63 Older adults with PD, mean age 69/6 (placebo) 65.5 (intervention) (p=0.97) H&Y score no difference between groups	Fesoterodine 4m vs placebo for 4 weeks followed by 4 weeks open label	Micturitions per day, MMSE	The number of micturition episodes per 24 h period significantly improved with the use of fesoterodine fumarate in the double-blind phase ($p < 0.001$). Also, the mean number of nocturia and urgency episodes decreased in the fesoterodine group. In the open-label phase, the mean number of micturition, urgency and urgency urinary incontinence episodes were improved significantly. The number of nocturia episodes did not change in the open-label phase. Cognitive functions were stable after 4 weeks of fesoterodine 4 mg treatment.	31642953 [627]

5. BLADDER ANTIMUSCARINICS AND DELIRIUM

Since the 6th ICI, there have been no further studies reporting on the occurrence of delirium and OAB antimuscarinics. Delirium remains a rare adverse event from bladder antimuscarinics at therapeutic doses and, apart from a general recommendation to reduce anticholinergic load in cases of delirium, as they may prolong delirium. There appears to be no reason to exclude even frial older adults from treatment based on presumed risk of delirium. (**LoE 4**)

6. CHOLINESTERASE INHIBITORS AND BLADDER ANTIMUSCARINICS

There is evidence cholinesterase inhibitors can cause or worsen UUI. Evidence of this association is discussed in depth in the previous chapter. Since the last ICI, we located one cohort study which examined the association between individual cholinesterase inhibitor (AChEI) use and antimuscarinic usage in older adults with dementia. The study included 47,059 older adults who were incident users of AChEIs. Most of these patients were initiated with donepezil (83.1%), followed by rivastigmine (12.3%) and galantamine (4.6%). Overall, 8.16% of the study cohort had incident OAB diagnosis or an antimuscarinic prescription. Antimuscarinics were initiated by 1725 (3.7%) older adults with dementia within 6 months of AChEI prescription, this varied widely across individual agents-donepezil (3.9%), rivastigmine (2.6%), and galantamine (2.9%). Cox proportional hazard analyses revealed that donepezil users had an increased risk of receiving antimuscarinics (adjusted hazard ratio 1.55, 95% confidence interval 1.31-1.83) compared with rivastigmine. The findings were consistent in sensitivity analyses. Donepezil use was more likely to lead to antimuscarinic cascade than rivastigmine [630].

There have been no further trials reporting on UI outcomes in older adults living with dementia taking cholinesterase inhibitors. Based upon limited evidence, there remains no reason not to use bladder antimuscarinics for older people with dementia on AChEI with UUI. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living (**LoE 3**).

7. NON - ANTIMUSCARINIC AGENTS

There are no data on frail older adults or those with a dementia diagnosis. However, a prospective randomised study examining the neurological safety and clinical efficacy of darifenacin and mirabegron in patients with a history of cerebrovascular accident (CVA) who had overactive bladder was located. In 60 patients, 30 per arm, after 3 months of treatment with darifenacin or mirabegron, ICIQ bladder diary parameters improved and there was no deterioration in cognitive function measured with MoCA-B score in either of the arms. The mean change in bladder diary parameters and the MoCA-B scores was similar between the two groups. The sample size was small, frailty status was not described [631].

Patients that might be at risk of impaired cognition have been well described [632] and consist of those with mild cognitive impairment, long-standing type II diabetes, poorly controlled hypertension, alcohol misuse, dementia, Parkinson's disease and the other akinetic-rigid syndromes. Those with Parkinson's disease may be exquisitely sensitive to the cognitive adverse effects of antimuscarinics [633]. These individuals will need to be carefully assessed, both prior to, and shortly after, initiation of treatment with bladder antimuscarinics. Treatment may necessarily depend upon a global assessment of cognition during the clinical assessment and, if possible, a carer's impression of change. In addition to the of likely benefit from drug treatment, considering the life expectancy and wishes of the patient, account should be taken of total anticholinergic load, as this clearly increases the likelihood of cognitive impairment. There is evidence of the short-term cognitive safety of bladder antimuscarinics, with the exception of immediate release oxybutynin, for the most part in cognitively intact older adults, and therefore, prescribing bladder antimuscarinics as single agents is, on the whole, probably safe.

Those studies using high doses (20mg) of oxybutynin are associated with an increased likelihood of causing cognitive impairment, which may not be apparent to either the patient or the clinician [634]. This drug should probably be avoided in the elderly at high dose, and in those at cognitive risk, in any case. The other antimuscarinics should be initiated carefully, at the lowest dose for tolerability, with dose increases where indicated for efficacy, and reviewed early.

Summary of the evidence

There remains insufficient evidence to determine the efficacy, tolerability, and safety of OAB drugs in frail older adults **(Level 4)**:

VIII. SURGICAL TREATMENT IN FRAIL OLDER ADULTS

1. INCONTINENCE SURGERY IN FRAIL OLDER WOMEN

Surgical intervention, mainly the midurethral sling, is the most effective and durable treatment for SUI in women. Due to the minimally invasive nature of these procedures, the number of older women undergoing midurethral slings is increasing.

Multiple retrospective and prospective cohort studies report favourable outcomes for older women undergoing these procedures. One single institution case series reported excellent surgical results with well-selected older women >/=70 years of age compared to women <70 years of age undergoing surgeries for incontinence and other pelvic floor disorders [635]. These older women were shown to do well with anti-incontinence surgery and to have significant gains in QOL, that did not significantly differ compared to the younger cohort. Another study of 76 women >/=70 years of age who underwent tension-free vaginal tape (TVT) procedures also demonstrated good outcomes, with a 67% cure rate and no serious complications, either intra- or post-operatively [636].

However, the literature on this topic is somewhat mixed and not all studies demonstrate as favourable outcomes. A large secondary analysis of the National Health and Nutrition Examination study showed that the risk of perioperative complications from midurethral slings was higher among women ages 80 years or older,

compared to those who were younger (odds ratio [OR], 1.4; 95% CI, 1.3–1.5) [637]. Outcomes of a subgroup of women enrolled in the Stress Incontinence Surgical Treatment Efficacy (SISTEr) trial demonstrated that age was one of the preoperative baseline factors that was associated with recurrent urinary incontinence seven years following surgery [638].

A more recent retrospective study of 688 older women undergoing three different types of midurethral sling surgery [i.e., single incision slings, transobturator tape (TOT), and retropubic transvaginal tape (TVT)], also demonstrated inferior outcomes in older women. In this study, women were stratified by age according to three categories: <64 years (young), 65-74 years (elderly), and >75 years (old). Objective and subjective cure rates for young, elderly, and older women were 91.0%, 80.6%, 66.7% and 89.2%, 77.6%, 58.3%, respectively. There were no differences in operative time, perioperative complications, or hospital length of stay between the different age groups. Findings from this study may not be generalisable due to possible positive selection bias of the retrospective study design, whereby procedures were likely mostly selected to be done among healthier individuals [639].

The above studies, and most of the literature, use age as a binary predictor, and fail to consider any other important factors that account for the phenotypic heterogeneity demonstrated in older adults, including multimorbidity, frailty, or physical or functional impairment. Unfortunately, these omissions lead to major gaps in our knowledge regarding which older individuals may benefit from surgical treatment for their stress urinary incontinence, and which may not. Research inclusive of these important factors is critically needed to help identify which treatments for stress incontinence are most appropriate in which older women.

To this end, one study specifically looked at the association of frailty with postoperative outcomes in older adults undergoing sling surgery using the American College of Surgeons National Surgical Quality Improvement Project (ACS-NSQIP) data from 2013-2016. Approximately 10% of individuals undergoing sling surgery (with or without concurrent prolapse repair) were identified to be frail and frailty was associated with increased hospital length of stay (OR 1.2, 95% CI 1.1-1.4) and 30-day hospital readmission (OR 1.7, 95% CI 1.1-2.5) in this cohort [640].

Another study evaluated nursing home residents, a cohort characterised by frailty and physical and cognitive impairment, undergoing female pelvic surgery (inclusive of both sling and pelvic organ prolapse surgery). Residents were propensity score matched to community-dwelling older adults based on procedure type, age, comorbidity, race and calendar year. Among this cohort, 34% demonstrated 30-day complications and 1-year mortality was 7%. The relative risk of each outcome was higher among the nursing home residents, compared to matched community-dwelling older adults, highlighting that factors other than age and comorbidity (such as frailty and physical and cognitive impairment) may account for these inferior outcomes [641].

No further studies investigating the utility of onabotulinumtoxinA in older women with frailty were identified since the 6th ICI. A review article has noted the absence of evidence for the therapy in older adults [642]

2. INCONTINENCE SURGERY IN FRAIL OLDER MEN

As noted in the 6th ICI, no specific conclusions can be drawn regarding surgical treatment of UI in frail men. Since the last chapter, one cohort study described the health characteristics and treatment choices of male stress urinary incontinence (mSUI) patients to inform patient-centred decision-making. Of 130 participants (mean age 75) and moderately bothersome incontinence, nearly 80% had significant morbidity, three-quarters had >50% 10-year mortality risk, 10% needed help with 1 + ADL and 22% had an impaired Timed Up and Go test >10 seconds. Only incontinence characteristics, rather than any other considerations were statistically significantly associated with conservative vs surgical treatment choice [643]. Typical studies of anti-UI surgery in elderly men are very small or fail to stratify results by age and/or comorbidity [644]. One small study (n=46) found that advanced age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI [645], while another (n=12, mean age 80 years) of transurethral resection prostatectomy (TURP) for obstruction-associated urgency UI concluded that cognitively impaired men demonstrated the greatest UI improvement [646]. In a single institution case series of men aged > 80 years old undergoing TURP (68% of whom had urinary retention), 80% were satisfied with their outcome. Of the men with retention, 80% were able to void with a small PVR by six weeks. Complication rates were 41% (early) and 22% (late) age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI [647]. A retrospective cohort study of men undergoing AUS placement and removal procedures using data from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) (2006 to 2013) quantified frailty using the NSQIP-FI (frailty index) and was applied to logistic regression models predicting 30-day complications (overall, major, and minor) and the odds of having an AUS removal procedure (over an AUS placement procedure. 624 and 147men undergoing AUS placement and removal procedures, respectively were identified. NSQIP-FI of ≥0.27, but not age, was associated with major complications (aOR 3.5, 95% confidence interval 1.2-9.9), while age ≥85 years, but not NSQIP-FI, was associated with minor complications (aOR 7.9, 95% confidence interval 1.4-45.6). Men undergoing AUS removal procedures tended to be frailer compared to men undergoing AUS placement procedures (12.9% vs 6.1% had NSQIP-FI of ≥0.27, P<.01) [648]. There has been a push for minimally invasive, office-based procedures which can be performed without general anaesthesia. However, AUA recommendations on minimal invasive techniques such as the use of Prostatic UroLift®, RezümTM or Aqua Ablation are based on prostate size and not on comorbidities [563]. A systematic review and meta-analysis comparing endoscopic enucleation vs endoscopic vaporisation and laser enucleation procedures vs laser vaporisation procedures has been done by Xinbao *et al.* including 16 studies with 4907 patients [649]. Endoscopic enucleation and laser enucleation procedures favoured in perioperative data, rate of complications, and functional outcome. The clinical significance of the findings remained unclear and there was no consideration of risk factors common in frail older men. However, photoselective vaporisation and enucleation of prostate might be beneficial due to the better control of bleeding [565]. Prostatic stenting – either temporary or permanent is not mentioned in the AUA guidelines. The EAU recommends the use of prostatic stents as an alternative to catheterisation although the use of prostatic stents is due to complications still rare [566].

3. SURGERY FOR IDIOPATHIC OR NEUROGENIC DETRUSOR OVERACTIVITY

There remains only one study examining onabotulinumtoxin A therapy in frail older men [650]. The authors concluded that safety and efficacy were similar between older men without frailty and younger patients. However, an increased risk of finding a large post-void residual urine volume and a lower long-term success rate in frail patients were noted.

4. GENERAL ISSUES IN THE SURGICAL CARE OF FRAIL OLDER ADULTS

Frailty is becoming increasingly recognised as an important prognostic factor in surgical outcomes. However, measured, the presence of frailty is associated with an increased likelihood of surgical complications, increased lengths of hospital stay and a greater probability of requiring an increased level of care following hospital discharge [644, 651, 652]. Important factors in the surgical care of frail patients include: preoperative risk stratification (e.g., American Society of Anaesthesiology class, Charlson index, Modified Cardiac Risk Index, Burden of Illness Score) [653]; ensuring adequate nutrition, especially when patients cannot take oral feeding or become delirious; proactive management of comorbid heart disease, diabetes, and pulmonary disease; prevention [654, 655], recognition [656], and treatment of postoperative delirium [657]; adequate pain assessment and treatment, especially in cognitively impaired persons [658]; recognition of the hazards of prolonged bed rest [659] and the prevention [660] and treatment of functional impairment; use of specialised care units for older adults [661]; and discharge planning regarding rehabilitation, need for assistance, and site of discharge. All need to be actively considered and dealt with in any plan of surgical care of frail older patients. Although some single institution case series have reported excellent surgical results with well-selected octogenarians and nonagenarians undergoing surgery for incontinence and other pelvic floor disorders, these findings should be interpreted with caution because they tend to describe the results from surgery in robust, carefully selected patients undergoing procedures at specialised centres. To what extent these results are generalisable is unclear; the true risk of surgery in frail older patients is likely higher than in these reports.

Attention to cognitive and functional outcomes as well as quality of life are also important to consider in this population.

Summary of the evidence

1. gynaecological surgery in institutionalised older women appears to be characterised by poorer outcomes than in community dwelling women. (**LoE 4**)

2. Injection of bulking agents for SUI appears to give minor benefit in women, however the technique is minimally invasive, and age does not appear to correlate with outcomes. (**LoE 3**)

3. Injection of onabotulinumtoxinA might be an option in patients with idiopathic or neurogenic overactive bladder although risk of residual urine and a lower long-term success rate have been described. (**LoE 3**)

4. No studies were identified that evaluate functional or quality of life outcomes after UI surgery in frail older adults (**LoE 4**)

5. Risks of morbidity and mortality for frail patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures. (**LoE 2**)

6. Surgical mortality risks are still low in older adults, and when deaths do occur, they are often due to cardiac or cancer complications. (**LoE 2-3**)

7. Operative mortality is inconsistently associated with increased age, and most studies do not uniformly control for comorbid conditions (**LoE 2-3**)

8. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared to standard fixed and time-administered medications in cognitively intact patients. (**LoE 2**)

9. Choice of agent for patient-controlled analgesia may affect postoperative cognition. (**LoE 3**)

10. Some case series and waitlist-controlled trials suggest that minimally invasive surgical approaches may be useful in older adults, yet these trials may have little to do with whether surgical treatments are appropriate in frail older adults (**LoE 3**)

Recommendations for management

1. Age alone is not a contraindication to surgical treatment of UI (**Grade C**).

2. Urodynamic evaluation should be done before considering surgical treatment of UI in frail older adults (**Grade B**).

3. Preoperative risk should be stratified using established indices (**Grade A**).

4. Validated frailty scales may aid prognostication and planning from post-surgical care in frail older adults (**Grade C**)

5. Ensure adequate post-operative nutrition, especially in patients who cannot take oral feeding or who become delirious (**Grade C**).

6. Programmes to prevent post-operative delirium should be utilised (**Grade A**) along with proactive use of established measures to diagnose delirium (**Grade A**).

7. Pain assessment in cognitively impaired persons should use measures specially designed for this population (**Grade B**).

8. Proactive preventative approaches to hospitalisation-related functional impairment should be used (**Grade A**).

9. Specialised care units may improve selective outcomes for frail older patients (**Grade A**).

10. Discharge planning should begin before surgery takes place (**Grade C**).

11. Patient controlled analgesia can be used in cognitively intact frail older adults (**Grade B**).

12. Analgesic agents associated with delirium (e.g., meperidine) should be avoided (**Grade B**).

13. Long-term outcomes before the operation should be discussed with the patient (**Grade C**).

Recommendations for research

Further research is required to:

1. identify risk factors for surgical outcome in frail adults to identify which treatments for UI are most appropriate in real-world settings

2. Define pre- and post-surgical care to improve surgical outcome in frail older adults.

IX. NOCTURIA

1. BACKGROUND

Nocturia is defined as the number of times urine is passed during the main sleep period and is manifested by increase in both urination frequency and urine volume produced at night [662]. The definition refers to an individual's sleep cycle and commences with the intention to sleep. This allows the term to be applicable to shift workers and others who may sleep during daylight hours. Overall, nocturia is a highly prevalent symptom [663]. While a single episode of awakening to urinate would be considered nocturia, patients are more likely to experience significant bother and decreased quality of life when voiding twice or more per night and to have [664]. Overall individuals will likely consult a provider about nocturia if they have three or more episodes [665]. Given that nocturia of at least twice per night is associated with significant increased risk for comorbidities, many clinical trials include only participants with two or more episodes [666]. Of relevance in the older population is that the presence of nocturia at least twice each night increases 5-year mortality by 4% and is probably associated with a 1.3-fold increased risk of death.

The definition of nocturia does not take into account sleep patterns of older adults. Since some older adults will spend six hours sleeping while others might spend twelve hours in bed, having three episodes of nocturia would be very different for these individuals [667]. Additionally, it is hard to identify whether individuals wake to void or pass urine because of wakefulness or other specific sleep disturbances (such as seen with Parkinson's Disease or obstructive sleep apnoea) [668, 669]. Both primary and secondary insomnia that may be noted in older patients with nocturia, can be linked to depression, anxiety about life changes, disruption by a partner or pet, circadian sleep disorders and symptoms associated with comorbid disease.

The prevalence, impact, pathophysiology, diagnostic assessment, and treatment of nocturia differ meaningfully between older adults and frail older adults [669] where nocturia often results from the reduced physiological reserve of multiple systems. In older hospitalised patients nocturia has been reported in at least 76% of older inpatients [670]. Nocturia at least twice per night in older patients undergoing rehabilitation has been shown to be predicted by comorbidities (Charlson Comorbidity index OR 1.41) and lower urinary tract dysfunction (urinary frequency OR 10.9, daily urinary incontinence OR 4.9) [671]. Measures of frailty, such as the modified Frailty Index, cognitive dysfunction, decreased hand grip strength, diuretic use and cardiac parameters are significantly associated with nocturia in the older age group [672, 673]. Although the link between nocturia, morbidity and all-cause mortality is likely to be frailty, variables of poor health can increase the mismatch between bladder storage and rate of urine production. One example of this is increased diuresis rate at night inducing nocturnal polyuria, a finding in up to 77% of people with nocturia more than twice per night [674]. Accordingly, diagnostic assessment must be comprehensive enough to identify causality, directing multi-component interventions necessary for successful treatment.

2. PREVALENCE, CAUSATION & IMPACT

The prevalence of nocturia increases with age and has been reported to be as high as 90% for one episode per night in persons over age 80 [675-680]. The prevalence of two or more episodes among men between 70 and 79 is nearly 50 percent [680, 681]. This increasing prevalence is largely due to age-related conditions that underlie the pathophysiology of nocturia, such as smaller maximum voided volume and increased nocturnal polyuria [682]. With respect to sex, nocturia in young adults is more common for women than men, but this sex ratio reverses after age 60 when more men have nocturia [681]. For those over 75 years of age, the prevalence of nocturia of at least two or more times is much more common in men (70%) than in women (50%) [683]. Nocturia is a common symptom in nursing home residents and contributes to poor sleep and impaired quality of life [684].

Nocturia is a dynamic symptom related to hormonal, nephrological, urological, cardiovascular and sleep factors [685, 686]. In one study, participants recorded their urination frequency and voided volumes over a 2-year period; the incidence rate of nocturia of two or more times per night in the oldest adults participating (70-78 years) was 47.1% while the resolution rate was 26.2% [687]. This finding of resolution in one quarter of older adults is encouraging and warrants research into the identification of factors responsible for reducing nocturia. Reports of improved nocturia after successful treatment of non-dipping hypertension at night, nocturnal diuretic use, improved control of unstable diabetes mellitus in younger patients could account for some improvement in nocturnal polyuria in well managed older patients [688].

Recent data have also highlighted that the prevalence of nocturia in older adults differs by racial group. Multiple population-based epidemiological studies have shown a higher prevalence of nocturia in older men and women who are African American when compared to Caucasian cohorts [680, 689, 690]. While controlling for socioeconomic factors eliminated the differences in prevalence between non-Hispanic whites and Hispanics, differences persisted, although somewhat attenuated, between people of African versus European descent [691, 692].

Nocturia is associated with chronic medical conditions such as hypertension [693, 694] (including night time hypertension and absence of night time blood pressure dipping) advancing renal insufficiency [695-697] and cardiovascular disease [698, 699]. Nocturia has been shown to be associated with diabetes mellitus, [699], time since diagnosis, waist circumference, higher body mass index and

greater fat mass in men but not with the metabolic syndrome in older people [184, 700, 701]. Clinically, nocturia may be the herald symptom of significant underlying medical conditions, which, if overlooked, might result in significant morbidity and even mortality [666, 702] Therefore, an older patient presenting with bothersome nocturia should be evaluated for the causes of nocturia and unrecognised comorbidity. The presence of sleep apnoea, restless legs syndrome, moderate alcohol usage, poor nocturnal glycaemic control, and conditions causing night time pain should be identified [666].

Nocturia is associated with accidental falls, carrying a relative risk of 1.2 and likely to increase risk of fracture by 1.3 [275, 283, 703]. Significantly more difficulty climbing stairs and reduced skeletal muscle mass was found with older individuals who had increased frequency of nocturia episodes as compared to those who voided once or less per night. Frail older persons with nocturia, with coexisting gait and balance disorders are clearly at increased risk for falls [274, 704], injury and hip fracture [784], and consequent morbidity [705, 706]. Recent work suggests that urinary urgency further compromises posture, step length and walking speed, all factors known to predict falls. Despite these facts, no nocturia treatment trials to date have evaluated any impact on falls reduction. Nocturia also has adverse effects on quality of life [707], including an increased risk of depression and poor self-rated health, probably as the result of the impact on sleep. [708]. Adults with nocturia also complain that nocturia “makes them feel old” and they worry about falling at night [709]. Older individuals described nocturia as simultaneously debilitating, frustrating, distressing and puzzling [710].

Several recent studies have shown strong associations between nocturia and Parkinson’s disease (PD), including a negative impact on quality of life, depression, anxiety and severity of disease [711-714]. Nocturia is a frequent, early non-motor symptom in PD that is bothersome, and a common cause of sleep disruption [715, 716]. Nocturia in PD is associated with increasing age of the patient, but also with the increasing severity of PD [717]. Age of onset of PD, in addition to age, may be associated with worse nocturia [718]. Patients with PD have more nocturia episodes than their spouses, and number of nocturia episodes may be related to nighttime and total levodopa dosages [719]. While it might be difficult to clinically separate idiopathic PD from drug-induced Parkinsonism, urinary symptoms including nocturia are much more common in PD even after controlling for age and sex [720]. Additionally, nocturia and other non-motor symptoms often began prior to being diagnosed with PD, and may be a biomarker for the condition [720].

Bother attributable to nocturia increases with age. There is growing evidence to suggest that bother from nocturia relates to severity, both primary and secondary insomnia and the impact of poor sleep quality on daytime function [721-725]. Many papers have described the association between nocturia and disrupted sleep [666, 722, 726, 727]. When a group of 1,424 elderly individuals, ages 55–84 were presented with a checklist of symptoms that potentially disrupt sleep, nocturia was chosen by 53% of the sample as a self-perceived cause of sleep issues “every night or almost every night”. Nocturia was cited four times as frequently as pain, which was the next most identified cause of sleep disruption [728], and reported as a reason for insomnia in patients with congestive heart failure [721, 729]. Nocturia has been shown to be significantly associated with worse scores on sleep questionnaires, a shorter time asleep before first night void, longer awake duration and poor quality of whole-night sleep [726, 730, 731]. One of the outcomes of sleep disruption seen with nocturia is excessive daytime sleepiness [732]. Other lower urinary tract symptoms are also highly correlated with sleep disturbances with daily urinary urgency significantly predicting high nocturia-related bother [733, 734]. For older patients in hospital, waking at least twice to pass urine at night was significantly associated with daytime lower urinary symptoms: urinary frequency > half the time, urinary urgency > half the time, UI > half the time, mean AUA symptoms score, and with faecal incontinence score and the number of continence products used [671]. Nocturia is related to depression and anxiety [735, 736]. In particular, convenience voiding at night is more common in individuals with a mental health diagnosis than in those without and has been reported to be associated with a perception of urinary urgency despite equivalent urine volumes and diuresis rate [737]. All quality-of-life measures collected in a sample of older hospitalised individuals, using the EQ-5D-5L instrument, were significantly worse in patients who voided more than once at night. As nocturia episodes reduce, quality of life improves [738].

3. PATHOPHYSIOLOGY

The pathophysiology of nocturia is multifactorial, particularly in frail older persons. In age-adjusted analyses from a large survey in Finland, no single factor related to nocturia was present in greater than 50% of those with nocturia [739]. The factors with the greatest impact at the population level in men were (urinary) urgency, “benign prostatic hyperplasia” and snoring while for women being overweight or obese, urgency and snoring were risk factors [682, 739]. Colder ambient weather or internal temperatures may be associated with greater nocturia, possibly due to sleep disruption [740, 741].

A framework for clinical diagnosis and treatment is that one or a combination of primary causes underlie symptoms, all of which increase with age. Age-related changes to the bladder ± conditions that reduce bladder capacity (i.e., OAB, DO, urgency UI, or BOO in men) can cause nocturnal frequency. Nocturnal polyuria, particularly in the early hours after falling sleep, can overwhelm bladder storage. Finally, disruption of sleep for a variety of reasons, can precipitate nocturia, [742-744] although this relationship is likely bi-directional (with sleep dysfunction also likely resulting from nocturia) [745].

The proportion of a 24-hour urine volume produced at night increases with age, even among healthy older adults free of overt comorbid conditions [746, 747]. Studies of frail older adults have shown that the proportion of urine produced at night is close to 50%, as compared to 30% in young healthy adults [748-750]. In some older persons this is due to mobilisation of excess volume caused by peripheral oedema, which may be due to venous insufficiency, medications, and/or heart failure. Both hydrochlorothiazide and loop-diuretic usage in men have been associated with higher rates of nocturia, unless last dose is taken at least 6 hours before sleep. The definition selected for diuresis rate indicative of polyuria will influence prevalence and overlap of day, night and 24-hour polyuria in patients with nocturia [751, 752]. There may be an abnormality in the secretion and/or action of arginine vasopressin (AVP) or a loss of the normal diurnal rhythm (with inappropriately low values at night) in elderly patients with nocturia. [753-755]. Other research suggests that some frail older adults with nocturia have high atrial natriuretic peptide (ANP) levels at night; [756, 757] however, these investigators did not use echocardiography or evaluate brain natriuretic peptide levels to detect occult heart failure.

Sleep disordered breathing (as defined by an Apnea-Hypopnea Index >=15) is associated with circadian change in extracellular fluid, nocturia and nocturnal UI in the elderly [756, 758-761].

Community-dwelling older adult populations who have >25 breathing events per hour have nearly double the number of nocturia episodes compared with those with low rates of sleep apnoea [762]. Whether this relates to negative intra-thoracic pressure changing inducing ANP production, [756] mechanical forces on the bladder generated during apnoea event [759] or other mechanism(s) is unknown. Nocturia may be a marker or a result of endothelial dysfunction [763], vascular flow disruption, white matter hyper-intensities [764], or inflammation [765].

4. DIAGNOSTIC ASSESSMENT

The approach to the assessment of nocturia expands the routine process for UI to identify factors underlying causality. Special considerations include a frequency-volume chart of at least 24 hours duration that includes timing and volume of each void at night as well as during the day, as well as a specific indication of when the individual went to bed with the intention of going to sleep at night and awoke in the morning. Some patients may find this difficult to perform, [766] but face-to-face explanation of the procedure, a hand-held urinal or a receptacle to place in the toilet to measure volumes, and involvement of caregivers may improve compliance and accuracy. Alternatively, a collection of all urine passed during the night ± change in containment product weight and volume of first morning void will indicate nocturnal urine volume. The advent of smart technology is likely to substantially change this type of data collection [767-769].

A causality checklist for nocturia, TANGO, can be utilised to assist patients and clinicians to identify potential and co-existing causal factors [770]. This has domains related to increased urine production, sleep, urinary tract and wellbeing. Additional questions about leg movements at night, bed partner, household members and family pets may generate insightful information. Recently a symptom score for nocturnal LUTS in older people has been described that may have utility in describing the specific LUTS coexisting with nocturia. As high daily salt intake can increase frequency of voiding, history taking should include questioning about intake of sodium and other dietary osmoles in the afternoon and evening [771-773].

Older people are commonly prescribed multiple medications for comorbidities, many of which may exacerbate urine production, bladder storage or sleep quality affecting development or resolution of nocturia. Known pharmacological correlates of nocturia include calcium channel blockers (induce oedema), lithium, Sodium-glucose transport protein 2 (SGLT2) inhibitors and diuretics that increase osmotic clearance. A medication review for optimisation of polypharmacy is therefore warranted with attention to both type and timing of drugs known to influence nocturia [774-777]. Focused physical examination will evaluate volume overload (e.g., lower extremity venous insufficiency, congestive heart failure) and factors that induce nocturnal polyuria such as unstable blood sugar levels, postural hypotension and non-dipping nocturnal blood pressure can be identified with specific testing. A serum sodium check may also be considered [778]. Muscle strength, mobility impairment and any neurological disorder should be noted and considered for contribution to wakefulness, bladder storage, urgency and difficulty reaching a toilet. When poor mental health is suspected sleep parameters should be investigated (i.e., primary sleep latency, sleep efficiency, secondary insomnia, night worrying).

5. TREATMENT

While many clinical investigations are trials of single agents, experts [779] would argue that treatment of nocturia in elderly patients should be based on a holistic approach informed by identification of multiple potential underlying causes. It has been suggested that in frail older people the approach to nocturia be systematic. Firstly, optimisation of comorbidities and reduction of polypharmacy; secondly behavioural and lifestyle adjustments; thirdly addressing drug–disease interaction; and finally joint goal setting with patients and their families [777].

There is little high-quality evidence for most monotherapies or combined treatments for nocturia in older age groups. A recent review of therapies for nocturia management in the elderly cites evidence for efficacy of lower limb oedema prevention and treatment, fluid restriction up to four hours before sleep, pelvic floor muscle contraction at urge in patients with known overactive bladder, salt reduction if intake is excessive and behavioural treatment of insomnia [777]. Combination therapy is preferred over monotherapies [780]. Cure, or the complete resolution of nocturia, is infrequently achieved in either clinical practice or research.

The most common primary outcome in clinical trials is reduction in nocturia episodes, as measured by voiding diary or self-reported nocturia over a given period. Some trials have reported the percent of participants who achieve a 33% or 50% [755, 781-785] reduction in nocturia from the baseline level or the percent of individuals having a reduction equal to 1.0 fewer mean nightly episodes of nocturia [781, 783, 784]. There are few treatments that offer robust reductions of nocturia, with most ranging from 0 to 0.8 fewer episodes of nocturia. The net reduction of an intervention, subtracting the benefit seen in the control or placebo arm is often even smaller. Whether this is due to regression to the mean due to random variation in the symptom of nocturia or a result of monitoring and problematic recording night-time voids, is unclear. Patient-level outcomes related to general satisfaction questions, nocturia- related bother, and nocturia-specific quality of life are meaningful as secondary outcome measures. Recently the time initially asleep before the first nocturia episode has been reported as a measure of severity and holds potential to describe treatment response [724, 786]. The number of nocturia episodes correlates poorly with actual hours spent in bed, and may vary considerably in older persons who have no pressing need to rise at a given time [710].

There are several approaches to drug therapy for older patients with nocturia; most of the published guidelines suggest targeting “primary” or “principal” causes of nocturia (e.g., nocturnal polyuria). Because older adults with nocturia have multiple potential causes, treatment will require combination therapies of behavioural strategies, and intervention for medical, lower urinary tract and sleep disorders. In an uncontrolled study, lifestyle modification of 1) restriction of fluid intake, 2) refraining from excess hours in bed, 3) moderate daily exercise and 4) keeping warm in bed resulted in a positive reduction of nocturia from 3.6 episodes per night to 2.7 for 56 participants aged 59-85 (mean age 74.5, 84% male) [787]. While some trials may report statistical significance for reduction in nocturia, the clinical meaningfulness of these changes if a participant still voids multiple times per night is questionable [784].

6. BEHAVIOURAL APPROACHES AND TREATMENT OF COMORBIDITY

The use of specific behavioural strategies (e.g. altering fluid intake, reducing sodium intake, leg elevation for oedema) on nocturia in older patients have largely been made based on consensus and in light of their favourable safety profile [777]. Using bedside commodes or urinals, minimising the distance necessary to reach a toilet, providing a safe, adequately lit path may reduce the risk of night-time falls related to nocturia, especially in those with underlying gait instability and other risk factors for falls.

Trials of behavioural intervention for nocturia overwhelmingly fail to differentiate between patients with known OAB and those with confirmed nocturnal polyuria. Recent work suggests that nocturnal polyuria and reduced bladder capacity may co-exist, particularly when nocturia is severe [788, 789]. The interventions differ markedly between the patient groups, meaning generic treatment does not specifically target underlying causes. The first secondary data analysis of a RCT which demonstrated that behavioural therapy, with an emphasis on pelvic floor muscle exercises and urgency suppression strategies, showed that nocturia was reduced in women (mean age 68) with urgency- predominant UI [790]. The median reduction of 0.5 episodes per night was significantly more effective than drug treatment or placebo (no reduction). A second secondary data analysis of an RCT, that did not show benefit with respect to the primary endpoint of urgency incontinence in women (mean age 55), did not show benefit of behavioural therapy plus anticholinergic medication for nocturia [791]. An additional RCT in men (mean age 64) examined the impact of the addition of either titrated bladder relaxant therapy (oxybutynin XL 5-30mg) versus behavioural therapy for pelvic floor muscle exercise after failure of alpha-blocker therapy. Nocturia was a secondary outcome; the behavioural group showed greater reductions in nocturia (mean= -0.70 vs. -0.32 episodes/night; P = .05) [785]. Trials where individuals are sub-classified by nocturnal polyuria, OAB or both pathologies and where reduction in nocturia episodes is the primary outcome are warranted.

Individuals shown to have nocturia and obstructive sleep apnoea (OSA) should be treated for OSA initially, which may reduce nocturia and associated hypertension [792]. Similarly, initial management of non-dipping hypertension or postural hypotension should precede behavioural intervention.

7. PHARMACOTHERAPY

7.1. Antimuscarinic therapy

Members of a recent nocturia consensus conference agreed on the following statements with regards to overactive bladder and antimuscarinics:

1. Most patients with nocturia do not have OAB
2. Most patients with OAB do have nocturia
3. antimuscarinics are not usually efficacious for nocturia
4. Antimuscarinics may be effective for nocturnal voids due to urgency [793, 794].

In general, if the history, bladder diary, and physical examination suggest that nocturia is related primarily or in part to OAB/DO/urgency UI, then treatment with an antimuscarinic agent should be considered. While there are several trials examining the effect of antimuscarinics for nocturia reduction, there is poor evidence for efficacy in frail older adults, with the net benefit of reduction in nocturia being 0.0 to 0.3 episodes. Use of anticholinergic medications in older people has potential for serious detrimental side effects including constipation, dry eyes and mouth and urinary retention [777].

7.2. Beta-3- adrenoreceptor agonists

Whilst there are data demonstrating the efficacy of mirabegron for the treatment of nocturia on OAB, the effects are small, but superior to placebo treatment & tolterodine in a systematic review & meta-analysis [795]. In an exploratory pilot study investigating the effectiveness of mirabegron for improving sleep disturbance and nocturia, 34 men and women with disordered sleep and lower urinary tract symptoms received mirabegron 25 mg daily for 4 weeks, then 50 mg. Patients completed the Patient-Reported Outcome Measurement Information System Sleep Disturbance Short Form (PROMIS-SDSF), Jenkins Sleep Scale (JSS), International Prostate Symptom Score (IPSS), voiding diaries, and QoL questionnaires. The PROMIS-SDSF scores decreased from 26.5 points to 19.3, representing a categorical improvement from clinically 'mild' to 'none to slight' sleep disturbance ($p < 0.001$). JSS scores also decreased from 14.1 to 8.3 ($p < 0.001$). Voiding diaries revealed 0.8 fewer night-time voids ($p < 0.05$). There are no data which report efficacy in older or frail older adults [796].

7.3. Agents directed towards benign prostatic obstruction

Alpha-adrenergic agents used in patients with symptoms suggestive of BPO have a modest impact on nocturia, with a mean reduction of slightly less than one episode per night [754, 797]. 5-alpha reductase inhibitors [754] and saw palmetto (*Serenoa repens*, saw palmetto berry extract) [798] have not shown statistical benefit for nocturia except in one study within one subset of participants age >70 years [781]. This statistical advantage did not persist beyond one year, and the net benefit compared to placebo was a difference of < 0.2 fewer nocturia episodes. A recent systematic review concluded that potentially small benefits of α-blockers alone for the treatment of nocturia in men should be weighed against the risks of orthostatic hypotension and the risk of subsequent falls and that there was no evidence to support use of alpha-blockers in women [777].

7.4. Other medication approaches

Among postmenopausal women, one uncontrolled trial of oestradiol in combination with a progestogen showed a dramatic reduction in nocturia over 6 months [799]. There are few studies that have focused on treatment of nocturia with the use of medications for sleep. One RCT evaluated melatonin for treatment of nocturia associated with BOO in older men [800, 801]. Melatonin showed only a trend towards reduction in nocturia compared to placebo but did significantly reduce reported bother from nocturia. Reducing volume overload associated with lower extremity venous insufficiency or congestive heart failure with a late afternoon dose of a rapid acting diuretic may be helpful in reducing nocturnal polyuria and nocturia in selected patients [802, 803]. Treating sleep apnoea with continuous positive airway pressure can reduce nocturia severity, but these trials exclude the frail older adults [804].

7.5. Antidiuretic treatment: desmopressin

There is a potential role of exogenous AVP (desmopressin or DDAVP) for the treatment of nocturia in older patients [805-818] with meaningful reductions in nocturia and nocturnal urine volume and increases in first undisturbed sleep period. A major concern related to DDAVP treatment in older patients is fluid retention (which can exacerbate underlying cardiovascular disease) and hyponatraemia [819]. Many older adults may have pre-existent hyponatraemia due to a variety of medical conditions and drugs and will develop re-

nal insufficiency or congestive heart failure [820, 821]. Because so few frail older adults are included in anti-diuresis trials, the actual incidence of clinically significant hyponatraemia from DDAVP that might occur is unknown. Use of DDAVP is currently limited by risk in frail older adults and has been identified as a potentially inappropriate medication in the Beers [553]. Low dose sex-specific DDAVP has been shown to be effective in adults with nocturia and nocturia due to nocturnal polyuria, but not in frail older adults, without significant hyponatraemia [822, 823] [824]. A randomized controlled trial of desmopressin nasal spray (10 µg/spray once daily or placebo) in community dwelling older adults with nocturnal polyuria, showed that desmopressin was not superior to placebo with respect to micturition frequency or sleeping hours. Those with decreased ADH levels seemed to benefit from treatment with desmopressin. The unexpected results in the placebo group were thought due to the intensive outpatient care and information on NP given to all patients [825].

Summary of the evidence

Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions. **(LoE 2)**

If OAB, DO, and/or urgency UI is felt to be a major contributor to nocturia, antimuscarinic agents should be considered. **(LoE 3)**

If nocturia is due to insomnia alone, then a very-short acting sedative hypnotic may be considered. **(LoE 3)**

DDAVP (0.1microgrammes) should not be used in frail older adults because of the risk of hyponatraemia. **(LoE1)**

Recommendations for management

Nocturia investigations should be carried out utilising both frequency-volume charts and validated questionnaires capturing QoL, and bother related specific to nocturia (e.g., NQoL). **(GoR C)**

Recommendations for research

- Validation and clarification of the definition of both nocturia (in regard to any night awakening owing to the desire to pass urine, the ICS definition vs. the more clinically bothersome nocturia, of 2 or more episodes)
- Ways in which to understand, and potentially diminish, the robust effect of placebo/control arms
- Epidemiological research regarding studies of nocturia involving the following aspects: incidence/ natural history, bother, effect on quality of life
- Further clinical trials examining the impact of sleep focused treatments
- Trials examining the effects of multiple incremental and multicomponent therapies for nocturia

X. FAECAL INCONTINENCE IN FRAIL OLDER ADULTS

1. INTRODUCTION

Faecal Incontinence (FI) in older people is a distressing and social isolating symptom and is associated with a possible increased risk of morbidity [826, 827] and dependency [827-830]. Frailty is an independent risk factor for FI in community-based and institutionalised populations of older adults [347, 831-834] Many older individuals with FI will not volunteer the problem to their general practitioner or nurse, and, health care providers do not routinely enquire about the symptom or follow guidelines regarding evaluation and treatment [835-837]. The condition can especially take its toll on caregivers of home-dwelling patients, [838] with FI being a reason for requesting nursing home placement and leading to early mortality, especially in those with complex disease [827, 828, 839-841]. FI is associated with a significant decline in physical function in older adults [842] and any FI is associated with an increased risk of falls in older adults [342].

Even when older people are noted by health care professionals to have FI, the condition is often managed with the use of absorptive or containment products, especially in the long-term care setting where it is most prevalent. The importance of identifying treatable causes of FI in frail older people rather than just managing passively (e.g. pads provision without assessment) is strongly emphasized in national and international guidance, [826, 843] but audits show that adherence to such guidance is generally poor, with non-integrated services, and sub-optimal delivery by professionals of even basic assessment and care [837, 844].

For the 7th ICI, the literature review covered the period 2016 to 2021. Readers interested in seeking older data are referred to the relevant Chapter in the 6th ICI

FI is strongly associated with ageing in many studies and studies only involving older adults have higher prevalence estimates. The National Health and Nutrition Examination Survey (NHANES) in the United States (US) provides one of the best estimates of FI prevalence to date because it surveyed both sexes, all major races represented in the US, and a range of older adults by age decade (55-69 and 70 years of age and older) [845, 846]. NHANES also provided separate estimates for different types of FIS (e.g., solid, liquid, mucus, and flatus) and frequencies of stool loss. The age-adjusted prevalence of FI (defined as accidental loss of solid, liquid, or mucus incontinence in the month preceding the interview) in the non-institutionalised population of the United States is 8.9% of women and 7.7% of men, with higher rates in older adults (16.6% in adults aged 70 years of age and older, equally prevalent in older men and women) [845, 846]. Liquid stool incontinence was the most common type of FI reported in the NHANES data. Rates of FI in older, frail adults are not sex-specific, with recent studies suggesting equal rates of FI among older men and women [830, 831, 847-851].

2. PREVALENCE AND INCIDENCE ESTIMATES OF FI

In a study of 2517 older adult residents from 883 long term care facilities in Japan, 44 (1.7%) and had FI only and 1034 (41.1%) had

double incontinence [202]. In a multisite cross-sectional survey of 10 rural villages in China (1250 residents), the prevalence of faecal and double incontinence was 12.3% and 9.3%, respectively. Factors associated with faecal incontinence included urinary incontinence, lack of social interaction, traumatic brain injury, cerebrovascular disease, and poverty. Physical activities of daily living dependence, traumatic brain injury, lack of social interaction, and poor sleep quality were associated with higher odds of having double incontinence [852]. In a study in urban China, prevalence of FI in 28 196 adult females was 0.43% (95% confidence interval: 0.35%-0.51%). Among women with FI, 42.96%, 82.96%, and 42.22% reported having leakage of solid, liquid stool, and gas, respectively. The overall FI prevalence and the incidence rate of solid stool/liquid stool/gas leakage increased with age [853]. In a systematic review (up to 2017) of 23 studies of FI in older care home residents, there were 12 high-quality studies, 5 medium-quality studies, and 6 low-quality studies. The medians for prevalence (as reported by the studies) of isolated feacal incontinence, double incontinence, and all feacal incontinence were 3.5% [interquartile range (IQR) = 2.8%], 47.1% (IQR = 32.1%), and 42.8% (IQR = 21.1%), respectively. The most frequently reported correlates of faecal incontinence were cognitive impairment, limited functional capacity, urinary incontinence, reduced mobility, advanced age, and diarrhoea [854].

In an international cross-sectional study comparing the prevalence of incontinence among cognitively impaired older residents in long-term care facilities in East Asia, including Japan, Korea, China, Taiwan and Thailand between 2015 and 2016 of 662 participants (age 82.6 ± 9.9 years, 57.6% women, the prevalence of urinary incontinence ranged from 10.1% in Taiwan to 71.0% in Korea. The prevalence of faecal incontinence (FI) varied from 4.0% in Taiwan to 57.0% in Korea. A higher Clinical Dementia Rating score was a significant predictor of urinary and FI and toilet use dependence (P < 0.0001) For adults receiving home hospice care, in a retrospective cohort study the prevalence of FI was (64.5%; n = 4314) of 15 432 patients Increasing age represented a risk factor for FI (hazard ratio [HR] = 1.01 [confidence interval, CI = 1.01-1.01]) FI was detected on average 18 days after home hospice admission [855].

A nationally representative sample completing an internet survey on GI health in Mexico reported that among 71,812 individuals 14.4% reported FI in the past; of these, 33.3% had FI within the past 7 days. Older age, male sex, and Hispanic ethnicity increased the likelihood of having FI within the past week. Individuals with Crohn's disease, ulcerative colitis, coeliac disease, irritable bowel syndrome, or diabetes were more likely to report FI. Non-Hispanic black and Hispanic individuals and individuals with Crohn's disease, coeliac disease, diabetes, human immunodeficiency virus/acquired immunodeficiency syndrome, or chronic idiopathic constipation had more severe symptoms of FI than individuals without these features [856].

In a Brazilian prospective study in women aged 65 years or older evaluated in 2006 and re-evaluated in 2010, including 864 older women, the prevalence rate of double incontinence (DI) was 4.9%. The incidence rate of DI in the period between 2006 and 2010 was 13.8/1,000 person-years. Associated factors were the presence of chronic obstructive pulmonary disease, hypertension, difficulty with basic activities of daily living (BADL) and instrumental activities of daily living (IADL), polypharmacy and falls in the last year. Poisson's regression analysis showed that falls in the last year and difficulty with at least three IADL were risk factors for DI [857] .

Data on the prevalence of faecal incontinence in elderly patients admitted to outpatient clinics in Turkey were addressed in older outpatients in a cross-sectional survey. Three hundred and sixty-four patients (64.8% female, n = 236) with a mean age of 73.2 ± 8.1 years were enrolled. The prevalence of FI was 9.9% (10.2% female, 9.4% male). UI was 42.6%. Co-occurrence of FI and UI was 7.4%. The most frequent type of defaecation was liquid stool (61.1%). While the predictive factors for FI were polypharmacy (standardized coefficient, [r] = 0.203, 95% confidence interval [CI] = 0.009-0.040, p = 0.002), UI (r = 0.134, 95% CI = 0.006-0.156, p = 0.035), and being married (r = 0.200, 95% CI = -0.088 to -0.020, p = 0.002) in females, In males they were UI (r = 0.306, 95% CI = 0.093-0.309, p < 0.001) and polypharmacy (r = 0.251, 95% CI = 0.009-0.043, p = 0.003) [858].

3. FAECAL INCONTINENCE IN OLDER ADULTS – THE "HIDDEN" PROBLEM.

Evidence reaffirms that about 30% of adults with FI seek care and that health care practitioners are not likely to inquire or document discussions regarding FI [836, 837, 839, 859-861]. Increasing awareness is important aspect of the identification, prevention, and treatment of FI in older adults [826]. Using appropriate terminology for FI for individuals that is consistent with health literacy levels may be an important factor. Terminology such as "bowel" or "accidental bowel leakage" may be more appropriate than the term "faecal" or "faecal incontinence" [862]. Barriers that prevent adequate identification and treatment include social and cultural issues about discussing symptoms, duration of symptoms, perception that treatments may not exist, access to trained health care providers in the community, access to providers in long-term care settings, and access to training and treatment protocols. Given the high prevalence rates of FI in the hospital, home care, and long-term care settings, health care practitioners should directly inquire or directly observe bowel control issues and document any findings. Other high-risk groups of older adults that should be questioned about bowel control include older adults that have mobility problems, cognitive impairment/dementia, frailty, prior pelvic/lower abdominal radiation exposure, prior anal or rectal surgery, urinary incontinence, chronic constipation, chronic diarrhoea, and older adults with multi-morbidity.

4. PHYSIOLOGICAL FACTORS SPECIFIC TO FRAIL OLDER ADULTS.

Physiological studies of the lower bowel in older adults tend to be variable due to a) a variety of different techniques used in measuring anorectal function, b) unclear definition of the normative range of manometric measures for older people, c) poor matching between cases and controls of clinical factors which may affect gut function (e.g. level of mobility or functional status), or inadequate clinical information, d) usually small subject numbers, e) few studies deal with subjects over 80 years, and f) improvements in imaging quality with anorectal manometry with new 3-dimenisional equipment, endoanal ultrasound, and MRI with and without defecography [863-866]. Studies reviewed are cohort case-control to evaluate age-effect, [867-874] young-old healthy subject comparisons,[875-878] and age- and sex-matched case-control studies of continent versus incontinent patients [879, 880] .

5. ANORECTAL FUNCTION IN HEALTHY OLDER ADULTS

Studies of age effect in healthy volunteers have shown a linear reduction with ageing in squeeze pressures (external anal sphincter tone) in women after the age of 70, and in men from the 9th decade onwards [874]. Studies of normal men and women demonstrated a significant but similar linear decrease in anal resting pressure and maximum squeeze pressures in both men and women with increasing age [878, 881]. Studies of asymptomatic females showed a significant decrease in both anal resting and squeeze pressures with age [881, 882]. Two studies comparing young and old continent women found a decrease in anal resting pressure but no decrease in squeeze pressures between the two groups [869, 876]. Age beyond 70 years was associated with reduction in anal resting pressures (internal anal sphincter tone) in both sexes, but to a greater degree in women than men,[872, 874] but not reaching statistical significance [883].

Rectal sensory thresholds may also decrease with ageing in healthy older adults despite normal compliance and tone [877]. There was a significant increase in pudendal nerve latencies with age in women; [873] however, clinical practice guidelines do not recommend testing pudendal nerve latencies [884]. In patients older than 65 years there is >30% loss of enteric neurones when compared to people aged 20 to 35 years. This loss is associated with an increase in fatty tissue deposition [885]. Increase in thickness of internal sphincter may be related to an increase in collagen deposition, with increased thickness seen in older versus younger women and in older nulliparous women [871, 876]. In addition, the increase in internal sphincter thickness was associated with a significant decrease in the external anal sphincter thickness in women [863, 886, 887]. A study of men and women using endoanal MR imaging showed a significant decrease in the external anal sphincter thickness in men but not women with age [888].

Other studies in humans have found increases in elastin and collagen deposition in the myenteric plexus in the colon. It is unclear if rectal motility is affected by healthy ageing, [889] but there is an age-related increase in anorectal sensitivity thresholds [873, 877, 878]. Rectal compliance was not affected in one study but reduced rectal sensation was associated with reduced rectal compliance in another [877, 881]. Other studies have evaluated the impact of the relationship of glycaemic control on gastric emptying and found that fasting blood glucose levels were associated with faster gastric emptying [890].

Gut microbiome and metabolome studies in older adults show that diet and antibiotic usage have an impact on gut microbiome and metabolome findings [891, 892]. Older adults residing in long-term care have less variation in the gut microbiome compared to older adults in the community [893]. Changes in the gut microbiome from older adults in long-term care settings may also be influenced by diet and inflammatory biomarkers [893].

5.1. Anorectal function in older adults with faecal incontinence.

Studies have reported an age-related increase in pudendal neuropathy in incontinent women, which may be unrelated to squeeze pressures [894, 895]. A study comparing anorectal function in young (mean age 42) and old (mean age 72) women with FI (patients with constipation and/or pelvic floor dysfunction excluded) showed that older women were more likely to have bilateral pudendal neuropathy, but less likely to have a sphincter deficiency of >90 degree and less likely to have had a previous sphincteroplasty [875]. Anorectal function in older incontinent patients and continent age- and sex-matched controls showed that individuals with FI had reduced anal resting pressures [876, 896]. In one study comparing 8 older incontinent women (mean age 71.6 SD 7.5) with 9 older continent women (mean age 71.6 SD 7.5) and 9 younger continent women (mean age 28.7 SD (7.3) found women with FI were more likely to have decreased maximum squeeze pressures and levator ani (LA) defects [897]. Older FI females tolerated lower balloon anorectal manometry volumes before urge to defaecate indicative of rectal hypersensitivity [876].

6. CAUSES OF FAECAL INCONTINENCE IN OLDER ADULTS

Stool consistency is important aspect of determining the cause and the associated factors for the evaluation of FI in an older adult [898-900]. Loose, as well as hard, stool can be related to FI in frail, older adults [901 - 903]. Evidence shows that loose stool consistency and chronic diarrhoea are important contributing factors for FI [898-900, 904] [9179734]. Loose stool and chronic diarrhoea can result from multiple causes, such as malabsorption syndromes (e.g., lactose intolerance, gluten sensitivity, and fat-malabsorption), acute diarrhoeal illnesses, microcytic colitis, irritable bowel syndrome (diarrhoea dominant), and other chronic diarrhoea. Any change in stool consistency along with other warning symptoms (weight loss, bloody stools, change in stool calibre, and painful defaecation) should prompt further evaluation for colorectal cancer. Potential reversible causes of loose stools may include excessive laxative use, lactose intolerance, drugrelated sideeffects, bacterial overgrowth, and possible bowel obstruction with “overflow” FI. “Overflow” FI secondary to constipation and stool impaction is also important to consider in older adults, potentially more common in men than women [905, 906] those with mobility problems, [902, 903, 907] and those that reside in nursing home settings [902, 907]

Overflow incontinence or FI resulting from stool impaction can be difficult to diagnose, may be more common in certain frail, older populations, and should be evaluated and treated when suspected. Evidence suggests that constipation and symptoms of constipation are common among nursing home residents with FI [902, 907, 908]. However, the true prevalence of impaction and FI in nursing home residents remains unclear. Constipation and associated symptoms (straining and incomplete evacuation) were common among nursing home residents in a 4-site randomised controlled trial to improve FI and urinary incontinence among nursing home residents [902]. At baseline, 81% of the 111 nursing home study participants had less than 3 bowel movements in 5 days. Another study that identified factors associated with FI in different health care settings found that 70% of nursing home residents experienced “faecal loading” compared to 63% in rehabilitation wards, 57% in acute care wards, and 20% in the home care setting [907]. Constipation is also associated with FI in non-nursing home dwelling older adults [909].

Urgency associated with bowel movements should be assessed in older adults. Many studies do not evaluate urgency as an independent risk factor. However, among the studies that evaluated a sense of urgency associated with bowel movements, urgency consistently is strongly related to FI and having a negative impact on quality of life even after controlling for other known confounding factors [899, 909-911].

Other bowel-related disorders or complications of prior anorectal surgery and radiation can contribute to FI in older adults who otherwise would be continent, especially when functional status, mobility and cognition become impaired. Other bowel related disorders that have been associated with FI in adults (but not limited to frail older adults) include: haemorrhoids, [875, 905], posterior compartment prolapse (rectocele), [900], inflammatory bowel disease, [856, 912] and irritable bowel disease [856, 900, 913]. Types of prior anorectal surgery that contribute to FI include: haemorrhoid surgery, [905], prior fistula repair, [914, 915] sphincterotomy for anal fissures, [916], partial or total colectomy, [917] low anorectal resection and re-anastomosis for colorectal cancer, [918, 919], prostatectomy, [850] and prior pelvic/perineal radiation [850, 920]. All of these bowel-related disorders, surgeries, and radiation should be part of the focused history in older adults with FI. More studies are needed to identify causal pathways for FI in the older adult.

Functional FI, defined by mobility problems or restricted accessibility to the toilet despite normal bowel sensation and capacity, is also cited as a common reason for FI in epidemiological studies among community-dwelling older adults and those in residing in nursing homes [204, 832,833,901,921-928].

Other causes of FI in older adults can be related to **co-morbid chronic disorders, increased body mass index, and multimorbidity, especially diabetes and neurological disease**, which increases the risk having FI. Number of comorbidities and number of drugs have been associated with FI in a Spanish population-based study of people older than 65 years [909]. Poor self-rated health and depression are associated with bowel symptoms in adults 50 years and older [929]. Even after adjusting for age and sex, diabetes mellitus is associated with gastrointestinal symptoms including FI in population based studies, [909, 930-932], nursing home residents, [928] and has been associated with impaired rectal sensitivity and sphincter weakness [933]. Neurological diseases that contribute to FI in older adults include cognitive impairment, stroke, traumatic brain injury, and sacral cord dysfunction. Older adults are living longer with significant neurological conditions. Cognitive impairment and dementia have been found to be independent risk factors with FI in older adult populations from epidemiological studies and among those in nursing homes [850, 901, 922, 924]. Having a stroke is an important risk factor for FI with three and half times the rate of FI compared to adults who did not have a stroke in one population-based study [934]. FI affects 30-56% of stroke survivors in acute period after having a stroke (1-30 days), with a lower prevalence (11%) of FI after 3-months, and 11-22% at 12-months following the initial stroke event [935, 936]. Recent evidence demonstrates toileting disability can be present after stroke potentially linked to behavioural, cognitive and physical function impairments [388].Traumatic brain injury has also been linked with urinary incontinence and FI, but limited data exist on older adults from registry studies and single site studies [937, 938]. Spinal cord injury (depending on the level of injury) may result in impaired muscular strength of the external anal sphincter, delayed transit time, abnormal defaecation reflexes, and impaired sensation [939].

Summary of evidence for prevalence and risk factors for FI in frail older adults

Summarised below are key points that are specific to the frail elderly population. The level of evidence is given in brackets.

- FI affects 1 in 5 older people (aged 65+) living in the community and in residential care facilities, and half of those residing in long-term care homes [**LoE1**]
- The prevalence of FI increases with age alone, particularly in the 8th decade and beyond **[LoE1]**
- The prevalence of FI is higher in the acute hospital, and nursing home setting than in the community **[LoE 1]**, thus the group most affected is frail older people.
- The prevalence of FI in frail older men is equal to or greater than in women in the community and in long-term care residents **[LoE 2].**
- The prevalence of FI varies dramatically between institutions in nursing home studies due to measurement differences **[LoE 2].**
- FI usually coexists with urinary incontinence in frail older people **[LoE 1]**
- Aside from age, the following are primary risk factors for FI in older people **[LoE 2]:**
  - Stool consistency -- Loose stool
  - Bowel-related disorders, such as prior rectal surgery
  - Impaired mobility
  - Functional impairment
  - Dementia
  - Neurological disease
  - Diabetes mellitus
  - Chronic medical conditions
  - Depression
- Loose stool or diarrhoea may be a cause of transient FI in older people, if the diarrhoea is evaluated and treated **[LoE 2]**
- Faecal loading and constipation are clinically linked to FI, but there is little epidemiological work assessing this association **[LoE 3]**
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people **[LoE 2]**
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI **[LoE 2**], and there is a tendency toward passive management (e.g., use of pads only without further evaluation) [**LoE 2].** Faecal loading is often present in older care home residents with FI **[LoE 2]**
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider for social or cultural reasons, or due to a popular misperception that the condition is part of the ageing process and therefore 'nothing can be done about it' **[LoE 2]**
- FI is associated with reduced quality of life, and poor health perception **[LoE 2]**

Recommendations – identifying faecal incontinence in frail older people

Bowel continence status should be established by *direct questioning and/or direct observation* in:

- all nursing/long-term care and residential home residents
- hospital inpatients aged 65 and over
- people aged 80 and beyond living at home
- older adults with impaired mobility
- older adults with impaired cognition
- older adults with neurological disease
- older adults with chronic disease, especially diabetes
- older adults with constipation
- Primary care staff, hospital ward staff, home health staff, and long-term care staff should routinely enquire about FI in frail older patients
- Enquiry about FI should be systematic and include stool consistency, severity of FI and impact on activities of daily living and quality of life
- Health care providers should be sensitive to cultural and social barriers discouraging patients from talking about the condition
- Frail older patients with restricted ability to access primary care such as nursing home residents, and those with mobility, chronic illness, or cognitive impairment, should be screened for FI through systematic case-finding methods
- Systematic outreach programmes which make it easier for frail older people and those who care for them to volunteer the problem to their primary care provider should be implemented
- There are significant geographical variations in provision of specialist expertise in bowel care (both medical and nursing) nationally and globally, which may affect case-finding in older people
- Further examination of underlying reasons for the variations in prevalence of FI between nursing homes (standards of care, patient case-mix, reporting) is needed
- Urinary and FI often coexist; continence care workers (e.g., nurse specialists) should be trained in identification and management of fecal as well as urinary incontinence in older people
- Key requirements to improving detection in the practice setting should be implemented:
  - education of health care workers to embed both a sense of value in identifying FI, plus confidence that the condition can be treated
  - protocols should be in place clarifying all details of screening enquiry (who will ask, how to ask, when to ask, and who to ask)
  - patients and caregivers should have access to educational materials at the point of enquiry

7. EVALUATION OF FI IN FRAIL OLDER ADULTS

The algorithm contained in this chapter delineates a systematic approach to the clinical evaluation of frail older people with FI.

An initial assessment can be undertaken by any suitably trained health care practitioner, often this will be by either a physician or nurse practitioner. In the majority of cases, a clinical history of bowel symptoms, dietary assessment, [884, 940] and symptom evaluation will provide sufficient diagnostic information upon which to base further management. As many older patients will not offer the information, it is important for primary care providers to ask about feacal incontinence as well as urinary incontinence [941] Using questionnaires for assessment of symptoms is recommended, although psychometric validation of specific instruments to asses FI severity and impact on quality of life in frail older adults compared to healthy adults are not available. In spite of this, symptom assessment instruments can provide insight into concerns such as feacal urgency in nursing home residents [942], although high rates of dementia among residents may limit usability in some settings. Bowel diaries, including assessments of stool consistency, may also be useful to diagnose the type and frequency of FI [943, 944].

Physical examination should include skin inspection, pelvic exam (females) and a digital rectal exam. Faecal incontinence is also associated incontinence associated dermatitis, development of pressure injury and higher body mass index in older nursing home residents [945]. Thus, an assessment of skin integrity and provision of appropriate pressure relief is important. A pelvic examination to rule out rectal prolapse and posterior compartment vaginal prolapse is also important given the association between prolapse FI and other pelvic floor disorders in older community dwelling women [946]. A digital rectal examination should be undertaken to assess anal sphincter tone [944]. Digital rectal examination can assess resting anal sphincter tone, muscle isolation, and squeeze pressure and appears to be as good as sphincter manometry in discriminating continent from incontinent people. Constipated patients should also have an abdominal exam; those with an empty rectum on digital examination may have high impaction. Abdominal radiographs to assess the extent of faecal loading and to rule out an obstruction or sigmoid volvulus could be considered. For adults with FI, it is important that current guidelines for colon cancer screening be followed, along with careful consideration of screening in older adults with limited life expectancy [947]. While a change in bowel habits with weight loss, anaemia, rectal pain and rectal bleeding should raise the suspicion of an underlying malignancy, prior review of colonoscopy findings and discussion with gastroenterologists for further testing may be warranted. The symptom of FI and chronic constipation does not usually warrant colonoscopic investigation, however, little data exist to guide evaluation in frail older adults. The use of formal testing is hampered by both lack of relevant data from frail older people and the poor correlation between symptoms and abnormalities [869, 875, 948, 949, 863, 864, 869, 950-952]. Given the increased difficulty of adequately preparing frail older people for either endoscopy or barium studies and potential increased risks of hyponatraemia with hospitalisation [949, 953]; CT colonography, although not studied in frail older adults, may be considered as an alternative investigation where available as no sedation is required

[947]. Toileting disability may be present in frail older persons in residential care [333] and the evaluation of the capacity to successfully toilet should include an assessment of mobility, visual acuity, manual dexterity and cognition. If acceptable to the older person, observing the process of transferring to the toilet, manage their clothing, redress and leave the lavatory is a good measure of ability. Caregivers should additionally be aware of the surroundings in which the frail older person lives in terms of access, lighting, distance and clutter. The design of commodes should also be considered in the light of the individual's capabilities.

Evidence that the assessment of faecal incontinence in older people is poorly done, despite the existence of guidelines, has been a persistent finding throughout the history of this chapter and in other guidelines [837, 954]. What actions need to be taken to ensure that older people receive assessments which are consistent with current guidelines remain to be defined.

8. TREATMENT OF FI IN FRAIL OLDER ADULTS

In the previous review, it was noted many FI intervention studies have small sample sizes, inadequate power to detect clinically meaningful difference in outcomes, and biased methodology along with low strength of evidence ratings [955, 956]. Interventions for FI are reviewed in detail in Chapter 15

As in the previous edition, this section addresses FI treatments applicable or potentially applicable to older adults including multi-component behavioural treatments for FI, pharmacological treatments for FI, treatments aimed at specific populations of older adults (e.g. nursing home populations and neurological conditions), anal bulking injections, transcutaneous and percutaneous tibial nerve stimulation, bowel-control devices, and less-invasive surgical options. The section on combination biofeedback, behavioural treatments for FI was modified to include studies that included pharmacological treatments for FI combination with biofeedback and behavioural treatments. Issues related to more invasive surgery (including sacral nerve stimulation and antegrade continence enemata), containment with absorptive products or devices, and skin care are discussed in other chapters

8.1. Prevention of FI in older persons

Using data from the US Nurses Study, the association of risk of FI and long-term dietary fibre intake was studied in 58330 older women with a mean age of 73 years. Women in the highest quintile of fibre intake (25 gm/day) had an 18% decreased risk of FI [957]. Although this study focused on older women, no data on frailty were provided.

8.2. Multi-component biofeedback and behavioural treatments +/- pharmacological treatment for FI.

In the previous edition it was noted that few studies exist in the literature involving multi-component interventions for FI in older adults. In some studies, old persons are included, but those with risk factors for frailty such as stroke, cognitive impairment and neurological diseases such as Parkinson's are excluded e.g., Ussing, 2019 [958]. Given the multifactorial causes for FI in frail older adults and the wide range of ages in many trials, a definitive assessment of the role of pelvic floor muscle training and/or biofeedback, pharmacologi-cal therapy in the treatment of FI, or the treatment of FI and constipation in adults with central neurological diseases remains unclear as previously reported [959-962]. A small descriptive pilot study of a patient-controlled biofeedback device (n= 10 women, mean age 64.1 years, range 50-73 years) reported improvement on manometric, FI symptom scores and quality of life but details about the participants are minimal [963]. Given the demands of using the device it is not clear if frail older women would be able to benefit.

Studies that incorporated pharmacological treatment in the combination have included broad age range of participants with limited or no subgroup analysis of data from older participants. The last version included an RCT of 57 women attending an anorectal clinic (mean 58 years range age), treated with biofeedback on pelvic floor contraction, stool bulking agents (stericulia or isphagula husk) and loperamide showed a decrease in FI, urgency and loose stool [964]. However, those with neurological conditions and insulin dependent diabetes were excluded. In a recent four arm US trial in which 300 women (mean age 63.7 ±11.1) were randomized to placebo plus education, placebo with anal exercise plus biofeedback, loperamide plus education or loperamide plus anal exercises plus biofeedback, no treatment or treatment combination was found to be superior,[965] leading the authors to recommend combining loperamide, anal manometry-assisted biofeedback and a standard educational pamphlet with counselling on possible constipation. Those with neurological disorders, including Parkinson's and inability to provide written consent were excluded. Although both studies included older women, exclusion criteria potentially limit application to the frail population.

8.3. Pharmacological treatments for FI.

No studies focused solely on frail older adults were identified. Low-strength evidence exists that psyllium may be beneficial compared to placebo for improving FI episodes (n=206, mean age 55-60 years per randomisation group) [966]. Psyllium was better tolerated while having no differences in efficacy compared to loperamide for improving FI episodes (n=80, mean age 61 ±10 years) [967]. A non-randomised case series of methylcellulose also reported improvement in FI (N= 83, mean age 65 years SD +/- 12 [968]. No new trials of laxatives in frail older persons to treat constipation and faecal impaction leading to FI were identified.

According to the 2016 AHRQ review [955] included in the last edition, evidence was treatment benefit was insufficient for loperamide, topical phenylephrine, zinc-aluminium ointment, oestrogen cream, and valproate sodium. Clonidine given orally was not effective for improving FI severity compared to placebo. No new studies in frail older persons were identified.

Small studies were previously reported on the evaluation of the safety of a new adrenergic alpha-1 receptor agonist suppository to improve anal sphincter tone, NRL001, for FI treatment in adults, with safety data in older participants [969, 970]. Results from a 4 group parallel designed placebo-controlled RCT (n=446, mean age 62.1 years) did show difference in FI severity scores after 8 weeks of treatment with 3 different dosages of the alpha-1 receptor agonist suppository compared to placebo [971]. No new studies in older adults were identified. Evidence for pharmacological treatments for improving FI in community-dwelling frail older adults with cognitive or functional impairment was again not found.

8.4. Treatment of FI in long-term care/nursing home settings.

Treatments for FI in long-term care settings have involved the treatment of constipation and faecal loading or faecal impaction. Two studies were previously reported. In a French RCT (n=206 nursing home residents in 4 homes) lactulose alone was compared to lactulose plus daily suppositories along with weekly enemata. Although there was no difference in FI episodes between the groups,

residents in the intervention group that achieved complete rectal emptying had 35% reduced number of FI episodes by 35% with staff workload reduction of 42% compared to the rest of the group. [908]. Schnelle *et al* (2010) completed a multi-centre, multi-component RCT for improving FI and constipation in 112 cognitively impaired nursing home residents (mean age 86 ± 10 years) [972] . The intervention group received toileting assistance, exercise, and choice of food/fluid snacks every 2 hours for 8 hours/day for 3 months, with improved bowel movement frequency and percentage of bowel movements in the toilet ($p<0.01$), but not the frequency of FI episodes Urinary incontinence episodes also improved with this intervention ($p<0.05$). 29 nursing home residents had ano-rectal manometry, with a dyssynergic defaecation pattern identified in 89%. The authors concluded further work to improve stool consistency and treatments for dyssynergia may be warranted. No new studies of laxatives for constipation or faecal loading in the nursing home setting were identified.

Additional work is ongoing to improve nursing education, evaluation, and treatment of FI in long-term care settings [973, 974] . By improving knowledge of nursing staff, outcomes related to FI management and treatment may also improve [973]. A recent realist synthesis of what works to improve FI in care home residents [975] highlights the importance addressing dementia and FI in this setting. Potential areas for improvement include clinician led support, ongoing feedback to staff, interventions suitable for the cognitive and physical capacity of residents, common understanding of potential reduction and recovery and integrating the care of persons living with both dementia and FI into the everyday patterns of work for staff.

8.5. Treatment of FI in Adults with Neurological Conditions

In the previous edition, it was noted that a 2014 Cochrane report on the treatment of FI and constipation in adults (not yet updated) reviewed evidence from 20 clinical trials involving 902 adults [961]. and concluded that “remarkably little research” and “low methodological quality” evidence exists on bowel management in specific neurologic conditions. Most of trials are single site, measuring outcomes against control and without comparative effectiveness data. Individuals’ trials did report symptom improvement using bulk-forming laxative (psyllium) in Parkinson’s disease, an isosmotic macrogol laxative to manage bowel symptoms, abdominal massage, electrical stimulation and an anticholinesterase-anticholinergic drug combination (neostigmine-glycopyrrolate) in spinal cord injury compared to no treatment or controls. There was also evidence in favour of transanal irrigation (compared to conservative management) in spinal cord injury, oral carbonated (rather than tap) water, and abdominal massage with lifestyle advice (compared to lifestyle advice alone) in stroke survivors [961]. A previously reported 2015 RCT among 200 bedbound acute care patients over 60 years with acute neurological impairments were randomised to a suspension positioning system or usual care. Rates of perianal faecal contamination, skin break-down, incontinence associated dermatitis, pres-sure ulcer development, and urinary tract infection (UTI) were significantly lower in intervention vs usual care group ($p<0.05$) at 6-months after treatment [976]. Two new studies of transanal irrigation adherence that included older persons were identified. In a descriptive study of 507 patients using transanal irrigation (mean age 56, range 19-86 years) attending an anal physiology clinic with either FI or constipation reported 216 had continued use at 1 year with symptom improvement [977]. In the second retrospective study of (n= 108, predominantly women (mean age 55 years, range 18-83, only 43% continued to use the procedure after one year, with discontinuance attributed to technical problems or constraints [978]. Neither study provided detail on older participants health history nor was subgroup analysis of older persons was reported, limiting understanding of use of this technique among frail older persons.

8.5.1. Perianal injectable bulking agents for the treatment of FI

Perianal injectable bulking agents for the treatment of FI identified in the previous review have limited data related to older, frail adults [955, 979]. Use of dextranomer tissue-bulking injections were more effective than sham injections for improving FI-free days, 50% reductions in FI episodes and quality of life (n=206, mean age 61 years, age range for recruitment 18-75 years), but not more effective than pelvic floor muscle exercises and biofeedback (n=126) [955, 980, 981] One new small non randomised study (n= 17, mean age 54, range 40-87, 16 female) of patients who had failed conservative treatment received injection with hyaluronate [982]. Fourteen patients met the criteria for successful treatment (greater than 50% improvement on FI events) after first injection. No detail on the older persons included in this study were provided, thus the utility of this treatment in frail older people is not clear.

8.6. Percutaneous tibial nerve stimulation (PTNS) for FI

Two trials were included in the previous edition. In one trial, PTNS was compared to sham stimulation in an RCT (n=227 mean age 58 years) [983]. After 12 weeks of treatment, both groups had improvements with at least a 50% reduction in FI episodes, participants in the PTNS did reporting improvements in the total number of FI episodes ($p=0.02$) and the urge FI episodes ($p=0.02$) compared to sham stimulation group. Those with neurological diseases (Parkinson’s, diabetic neuropathy) were excluded; no subgroup analysis of older participants is reported. The other was pilot study in older adults (mean age 84.2 ± 10 years), transcutaneous posterior tibial nerve stimulation (TPTNS) or sham stimulation was given weekly for 12-weeks to older adults (n=30) in residential care homes. Lower urinary tract symptoms improved during the pilot study, but the rates of improvement in bowel leakage did not meet thresholds for statistical improvement (47% in the TPTNS group, 27% in the sham group, $p=0.11$) [984]. One new observational study of low quality was identified which included older adults (n=22 participants who failed conservative treatment, mean age 64.1 years, range 26-81, various causes for FI) [985]. The authors reported that 77.2% of participants improved in terms of episodes of FI with bilateral PTNS, but no detail on the older participants was provided. A larger, well controlled RCT of PTNS (mean age 64 years) versus sham (65.5 years) was undertaken in 59 participant who previously failed conservative treatment [986]. Results showed a decrease in medium number of FI episodes per week in the intervention group, but no details on older participants or subgroup analysis of these participants is reported.

8.7. Other Nonsurgical Management Options

Anal plugs (n=76) [987] and a new vaginal bowel control device (n=110) [988] have prospective trial data showing improvements in 50% reduction of FI episodes, overall FI episodes, and quality of life. A secondary analysis of the data from the second study reported that shorter vaginal length and previous surgery for prolapse were associated with risk of fitting failure for the device [989]. Subgroup analyses of older adults were not described in any of these trials.

In summary, most treatment studies of FI either exclude older persons at risk of frailty and/or do not provide subgroup analysis of data for older persons. Studies of treatments for FI in both community dwelling and nursing home frail older persons are needed.

Summary of evidence treatment of FI in frail older people

- Evidence shows that stimulant laxatives, osmotic laxatives (PEG and lactulose), suppositories and enemata can be effective in treating faecal impaction in older people at risk of overflow **[LoE2]**. ***Included in 5th ICI chapter***
- Complete rectal clearance is required to reduce overflow FI **[LoE2]** but may be hard to achieve in frail older patients **[LoE 2]**.
- Structured multi-component approaches to bowel care did not reduce the frequency of FI in the nursing home setting, but did improve bowel frequency and number of bowel movements in the toilet **[LoE 2]**
- Older people with FI may benefit from biofeedback and sphincter strengthening exercises, if they are able to comply **[LoE 3]**
- Loperamide can reduce frequency of FI, particularly when associated with loose stool (once infection and other causes have been excluded) but should be used with caution **[LoE 2]**
- Addition of fibre supplementation to loperamide may not improve FI outcomes **[LoE 2]**
- Multi-component structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients **[LoE 2].**

Recommendations: treatment of FI in frail older people

All following recommendations are Grade C

- Patients identified as having constipation with overflow should have effective bowel clearance (using a combination of laxatives and enemata), and then maintenance therapy with stimulant or osmotic laxatives ***Included from 5th ICI chapter***
- Suppositories are useful in treating rectal outlet delay and preventing recurrent rectal impaction with regular use
- Loperamide is a useful treatment in FI, in the absence of constipation, but should be used with caution in older adults
- Causes of loose stool must be identified and treated.
- All frail older adults with FI should have structured multidisciplinary assessment and treatment of their bowel problem.
- Patient and caregiver education (using verbal and written materials) should be undertaken to promote self-efficacy and other coping mechanisms, and where appropriate self-management (e.g., reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odour control, and continence aids is also important.
- Privacy and dignity of care during defaecation should be afforded to all older people in insitutionalised settings. Particular attention should be paid to this in patients with FI, as privacy may be relatively overlooked in their care.
- Greater emphasis needs to be placed on systematic and effective management of FI in older people backed up by sound communications between all health care providers, especially in the nursing home and acute hospital setting.
- Education of health care providers with regards to heightening awareness of the problem plus methods of identification, assessment and management of FI in older people should be broad-ranging and include geriatricians, general practitioners, hospital physicians, hospital, community, general practice and long-term care nurses, and related disciplines (physiotherapists, occupational therapists, dieticians, pharmacists).
- Cyclical national audit with provider accountability, of current practice in managing FI in older people is needed to lay the groundwork for standardised care and provide a culture of continuous quality improvement. Such audit tools should be developed using standardised consensus methods. Incentives to providers could be benchmarking their practice against national averages, opportunities to share successful practice change strategies, and professional validation linked to good practice.

Recommendations for research

- Trials of laxative and nonpharmacological treatment and prevention of faecal impaction and overflow are needed to optimise standards of prescribing and care.
- Future studies focused on frail older adults, both community dwelling and in nursing homes, are needed to identify treatments that are efficacious and reasonable in this population

XI. CONTINENCE AT THE END OF LIFE

1. BACKGROUND

Palliative care is an approach that aims to improve the quality of life of people and their families who are facing problems associated with life-threatening illness that cannot be cured. It prevents and relieves suffering through the early identification, assessment and treatment of pain and other problems, whether physical, psychosocial or spiritual. As they approach death, people identify loss of dignity as a major concern. In up to 83% of patients This concern is often related to lack of control of their bodily functions [990] and loss of privacy, particularly during intimate care such as washing, toileting and potential bowel interventions.

In a study looking at the preferences for continence care at the end of life in patients receiving palliative care, [390] patients prioritised pain, responsive behaviour and urinary incontinence as the most important symptoms. This is closely aligned with a study of nursing home residents at end of life [991]. if necessary, Patients were willing to give up dignity to address the symptoms causing them more distress.

End of life care is defined as support for people who are in the last year or months of their life. This group often comprises people who have an advanced incurable illness or who are generally frail and have co-existing conditions such that death is expected within 12 months. The 2 terms are often used synonymously but differ in their meaning. Here we have provided evidence from studies in both areas

The most frequent primary diagnoses in studies examining faecal and urinary incontinence and other bladder and bowel related symptoms in palliative or end of life care are:
- cancer
- dementia
- heart failure
- stroke
- pulmonary disease

and patients cared for in a variety of settings:
- home
- care home
- hospice
- hospital

Cognitive decline and functional decline increase risk of developing UI or FI or both [834] and these are often affected when people are progressing towards end of life with any underlying condition leading to increased need for help and intervention.

2. PREVALENCE & IMPACT

There are few studies describing the prevalence of UI and FI in palliative/EOL care settings. However, what evidence does exist suggests that approximately 14% of patients in receipt of palliative care have urinary symptoms of some description [992]. For older patients with cancer receiving palliative care, the proportion experiencing UI, constipation or FI is much higher, occurring in up to 77% of patients [993].

In the home hospice setting, approximately 30% of patients are diagnosed with UI, with women and those with stroke or dementia at higher risk [199]. Nurses providing care viewed UI as an important issue facing patients and their families and stated that failing to manage it properly resulted in adverse events such as wounds, sores, rashes, skin breakdown, pain, discomfort, loss of dignity and emotional distress [994].

In patients with genitourinary cancer, late or long term effects of treatment included alterations in skin integrity, pain, altered urinary function and organ dysfunction specific to the type of cancer [995].

There is a high prevalence of FI in the home hospice setting with >40% presenting with some FI and > 64% of those having FI when referred [996]. In patients with heart failure, FI occurred in 16 % of patients and it was the symptom most frequently reported as being very distressing (64%). UI occurred in 29% and persisted for greater than 6 months in 55% of the cohort. Constipation was reported in 37% of patients, 42% of these found it very distressing; over 50% of patients In this study died in hospital [997].

Constipation is one of the most common problems experienced patients in receipt of palliative care. Fifty percent of patients admitted to the hospice cited constipation as a concern [998]. Chronically ill patients and palliative care patients share risk factors for constipation. These include decreased physical activity, fibre-deficient diets, illnesses that are progressive and often severely incapacitating and the use of constipating medications. Constipation has been identified as the most troublesome side effect of pain management in patients with cancer [999].

3. QUALITY OF THE DATA

There is a paucity of data to guide continence practice in palliative and end of life care. Comprehensive validated end of life assessment tools are lacking. The majority of clinical care guidelines are aimed at curative treatment as opposed to providing management that promotes comfort although there is clearly some overlap. Clinical guidelines do not tailor for those people who have terminal illnesses with urinary and /or faecal incontinence but available end of life guidance suggests that management of symptoms should be focused on maintenance of quality of life in accordance with the patient's values and preferences.

The principles applied to managing all incontinence should be carried through to palliative and end of life care. There should be structures that support dignity-protective continence care for care dependent older adults: time to deliver care and flexible working practices; staff knowledge and beliefs about incontinence; an adequate number of staff as well as staff who are trained; managerial support and leadership; a predictable work environment; regulation that does not constrain caring practices and a health system that ensures an equitable access to adequate and appropriate care and treatment, across the population.

4. MANAGEMENT OPTIONS

Managing incontinence at the end of life is complex and requires a comprehensive assessment of symptoms a drive to understand the underlying causes and realistic goals for treatment. It is also important to include patients and their relatives or care partners in medical decision making. Alongside the ethical imperative to deliver patient-centred care and respect patient autonomy, shared decision making is also associated with positive patient outcomes such as higher satisfaction with the decision and trust in the physician [1000].

5. ASSESSMENT

Assessment at the end of life should be focused on thorough investigation of the patient's experience of their symptoms, changing needs and preferences and planning ahead, including a holistic assessment of the impact of symptoms [1001, 1002]. No validated assessment or outcome measurement tools focusing on end-of-life incontinence were found. Despite the high prevalence of incontinence at the end of life, generic assessment tools assessing a broad range of symptoms at the end of life often exclude reference to incontinence (for example Edmonton Symptom Assessment Scale or Memorial Symptom Assessment Scale). Although many elements of generic incontinence questionnaires discussed in Chapter 4 such as the Kings Health Questionnaire are unlikely to be relevant at the end of life, they may offer prompts for assessing the impact of incontinence on patients' quality of life.

As patients' ability to communicate deteriorates in the last days and hours of life and many care settings implement a 'dying phase' care pathway to manage symptoms [1003]. A recent Cochrane review of these pathways concluded that there is currently limited evidence to support their use [1004]. In the UK, there has been considerable activity to provide individualised care, including the Royal College of Physicians "End-of-Life Care in the Acute Care Setting [1005] and NICE Guideline "Care of dying adults in the last days of life" [1002]. Neither of these resources refer to incontinence.

6. URINARY INCONTINENCE

There is evidence that nursing staff rely on 'practical wisdom' rather than evidence-based guidance to care for patients with urinary problems approaching end of life. [1006].

6.1. Containment products:
Pads are often used at end of life. A wide variety of product options should be available to meet individual patient needs and preferences. [1007].

6.2. Female urinals:
In a multicentre evaluation testing 13 female urinals with community-based women, they were described as easy to use without spillage when standing or crouching, or when sitting on the edge of a bed or chair. Few were used successfully when lying and women who had a higher level of dependency found fewer suitable products [1008].

In a further study looking at using a female urinal as an acceptable, safe and effective product to meet the toileting needs of women receiving palliative care on oncology wards in hospitals, the Vernafem disposable female urinal was found to be a suitable option for consideration of use in palliative patients. Its use was particularly appropriate for hospital as it can be pulped [1009].

6.3. Catheterisation:
There has been very little published on the management of urinary incontinence and the use of urinary catheters in terminally ill patients. An audit of case notes of patients who died on two oncology wards and a hospice at a large teaching hospital showed that 63% of patients had an indwelling catheter during their admission confirming that indwelling catheters are frequently used as a tool to manage urinary difficulties at the end of life [1010].. Potentially, there are several indications for catheterisation including, existing wound damage or pressure ulcers exacerbated by incontinence, pain or difficulty caused by getting in and out of bed or frequent changes of pads or bedlinen and urinary retention. In a prospective study [1011], 61 patients were admitted to the hospice and either had catheters already (23) or they were inserted in the hospice (22) for patient comfort, the conclusion for the 45 of 61 patients who were catheterised, was that it did not contribute to mortality and morbidity was mostly due to bacteriuria and any complications were relatively easily treated.

In a study of 145 deaths in an Intensive care Unit, 52 patients had UI in their final week, and 13 of these patients had extreme problems with UI. It was found that extremely poor Quality of death (QoD) measured with a validated score was associated with extreme UI problems. Indwelling catheter use was associated with a significantly better QoD [1012].

A further study to elicit preferences for different urinary incontinence (UI) treatments of cognitively intact, over age 80, geriatric patients in a geriatric hospital (not palliative or necessarily end of life but potentially nearing this phase, found that in discussion surrounding potential UI most respondents preferred diapers (79%), medications (78%), and scheduled toileting (79%) to urinary catheters. In addition, the study looked to contrast these answers with those from potential health proxies and providers and found that the preferences of cognitively competent geriatric patients for treatment of UI differed from those of their potential proxies e.g. health care providers or family members (other than spouses) illustrating the importance of early conversations regarding patient's wishes. [472].

6.4. Faecal incontinence, constipation & bowel care
Palliative care and end of life patients can experience many difficulties with bowel habit including diarrhoea, faecal incontinence and constipation. Assessment of bowel dysfunction should be part of an overall holistic palliative care assessment but currently there is no standardised assessment.

Some patients, for example those with end stage neurological diseases such as Parkinson's disease and MS, may have experienced FI or constipation since their initial diagnosis and therefore usual regimens should be maintained if they are successful.

There are guidelines for managing complex neurogenic bowel in patients with spinal cord injury [1013]. Spinal Cord Compression included studies related to bowel management in patients with MSCC specifically [1014]. Even specialists at a regional cancer centre lack the necessary skills to give effective bowel care for these patients. Given the lack of guidance, there can be many dilemmas presented to the clinicians looking after patients.

Diarrhoea: The Scottish Palliative care guidelines define diarrhoea as the passage of frequent loose stools with urgency or the passage of more than 3 unformed stools within a 24-hour period. These guidelines suggest considering the following potential causes as part of an assessment:

Drugs such as laxatives, antacids, antibiotics, NSAIDS, chemotherapy agents, disaccharide-containing (sugar free) elixirs and iron.

Radiotherapy, particularly when involving the abdomen or pelvis

Faecal impaction resulting in diarrhoea as overflow.

Obstruction – malignant faecal impaction, narcotic bowel syndrome (severe constipation caused by opioid analgesia) as well as malabsorption.

Concurrent disease such as diabetes mellitus, hyperthyroidism, pancreatic insufficiency, inflammatory bowel disease Pancreatic carcinoma, pancreatic islet cell tumour, carcinoid tumour, GI infection

Diet – ingestion of bran, fruit, hot spices or alcohol.

Specific measures can be undertaken to reduce the adverse consequences of the diarrhoea even if it is part of the patient's palliative or end of life condition. In trying to ascertain the cause of the diarrhoea, there could be potential improvements, for example treating proven infections or changing medications, disimpaction, if required, or considering bacterial overgrowth in certain groups such as ileo-colic resection. In carcinoid syndrome – octreotide can be considered.

The consequences of diarrhoea, such as depletion of vitamins and minerals may require replacement. If absorption of medicines is affected – alternative routes of administration can be sought. if the skin becomes excoriated as a consequence of diarrhoea or faecal incontinence, the area should be cleaned with a soft disposable cloth, patted dry and barrier cream should be applied to protect the skin.

6.5. Faecal incontinence
Management strategies for patients with faecal incontinence in frail older men and women at the end of life should be focused on promoting comfort rather than on cure. Data on the effectiveness of

these methods in palliative care or EOL patients in the home, care home, hospital or hospice are lacking.

Causes of faecal incontinence at the end of life are similar to those leading to diarrhoea.

The National Institute of Clinical and Healthcare Effectiveness (England & Wales) guidelines suggest that patients at the end of life may benefit from a faecal collection device if they experience persistent faecal incontinence as this would be best to maintain their dignity in the dying process. These devices are only suitable for very loose stool, and they might be used when a patient is confined to bed and needs assistance with bowel management. These devices also aid in maintaining skin integrity by preventing faecal leakage to delicate skin areas or reduce disruption when frequent linen changes are difficult.

6.6. Constipation

Constipation is one of the most common problems experienced by palliative care patients. Patients' perception of constipation is more influenced by ease of defaecation than bowel frequency and factors that healthcare professionals use to assess constipation such as absolute frequency of defaecation, frequency compared to normal habits and difficulty defaecating do not always align with those of patients [1015].

The Scottish Palliative care guidelines suggest possible causes of constipation including:

- Medication (opioids, antacids, diuretics, iron, 5HT3 antagonists)
- Secondary effects of illness (dehydration, immobility, poor diet, anorexia)
- Tumour in or compressing bowel wall
- Damage to lumbosacral spinal cord, cauda equina or pelvic nerves
- Hypercalcaemia
- Concurrent diseases such as diabetes, hypothyroidism, diverticular disease, anal fissure, haemorrhoids, Parkinson's disease, hypokalaemia.

Non-pharmacological management strategies include, considerations of diet and fluids, ensuring privacy, mobility and optimised toileting.

The Cochrane Collaboration review on laxative use for the management of constipation at the end-of-life notes uncertainty about the 'best' management of constipation [1016]. in this review all considered laxatives were of similar effectiveness but the evidence was limited by data from only a few small RCTs. None of the studies evaluated polyethylene glycol or any intervention given rectally. There is a need for more trials to evaluate the effectiveness of laxatives in palliative care populations. Extrapolating findings on the effectiveness of laxatives evaluated in other populations may be invalid.

In the UK, senna, lactulose and docusate are the three oral laxatives with the lowest cost base and these options were used as primary laxatives for 46% of patients, in keeping with previous hospice based research in the UK [998] and USA [1017]. No studies examining the effectiveness of docusate for constipation specifically in palliative care patients have been published. Treatment of constipation with docusate in chronically ill patients and terminally ill patients is based on inadequate experimental evidence [1018].

For opioid induced constipation, peripheral opioid antagonists can relieve constipation but allow preservation of centrally mediated analgesia. Methylnaltrexone and naloxegel should only be used under specialist advice, and use is often restricted to those with expertise in palliative care.

Comprehensive assessment, including a full history and performing a physical examination is variably recorded in practice. Education on prevention is poorly recorded and evidence of non-pharmacological intervention is less likely to be recorded than if pharmacological intervention is prescribed [1019].

Recommendations for practice

1. Physical and cognitive function will often vary from day-to-day. Regular assessment and individual management plans are required, taking in to account patient preferences and the context of care.

2. Timely environmental or behavioural interventions might be of benefit for individual patients for a limited period dependent on the illness trajectory.

3. Caregivers (professional and informal) should be educated in supporting the changing incontinence needs of dying patients.

Recommendations for research

Further research is required to:

1. Explore the patients' preferences for the management of UI and FI at the end of life.

2. Explore how carers (professional and informal) can be supported to care for the incontinence needs of people dying in different settings.

3. Identify the risks and benefits of using IDCs to provide comfort at the end of life.

Evaluate the impact of environmental and behavioural interventions to improve comfort and quality of life.
