FOREWORD

The 7th International Consultation on Incontinence was held virtually in November 2021 under the restrictions placed upon us all by the ongoing Covid-19 pandemic. Once again, the Consultation was facilitated by the generous support of the International Continence Society.

This consultation has seen the incorporation of a joint ICI and ICS advisory board which proved to be invaluable in the identification and selection of experts across the 22 committees which, for this Consultation, has included more than 200 experts from across the world. We have also welcomed Eric Rovner to the Editorial Board, as Paul Abrams stepped back from the forefront of responsibility. As Editors, we remain grateful for Paul's ongoing advice and guidance. We are also grateful for the tremendous support of the team in the ICS office who finalize the proofing and production of the chapters as they emerge from the process.

The principle of the Consultation remains the same; the production of a contemporary, evidence based, wide ranging publication which should prove invaluable to all those who commit their professional lives to men and women suffering from the conditions with which they deal. The Consultation was well received by its international audience. Considerable feedback on the committee presentations was acknowledged and responded to, resulting in improvements to the committee's work, where relevant.

We should like to thank all those who watched, participated online and sent in their comments and suggestions

We feel that the work of the ICI remains vitally important to the many millions of men, women and children who suffer from pelvic floor and allied disorders and hope that the resulting publication is equally useful to clinicians and researchers throughout the world.

MEMBERS OF THE COMMITTEES:

By Committee

1. Epidemiology of Urinary Incontinence (UI) and other Lower Urinary Tract Symptoms (LUTS), Pelvic Organ Prolapse (POP) and Anal (AI) Incontinence

Altman, Daniel (Sweden)
Cartwright, Rufus (United Kingdom)
Lapitan, Marie Carmela (Philippines)
Milsom, Ian. Chair (Sweden)
Nelson, Richard (United States)
Sjöström, Sofia (Finland)
Tikkinen, Kari (Finland)

2. Neural Control and Cell Biology

Birder, Lori. Co-Chair (United States)
Chess-Williams, Russ (Australia)
Clarkson, Becky (United States)
Feng, Bin (United States)
Fry, Christopher. Co-Chair (United Kingdom)
Gebhart, Jerry (United States)
Griffiths, Derek (Canada)
Hashitani , Hikaru (United States)
Kanai, Anthony (United States)
Lovick, Thelma (United Kingdom)
McCloskey, Karen (United Kingdom)
Mitsui, Takahiko (Japan)
Takeda, Masayuki (Japan)

3. Pathophysiology of Urinary Incontinence, Pelvic Organ Prolapse and Faecal Incontinence

Braga, Andrea (switzerland)
DeLancey, John (United States)
Fernando, Ruwan (United Kingdom)
Finazzi Agrò, Enrico. Co-Chair (Italy)
Iacovelli, Valerio (Italy)
Laterza, Rosa (Austria)
Lowry, Ann (United States)
Salvatore, Stefano. Co-Chair (Italy)
Serati, Maurizio (Italy)
Sievert, Karl-Dietrich (Germany)

4A. Initial assessment of urinary incontinence in adult male and female patients

4B. Patient-Reported Outcome Assessment

Arlandis Guzman, Salvador (Spain)
Bosch, JLH (Netherlands)
Castro-Diaz, David. Chair (Spain)
Costantini, Elisabetta (Italy)
Cotterill, Nikki (United Kingdom)
Espuña Pons, Montserrat (Spain)
Lemos, Nucelio (Canada)
López-Fando Lavalle, Luis (Spain)
Robinson, Dudley. Co-Chair (United Kingdom)
Shelly, Elizabeth (United States)
Yoshida, Masaki (United Kingdom)

5. Urodynamic Testing

Abranches-Monteiro, Luis (Portugal)
de Wachter, Stefan. Chair (Belgium)
Gammie, Andrew (United Kingdom)
Hashim, Hashim (United Kingdom)
Nitti, Victor (United States)
Rosier, Peter (Netherlands)
Sinha, Sanjay (India)
Tarcan, Tufan (Turkey)
Toozs-Hobson, Philip (United Kingdom)
Wen, Jian Guo (China)

6. Imaging, Neurophysiological Testing and Other Tests

Amarenco, Gerard (France)
Asfour, Victoria (United Kingdom)
Baumfeld, Yael. Consultant (United States)
Betschart, Cornelia . Consultant (Switzerland)
Broughton, Sophie. Consultant (United Kingdom)
Derpapas, Alexandros (Greece)
Doumouchtsis, Stergios (United Kingdom)
Eisenberg, Vered (Israel)
Fernando, Ruwan (United Kingdom)
Khullar, Vik. Chair (United Kingdom)
Sekido, Noritoshi (Japan)
Shobeiri, Seyed Abbas (United States)
Tubaro, Andrea (Italy)
Vodušek, David (Slovenia)

7. Diagnosis and management of urinary incontinence in children

Austin, Paul (United States)
Chase, Janet (Australia)
Kamperis, Konstantinos (Denmark)
Mosiello, Giovanni (Italy)
Nijman, Rien. Co-Chair (Netherlands)
Tekgul, Serdar (Turkey)
van der Walle, Johan (Belgium)
Van Gontard, Alexander
Van Laecke, Erik. Chair (Belgium)
Wood, Daniel (United States)
Yang, Stephen Shei-Dei (Taiwan)
Zderic, Stephen (United States)

8. Conservative Management of UI and POP in Adults, including neurological patients

Booth, Jo (United Kingdom)
Cacciari, Licia (Canada)
Campbell, Pauline (United Kingdom)
Dumoulin, Chantale. Chair (Canada)
Hagen, Suzanne (United Kingdom)
Homsi Jorge, Cristine (Brazil)
Morin, Melanie (Canada)
Morkved, Siv (Norway)
Nahon, Irmina (Australia)
Pang, Ran (China)
Panicker, Jalesh (United Kingdom)
Vesentini, Giovana (Canada)
Wallace, Sheila (United Kingdom)
Yamanishi, Tomonori (Japan)

9. Pharmacological Treatment of Urinary Incontinence

Andersson, Karl-Erik. Co-Chair (United States)
Cardozo, Linda (United Kingdom)
Chermansky, Christopher (United States)
Cruz Miranda Rodrigues, Francisco. Co-Chair (Portugal)
Igawa, Yasuhiko (Japan)
Lee, Kyu-Sung (Korea, Republic of)
Michel, Martin (Germany)
Sahai, Arun (United Kingdom)
Wein, Alan (United States)

10. Surgery for Male Urinary Incontinence

Averbeck, Marcio. Co-Chair (Brazil)
Chung, Eric (Australia)
Collado Serra, Argimiro (Spain)
Comiter, Craig (United States)
Goldman, Howard. Co-Chair (United States)
Guralnick, Michael (United States)
Herschorn, Sender (Canada)
Singla, Ajay (United States)

11. Surgery for Urinary Incontinence in Women

Athanasiou, Stavros (Greece)
Chen, Zhuoran (Australia)
Gomelsky, Alexander (United States)
Gomes, Cristiano (Brazil)
Harding, Christopher (United Kingdom)
Moore, Kate. Chair (Australia)
Peyronnet, Benoit (France)
Rovner, Eric (United States)
Serati, Maurizio (Italy)
Smith, Ariana (United States)
Tomoe, Hikaru (Japan)

12. Surgery for neurological urinary incontinence

Apostolidis, Apostolos (Greece)
Castaño, Juan (Colombia)
Corcos, Jacques (Canada)
Game, Xavier (France)
Hamid, Rizwan (United Kingdom)
Kessler, Thomas. Chair (Switzerland)
Liao, Limin (China)
Padilla Fernández, Bárbara Yolanda (Spain)
Sekido, Noritoshi (Japan)
Stoffel, John (United States)
Trigo Rocha, Flavio (Brazil)

13. Fistulae

de Ridder, Dirk. Chair (Belgium)
Goh, Judith (Australia)
Greenwell, Tamsin (United Kingdom)
Mourad, Sherif (Egypt)
Vaze, Ajit (India)

14. Incontinence in Frail Older Adults

Bower, Wendy (Australia)
Gibson, William (Canada)
Hunter, Kathleen (Canada)
Kirschner-Hermanns, Ruth (Germany)
Kuchel, George (United States)
Morris, Vikky (United Kingdom)
Ostaszkiewicz, Joan (Australia)
Suskind, Anne (United States)
Suzuki, Motofumi (Japan)
Wagg, Adrian. Chair (Canada)
Wyman, Jean (United States)

15. Assessment and Conservative Management of Faecal Incontinence and Quality of Life

Berghmans, Bary (Netherlands)
Bharucha, Adil (United States)
Bliss, Donna. Chair (United States)
Carrington, Emma (United Kingdom)
Emmanuel, Anton. Consultant (United Kingdom)
Hunter, Kathleen (Canada)
Kumaran , Thiruppathy (United Kingdom)
Mimura, Toshiki. Co-Chair (Japan)
Panicker, Jalesh. Consultant (United Kingdom)
Sakakibara, Ryuji (Japan)
Santoro, Giulio (Italy)

16. Surgery for Faecal Incontinence

Bisset, Ian (New Zealand)
Bordeianou, Liliana (United States)
Bridoux, Valerie (France)
Knowles, Charles. Chair (United Kingdom)
Lehur, Paul-Antoine (France)
Lundby, Lilli (Denmark)
Matzel, Klaus (Germany)
Mimura, Toshiki (Japan)
O'Connell, Ronan (Ireland)
Oliveira, Lucia (Brazil)

17. Pelvic Organ Prolapse Surgery

Antosh, Danielle (United States)
Baessler, Kaven (Germany)
Cheon, Cecilia (Hong Kong)
de Tayrac, Renaud (France)
Deffieux, Xavier (France)
Gutman, Robert (United States)
Lee, Joseph (Australia)
Maher, Christopher. Chair (Australia)
Nager, Charles (United States)
Schizas, Alexis (United Kingdom)
Sung, Vivian (United States)

18. Interstitial Cystitis / Bladder Pain Syndrome

Cervigni, Mauro (Italy)
Choo, Myung-Soo (Korea, Republic of)
Clemens, J. Quentin (United States)
Gold , Daniela (Austria)

Takahashi, Satoru (Japan)

EVIDENCE–BASED MEDICINE OVERVIEW OF THE MAIN STEPS FOR DEVELOPING AND GRADING GUIDELINE RECOMMENDATIONS

INTRODUCTION

The International Consultation on Urological Diseases (ICUD) is a non-governmental organization registered with the World Health Organisation (WHO). In the last ten years Consultations have been organised on BPH, Prostate Cancer, Urinary Stone Disease, Nosocomial Infections, Erectile Dysfunction and Urinary Incontinence. These consultations have looked at published evidence and produced recommendations at four levels; highly recommended, recommended, optional and not recommended. This method has been useful but the ICUD believes that there should be more explicit statements of the levels of evidence that generate the subsequent grades of recommendations.

The Agency for Health Care Policy and Research (AHCPR) have used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions. The Oxford Centre for Evidence Based Medicine have produced a widely accepted adaptation of the work of AHCPR. (June 5th 2001 http://minerva.minervation.com/cebm/docs/levels.html).

The ICUD has examined the Oxford guidelines and discussed with the Oxford group their applicability to the Consultations organised by ICUD. It is highly desirable that the recommendations made by the Consultations follow an accepted grading system supported by explicit levels of evidence. The ICUD proposes that future consultations should use a modified version of the Oxford system which can be directly 'mapped' onto the Oxford system.

1st Step: Define the specific questions or statements that the recommendations are supposed to address.

2nd Step: Analyse and rate (level of evidence) the relevant papers published in the literature.

The analysis of the literature is an important step in preparing recommendations and their guarantee of quality.

2.1. What papers should be included in the analysis?

- Papers published, or accepted for publication in the peer reviewed issues of journals.
- The committee should do its best to search for papers accepted for publication by the peer reviewed journals in the relevant field but not yet published.
- Abstracts published in peer review journals should be identified. If of sufficient interest the author(s) should be asked for full details of methodology and results. The relevant committee members can then 'peer review' the data, and if the data confirms the details in the abstract, then that abstract may be included, with an explanatory footnote. This is a complex issue – it may actually increase publication bias as "uninteresting" abstracts commonly do not progress to full publication.
- Papers published in non peer reviewed supplements will not be included.

An exhaustive list should be obtained through:

i. **the major databases** covering the last ten years (e.g. Medline, Embase, Cochrane Library, Biosis, Science Citation Index)
ii. **the table of contents** of the major journals of urology and other relevant journals, for the last three months, to take into account the possible delay in the indexation of the published papers in the databases.

It is expected that the highly experienced and expert committee members provide additional assurance that no important study would be missed using this review process.

2.2. How papers are analysed?

Papers published in peer reviewed journals have differing quality and level of evidence.

Each committee will rate the included papers according to levels of evidence (see below).

The level (strength) of evidence provided by an individual study depends on the ability of the study design to minimise the possibility of bias and to maximise attribution.

is influenced by:

the type of study

- The hierarchy of study types are:
- Systematic reviews and metaanalysis of randomised controlled trials
- Randomised controlled trials
- Non-randomised cohort studies
- Case control studies
- Case series
- Expert opinion

how well the study was designed and carried out

Failure to give due attention to key aspects of study methodology increase the risk of bias or confounding factors, and thus reduces the study's reliability.

The use of **standard check lists** is recommended to insure that all relevant aspects are considered and that a consistent approach is used in the methodological assessment of the evidence.

The objective of the check list is to give a quality rating for individual studies.

how well the study was reported

The ICUD has adopted the CONSORT statement and its widely accepted check list. The CONSORT statement and the checklist are available at

http://www.consort-statement.org

2.3. How papers are rated?

Papers are rated following a **«Level of Evidence scale»**.

ICUD has modified the Oxford Center for Evidence-Based Medicine levels of evidence.

The levels of evidence scales vary between types of studies (ie therapy, diagnosis, differential diagnosis/symptom prevalence study).

the Oxford Center for Evidence-Based Medicine Website:

http://minerva.minervation.com/cebm/docs/levels.html

3rd Step: Synthesis of the evidence

After the selection of the papers and the rating of the level of evidence of each study, the next step is to compile a summary of the individual studies and the overall direction of the evidence in an **Evidence Table**.

4th Step: Considered judgment (integration of individual clinical expertise)

Having completed a rigorous and objective synthesis of the evidence base, the committee must then make a judgement as to the grade of the recommendation on the basis of this evidence. This requires the exercise of judgement based on clinical experience as well as knowledge of the evidence and the methods used to generate it. Evidence based medicine requires the integration of individual clinical expertise with best available external clinical evidence from systematic research. Without the former, practice quickly becomes tyrannised by evidence, for even excellent external evidence may be inapplicable to, or inappropriate for, an individual patient: without current bestevidence, practice quickly becomes out of date. Although it is not practical to lay our “rules” for exercising judgement, guideline development groups are asked to consider theevidence in terms of quantity, quality, and consistency; applicability; generalisability; and clinical impact.

5th Step: Final Grading

The grading of the recommendation is intended to strike an appropriate balance between incorporating the complexity of type and quality of the evidence and maintaining clarity for guideline users.

The recommendations for grading follow the Oxford Centre for Evidence-Based Medicine.

The levels of evidence shown below have again been modified in the light of previous consultations. There are now 4 levels of evidence instead of 5.

The grades of recommendation have not been reduced and a “no recommendation possible” grade has been added.

6 Levels of Evidence and Grades of Recommendation Therapeutic Interventions

All interventions should be judged by the body of evidence for their efficacy, tolerability, safety, clinical effectiveness and cost effectiveness. It is accepted that at present little data exists on cost effectiveness for most interventions.

6.1. Levels of Evidence

Firstly, it should be stated that any level of evidence may be positive (the therapy works) or negative (the therapy doesn’t work). A level of evidence is given to each individual study.

- **Level 1** evidence (incorporates Oxford 1a, 1b) usually involves meta-anaylsis of trials (RCTs) or a good quality randomised controlled trial, or ‘all or none’ studies in which no treatment is not an option, for example in vesicovaginal fistula.
- **Level 2** evidence (incorporates Oxford 2a, 2b and 2c) includes “low” quality RCT (e.g. < 80% follow up) or metaanalysis (with homogeneity) of good quality prospective ‘cohort studies’. These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, where those with the condition in the first group are compared with those in the second group.
- **Level 3** evidence (incorporates Oxford 3a, 3b and 4) includes:
  - **good quality** retrospective ‘case-control studies’ where a group of patients who have a condition are matched appropriately (e.g. for age, sex etc) with control individuals who do not have the condition.
  - **good quality** ‘case series’ where a complete group of patients all, with the same condition/disease/therapeutic intervention, are described, without a comparison control group.
- **Level 4** evidence (incorporates Oxford 4) includes expert opinion were the pinion is based not on evidence but on ‘first principles’ (e.g. physiological or anatomical) or bench research. The Delphi process can be used to give ‘expert opinion’ greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of ‘options’; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.

6.2. Grades of Recommendation

The ICUD will use the four grades from the Oxford system. As with levels of evidence the grades of evidence may apply either positively (do the procedure) or negatively (don’t do the procedure). Where there is disparity of evidence, for example if there were three well conducted RCT’s indicating that Drug A was superior to placebo, but one RCT whose results show no difference, then there has to be an individual judgement as to the grade of recommendation given and the rationale explained.

- **Grade A** recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a Grade A recommendation, for example, if the therapy is prohibitively expensive, dangerous or unethical. Grade A recommendation can follow from Level 2 evidence. However, a Grade A recommendation needs a greater body of evidence if based on anything except Level 1 evidence
- **Grade B** recommendation usually depends on consistent level 2 and or 3 studies, or ‘majority evidence’ from RCT’s.
- **Grade C** recommendation usually depends on level 4 studies or ‘majority evidence’ from level 2/3 studies or Dephi processed expert opinion.
- **Grade D** “No recommendation possible” would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Dephi.

7. Levels of Evidence and Grades of Recommendation for Methods of Assessment and Investigation

From initial discussions with the Oxford group it is clear that application of levels of evidence/grades of recommendation for diagnostic techniques is much more complex than for interventions.

The ICUD recommend, that, as a minimum, any test should be subjected to three questions:

1. Does the test have good technical performance, for example, do three aliquots of the same urine sample give the same result when subjected to 'stix' testing?
2. Does the test have good diagnostic performance, ideally against a "gold standard" measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

For the third component (therapeutic performance) the same approach can be used as for section 6.

8 Levels of Evidence and Grades of Recommendation for Basic Science and Epidemiology Studies

The proposed ICUD system does not easily fit into these areas of science. Further research needs to be carried out, in order to develop explicit levels of evidence that can lead to recommendations as to the soundness of data in these important aspects of medicine.

CONCLUSION

The ICUD believes that its consultations should follow the ICUD system of levels of evidence and grades of recommendation, where possible. This system can be mapped to the Oxford system.

There are aspects to the ICUD system that require further research and development, particularly diagnostic performance and cost effectiveness, and also factors such as patient preference.

I. INTRODUCTION

In this report we focus on the epidemiology (distribution and determinants) of urinary incontinence (UI) and other lower urinary tract symptoms (LUTS), pelvic organ prolapse (POP) and anal incontinence (AI). We also discuss important topics such as differences between epidemiological and clinical approaches to health problems, help seeking behaviour, and methodological issues for research.

A section on overactive bladder and nocturia which are commonly occurring LUTS has been included. A worldwide estimation of the current and future number of individuals with LUTS including urinary incontinence and overactive bladder is also included at the end of this chapter.

The epidemiological population under study for this review will mainly be community dwelling non-institutionalisedpersons. The review will include discussion of the prevalence, incidence, natural history, and the presence of racial and ethnic differences. We also review correlates and potential risk factors that have been revealed in epidemiological studies. We have searched the literature for relevant new articles, thus reviewing a large number of high-quality and population based studies, as well as clinical trials that might include relevant epidemiological data. Because of an abundant number of studies, only a small fraction can be presented in a text like this. Other studies not presented here may have equally useful information, but lack of space precluded their inclusion.

Summary points:

- This review includes discussion on the prevalence, incidence, natural history, and presence of racial and ethnic differences in the epidemiology of UI, overactive bladder (OAB), nocturia, POP and AI.
- Correlates and potential risk factors that have been identified in epidemiological studies are also reviewed.

II. BASIC EPIDEMIOLOGICAL CONSIDERATIONS

Epidemiology is the scientific study of the distribution and determinants of disease in people. Descriptive epidemiology is the description of disease prevalence, incidence, (and mortality) by persons, place and time, while the term analytical epidemiology describes the search for determinants of disease risk. The discovery of risk factors and protective factors may then in turn lead to primary or secondary prevention.

In order to collect knowledge about risk factors or natural history, observational studies are needed. Cohort studies and case-control studies are the most common. However, caution is always needed when interpreting the results from such studies, as associations found in epidemiological studies may not be the same as causes. Longitudinal study designs and appropriate control for confounding factors are preferred, as these increase the validity of epidemiologic studies. For practical and ethical reasons, experimental designs are seldom used.

Recommendations and conclusions should always be based on the best available evidence. Studies of interventions, and studies of risk factors generally cannot be randomised´because they relate to inherent human characteristics or practices, and exposing subjects to harmful risk factors is unethical. No uniform guidelines for assessing the results of observational studies exist, and the level of evidence for risk factors from observational studies should be judged on the soundness of the exclusion of alternative explanations by statistical and other controls. But some initiatives for how to report meta-analyses of observational studies have been taken.

Studies of disease frequency should rely on a very specific definition of the condition under investigation. The absence of unifying definitions for the conditions reviewed here is a fundamental problem which has not been resolved. Definitions used and problems associated with them are discussed in the subsections for the particular populations below.

Prevalence is defined as the probability of experiencing a symptom or having a condition or a disease within a defined population and

at a defined time point. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services.

Incidence is defined as the probability of developing the condition under study during a defined time period. Incidence is usually reported for one-, two- or five-year time interval.

Even in many of the recent studies reviewed analyses are very simple. Often only proportions or percentages are used to describe differences in different subgroups. Many analyses do not control for confounders (by stratification or multivariate analysis techniques). There is an obvious need for more advanced epidemiological analyses of risk factors and comorbidity, and strength of associations should be determined by relative risks and odds ratios.

The relative risk (RR) estimates the magnitude of an association between exposure and a condition, and indicates the likelihood of having the condition in the exposed group relative to those who are not exposed (e.g. do not have the risk factor). A RR of 1.0 indicates that the rates in the exposed and non-exposed groups are identical and thus that there is no association between the exposure and the condition in that specific dataset. A value greater than 1.0 indicates a positive association or an increased risk. A RR of 2.5 for UI indicates that there is a 2.5 times increased risk or that the persons in question are 150 percent more likely to have incontinence than those without the risk factor.

The odds ratio (OR) is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition. An OR of 2.5 for UI my be interpreted as meaning that in this sample the odds in favour of having incontinence are 2.5 times higher among those with the risk factor than among those without.

For a condition with high prevalence, like UI or POP, OR and RR will not be identical, but in practice the results can be interpreted similarly. Results should always be given with a 95% confidence interval (CI).

Words like well established and established may be used about risk factors and findings with a high level of evidence in the literature. For less documented findings words like " indications of" or " data are suggestive" may be used.

Summary points:

- Descriptive epidemiology reports disease incidence, prevalence (and mortality) by persons, place and time.
- Analytical epidemiology searches for determinants of disease risk. There is a need for good longitudinal cohort studies.
- Variations in definitions and measurement issues are fundamental, and lead to problems with assessing the findings in epidemiological studies.
- There is a need for more advanced epidemiological analyses of risk factors and comorbidity using multivariable techniques, and strength of associations should be determined by relative risks and odds ratios.

III. EPIDEMIOLOGY OF ENURESIS AND URINARY INCONTINENCE IN CHILDREN

1. GENERAL COMMENTS AND DEFINITIONS

The International Children's Continence Society (ICCS) has issued recommendations regarding the terminology of lower urinary tract (LUT) function and dysfunction in children in 2006 [1], with a standalone updated document in 2014[2] and again in 2016 [3]. Bedwetting or nocturnal enuresis (NE) is the term for all urinary incontinence during sleep taking place in discrete episodes in children aged five years or more, regardless of the presence or absence of concomitant daytime symptoms. Monosymptomatic nocturnal enuresis (MNE) denotes bedwetting without any other LUTS, and non-monosymptomatic nocturnal enuresis (NMNE) should be used for those with any concomitant LUTS.

NE is caused by relative nocturnal polyuria [4] and/or nocturnal bladder over-activity [5], combined with the lack of arousal [6] at the time when the bladder needs to be emptied. The most important cause is, of course, the lack of arousal, otherwise the child would have had nocturia.

Any other leakage of urine in children during both the day and night is referred to as urinary incontinence (UI), just as it is in the adult population. UI can be continuous or intermittent. Continuous leakage in children is often caused by a congenital malformation, such as ectopic ureter or exstrophy epispadias complex. Other causes of continuous leakage can be neurogenic bladder in children with spina bifida, tethered cord or other spinal or sacral malformations. Daytime UI with no obvious cause, i.e. without neurological or congenital anatomic alterations, is often seen together with other urinary symptoms such as frequency, urgency and infections. Altogether these symptoms are referred to as functional LUT dysfunction, which is the term used to describe the entire spectrum of functional filling-voiding disturbances [2]. Several sub-classifications have been used for children who present with varying degrees of "functional" urinary symptoms. Some are based on urodynamic patterns, others on clinical presentation.

According to definitions by the ICCS [3], based on symptoms and flow-residual studies rather than invasive urodynamic investigations, incontinence as a result of a storage-phase dysfunction, is in most cases due to an OAB, which can also be referred to as "urge syndrome" and "urgency incontinence". Children with OAB usually have detrusor overactivity, but this label cannot be applied to them without cystometric evaluation. SI is the involuntary leakage of small amounts of urine during effort or physical exertion that increases the intra-abdominal pressure, for example, coughing or sneezing. During urodynamic investigation, this leakage is confirmed in the absence of detrusor contraction. When incontinence is the result of a voiding-phase dysfunction, the diagnosis is often dysfunctional voiding (DV), which is induced by increased activity in the sphincter and pelvic floor during voiding. It is subdivided into staccato and fractionated voiding, and the terms cannot be applied unless repeat uroflow measurements have been performed. Voiding postponement (VD) is another common LUT dysfunction causing UI in children, but differs from the other since it is induced by a habitual postponement of voiding and not a LUT dysfunction per se.

The healthy infant is socially incontinent but physiologically continent, because micturitions (about once every hour) are discrete and there is no leakage of urine between micturition [7]. Bladder control develops during the first four to six years of life and is a highly complex process, which is still not fully understood. Most children are toilet trained by the age of three years, although there is a huge social and cultural variation. By the age of five years, the child is normally able to void at will and to postpone voiding in a socially acceptable manner [8]. By this age, night-time and daytime involuntary wetting becomes a social problem and a cause for therapeutic intervention.

NE and UI due to functional LUT dysfunction in children are the wetting problems addressed in this section. Both can be either primary (the child has not been dry for more than six months) or secondary (the wetting has recurred after a dry period lasting more than six months). If the complaints are secondary, they may signify psychological, neurological or even structural anomalies and therefore require careful consideration.

Although the ICCS standardization of terminology of LUTS in children and adolescents has allowed for clarity and a more uniform communication in scientific publications, there is still a variety of descriptions regarding frequency of symptoms in epidemiological studies. According to the ICD-10 and DSM-5 definitions and criteria the symptoms of incontinence (daytime UI and/or enuresis) requires a minimum age of 5 years, a minimum of one episode per month and a minimum of three months to be diagnosed as a condition. The ICCS standardisation terminology updated document in 2016 further proposes to qualify the significance of enuresis as frequent (>4 times a week) or infrequent (< 4 times per week)[3].

Smaller study populations (Total N in study <1000) not included in meta-analyses of total prevalence.

2. PREVALENCE OF NOCTURNAL ENURESIS (NE)

As bladder control is something that develops over time, longitudinal studies are the best way of defining the dynamics of this process. Studies giving the prevalence for all children between five and 15 years of age are less useful and cannot be applied in general, as all the developmental stages are clustered together. It is more accurate to report the prevalence for a cohort of a specific age, such as seven-year-olds. Furthermore, random sampling should preferably be used in order to be able to say anything about the population. These problems associated with understanding epidemiology were summarised by Krantz [9], who also reviewed the epidemiological studies that had been published by 1993.

One explanation for the variation in prevalence in different studies is the fact that some studies include only monosymptomatic enuresis (MNE), whereas others also include what is defined as nonmonosymptomatic enuresis (NMNE). Another explanatory factor is that the frequency of enuretic episodes differs or is not taken into account in some studies. Moreover, most epidemiological studies link primary and secondary enuresis together.

2.1. Prevalence of all night wetting (MNE+ NMNE) according to age

Longitudinal cohort studies are ideal when analysing epidemiology in childhood NE, as there is a successive reduction in prevalence. Only a few studies are available [10-17] and cross-sectional studies at different ages therefore have to be used.

Most studies investigate cohorts of children in an age span of six to twelve years of age, for example, and give the prevalence for the entire group. Some of them also give the age-related prevalence [13, 18-38] which is summarised in Table 1. Cross-sectional studies of a specific age are also included [16, 17, 39-46] in Table 1.

In most studies the prevalence for seven- year-olds was between 7% and 10%. In a some studies, the prevalence was higher; 15% to 23% for children in Turkey [22,34,47], India [32], Denmark [46], Korea [23] and Egypt [36], despite the fact that the inclusion criteria were similar in all the studies of seven-year-olds (NE=night wetting once/month or more). Two cross sectional epidemiological studies from Yemen and one study from the Republic of Congo [30] have showed markedly higher frequencies with 31%-45% NE among children 6-8 years declining to 8.7% in adolescents 15 years or older [29, 33]. These studies have smaller study populations compared to other studies cited and selection bias can therefore not be ruled out, but the findings are interesting. The studies by Hellström [39] and Järvelin [40] differ in NE criteria (once/3 months or more and once/6 months or more respectively). The prevalence of more frequent wetting (once/week or more) was lower compared to the prevalence for all wetting (once/month or more) by age, which has been illustrated in Fig.1.

In 18 studies at age seven years [12, 16, 18, 21, 23-26, 31, 32, 34, 35, 37-40, 44, 46] the numbers of both non-enuretic and enuretic children were given and the definitions for enuresis were similar (MNE and NMNE, wetting once/1-3 months or more). A prevalence of 11.4% was obtained by meta-analyses of these studies (a cohort of 29 097 seven-year-old children, of whom 3320 were enuretic). Only a few studies included groups of children that were chosen at random from the population [18, 23, 26, 30, 40].

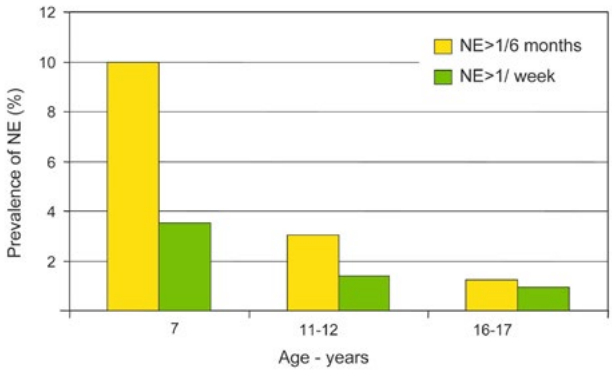

Figure 1. Prevalence of nocturnal enuresis (NE) by frequency of enuretic episodes and age. The data were obtained from metaanalyses of the epidemiological studies included in table III.1. NE>1 episode/6months: at 7 years [18, 21, 23-27, 39, 40], 11-12 years [18, 21, 23-26, 42] and 16-17 years [26, 41, 43]. NE>1 episode/week: at age 7 years [25, 26, 39, 40], 11-12 years [25, 26, 42] and 16-17 years [26, 41].

At age 11-12 years, the prevalence of NE had decreased and in most of the studies summarized in Table I the prevalence varied between 1.7% and 5.4%. In eleven of the studies, the number of non-enuretics and enuretics were available and the definition of NE was similar (once/month or more), apart from Swithinbank's [42] study (once/3 months or more). In these studies, the total number of children included was 15 924, with a total number of children with NE 589, giving a prevalence of 3.7%. So, of those children with NE at age seven years, almost 15% spontaneously grow out of the wetting every year. In a Japanese study a higher resolution rate was reported in children with MNE compared to NMNE in children 7 to 12 years of age (21% and 15%, respectively) [24]. Similar results were found in a study from Hong Kong in which the proportion of children with NMNE was significantly greater in adolescent boys than in boys aged 5-10 years (32% vs 14.6%), even if the total prevalence of NE was decreasing as in other studies [26]. The variation in the prevalence of NE at 11-12 years between the studies is less than that seen at age seven years.

At age 16-17, four cross-sectional studies show a further reduction in prevalence to 0.5-1.7%. Two of the studies re-investigated children who had previously been studied; at age seven years [41] and 11-12 years [42] respectively. The prevalence when the cohorts were added together was 1.3% (cohort=5679, NE=72) [26, 37, 41, 43], which gives a spontaneous cure rate of 11% a year among those who wet at age 11-12 years.

In a study of 13,081 adults randomly sampled in the Netherlands [48], an overall prevalence of NE of 0.5% was found. There was no significant difference between age groups. Primary NE was reported by 50% of the men and 19% of the women, indicating that a small group of the enuretic children remain enuretic as adults. Yeung et al found persistent primary NE in a 2.3% of Hong-Kong adults aged 16-40 years[49] and 1.9% had monosymptomatic enuresis. Enuretic symptoms in this adult population were more severe than in children, and of those with NE 53% wet > 3 nights a week and 26% every night[49]. In this later study the prevalence remained unchanged with increasing age indicating that NE persistent in early adulthood have a high risk of remaining.

2.2. Prevalence of monosymptomatic enuresis (MNE)

Few studies make a distinction between MNE and NMNE and it is therefore difficult to obtain relevant figures for MNE (Table 2). In two studies from Scandinavia dealing exclusively with seven-year-olds, there was agreement between the studies; 6.4% [40] and 7.4% [39]. A Japanese study gave similar figures for MNE; 6.2% at age 7 years. In this latter study MNE corresponded to approximately 60% of all NE in ages from 7 to 12 years [24]. When it comes to studies in which all ages were mixed (5-12 years), eight studies were identified in which those without daytime voiding problems could be identified. However, the difference in prevalence of MNE varied in these studies from 3.5% to 15%.

Table 2. Prevalence of Monosymptomatic nocturnal enuresis (MNE) at age seven years and overall (including all ages)

Author	Year	Prevalence of MNE (%)	
		Age 7 years	All ages included
Järvelin [40]	1988	6.4	
Hellström [39]	1990	7.4	
Yeung [19]	1996		3.5
Bower [50]	1996		15
Neveus [52]	1999		6.9
Kanaheswari [27]	2003	9	6.2
Lee [23]	2006	13.6	9.4
Kajiwara [24]	2006	6.2	3.5
Srivastava [32]	2011	15.5	12.6
Fockema [44]	2012	11.3	14.4
Mota [16]	2015	9.8	

2.3. Prevalence of NE versus gender

Almost all epidemiological studies of NE report a higher prevalence in boys than in girls, with the most reported ratio of 2:1 in western countries [16, 18-25, 28, 31, 32, 39, 40, 42, 50-52] . It appears that the gender difference diminishes with age and becomes less visible and less proven among older children [41, 43, 53] (Fig.2).

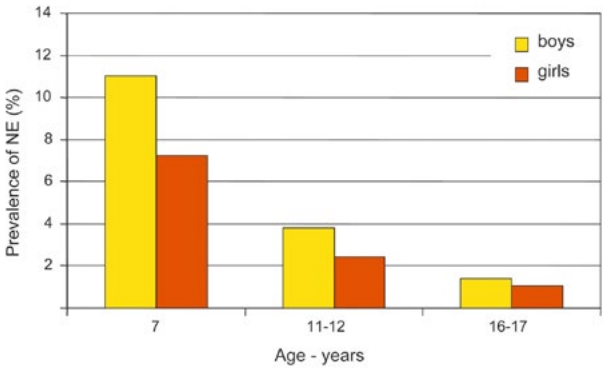

Figure 2. Prevalence of nocturnal enuresis (NE) >1 episode/6months, by gender and age. The prevalence data were obtained from metaanalyses of the following epidemiological studies: at age 7 [18, 24-26, 39, 40], age 11-12 [18, 24-26, 42] and age 16-17 [26, 41, 43].

2.4. Prevalence of NE versus ethnicity

In a study from The Netherlands [20], a higher prevalence was reported in the Turkish/Moroccan group (14%) than in Dutch children (6%) (OR 3.76 (95%CI 1.98-7.12)). An equally high prevalence was found in a Turkish study of children with NE [22] at age seven years (15.1%). In a study from Korea [23], the same high prevalence at age 7 years was identified (16.4%). However, other studies from South-East Asia had comparable [21, 24, 26] or even lower levels of prevalence to those in western countries. In fact, two Chinese studies have shown a low prevalence of NE [19, 54], 3.6% and 4.3% for children aged 4-12 and 6-16 respectively, which they attribute to earlier nocturnal urinary control in Chinese children, due to earlier toilet training. A recent survey from Mainland China showed a significant increase in prevalence of NE during the last decade (7,3% compared to 4.07%) and reported longer use of disposable diapers and delay of elimination communication to be significant risk factors for PNE [37].

2.5. Prevalence of NE versus frequency of wet nights and age

Yeung et al showed in a large epidemiological study that that the relative proportion of subjects with frequent bed-wetting increased with age [26,55]. Over all 82% of the adolescence had >3 wet nights/week versus enuretic children aged 5-10 (42%) (Fig.3). Such a relationship is also evident in Fig 1, in which the proportion of children with severe NE increase with age, even if the total number decrease. Further support for severe NE to remain in a higher proportion as compared to children with infrequent bedwetting was results in a study by Butler and Heron [15]. Findings in epidemiological studies also show a correlation between severity of the NE and NMNE [15, 18, 56], meaning that NE in adolescents often is combined with LUT dysfunction.

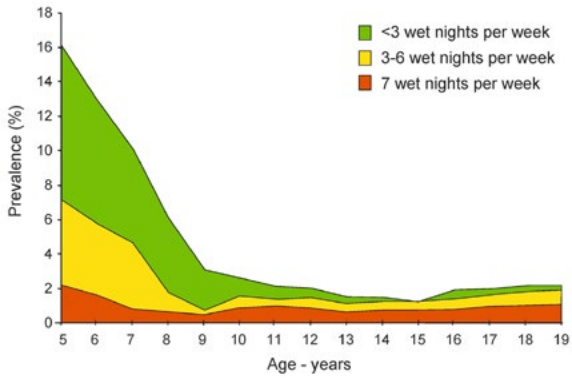

Figure 3. Prevalence of nocturnal enuresis by frequency of enuretic episodes and age. Data from [26].

3. POTENTIAL RISK FACTORS FOR NE

Several risk factors have been established or suggested by epidemiological studies and the most important ones will be discussed here.

3.1. Daytime UI and LUT dysfunction

Daytime UI, a symptom of LUT dysfunction, have in epidemiological studies been shown t**o** be the strongest predictor for NE (OR 4.8 (2.9-7.9)) and have been identified in a third of the patients (NMNE) ([56]). However, poor concordance was revealed (kappa 0.25),

which confirmed the two to be separate entities that should be evaluated and treated separately.

3.2. Family history
NE is a hereditary disorder and this has been demonstrated in many studies [18, 19, 22, 31, 32, 34, 35, 40, 50, 52, 57]). The mode of inheritance appears to be autosomal dominant. Järvelin [40] showed that, if both parents were enuretics as children, the RR (95% CI) for the child to have NE was 16 (6.3-20.1), while if only one was enuretic, the RR was 7.8 (5.1-9.8). It has recently been shown that the risk for the child to have hereditary NE is increased with the severity of the enuresis. Children with severe NE (>2 episodes/week) were combined with odds ratio for maternal NE 3.63 (2.56-5.14), whereas mild and moderate NE (<2 episodes/week) had 2.14 (1.74-2-64) [58]. The association with paternal NE was less pronounced, but a similar increased association to severe NE was observed. Using molecular genetic methods, foci have been found on chromosomes 13, 12, 8 and 22 [59, 60]. A picture of pronounced heterogeneity for both genotype and phenotype emerges [61]. Time to spontaneous resolution of MNE also seems familial with a positive correlation between the age of cessation of MNE of the child and their mothers and fathers [62]

3.3. Psychopathology
There are evident connections between childhood enuresis and mental well-being [13, 14, 54, 57, 63-66]. The children are increasingly negatively affected by their NE with increasing age [67]. Evidence is accumulating to show that psychological consequences are probably caused by enuresis and not by the cause of primary NE, which has been thought for a long time [64]. The findings presented by Feehan [14] support this latter statement, as he only found an association between psychopathology and secondary NE, while children with primary NE did not display a connection of this kind.

3.4. Developmental delay and ADHD
Children with developmental delay and mental retardation have been shown to have a higher prevalence of NE [12, 20, 40, 68]. Spee-van der Wekke [20] found that children who were given special education in school, including both those with and without mental retardation, had an OR of 3.74 (95%CI 2.32-6.03) for NE.

Perinatal events such as toxaemia and low birth weight, possibly involving an increased risk of minor neurological dysfunction, have also been shown to be associated with NE [12, 40, 57]. A connection between NE and minor neurological dysfunction of this kind has also been shown by Lunsing [69] in 12-year-old enuretic children. Furthermore, children with attention deficit hyperactivity disorders (ADHD) are more likely to have enuresis than the general child population [65, 70-72] The other way around was also confimed in a case control study by Yosefichaijan who found a threefold increase of ADHD in children with MNE compared to a control group[73]

3.5. Sleep and arousal
The main pathology behind NE in children is the inability to wake up to the sensation of a full bladder. Parents often say that their enuretic child “sleeps very deeply”. Some recent studies support this view. By using auditory signals [74], computerised EEG [75] or questionnaires [52], a defect in arousal has been largely validated. In the study by Neveus [52], the odds ratios were significantly high for a high arousal threshold (2.7), pavour nocturnus (2.4) and confusion when awoken from sleep (3.4). Computerised EEG energy analysis has indicated both greater depth of sleep and impaired arousal in enuretics [76]. Difficulties in arousal from sleep has also been shown in children with NE compared to children with isolated daywetting problems and controls, by using a scoring system in a questionnaire [77]

3.6. Socio-cultural factors
Differences in the prevalence of NE [19, 22, 23, 54, 78] at early ages in different parts of the world are probably partly due to socio-cultural differences and not to differences in genetic predisposition [20]. It has been suggested that socio-economic status correlates with NE in some studies [18, 65], whereas in others no correlation was found [12]. Habits of tea-drinking in the evenings have also been identified as a risk-factor for NE[29, 33].

3.7. Other risk factors
Obstructive sleep apnoea (OSA) has been associated with enuresis in some patients [79]. In an epidemiological study an association between severe OSA and NE in girls was shown [28], but when including both sexes and all forms of OSA no difference was seen. In another study dealing with OSA patients versus controls, a significant correlation between NE and OSA was found (OR 5.1 (2.4-10.7) [80]. Removal of large adenoids or tonsils causing upper airway obstruction in children with NE significantly reduced or cured NE [81]. There are recent studies presenting an independent association between asthma and allergic disease and NE [82] Constipation (see co-morbidity below) may cause secondary NE or make primary NE persist [83]. Enkopresis has been shown to be a risk factor for NE in an epidemiological study (OR 2.7 (1.6-4.4)), while no association with constipation could be identified [56]. The correlation between encopresis and NE was also confirmed in an epidemiological study from Brazil [16]. Children suffering from obesity has also shown increased risk of having NE compared to non-obese children[84]. Children with Sickle Cell Disease are found to have increased prevalence of NE with studies reporting prevalence of 30-32% in paediatric populations with Sickle Cell Disease [85, 86]. Sexual abuse must also be included among the factors that may lead to NE [87], with increased prevalence of enuresis, compared to expected for age, in children referred for allegations of sexual abuse[88] Organic conditions such as infravesical obstruction and neuropathic bladder may also present as NE. In most cases, however, additional symptoms are present to make detection possible. Type1 diabetes was reported to be a risk factor for secondary MNE due to the polyuria seen at presentation [89]

4. PREVALENCE OF FUNCTIONAL INCONTINENCE IN CHILDREN

In children with functional LUT dysfunction, OAB is far more common than dysfunctional voiding. In a urodynamic study of 1,000 patients with functional LUT dysfunction, approximately two-thirds had an overactive bladder and one-third had dysfunctional voiding [90]. Based on clinical information, another study comprising 226 children revealed that 76% were considered to have OAB and only 1% dysfunctional voiding. The difference illustrates that different inclusion criteria influence the prevalence rate [91].

When considering the total prevalence of UI (all frequencies of UI included) (Table 3), there was a variation between 3.2% and 11.2% in different studies at the age of seven years. In the earliest studies the prevalence was lower (3.2%-5.0%), whereas in the studies performed later than 2000 [16, 23, 25, 92-94], the prevalence was higher 6.3%-11.2%. One explanation for the difference was probably an increased recognition of the problem in the population through information via media etc. At 11-13 years the reported prevalence varied between 0.9% and 12.5%. Swithinbank’s study [42]

Episodes of UI: 1 >1/6 months, 2 >1/3 months, 3> 1/ month, 4 >1/2 weeks, 5 occasionally

showed a high prevalence (12.5%) and differed most from the rest (0.9%-4.2%). The difference could probably partly be explained by different limits for frequency of UI (occasionally [42] vs once/month or more). The fact that the studies were performed in different parts of the world was also a possible explanatory factor (UK, Turkey and Korea).

The frequency of UI decreased with age (Table 3), which was clearly demonstrated in the subjects with frequent episodes of UI (>1/week) (Fig.4). The prevalence at 7 years, 11-13 years and 15-17 years was 2.6%, 1.1% and 0.3% respectively. There were only two authors who investigated the same cohort of children on two occasions; Hellström [39, 41] in Sweden and Swithinbank [42, 43] in the UK. According to the studies by Hellström, the reduction from seven years to 17 years was 0.2% per year in those with wetting at least once a week and 0.3% when including all kinds of wetting. Swithinbank reported a far higher frequency for all kinds of wetting at age 11-12 years but not at 15-16 years and the reduction in his cohort of children was therefore approximately 2% per year.

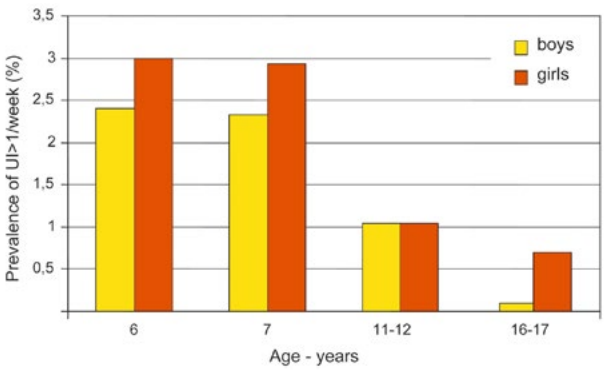

Figure 4. Prevalence of day UI (including mixed day/night) >1 episode/week by age and gender. Data are from: at age 6 years [98], 7 years [25, 39], 11-12 years [25, 42] and 16-17 years [41]

UI was more common in girls in most studies, especially in the older age groups (Table 3, fig. 4). From the prevalence found in the different studies, daytime UI could be suggested to be 1.5 times more common in girls than in boys at age seven years, whereas at age 16 years the difference was even more pronounced: 5-10 times more common in girls than in boys (Table 3). Overall in a population based study in 2856 children between 4.8-12.8 years, female gender was an independent riskfactor for UI (OR 5.4 (2.6-11.1), [95].

4.1. Prevalence of overactive bladder (OAB)

In a Japanese study [92], the prevalence in children between 7 and 12 years of age, OAB was seen in 17.8%, with no significant difference between boys and girls. There was a gradual decrease in prevalence from 19.8% at the age of 7 years to 12.8% at 12 years.

4.2. Comorbidity:

4.2.1. Prevalence of NE

NE in combination with UI is denoted as NMNE as mentioned above. NE has been identified as an independent risk-factor for day-UI (OR 7.2 (3.4-15.2)) [95]. Association of NE to day UI was more often reported in children with frequent UI (≥ 2 episodes/week), as compared to infrequent UI (< 2 episodes/week) at 7.5 years [94]. In boys NE was seen in 70-80% of those with frequent day UI compared to about 50% in those with infrequent. Corresponding figures for girls was about 55% and 30%, respectively.

4.2.2. Prevalence of Bowel problems

Urinary and fecal incontinence often coexist in different combinations. Constipation in childhood is a very common condition and when functional FI is seen, constipation is often the cause. The term encopresis can be used synonymously with functional FI. An increasing number of epidemiological studies reporting the frequency of bowel problems have been published, either as constipation or functional FI, in children with daytime wetting. Table 4 shows that the prevalence of bowel problems in day-wetting children approximately corresponded to a third of the children (21%-35%) [25, 77, 92, 93, 95, 96], with even higher prevalence in the subgroup with dysfunctional voiding (43%) [96]. A significant association between daywetting and bowel problems was shown [25]. These results support the new treatment concept of day-wetting children, with

Table 4. Comobidities. The prevalence of concomitant bowel problems in children with day-wetting and nocturnal enuresis

Author	Number children bowel problems in day-wetting group	OR (95%CI)	Number children bowel problems in NE	OR (95%CI)
Söderstrom 2004 [25]	35%	7.2 (4.1-12.7)		1.2 (0.6-2.5)[2] 2.0 (0.6-6.3)[3]
Kajiwara 2004 [92]	33%

Chandra 2004 [77]	24%		1%-24%[1]	
Joinson 2006 [93]	33%			
Sureshkumar 2009 [95]	21%	3.3 (1.4-7.7)[2]		
Fockema 2012 [44]			15.8%	
Sarici 2015 [34]			13.2%	1.52 (0.92-2.5)[3]

[1]low value represents MNE, high value NMNE, [2]OR for fecal incontinence, [3] OR for constipation, [4] Subgrouping of daywetting in OAB, VP and DV the prevalences are: 18%, 25% and 43%, respectively.

treatment of bowel problems as the first step. MNE, on the other hand, seldom have bowel problems (0%-1%), whereas in NMNE it is more common (16%-24%) [77, 96].

In an epidemiological study from Japan including 5282 children, aged between 7-12 years, 81.5% were reported to have daily bowel movements. A significant higher prevalence of NMNE was found in those with constipation, compared to among those with regular daily bowel movements (3.4% vs 2.2%) [24].

5. POTENTIAL RISK FACTORS FOR DAY WETTING

5.1. Family history

Day wetting, also including those subjects with mixed day and night wetting, has been shown to be correlated to hereditary factors, in parallel to what is known about children with NE. However, the number of studies is limited (Table 5). Hereditary factors have been shown to be more pronounced in those with severe UI (>2 episodes/week), especially when paternal day UI is present (Table 5) ([58, 97].

Table 5. Day wetting vs family history (including mixed day/ night wetting)

Author	RR (95% CI)	OR (95% CI)	Positive history (%)
Järvelin [57]			
-enuresis in mother	10.1 (3.4-29.3)		
-enuresis in father	5.9 (1.9-17.8)		
Sureshkumar [98]			
-daytime wetting in male sibling		5.3 (1.6-18.2)	
-daytime wetting in paternal lineage		9.3 (3.2-27.3)	
Chiozza [18]*			
-enuresis in parents		12.3	
Bower [50]			
-family history of enuresis			70**
Neveus [52]			
-family history		2.0 (1.1-3.7)	
Von Gontard [58]			
<2 episodes/week			
-maternal NE		1.2 (0.9-1.6)	
-paternal NE		1.3 (0.9-1.8)	
-maternal day UI		2.6 (1.4-5.1)	
-paternal day UI		5.5 (2.4-12.5)	
>2 episodes/week			
-maternal NE		2.1 (1.2-4.0)	
-paternal NE		2.1 (1.0-4.3)	
-maternal day UI		3.3 (0.8-13.7)	
-paternal day UI		10.1(2.3-44.1)	

Only children with mixed day and night wetting, **compared with 45% in dry children

5.2. Psychopathology

Children under stress as a result of marital separation, for example, have a higher incidence of diurnal or mixed UI, according to some authors [18, 57, 98]. Moreover, psychopathology investigated by Järvelin [57] using the Children's Apperception Test (CAT) revealed a significant increase in the signs of repression, including an inability to express one's emotions and feelings (p=0.027), when comparing day wetting children with controls. Neveus [52] found that day-wetting children had more difficulty falling asleep (OR 2.4, CI 1.4-4) and he interpreted them as "anxious children". Lettgren [99] found a significant increase in attention problems and delinquent behaviour in a certain form of day-wetting children (voiding postponement) using the Child Behaviour Check List (CBCL, Achenbach). In a recent paper [100] similar results were found with the highest rate of psychiatric comorbidity in children with UI due to voiding postponement and the lowest in children with MNE. In the group with encopresis 65% were considered to have severe behavioural problems [96], meaning that children with both wetting and bowel problems are at the highest risk for psychopathology.

In a population-based study investigating psychological problems associated with day UI, 8213 children were included of whom 643 suffered from daytime wetting at median age of 7.5 years [93]. Over all the results indicated a rate of psychological problems that was twice the rate reported for children with no daytime wetting, particular notable was the increase in externalizing problems. After adjustment for developmental delay, gender, stressful life events, variables associated to family sociodemographic background and soiling, there was still an independent association of daytime wetting and behaviour problems (OR 2.04, CI 1.67-2.51). In another epidemiological study UI was found to be associated with parenteral concerns about the child's social behaviour (OR 3.4 (1.4-8.3)), [95]. It is not clear whether the behavioural problems described in these studies are a cause or a consequence of daytime wetting.

5.3. Minor neurological dysfunction and developmental delay

Children with minor neurological dysfunction have also been shown to have an increased rate of day wetting. Duel [70] found that children with ADHD are three times more likely to have daytime UI than controls (p<0.0005). Von Gontard and Niemczyk also found children with daytime urinary incontinence to have a significantly higher risk for ADHD and opposite deficient disorder (ODD) symptoms [101, 102]. Also in children with delayed maturation or with mental retardation, the risk of day wetting is increased (OR 1.9 and 4 respectively), according to studies by Järvelin [40]. Perinatal events, which can also be suggestive of minimal brain dysfunction, have also been shown to be over-represented in day-wetting children. For example, Järvelin [57] found that the children of mothers who had suffered from toxaemia had an RR of 8.5 (CI1.4-51.9) for day UI.

5.4. Other risk factors for daytime UI

Sometimes, functional daytime UI is difficult to distinguish from UI due to organic anomalies. The most prominent examples are the adolescent form of posterior urethral valves in boys and ectopic ureter and epispadias in girls.

In many papers, UTI is regarded as a risk factor for daytime UI. Järvelin [57] found a RR of 8.6 (2.3-32.3) for UTI in daytime UI children. Neveus [52] was able to demonstrate similar connections; OR 2.3 (1.3-3.9) and similar results were seen in Sureshkumar´s study

[95]; OR 5.6 (2.0-15.6). However, these infections should probably be regarded as a consequence of the functional bladder disturbance with UI and not the other way round as a cause of the UI.

6. SUMMARY POINTS

Nocturnal enuresis (NE)

- The prevalence of NE at age 7 seems to be around 11% for most countries, at age 11-12 years around 3.7% and at age 16 around 1.3%.
- The spontaneous cure rate seems to be around 15% annually between 7 and 12 years, and between 12 and 17 years 11%.
- In an adult population the prevalence of NE seems to be 0.5-2%. The prevalence was 1% when including only those with childhood enuresis. Thus the risk of having persistent NE as adult if having the condition at 7 years of age can be calculated to 1%.
- Potential risk factors for NE in children include OAB, polyuria, family history, psychopathology, developmental delay, mental retardation, socio-cultural factors, sleep and arousal problems, sleep apnoea, constipation, sexual abuse and organic conditions such as infravesical obstruction.

Functional incontinence

- Children who are and remain dry in the daytime seem to attain their diurnal continence between the age of 4 and 5 years
- Diurnal UI, or combined diurnal and nocturnal UI, in children is caused by OAB in the great majority of cases.
- Prevalence for functional UI decrease with age. At age 7 years prevalence figures varies between 3.2% and 9%, with the highest prevalence in recent studies. At age 15-17 years the corresponding prevalence is 1.2-3%.
- Variation in prevalence figures is mainly dependant on differences in frequency of incontinence episodes in the studies.
- Potential risk factors for diurnal UI in children include bowel problems such as constipation and functional fecal incontinence, family history, psychopathology, socio-cultural factors, minor neurological dysfunction, developmental delay, organic anomalies such as infravesical obstruction in boys and sexual abuse.

IV. EPIDEMIOLOGY OF URINARY INCONTINENCE IN WOMEN

This section presents a narrative account of a targeted selection of high quality studies that illustrate what is currently understood about the prevalence, incidence, and risk factors for UI including its common subtypes, stress UI, urgency UI, and MUI.

1. GENERAL COMMENTS AND DEFINITIONS

Current terminology for female UI is drawn from the 2010 IUGA/ICS joint terminology report [105], but in most instances is entirely compatible with current terminology for men [106], and children [107]. In considering the epidemiology of female UI, researchers have mainly addressed the epidemiology of the symptom of UI, defined as the complaint of involuntary loss of urine. There remains a paucity of work at a population or community level concerning either the sign of UI, defined as observation of involuntary loss of urine on examination, or on the formal laboratory diagnoses of USI or DO.

A large majority of epidemiological studies have either not considered subtypes of UI, or only reported on SUI (complaint of involuntary loss of urine on effort or physical exertion), UUI (complaint of involuntary loss of urine associated with urgency), and MUI (complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing). A small number of studies have reported prevalence and risk factors for adult NE (complaint of involuntary urinary loss of urine which occurs during sleep). With a lack of validated questionnaire items for less common subtypes, the current literature is almost silent regarding the population prevalence and risks for postural incontinence, continuous incontinence, insensible incontinence, and coital incontinence, although they are sometimes grouped as “other incontinence”. Finally, there remains a separate category of incontinence, so called “functional incontinence”, more typical of institutionalised older adults, for whom physical or cognitive impairment limits their ability to use a toilet.

There are a large number of urinary symptom questionnaires employed in epidemiological research all with varying evidence of validity. Most questionnaires were initially developed using secondary care, i.e. hospital and institutional samples, with criterion validity demonstrated in comparison to bladder diaries, pad tests, or urodynamic diagnoses. Quite widely varying terminology is used in the items assessing SI and UI in different questionnaires (see Table 1 overleaf), and some items do not capture all aspects of the standardized definitions. Even the surrounding context for the items is known to strongly affect prevalence estimates [108-109], and small variations in terminology from different questionnaires may have similar effects.

The optimal assessment of incontinence subtypes remains controversial [110-111], but it is clear that self-report of symptoms differs systematically from detailed clinical evaluation. In particular, for women, MUI is more common than would be expected by chance, at least using questionnaire evaluation [112], and is reproduced less frequently using urodynamics [113-114]. SUI and UI have different treatment options, and are presumed to have different underlying pathophysiology. Caution is therefore needed when comparing epidemiological studies that either do or do not report a separate MUI subgroup, and when generalizing from population level data on MUI to clinical practice.

Self-report of UI symptoms should reflect the woman’s own experience of incontinence, but may bear little relationship to felt or expressed need for treatment. Across multiple measures, incontinence severity is shown to be only a moderate predictor of incontinence specific quality of life impairment [115-116]. It is important therefore to characterize both the severity of symptoms, through frequency of leakage and/or quantity of loss, and the perceived bother or impact on activities. Most questionnaires in contemporary use, including the ICIQ-SF, ICIQ-FLUTS and DAN-PSS, therefore ask patients to report both the frequency of UI, and its perceived bother (Table 6). Cautious interpretation should be made of high prevalence rates obtained with case definitions that do not incorporate some measure of symptom bother or impact.

UI is a stigmatizing condition in many populations [117], which creates a high risk for respondent bias in UI epidemiology [118-119]. Perhaps because of stigma, incontinence is also associated with low rates of presentation for care. Surveys assessing UI in healthcare settings may therefore also be highly prone to both medical

Table 6 Stress incontinence and urgency incontinence items from a range of validated questionnaires widely used in epidemiologic research

Questionnaire	Validation Paper	Stress Incontinence Item	Urgency Incontinence Item
King's Health Questionnaire	Kelleher et al., 1997 (127)	Urinary leakage with physical activity e.g. coughing, running	Urinary leakage associated with a strong desire to pass urine
BFLUTS & ICIQ-FLUTS	Jackson et al, 1996 (128)	Does urine leak when you are physically active, exert yourself, cough or sneeze?	Does urine leak before you can get to the toilet?
Dan-PSS (English version)	Schou et al, 1993 (129)	Do you experience leakage of urine when you physically exert yourself (e.g. coughing, sneezing, lifting)?	Is the compulsion to pass urine so strong that urine starts to flow before you reach the toilet?
OAB-q	Coyne et al, 2002 (130)	N/A	Urine loss associated with a strong desire to urinate
Urogenital Distress Inventory	Shumaker et al, 1994 (131)	Do you experience urine leakage related to physical activity, coughing or sneezing?	Do you experience urine leakage related to the feeling of urgency?
EPIQ	Lukacz et al, 2005 (132)	Do you experience urine leakage related to activity, coughing, or sneezing?	Do you experience urine leakage related to a feeling of urgency?
PFDI	Barber et al, 2005 (133)	Do you usually experience urine leakage related to laughing, coughing, or sneezing?	Do you usually experience urine leakage associated with a feeling of urgency; that is, a strong sensation of needing to go to the bathroom?

surveillance bias, in which presentation to care for other reasons results in a diagnosis of UI; and Berkson bias, in which selection of cases from within hospitals tends to reduce generalizability to the population, and may suggest associations with spurious risk factors. We therefore focus on community or population based samples with response rate over 60% [120]. To further minimize differential effects of such biases, where possible we report outcomes stratified by age, by type of UI, and by major subgroups of interest.

The majority of work reviewed in previous editions of this chapter, originated from the OECD countries. There have been many recent studies from both BRIC and developing countries [121] which are now reviewed. Subsequent discussion excludes however the epidemiology of obstetric vesico-vaginal fistula, which is covered in a later chapter.

2. PREVALENCE

Among general population studies unadjusted prevalence estimates for the most inclusive definitions of UI ('ever' 'any' or 'at least once in the past 12 months') have ranged from 5% to 69% [122], with most studies reporting a prevalence of any UI in the range of 25% to 45%. This enormous variation between studies is seen both within and between countries, and with few studies reporting age standardized rates, largely precludes meaningful comparison between countries. If there is variation in true prevalence rates between countries, it is obscured by cultural differences in the perception of UI and willingness to report UI, as well as methodological differences [123], including in the wording of questionnaire items, in the method of administration of questionnaires, and perhaps most importantly, with differences in case definitions employed [124-125]. There remains a severe lack of studies from the developing world [126].

Very few studies have used the same survey tools and methods to report female UI general population prevalence in more than one country (Table 7). Four studies have attempted to assess the relative prevalence in western nations [134, 136,138-139]. Across all countries surveyed, all these studies find that SUI is the most common subtype, followed by MUI, and then UUI. Hunskaar and colleagues surveyed 29,500 women in France, Germany, the UK and Spain [134]. By demonstration of similar age trends across all countries, they suggested both lower overall prevalence of incontinence in Spain, and a relative excess of urgency incontinence in France. The EPIC (Epidemiology of Incontinence) and EpiLUTS (Epidemiology of Lower Urinary Tract Symptoms) studies [136,140] used similar questionnaire items explicitly based on standard definitions. However, there was inconsistency between studies. The EpiLUTS study found similar prevalence of each UI subtype in the US, UK, and Sweden, while the EPIC study reported a more than 3-fold variation in prevalence between countries, with Sweden having a prevalence of 29.5% and Italy only 9.3%. The disparity in results could be explained by differences in sampling methods, or different response rates (58%, 33% and 59% respectively). A further study set in Senegal, Mauritania, and Chad, reports substantial variation in prevalence across countries, even after age stratification [135]. Finally, in a recent survey using identical methods across Russia, the Czech Republic and Turkey (n=3,130) [141] there was noted similar prevalences in Russia and Czech Republic, but an excess of urinary storage symptoms (including UI) in Turkey. Again, it is unclear whether such differences are due to linguistic differences in questionnaires, differences in response proportion, or true cultural or biological differences. The lack of consistency in between country comparisons, even for large surveys set in western nations, makes it impossible to assess the extent of true variation between countries. It also remains difficult to establish stable, meaningful prevalence rates for female UI, when there is no consensus about what constitutes significant UI. Again, extreme caution is needed in making direct comparison of crude prevalence rates.

Although between study comparisons of female UI prevalence are largely unrewarding, we can meaningfully compare within study distributions of UI by age and UI subtype. Table 8 summarizes prevalence estimates by age for female UI from community or population based studies with response rate >60%. Again a 10 fold variation in

unadjusted prevalence rates is evident between studies, so where available, overall prevalence rates are given by UI subtype, while age trends are depicted with sparklines. These depict the variation in age specific prevalence across the full age range of each study.

Table 7 Population prevalence rates for female UI from studies sampling in more than one country.

As in the studies comparing prevalence between countries, absolute prevalence rates vary widely in recent cross-sectional work. However, the distribution of UI subtypes is consistent. Isolated SUI accounts for approximately half of all incontinence, with most studies reporting 10-39% prevalence. With few exceptions, mixed incontinence is found to be next most common, with most studies report 7.5-25% prevalence. Isolated urgency incontinence is uncommon, with 1-7% prevalence, and where recorded at all, other causes of incontinence occur with approximately 0.5-1% prevalence. In summary, current data provide very disparate estimates of population prevalence for UI in women. Approximately 10% of all adult women report leakage at least weekly. Occasional leakage is much more common, affecting 25%-45% of all adult women. Prevalence rates from cross-sectional studies uniformly demonstrate an association with age, which is explored in more detail in the subsequent section on risk factors.

3. INCIDENCE AND REMISSION

Many prospective longitudinal studies have examined UI in women, either in the general population, or focused on pregnancy, menopause or old age. However, interpretation and comparison of incidence and remission rates is fraught with difficulties. Incontinence is not intuitively a condition, with fluctuating severity, indeed the popular perception in both the medical community and the general public, is of a chronic condition. However, misclassification due to the unreliability of symptom assessment tools may cause the appearance of symptom fluctuation. Measuring the short term test re-test reliability for the BFLUTS questionnaire [128], the DAN-PSS [172], the IIQ [173], or any of the other commonly used questionnaires suggests that only 80-85% of item responses are stable over even a brief retest period. Thus even when a longitudinal study is able to use the exact same item for assessment across even relatively long periods of follow up, the effect of misclassification due to questionnaire unreliability may obscure a true effect of incidence or remission. Even non-differential misclassification bias, can have serious consequences both for estimates of absolute cumulative incidence, and relative incidence risk, and such effects are largest for conditions such as UI, with high prevalence and low incidence [174].

Other methodological differences may also cause wide variation. Questionnaires that use different recall periods (e.g. any leakage in last week, any leakage in last year, any leakage ever) will produce different estimates of incidence and remission. Due to changes in standard definitions, many studies have also used different case definitions at baseline and follow-up. Finally, although loss to follow up itself is very variable between studies, differential loss to follow-up is observed in almost all studies, and must substantially decrease generalizability.

Annual incidence rates for broad definitions of UI (“monthly” or “any”) range from 0.9% to 18.8%, while rates for weekly UI show less variation at 1.2-4.0%. There is a significant negative correlation between the length of a study and its reported annualized incidence rate, suggesting that short studies of 1-2 years overestimate incidence due to a dominating effect of misclassification. Limiting comparisons to studies with >5yr follow up suggests incidence of 1.3-4.9% even for inclusive definitions of UI. Fewer studies have reported remission rates, and again estimates vary widely between 1.2 and 42%. Again, limiting the comparison to longer studies of >5yrs suggests rates of 2.1 to 5.0%. Overall these results are compatible with findings from cross-sectional studies, with modest increases in UI prevalence across the whole female population of 0.5-1% per year. Although the extent of cohort effects has rarely been reported, current data suggests that earlier cohorts are less likely both to report incontinence [167, 175], and to seek care for it [176].

4. POTENTIAL RISK FACTORS

This section summarises the most important reported demographic, social, environmental, and lifestyle correlates of urinary incontinence in women. Familial risk factors for UI and POP are considered together in the section on genetic epidemiology.

While a majority of previously cited studies have reported associations with incontinence, great caution is again needed in assigning these as causal risk factors. As already seen, a large majority of studies are cross-sectional in design, providing no evidence of causation, since the temporal association of the putative risk factor and the onset of UI cannot be assessed. Where possible we therefore try to focus on risk factors for incident UI, from longitudinal studies. Again though, with the exceptions of mode of delivery, menopause hormone therapy, and weight loss, there remains a dearth of interventional studies. Even the highest quality observational studies may suffer from residual or unmeasured confounding, further limiting conclusions about causality.

4.1. Age

The age distribution for UI of all causes reported in the widely cited EPINCONT study [200], depicts a steady increase in moderate and severe UI throughout the adult lifespan, but with a distinct peak in slight UI around the time of the menopause. Other large studies have, however, reported a steady increase in prevalence for both slight and severe UI, without a distinct menopausal peak [201]. The timing and causes of a fifth and sixth decade peak has been explored in a number of high quality longitudinal studies of menopausal transition, discussed subsequently. Where such a peak is identified from cross-sectional studies, it is most pronounced for SUI [134,202]. Across most cross-sectional studies isolated SUI declines into old age, as MUI becomes relatively more common [200,203]. Besides methodological differences, disparity in age ranges, severity thresholds, and proportion of each subtype of UI probably therefore explains the modest differences in age trends seen in Table 8. These age trends, drawn from cross-sectional studies, may in any case be biased by cohort or period effects.

While most cross-sectional studies find an increase in prevalence into old age, some high quality studies have identified a peak in all cause UI, with a decline in the eighth and ninth decade [165]. Such a large disparity might be explained by sampling strategies that include or exclude institutionalized adults. The epidemiology of UI in this vulnerable group deserves special attention, and of course remains of key interest to geriatricians. The epidemiology of UI in nursing home residents has been the subject of one systematic review [204]. Only one primary study provides data from more than one country, allowing cross-border comparisons. From a population of 279,191 elderly people in care homes, from Denmark, France, Iceland, Italy, Japan, Sweden, and the US, the prevalence of female UI was relatively stable at 42.0-72.5% [205], with much of that variation accounted for by differences in age structure, and proportion of residents with functional or cognitive impairment. Indeed variability in prevalence estimates for female care home residents across the entire literature is much less than for the general population [204], ranging from 42.0% in Japan [205] through to 78.4% in the US (using a much more inclusive definition) [206]. UI is associated with nursing home admission from the community [207]. This may in part explain the apparent steeper increase in prevalence with age in nursing homes compared to community dwelling samples [206]. Loss to follow up certainly limits our ability to accurately assess age trends in the elderly from cross-sectional studies.

Given the difficulties in establishing robust incidence estimates, most longitudinal studies do not provide good evidence of age trends in incidence. Studies have variably reported no change in incidence with age, or a stable incidence in middle age, with a sharp increase in old age. However, the large Nurse's Health Study cohort [180] provided good evidence of a decrease in incidence of SUI following the menopause, which has more recently been explored in analyses of the SWAN study [208], the 1946 British Birth Cohort [202] and the Hordaland Women's Cohort [209]. All these studies provide consistent evidence of a peak in UI at the time of the menopause, with pre- and peri-menopausal status being associated with increased incidence of UI and decreased remission of UI compared to post-menopause. As will be discussed in the section on menopausal replacement therapy, part of this peak may be iatrogenic. Consistent with evidence from cross-sectional studies [134,200] the peak is attributable mainly to mild SUI.

While the association between age and female UI is clearly important for planning healthcare resource allocation, in many studies this is not an independent association. Other risk factors associated with age, including parity, co-morbidities, and BMI attenuate the association with UI [201], and additional adjustment for relevant co-morbidities typically eliminates the association [145]. Confounding factors adequately explain the association between age and UI, and therefore UI in women should not be considered as an intrinsic consequence of the aging process itself.

4.2. Obesity and Adiposity

Obesity is perhaps the most clearly established risk factor for UI in women. There is a wealth of cross-sectional, longitudinal, and interventional data demonstrating positive association between BMI and UI, which has been subject of several systematic reviews [210-212]. Across a wide range of studies obese women have approximately double the risk of UI. A typical pattern of association, taken from the large (n = 83,355) Nurses' Health Study II [213] is demonstrated in Figure 5. The ORs for UI by severity are plotted against BMI, from underweight through to obese. Although the Nurses' Health Study II is limited to middle aged women, such findings are consistent across all age groups, both within studies [214] and between studies [210]. This association is quite minimally attenuated by adjustment for other risks for UI.

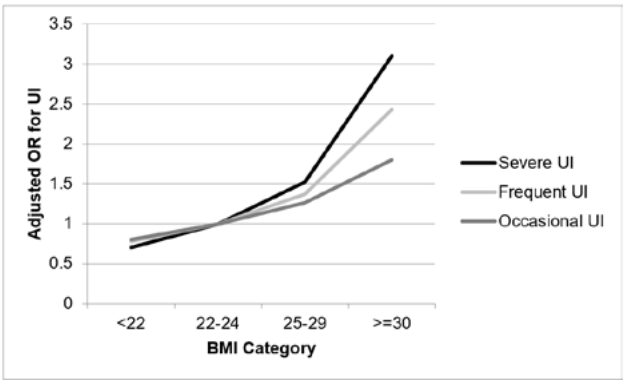

Figure 5 Associations between BMI and UI severity from the Nurses' Health Study II. Original figure created based on data reported in Danforth et al, AJOG 2006 [213].

Data from the EPINCONT survey also demonstrate the same positive association between BMI and more severe UI. Additionally they indicate that such associations hold for the major subtypes of UI (Figure 6), but are most pronounced for mixed UI, and relatively modest for UUI. Similar findings were reported for data from the Heart and Estrogen/Progestin Replacement Study [215] and the 1946 British Birth Cohort [216] with the associations with BMI being greater for SUIor MUI compared with UUI.

The temporal association between BMI and UI is also established with data from the 1946 British Birth Cohort, SWAN, MRC Incontinence [181] and the Nurses' Health II studies demonstrating that earlier onset of obesity is associated with increased risk for UI in middle age [217] and that both higher BMI and greater weight gain are associated with increased risk of incident UI [181,184, 218]. Although again it is hard to compare between studies, it appears that BMI may be a greater risk factor for incident UI than for prevalent UI adding credence to the association [184]. As for cross-sectional studies, the association is stronger for incident SUI and MUI, compared with incident UUI [181, 184].

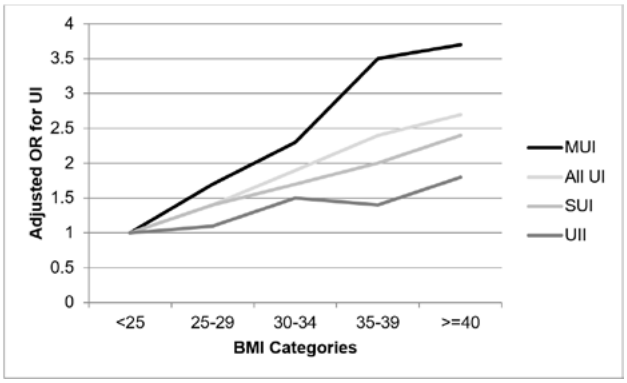

Figure 6 Associations between BMI and UI subtype from the EPINCONT study. Original figure created based on data reported in Hannestad et al, BJOG 2003 [231].

There is adequate evidence [219-220] that obesity increases intra-abdominal pressure, predisposing to SUI, while metabolic syndrome associated with obesity predisposes to UUI [221-224]. Consistent with this, waist circumference and waist to hip ratio appeared to be associated only with stress UI, and not with urgency UI in the SWAN [184] and HERS studies [215]. More recent data from BACH [225] and KNHNES [226] indicate that measures of central adiposity are also correlated with UUI.

Finally, intervention studies for weight reduction have reported that even modest weight loss is associated with improvement or resolution of both SUI and UUI, with the probability of resolution correlated to the degree of weight loss [219, 227-230]. Despite the complex interplay between weight and other risk factors for UI, we still have robust evidence to support a causal role of BMI in the development of UI.

4.3. Parity, pregnancy & mode of delivery

Parity is considered by the laity as among the most important risk factors for UI. This is reflected in almost all large cross-sectional surveys (Figure 7). Some early studies reported a threshold effect at one delivery and little or no additional risk with increasing parity [232-234] but in most subsequent work, increasing parity is associated with increased risk of UI. A single delivery is typically associated with adjusted OR of around 1.3-1.6 for UI, and further deliveries linearly increasing the risk up to an adjusted OR of 1.5-2.0 [184,201,213,235].

As expected these effects are strongest in the third and fourth decades, with substantial attenuation through middle age, and in many studies no persistent effect in old age [214,235-237] as other risk factors come to dominate. Although the EPINCONT [235] and SWAN [184] studies reported only association between parity and SUI or MUI, other studies have also suggested, a reduced but significant association with UUI [238-239].

There is a substantial difference in effect between vaginal delivery and caesarean delivery, that has also been the subject of systematic reviews [250-252]. Over short term follow-up meta-analysis of data from four large cross-sectional studies [253-256] suggested a significant protective effect of caesarean on stress UI (OR 0.56) and MUI (OR 0.70). For long term follow up, meta-analysis of 15 studies again found almost double the risk of SUI after any vaginal delivery (spontaneous, or assisted) compared to any caesarean section (adjusted OR 1.85, absolute risk difference 8.2%), with a smaller effect on UUI (adjusted OR 1.30, risk difference 2.6%). In meta-regression of long term studies the effects on SUI were much more pronounced for younger women, further adding to our confidence in assigning a causal role for vaginal delivery.

Generally across all observational studies, women delivering exclusively by caesarean have similar prevalence for UI as age matched nulliparous women. While the existing interventional studies remain significantly underpowered, the same direction of effect for caesarean is still seen [257].

Pregnant women, and those in the early post-partum period are typically excluded from population-based studies of UI, but a large body of work considers the specific epidemiology of UI in and around pregnancy. A systematic review [258] including 33 population-based studies, each with response rate over 50% concluded that the prevalence of UI in the first three months post-delivery was 30%, with infrequent SUI being the most common. The difference in UI rates between women delivering vaginally and those delivering by caesarean is evident immediately after delivery. As demonstrated in Table 5 (adapted from Abrams et al 2009 [122]), there is a gradual decrease in prevalence during the first post-partum year.

Despite the protective effect of caesarean, for many women the onset of UI is during pregnancy itself. The point prevalence of UI is low in the first trimester, rising rapidly in the second trimester and increasing slightly in the 3rd trimester [259-260]. In the population based Norwegian Mother and Child Cohort Study, (n=43,279), the prevalence of SUI from before to during pregnancy, rose from 9% to 31% in nulliparous women, and from 24% to 42% in parous women [261]. In contrast, MUI showed a similar rise in both groups (from 6% to 16% and from 8% to 20%, respectively). UUI remained virtually unchanged in both groups at less than 5%. In follow up of these women, the onset of UI during pregnancy was strongly predictive of post-partum UI (adjusted RR 2.3, 95%CI 2.2-2.4), with little modification by mode of delivery. Such an effect seems to persist into long term follow up [262-265] even for women who return to full continence in the immediate post-partum period. It seems that the temporary physiological changes during pregnancy may reveal women with a predisposition to UI in later life, in a manner analogous to gestational diabetes [266].

There are other suggested potentially modifiable obstetric risk factors, including induction of labour, forceps delivery, and use of episi-

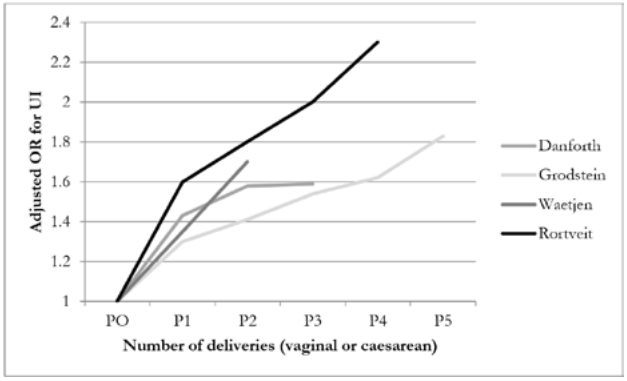

Figure 7 Adjusted OR for UI from selected large cross-sectional surveys. Figure created for this chapter combining data in references (Danforth et al., 2006; Grodstein et al., 2003; Rortveit et al., 2001; Waetjen et al., 2007) [184,201,213 och 235].

otomy. Regardless of conflicting observational evidence of an effect of episiotomy (for example references 241,249,267-268) there are a large number of interventional studies that have not shown either harm or benefit [269]. Similarly while forceps delivery has conflicting evidence from observational studies (for example references 245,269,270-272) within the context of the second stage of labour, maternal UI is of secondary importance in decision making regarding choice of delivery instrument [273]. In a similar vein, while induction and augmentation of labour, and use of epidural anaesthesia have each been identified as being associated with both early postpartum and persistent UI [244, 274-276] it is doubtful whether this should have any effect on current obstetric practice.

Many other suggested obstetric risk factors, including age at first delivery, and birth weight, are perhaps not meaningfully modifiable. Several studies have suggested that older age at either first or last birth is associated with UI [216,277-279] although more recent data from the RRISK study suggested a U shaped distribution [275] with very young mothers also at increased risk. Inadequate adjustment for socio-economic class may explain all these effects. Numerous studies have suggested that greater birth weight at a single delivery, or maximum weight of infant across all deliveries may also be associated with UI [236,247,275,280]. Although elective caesarean would be protective, birth weight is still challenging to predict, and again pragmatic randomized interventional trials are needed before making clinical recommendations.

4.4. Menopausal Replacement Therapy

Menopausal oestrogen replacement therapy was once widely prescribed as a treatment for UI during or after menopause, on the basis of rather heterogeneous data from clinical trials [281] and inconsistent associations in cross-sectional studies [276,282]. While current evidence overall continues to support prescribing of topical oestrogen [283], the Nurse's Health Study [284], the Heart Estrogen/Progestin Replacement Study (HERS) [285], and Women's Health Initiative (WHI) Hormone Replacement Trial [286] all provided strong evidence that oral oestrogens, with or without combined progestogens were associated with increased incident UI. In the placebo controlled HERS trial, women randomized to conjugated oral oestrogen plus medroxyprogesterone were more likely to experience worsening of their incontinence over 4 years (39% vs. 27%, p<.001) [285]. In the randomized WHI trial, continent women receiving oestrogen, with or without progestogen, were approximately twice as likely compared to women receiving placebo to have developed SUI at 1 year (16% vs. 9%, p<.0001) [286]. The risks of MUI and UUI were also significantly increased, though more modestly. Further trials including oestrogen arms have subsequently been reported during development of selective estrogen receptor modulators (SERMs), confirming these findings [287]. Some SERMs have themselves been associated with an increased risk of UI [288], although raloxifene appears safe [289].

4.5. Hysterectomy

Hysterectomy is among the most common major procedures performed for women in Western nations. Many women date the onset of UI to a hysterectomy, but uncontrolled case series and small randomized trials have produced conflicting results. Evidence from large population-based observational studies has increasingly suggested a causal link, although the underlying pathophysiological mechanism is poorly understood.

Among a sample of 1,517 Taiwanese women aged 65 years and over, hysterectomy was associated with OR 1.8 for UI, with no difference between abdominal and vaginal hysterectomy [290]. Earlier trials had, however, suggested either no effect [177, 198] or rather more modest effects [291]. Where an association is found, it is strongest with case definitions consistent with "severe UI" [192,213,254] perhaps reflecting high rates of mild UI in controls. Using a sample of more than 900,000 women from the Swedish Population Register, abdominal hysterectomy for benign disease was associated with a hazard ratio of 2.1 for subsequent SUI surgery, while vaginal hysterectomy for prolapse was associated with a hazard ratio of 6.3 [292]. Similar results were observed comparing hysterectomy and endometrial ablation in the Scottish Morbidity Returns database [293]. Recent data from a randomized trial of levonorgestrel-IUS versus hysterectomy [294] does confirm this effect. In follow up of 236 women, increased incidence of stress UI (OR 1.83 95%CI 1.01-3.22) was first apparent at 10 year follow, with significantly higher rates of treatment for both SUI and UUI.

Overall, hysterectomy appears to be associated with development of subsequent UI symptoms, and particularly with the need for SUI surgery. One potential mechanism is loss of pelvic floor support at the time of surgery. The data from observational studies should still be considered cautiously, as findings may be influenced by both healthy responder bias and medical surveillance bias, the latter of which may also affect unblinded interventional studies.

4.6. Diet

Many dietary constituents including coffee, tea, alcohol and carbonated beverages have all implicated in the pathogenesis of UI. Dietary data are difficult to obtain reliably [295] and women may change dietary intake in response to UI, making cross- sectional studies of diet and UI difficult to interpret.

The consumption of coffee or other caffeinated drinks as a risk factor for UI has been most widely studied. While some studies report a positive association associated with an increased risk of UI [187,296-298] others have either report no association [299-301] or a protective effect [181,302]. Even within the large EPINCONT study there were conflicting findings regarding coffee, with a positive association with mixed UI, but a negative association with SUI [231]. The WHI study demonstrated a dose-dependent positive association between caffeinated coffee and UUI, but not for decaffeinated coffee or for other UI subtypes [303]. The EPINCONT study suggested a positive association between tea drinking and SUI or MUI [231] while analysis of the Swedish Twin Registry Cohort showed an association only with OAB [302]. The Leicester MRC Incontinence study is one of two studies to have used food

frequency questionnaires, and found no association with tea [181]. It is unclear whether tea consumption contributed significantly to the overall association between UI and dietary caffeine in the WHI study [303]. At a population level the overall picture is therefore unclear, despite suggestive evidence of improvements in symptoms reported from interventional trials of caffeine reduction [304].

Anecdotally, alcohol consumption may be acutely associated with urinary urgency and UI. A positive association between alcohol consumption and UI has been reported by some studies [305] but is found to be either protective [181,306] or of no significance [231] in other studies. Differences between studies may reflect confounding associations between age and alcohol consumption.

The most comprehensive assessment of diet as a risk factor for UI comes from the Leicester MRC study [181]. Besides effects reported above, this study also found increased incidence of SUI with increased intake of carbonated drinks, and reduced incidence of OAB with increased intake of bread, potato and vegetable consumption. While these effects certainly provide interesting avenues for further research, there is no evidence of a causal association, and instead these dietary components may be surrogates for other unidentified socioeconomic risks. Overall there is a lack of consistency in reports of dietary associations with UI that most likely reflects methodological limitations rather than differences between populations.

4.7. Socio-economic status

Socio-economic status (SES) is strongly correlated with many of the other risk factors for UI including parity, BMI, diabetes, depression, smoking and timing of menopause. Higher SES is consistently associated with increased care seeking for UI, but there is conflicting evidence of association between SES and UI prevalence, or its bothersomeness. While many studies do include some measure of SES as a potential confounder, its effect is frequently not reported. Table 11 summarises some of the major studies that have reported associations, to highlight inconsistencies both by SES definition and UI definition. In the table a positive association is cited where women of higher SES, i.e. higher income/more education, report a greater prevalence of UI.

Table 11. Selected studies reporting associations between socioeconomic status and UI in women. Directions of effect summarized across multiple measures of SES. Positive association reported where statistically significant association (OR or RR) of more UI among women of higher social status, and vice versa for negative association.

Defined using either quality of life questionnaire, or symptom bother rating.

4.8. Smoking

Data from observational studies on smoking is again quite inconsistent. It has been reported to be an independent risk factor for UI in women in some cross-sectional studies [156,213,231,308, 312] but not in many others [145,158,251]. Within studies that do find an association, former smokers have a risk intermediate between never smokers and current smokers, and some dose response effect is evident, adding plausibility.

However, with one exception longitudinal studies have consistently failed to find a significant association between either past or current smoking and incident UI in multivariate analysis [184,187,191,213]. Only in the Leicester MRC study [181] was current smoking associated with increased risk for incident stress UI. The conflicting data from cross-sectional studies and lack of association between smoking and incident UI in most prospective studies suggests that smoking is probably not a causal risk factor for UI.

4.9. Exercise

Evaluating associations between physical activity and UI remains complex. It is clear that high impact exercise such as gymnastics [313-314] or trampolining [315-316] leads to SUI, with a dose dependent deleterious effect. However, women who suffer with UI, and particularly stress UI, may feel less able to engage in such sports [317]. Furthermore with increasing interest in core training as a treatment for UI [318] there are theoretical reasons to believe that low impact exercise might have a direct therapeutic effect. With these competing mechanisms at play, unsurprisingly cross-sectional studies have again produced conflicting evidence (see for example [145,147,319]. However, among cross-sectional studies, comparison of low impact and high impact exercise is suggestive that as hypothesized, high impact sports might be harmful, while low impact sports might be protective [231,320].

Evidence from longitudinal studies overall suggests that exercise does have a protective effect against incident UI, but perhaps only mediated via an effect on weight. In the Leicester MRC study, women who reported that they exercised less frequently were at increased risk for both incident SUI and OAB in a model that adjusted for physical functioning, although notably this association was eliminated in a full model, adjusting for obesity [181]. In a study of 4,291 older women exercise at baseline was not associated with incident UI at 10 year follow up after multivariate adjustment [187]. Perhaps the strongest evidence comes from the Nurses' Health Study [321]. In this population of US nurses aged 54-79, a higher level of physical activity across 14 years of follow-up, was associated with a reduced risk of UI overall, and specifically SUI, although after adjustment for BMI and other factors, the overall effect was small.

4.10. Comorbidities: Diabetes, Urinary Tract Infection, Cognitive Impairment, Ischaemic Heart Disease, Physical Impairment, and Depression

In cross-sectional studies many different comorbidities have been associated with UI in univariate analysis [282,311,322]. However, in most cases these have no explicatory power, being neither a cause nor consequence of UI, but only associated with other known or unknown mediators of UI, or differentially diagnosed due to medical surveillance bias. In this section, we therefore concentrate on studies that are able to adjust for a wide range of confounders, and again give priority to associations of incident UI.

Many cross-sectional studies have reported UI to be more common in women with either type 1 or type 2 diabetes, than among women with normal glucose levels, even after extensive adjustment for known risk factors [168,184,191,254,311,323-324]. There are conflicting data regarding a dose dependent association, e.g. between HbA1C and UI severity [323,325]. Longitudinal evidence is also conflicting. In the Nurses' Health Study cohort [326] Type 2 diabetes was a slight but significant predictor of incident UI (RR=1.21), and the magnitude of the association was seen to increase both with duration of diabetes and with severity of incontinence. Despite significant associations with prevalent UI in the SWAN study, no association with either incident UI [184] or worsening UI was found [184]. Perhaps the best evidence however comes from recent analyses of women enrolled in the Epidemiology of Diabetes and its Complications study. Over 7 years of follow up, more than 10 years after a diagnosis of type 1 diabetes, HbA1C was shown to be a powerful predictor of incident incontinence (odds ratio 1.41, per % HbA1c increase) [327] even after careful adjustment. There are plausible pathophysiological mechanisms by which diabetes might induce incontinence, and it seems likely based on the totally of current evidence that it truly has a causal role.

Acute UTI is a direct cause of transient UI [328] but caution is required regarding a causal association with chronic UI. UTIs are often diagnosed and treated based on symptoms alone, and there may therefore be a risk of misclassification between exposure and outcome. Many cross-sectional studies have found that women with UI are more likely to report having had one or more lifetime UTIs [225,321,329,331] and longitudinal data suggest both that UI can cause UTI, and that UTI can lead to UI. Two prospective studies found that baseline UI was a risk for incident UTI [332-333] among middle aged and elderly women, and in the Leicester MRC study, a history of UTI was associated with both incident SUI (OR 1.9) and incident OAB (OR 2.1) in women aged >40 [322].

Prevalent UI has a clear association with dementia [261,334] but until recently longitudinal studies did not identify an association with incident UI. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by the modified mini mental status exam (MMSE) was not associated with increased frequency of UI over 6 years, but did predict a greater impact [345]. Despite strong associations with baseline UI in the Canadian Study of Health and Aging, moderate or severe cognitive impairment, again defined by the modified MMSE, was not associated with incident UI over 10 years [187]. However, in a sample of 12,432 women aged 70-75, followed up for 9 years, the Australian Longitudinal Survey of Women's Health did demonstrate an association with diagnosed dementia (OR 2.34) [190]. In a 9 year follow up of 1,453 women aged 65 years and over enrolled in an US HMO, diagnosed dementia was strongly associated with incident diagnosis of UI (RR 3.0 95%CI 2.4-3.7) [335]. Given the strength and consistency of associations with prevalent and incident UI, and given that treatment for reversible dementia can improve UI [336-337] a causal role seems certain.

Ischaemic heart disease is associated with many risk factors for UI, but perhaps because of Neyman's bias, caused by exclusion of participants who have died, cross-sectional studies have often failed to identify an association with UI itself even in univariate analysis [287,338].The BACH study reported a strong association only among Black participants (OR 2.52) in multivariate analysis [145]. In the Leicester MRC study [322] a history of ischaemic heart disease was associated with baseline SUI and OAB only in univariate analysis, and with no association with incident symptoms. In contrast, the Nurses' Health Study found that coronary heart disease was associated with incident weekly UI (OR 1.46), and incident severe UI (OR 1.79) [212]. If ischaemic heart disease is a risk factor for incident UI, its effects might be mediated by cardiac failure [335] or polypharmacy [339-340].

Several cross-sectional studies have documented an association between depression and UI [184,254,291,341,-342,396]. In the SWAN study, depression was not associated with incident UI, but in the UAB Study of Aging, in a sample of 490 women aged 65 years and older, baseline depression was weakly associated with incident UI (OR 1.2) over 3 years of follow-up [186]. Similarly in the Health and Retirement Study participants (n=5,820), major depression was a modest predictor of incident UI (OR 1.46) over six years of follow-up, and including extensive adjustment for confounders. Baseline UI did not predict incident depression in the same study. In a follow up of women aged 65 years and older enrolled in an HMO, diagnosed depression was also associated with incident diagnosed UI over 9 years (OR 1.6) [335]. Although it seems plausible that the stigma of UI leads to depression (for example by reducing a woman's social network), current evidence supports causality in the opposite direction, most likely as depression increases the bother of UI symptoms.

Functional impairments, particularly mobility limitations, a history of falls, arthritis, dizziness, use of a walking aid, and poor lower extremity strength, have been correlated with UI in many community-based and nursing home studies [145, 270,272,343-344]. In the Nurse's Health Study osteoarthritis and functional limitations were plausibly associated only with incident UUI (RR 1.86 and 2.10 respectively), not with incident SUI or MUI [191]. In a study of 2,025 older women, improvement in Activities of Daily Living was associated with remission of UUI at 3 year follow up [272]. Other longitudinal studies have shown similar findings [181,345]. It remains unclear whether UI is a direct consequence of difficulties in getting to the bathroom and/or removing clothing, or whether mobility limitations and UI may both be consequences of general frailty in older age or of an underlying systemic illness.

4.11. Ethnic Variation

Ethnic variation in any disease provides only limited evidence for any underlying genetic predisposition. Environmental or cultural differences rather than genetic differences may explain differences in prevalence between populations. As there are very wide variations in UI prevalence between studies, meaningful comparison by race and ethnicity can be made only where such data has been reported within one study. Almost all population-based studies comparing the prevalence of UI among women from one or more racial or ethnic groups originate from the US, which may limit generalizability of conclusions. Results are summarized in table 7. In general, across all studies, white women have a higher prevalence of UI, and in particular SUI than all other groups.

The starkest and most consistent contrast is in rates of SUI for black and white women. In most studies (Table 12), black women have half the prevalence of SUI compared to white women, with differences persisting after adjustment for age, parity and BMI. In comparing prevalence of MUI and UUI for white and black women, there is less consistency. Most studies suggest similar prevalence of urge UI and MUI, however, the BACH survey found very high rates of MUI [145] among black women, while the EPI study reported very high rates of pure urgency UI [257]. These cross-sectional data are supplemented by longitudinal studies. In the SWAN study [184] black women were at half the risk of incident SUI, but nearly double the risk of incident UUI. In the Nurse Health Studies [346]4 black women had lower risk of both overall UI, and SUI after adjustment. The consistency of this difference across both cross-sectional and longitudinal studies, employing different case definitions suggests a real difference in prevalence rather than simply reporting bias.

Table 12 (overleaf): Population-based studies reporting ethnic variation in incontinence prevalence (Table updated from Abrams, Cardozo, Khoury and Wein, 2009) [122].

Typically smaller groups of East Asian or Hispanic women have been included in these studies, which precludes clear conclusions. Broadly though, Asian women report lower prevalence of both SUI and UUI. There is less consistency in comparisons of Hispanic and non-Hispanic white women, with some studies reporting higher, and others lower overall prevalence. This heterogeneity may be explained, at least in part, by differences in prevalence among sub-populations, with Mexican-American women being at higher risk than other Hispanic women [347] or differences in extent of adjustment for covariates.

These studies therefore clearly demonstrate wide variation in self-report of UI, and particularly SUI between women of different ethnicities. There may be substantial differences between women of different ethnicities in major risk factors for UI, including BMI, and perhaps parity, which might explain differences in UI. However, variation in prevalence might also reflect true differences in genetic susceptibility, particularly since in some studies the wide disparity in rates persists even after adjustment for the major known environmental risk factors.

5. THE GENETIC EPIDEMIOLOGY OF INCONTINENCE IN WOMEN

Geneticists have historically pursued a specific sequence of studies to establish the genetic basis of diseases [348]

The first step was measurement of familial correlations, followed by formal twin or adoption studies. Analysis of segregation patterns in extended pedigrees was used to identify the likely mode of inheritance. This information was used to inform linkage studies, designed to identify putative chromosomal risk loci. Only once these steps were complete would association studies be attempted. Although it remains relevant to establish the heritability of a trait, this traditional sequence of investigations has been supplanted by the success of GWAS, with many new discoveries now coming from association studies without the prior steps. Nonetheless here we recapitulate the history of our understanding of UI as a complex genetic disease, with multiple genetic and environmental risk factors, and review the studies that formed the basis for the genetic epidemiology of incontinence.

5.1. Family Studies

The existence of both acquired and inherited risk factors for UI was first recognized more than 150 years ago [395] by observation of familial aggregation. However, familial aggregation provides limited evidence of heritability, since it fails to control for the effects of shared environmental factors. For UI, exposures to all major lifestyle risk factors are likely to be at least partly determined by socio-cultural values that are shared within families. Such effects are at least plausible for family size, smoking, socio-economic status, care seeking behaviour, physical exercise, dietary and drinking habits, and toilet training. As UI is considered stigmatizing in all populations, family studies may be at risk of differential misclassification bias. This might be expected to have particular impact on the validity of estimates obtained from studies employing the family history method, and any study with non-random sampling of families, for example those relying on probands recruited in secondary care, or those recruiting volunteers via advertisement. Finally, while age correction of risks is possible, to account for increasing disease prevalence with age, this has typically not been employed in family studies of UI.

Although family studies may not provide robust evidence, there have been many studies that examined prevalence of UI (Table 13) among relatives of women with incontinence [204,350-354]. Despite considerable variation in case ascertainment and sampling methods, almost all studies have demonstrated increased risks for UI among first degree relatives of probands. This appears to have a plausible biological gradient, with higher risks among relatives of women with severe UI.

Table 13: Family studies of urinary incontinence among women.

Study	Setting	Design	Age range	n (♀ probands and controls)	Proband phenotype	Family member outcomes	OR or RR (95%CI)
Diokno et al, 1990 [204]	Population Based	Family History Method	>60	1,154	Any UI	Either parent with UI as adult	2.04 (1.55-2.68)

Lapitan et al, 2001 [356]	Secondary Care	Family history	>18	5,502	OAB	Any family history	1.62(1.42-1.83)
Andrada Hamer et al, 2013 [357]	Population based	Direct ascertainment (registry)	Any age	3,678,556	Surgery for Stress UI	Surgery for Stress UI among sisters	6.09(5.73-6.48)$
						Surgery for Stress UI among mothers	2.56 (2.27–2.89)$

RR adjusted for age, BMI, and parity **RR adjusted for age, BMI, and parity and restricted to subgroup of daughters of mothers with severe UI $ RR adjusted for age and parity. Note: unadjusted risks generally higher across all outcomes, indicative of substantial concordance/correlation in age, BMI, and parity between family pairs.

The most modest estimates come from the EPINCONT study, which is also least likely to be affected by bias, with the direct ascertainment method employed in a large population representative sample [353]. With a total sample of 8,125 pairs of probands and their daughters or younger sisters, they found less than two-fold increased risk of stress UI among daughters of women with SUI (RR 1.52 95%CI 1.28-1.81), and a non-significant but directionally consistent increased risk of UUI among daughters of women with UUI (RR 1.80 95%CI 0.83-3.92). Similarly, in a survey spanning 11 countries in South and East Asia (n=5,502), a family history of OAB was also a modest predictor of OAB symptoms including UI (OR 1.62 95%CI 1.42-1.83) [356]. In the studies that have used multivariate analyses, it appears that these familial risks are attenuated but not eliminated by adjustment for classic risk factors for UI including age, parity, and BMI.

Risks seem particularly elevated in relation to incontinence surgery. For example in a registry based study of 3,678,556 Swedish women, surgery for SUI among sisters was associated with greatly increased odds (OR 6.09 95%CI 5.73-6.48) [357]. This exaggerated association might be a consequence of low rates of presentation for care, such that care seeking rather than the underlying symptoms are particularly familial. In contrast to the twin studies discussed in the next section, family studies have demonstrated much more clearly that SUIrather than UI is familial. This might be a reflection of more stigma around UI, or simply lack of statistical power for a rarer condition.

Three studies have also assessed family history as a risk factor for incident post-partum UI, with some evidence of familial aggregation [317,358-359]. Again, however, estimates from these studies may be compromised by use of the family history method, rather than direct ascertainment. A single large study has assessed correlations between adult UI and childhood daytime wetting, using the ALSPAC cohort [97]. Using a sample of 8,145 children aged seven they reported excess risks associated with incontinence in the children for UI among their mothers (OR 2.64, 95%CI 1.38-5.07) and particularly among their fathers (OR 5.47, 95%CI 2.39-12.50).

In summary, a family history of UI is associated with approximately two to three fold increased risk. Such an effect appears to hold for all subtypes of UI, although the evidence is more robust for SUI. Among adults there is plausible evidence that family history is associated with both earlier onset, and more severe phenotype. Additionally, there is also clear evidence that this familial predisposition stretches right across the lifecourse. These effects are however partly explained by known environmental risk factors, and family studies cannot exclude the risk of further unmeasured confounding from shared environmental risks. For this we should consider evidence from classical twin studies.

5.2. Twin Studies

Twin studies compare the concordance in a trait or condition between monozygotic (MZ) twins and same-sex dizygotic (DZ) twins, to estimate heritability. Heritability, and here specifically broad-sense heritability, is defined as the proportion of phenotypic variation (V_P) that is due to variation in genetic values (V_G). For genetically determined traits higher concordance is observed in MZ twins compared to DZ twins, while for entirely environmentally determined traits, concordance should be the same in both types of twin pairs.

This idea is illustrated by consideration of a fully penetrant autosomal single gene disorder, which will display 100% concordance in MZ twins, while in DZ twins will have only 50% concordance for a gene with dominant mode of inheritance.

A fundamental assumption of analyses of classic twin studies is that both types of twin pairs share equal environment. This assumption is clearly violated both antenatally, and in later life. This bias can be further investigated in studies of twins reared apart, or in adoption studies, but these designs have not been applied to the study of UI A second central assumption is that MZ twins are genetically identical, which again is violated both by epigenetic effects, and by somatic mutation.

Three major twin resources have been used to assess genetic influences on UI: the US Twins Days festival, the Danish Twin Registry, and the Swedish Twin Registry. The Twins Days festival relies on volunteers, and the resulting recruitment bias is likely to overestimate concordance for many traits for both MZ and DZ twins. In the sample of 1,764, predominantly MZ, middle-aged twins from Twins Days, concordance of symptomatic SUI was 79.5% for MZ and 78.6% for DZ twins [397]. Such a result suggests no significant genetic contribution to SUI at all.

Among a sample of 2,336 twins surveyed as part of four surveys from the Danish Twin Register, concordances for both MZ and DZ twins were much lower not only for SUI, but also for urgency and mixed incontinence [360]. With cohorts for middle-aged and elderly women, heritability was calculated separately in each age group. As in the Twins Day sample, genetic factors were not significant for SUI in middle-aged women, but rose to a heritability of 39% in the elderly women. Similarly heritability increased with age for UUI(42% rising to 49%), and MUI (27% to 55%).

Women participating in the Swedish Twin Register have provided relevant data as part of two separate analyses [361-362]. Treatment codes corresponding to SUI and POP surgery from a nationwide surgical register were used to estimate heritability for a sample of 16,886 twins aged >50. Concordances for surgical treatment were low, but produced heritability estimates of 41% for SUI surgery, and 43% for POP surgery. Similarly for female twins aged 20-46 from the same register (evaluable sample 4,550), using self-completed questionnaires, produced an estimate of 34% heritability for SUI. From the same survey, heritability was estimated for UUI (37%), MUI (18%), “any” UI (51%), nocturia (48%), and urinary frequency (40%). It was however noted that because of sample size limitations, an absence of genetic effects cannot be entirely precluded for SUI, or MUI.

The mechanism of these probable genetic effects has also been explored in analyses of joint hypermobility and pelvic floor mobility in twins [363-364] which is one pathophysiological correlate of SUI. These data suggest heritability of 59% for oblique bladder neck descent on Valsalva in nulliparous twins aged 18-24, with a shared genetic component to both pelvic floor and elbow mobility.

In summary, twin studies to date have suggested significant heritability for SUI and UUI with genetic variation potentially contributing up to half of population phenotypic variation. Heritability appears to be highest for UUI, with apparent heritability increasing with age as environmental factors reduce in importance. This is consistent with our understanding of childbirth as a major environmental determinant of incontinence. Genetic predisposition to UI may manifest at a preclinical stage in pelvic floor hypermobility. Together with data from family studies this provides strong evidence of genetic risk factors for UI.

5.3. Segregation Analyses

Despite the large number of family studies for UI in adults, there have been few studies to examine segregation among extended pedigrees. Studies of families affected by nocturnal enuresis [365] have however included some adults affected by UUI. Analysis of different enuretic families has usually suggested autosomal dominant inheritance with high penetrance, but low penetrance and autosomal recessive modes have also been reported. These findings could be a consequence of selection or ascertainment bias. In contrast results from more recent association studies strongly suggest that polygenic inheritance is most likely across the population as a whole.

5.4. Linkage Studies

A linkage study can be used to map a condition to one or more genomic loci by demonstrating co-segregation of the trait among an extended family with specific genetic markers. The association between two SNPs is measured using Linkage Disequilibrium (LD) statistics, typically D’ or r^2. With the success of the International HapMap Project [366] and the 1000 Genomes Project [367] LD has been established for the majority of all known common SNPs. Although there are more than 60 million catalogued human SNPs, common SNPs less than 10 kb apart are often highly correlated. Thus without a requirement for dense genotyping, linkage studies can successfully identify loci containing a causal genetic variant [368]. Given the power constraints of assembling extended families for study, this technique is most successful for monogenic or oligogenic traits in which the causal variants have large effect sizes. Several linkage studies have been conducted using families of chil-

dren affected by nocturnal enuresis, and two studies have considered uniquely adult symptoms. Earlier reports suggested a range of loci associated with nocturnal enuresis [365,369] and in the largest attempted replication using a collection of 32 families with at least three members with nocturnal enuresis, there was evidence in favour of a locus at chromosome 22q11 (cumulative logarithm (base 10) of odds (LOD) score 3.63), and weak evidence for loci at 13q13 (cumulative LOD score 1.53) and 12q(cumulative LOD score 1.95) [370]. Allen-Brady and colleagues genotyped women from 32 families, including 70 patients needing surgical treatment for POP. There was strong overlap with other pelvic floor disorders including a high prevalence of treatment for both SUI and UUI [371]. Using a set of 27,157 markers from a predesigned array, they observed a significant peak at 9q21 (maximum HLOD 3.41), and further suggestive peaks at 9q31(maximum HLOD 1.90), and 1q42(maximum HLOD 1.89). Subsequent unpublished work from the same group did not however replicate these findings specifically for SUI surgery [372] but suggested separate loci on chromosomes 2, 4, 8,10 and 11 (maximum HLOD scores 2.15-2.98). Such problems with replication of linkage studies [373] have been recognized right across medicine, and may be particularly pronounced with multiple common variants each with small true effect sizes.

5.5. Gene Association Studies

A recent systematic review has summarized all prior candidate gene and genome-wide association studies [374]. Replication is an essential step in establishing the validity of genetic associations, and yet meta-analyses were possible for only three polymorphisms.

Variation in the beta-3 adrenoceptor, particularly of the rs4994 SNP, also known as Trp64Arg, has been extensively investigated in association with obesity, type 2 diabetes mellitus, and other metabolic syndrome phenotypes. The beta-3 adrenoceptor is highly expressed in bladder, and mediates detrusor muscle relaxation [375]. A beta-3 adrenoceptor agonist has recently been approved for treatment of OAB symptoms [376-377]. One conference abstract and two published papers[378-380] provided relevant information on the common rs4994 missense mutation, of which two could be included in a meta-analysis. In the initial report, in a heterogeneous Japanese sample of 13 men and 31 women, with diverse urological pathologies including neurogenic bladder and benign prostatic hyperplasia, the rs4994 SNP was not associated with LUTS (OR 1.20 95%CI 0.32-4.47) [379].

. Results were not available stratified by gender, and could not be included in quantitative synthesis. Subsequent reports used larger samples of Japanese women (n=100) [378] and Brazilian women (n=49) [380] and looked specifically at the OAB phenotype, finding a large effect size (pooled OR 2.46 95%CI 1.67-3.60), with no heterogeneity. Despite a lack of information about genotyping QC, and some risk of population stratification, this large effect size confers some protection from bias, providing moderate epidemiological credibility.

rs1800012 also known as the Sp1-binding site polymorphism of collagen, type I, alpha 1, modifies transcription factor binding and gene expression. It has been most extensively studied in association with osteoporosis, where the minor allele is modestly associated with reduced bone mineral density and increased fracture risk [381]. Collagen, type I, alpha 1 is a major structural component of the vaginal epithelium and endopelvic fascia [382]. The available data on gene and protein expression in pelvic tissue from women with POP or SUI are heterogeneous but suggest increased *COL1A1* expression with reduced type 1 collagen content (see a previous comprehensive review [382].

Two studies of Polish [383] and Greek [384] women reported associations of the same polymorphism with SUI, in both cases using a combined symptomatic and objectively measured case definition. The pooled effect size was large (OR 2.09 95%CI 1.35-3.22) with no heterogeneity (I^2=0%). There was significant deviation from Hardy-Weinberg equilibrium in one sample, and therefore only weak epidemiological credibility for this finding.

Matrix metalloproteinase-1, also known as interstitial collagenase, is one of a number of enzymes that cleave collagen type 1. The *MMP1* gene is upregulated in pelvic tissues of women with POP [385]. Common variants of this gene have been extensively studied in association with chronic obstructive pulmonary disease [385] cardiovascular disease [398] and a number of cancers including of lung, colon and breast. Two studies tested associations with SUI [387-388] and the pooled effect was non-significant (OR 0.87 95%CI 0.63-1.20), with no heterogeneity.

Finally there remain a number of candidate gene studies of UI for which no replication has been reported. Statistically significant associations have been suggested between UI and the CAG copy number variant of *AR*, the androgen receptor [389] between UI and the rs6313 polymorphism of *HTR2A*, the serotonin 2A receptor [390] and between SUI and both the rs2165241 and rs1048661 variants of *LOX-L1*, lysyloxidaselike-1 [391]. Following the Venice recommendations [392] these nominally significant but unreplicated associations are all assigned weak epidemiological credibility.

As the first genome wide association studies (GWAS) for UI are reported, these results from candidate gene studies are all likely to be overturned. Initial GWAS results from the WHI found no replicable loci for UUI [393] while a subsequent consortia of European and US studies have reported one replicated locus for SUI close to the *EN1* gene and one for UUI close to the *EDN1* gene [394]. Notably no previously suggested gene for UI was re-identified in either of these studies.

6. SUMMARY POINTS

- Despite a vast literature, there remain many uncertainties about the aetiology of UI.
- Despite wide consensus on the definitions of the symptoms of UI and its subtypes, there is no universally accepted threshold for clinically or biologically significant UI, and no objective tests that can be applied in the community.
- For these reasons, even the prevalence of UI is not well established, and the incidence and remission are even less clear.
- Family studies and twin studies have provided convincing evidence of genetic predisposition to UI with genetic variation contributing up to half of population phenotypic variability.
- Heritability is most pronounced for UUI.
- Although some families may be affected by severe dominant monogenic forms of incontinence, for the general population no clear mode of inheritance is apparent, consistent with our understanding of both SUI and UUI as complex polygenic conditions.
- Linkage studies have not yielded consistent results, nor led to identification of any candidate genes.
- The few available candidate gene studies are underpowered for large genetic effects, but suggest the possibility of *ADRb3* as a candidate gene.
- Emerging results from GWAS are likely to substantially change our understanding of the genetic architecture of these conditions.

V. EPIDEMIOLOGY OF URINARY INCONTINENCE IN MEN

1. GENERAL COMMENTS

The epidemiology of UI in men has not been investigated to the same extent as for females. However, progress has been made during recent years, particularly in the reporting of population-based studies of UI among men and more specifically, of UI associated with radical prostatectomy. In addition, more reports have been published on the risk factors for the development of UI in men.

Recent community-based studies consistently report lower prevalence rates of UI in men than in women by a 1:2 ratio [399-401]. The type and age distribution of UI appears to be different between the sexes, and risk factors, although less investigated in men, are distinct from women. It is also important not to consider UI as an isolated problem in men, but rather as a component of a multifactorial problem. Often other urogenital symptoms (LUTS) such as weak stream, hesitancy, and dribbling, or erectile dysfunction, exist.

Post-prostatectomy UI has been studied and reported with increasing regularity in the last few years. Since UI is one of the main complications of the procedure, a separate review of UI in the post-prostatectomy patient population is presented in this section. In addition to epidemiological studies, we included clinical trial data on post-prostatectomy UI.

2. PREVALENCE

Several surveys from the general population have been conducted to determine the prevalence of UI in men (Table 14). Prevalence rates ranging from 1 – 40% have been published. The wide range of results may be explained by the variation in the population studied, the definition of UI used, and the methods used in the surveys. A systematic review of 21 studies reported a prevalence of UI in older men ranging from 11-34% (median = 17, pooled mean = 22%), while that among middle-aged and younger men was from 3% to 5% (median = 4%, pooled mean = 5%). In the same review, the prevalence of daily UI in men ranged from 2-11% (median = 4%, pooled mean = 5%) [402]. A more recent systematic review of 69 prevalence studies on UI in community-dwelling men showed overall prevalence rates from 4.81% to 32.17%, with prevalence increasing with age [403]. A wide definition of UI, older age, the inclusion of institutionalized men, and the use of self-reporting methods tend to result in higher prevalence rates [402,404-405].

Table 14 Examples of prevalence studies of UI among men (study population at least 400)
A. General Population Sampling, all adult age groups

Author and year [ref]	N	Response rate (%)	Country	Population (age)	Definition of UI used	Method of assessment	Prevalence (%)
Akbar 2021 [413]	1446	94 %	USA	45-84 yrs	based on the International Consultation on Incontinence Questionnaire Short Form (ICIQ-SF)	Interviewer administered questionnaire	11.1
Tsui 2018 [435]	1059	76.4 %	UK	68 yrs	ICIQ-SF	postal questionnaire	7
Donnelly 2018 [425]	2955	29.60%	Northern Ireland	≥40 years	any degree of urinary leakage	postal survey	35.6
Helfand 2018 [539]	477	92 %	USA	≥18 years	leakage of urine in any of the described occasions (based on the LUTS tool definition)	Patient-reported urinary symptoms	32

Due to differences in the pathological anatomy and pathophysiology of UI in men and women, there is a different distribution in incontinence subtypes. A predominance of urge incontinence (40-80%), followed by mixed forms of UI (10-30%), and stress incontinence (<10%) is observed [331]. The pooled prevalence rates in a systematic review confirmed that such distribution pattern across the different types of UI is consistent across the different age groups [403]. (Table 16).

The higher percentages of the urge and mixed types of UI are more significant in studies involving older people. The increasing prevalence of any UI by age in men is largely due to the contribution of UUI rather than SUI. One study demonstrated an increased rate of urge UI from 0.7% between age 50-59, 2.7% between 60-69, and 3.4% for 70 years and older respondents. SUI was steady at 0.5%, 0.5% and 0.1% for the above groups, respectively [406]. A similar trend of increasing proportions of urge and mixed UI with increasing age is demonstrated in the large population-based study in the US [407], and a smaller population-based Canadian study [143]. On the other hand, Maral and coworkers reported increasing prevalence also of SUI with age, from 0.9% between age 35-44 to 1.2% between 45-54, 3.8% between 55-64, and 4.9% at age 65 and older [408].

Most studies report a significant proportion of other/unclassified types of UI. One study reported that a majority of men with UI had overflow and functional types of UI[299], while another found constant dribbling in 7% of their respondents [409]. Terminal dribbling or postvoid dribbling is another type of leakage in men that is difficult to assign to the conventional subtypes of UI. In an Australian survey, 12% of respondents reported frequent terminal dribbling [410].

When it comes to severity, the distribution in men follows that of women. Available data have shown that the overall prevalence of UI in men is largely due to mild UI. Men reporting moderate to severe UI are significantly less than those reporting mild UI [411-412]. Estimates for severe UI in older men tend to be about half that of older women [331].

Few studies have studied the impact of race or ethnicity on the prevalence of UI among men. Akbar and colleagues [413] utilized the data from the Multi-Ethnic Study of Atherosclerosis to analyze the variation and distribution of UI subtypes among non-Hispanic White, Chinese, non-Hispanic Black, and Hispanic. The prevalence of any UI was highest among non-Hispanic Blacks (15.7 %) followed by Hispanics (15.3 %), non-Hispanic Whites (7.9 %), and Chinese (5.8 %) [413]. A four-country study presented lower prevalences of reported UI among men from Korea (4%) and France (7%) than in men from Britain (14%) and Denmark (16%) [414]. On the other hand, unpublished data from the MESA study did not indicate differences in prevalence among white male respondents compared to African American respondents. Similarly, the National Health and Nutrition Examination Survey did not find any difference in the prevalence of UI by racial/ethnic group [415].

Literature on the incidence of male UI is scarce. One recent prospective cohort study of community-dwelling Medicare enrollees has reported on this issue. From the University of Alabama at Birmingham Study of Aging, 77 men with no UI at baseline were followed for 42 months for evaluation of incident UI, which occurred in 38% of men [416]. The MESA study [331] found a one-year incidence rate for men older than 60 years at 9-10%. In a population-based survey in the UK among men with at least 40 years of age, the one-year incidence of UI was noted to be 3.8% [182]. A

review of a health organization database of males at least 65 years old revealed a UI incidence of 23.8 per 1000 person-years. Malmsten [417] analyzed the age of onset of UI for each age cohort. The mean debut age for all men was 63 years. The mean duration was about 8-10 years in the cohorts. A longitudinal population-based study in Sweden showed that 8.6% (212/2471) of those without UI at the initial survey was found to have UI at the survey done 11 years later [418].

Substantial remission rates for UI in males were noted by the MESA study, higher among men (27-32%) than women (11-13%) [331]. A similarly high one-year remission rate of 39.6% was noted among British males [182]. In the Swedish longitudinal study, 47.8% (55/115) of those found to have UI at the initial survey did not present with the problem at the time of the follow-up survey 11 years later [418].

One possible explanation for the differences in the published incidence and remission rates in men compared to women is the predominance of the UUIamong men, and its close relation to the overactive bladder with and without UI. Another factor is the close association between urge UI and prostate gland disease, infections, or bowel dysfunction, all of which are relatively amenable to treatment or may improve even without treatment.

3. POTENTIAL RISK FACTORS FOR UI

There is relatively little research concerning conditions and factors that may be associated with UI in men, and clear risk factors are seldom scientifically documented. However, a few available studies have identified potential risk factors, which are described below.

3.1. Age

As in women, increasing age is correlated with an increasing prevalence of UI in men (Table 15). Multivariate analyses in several studies have shown that age is an independent risk factor for incontinence [405,407,412,419-425] Compared to women, however, there seems to be a steadier increase in the prevalence in men with increasing age. The National Health and Nutrition Examination Survey in the US reported an odds ratio for moderate to severe UI of 1.8 (95% CI 1.6-2.0) for every 10-year increase in age in a cohort of 5,297 men 20 years or older [415].

3.2. Lower Urinary Tract Symptoms (LUTS) and Infections

In postal and telephone surveys of community-living incontinent men, a majority has experienced a variety of other medical conditions, many of which may cause or aggravate UI. LUTS like urgency, nocturia, feeling of incomplete voiding and reduced flow are typically associated with UI [305,426-428]. In one study, UI was reported by 15% of men without voiding symptoms, frequency, or urgency and by 34% of those with such symptoms [426].

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI [409,429], with an odds ratio of 3.7 for UI in men reporting cystitis [406] and an odds ratio of 12.5 among men with recurrent infections [299]. The meta-analysis of 5 studies including the previously mentioned studies showed a significantly higher risk of UI among men with UTI, with a pooled odds ratio of 3.6 (95% CI 2.17-6.00) [403]. It should be noted that most reports indicating a positive association between UTI and UI involved men aged older than 60 years.

3.3. Functional and Cognitive Impairment, Physical Activity

Mobility problems such as the use of a wheelchair or aids to walking, as well as diagnosed arthritis or rheumatism or having a fall the last year, were significantly greater among incontinent than continent men [282,429]. The Canadian National Population Health Study involving 25,400 men found that those afflicted with arthritis were more likely to have UI with an odds ratio of 1.59 (95% CI 1.07-2.38) [431]. The same study demonstrated that men with back problems were 2x more likely to have UI (OR 2.1, 95%CI 1.50-2.93).

Several other reports identified frailty and functional dependency as more significant associations to male UI than chronological age. A Japanese study on community-dwelling men noted that UI is more likely among men whose activities of daily living (ADL) are impaired, specifically those who are unable to change clothes and unable to walk outside, with an odds ratio of 17.4 and 4.36 respectively [406]. A Canadian study found odds ratios of 1.8 and 6.4 for partially and totally immobile men aged 65+, respectively, for daily UI compared to those with normal ambulatory function. Similarly, the Silver Network Home Care project among the frail older persons in Italy showed that those with higher ADL scores (i.e., greater functional impairment) had 2-4x higher odds of having UI [420]. A survey of nursing home residents in Wisconsin identified dementia and poor ADL as risk factors for the occurrence of UI [422]. These results were corroborated by a recent population-based cross-sectional study that identified ADL impairment as a risk factor (OR=2.4, 95% CI=1.2-4.9) for UI among 3604 men included in the National Health and Nutrition Examination Survey [432]. Among hospitalized older adults, the incidence of UI was more common in frail subjects (at discharge: 24.3% vs 9.6%, p-value= .038; 6 months: 43.2% vs 21.7%, p-value = .020; and 12 months: 56.8% vs 33.3%, p-value = .020) compared to the control group in a 1-year prospective cohort study [433]. Hence, the current scientific evidence recognizes functional and cognitive impairment as risk factors for UI.

Congruent with the previous observations, the association between physical activity and UI has been studied by Kikuchi and co-workers among the elderly, community-based population in Japan [437]. They found that men with middle-level physical activity have lower UI prevalence compared to those with low-level physical activity, with an odds ratio of 0.38 (0.17-0.78). High-level physical activity showed similar relations but was not statistically significant [419,435,437].

Finally, 383 Men from the I-Lan Longitudinal Ageing Study (ILAS) in Taiwan were evaluated to identify the association between muscle mass, muscle strength, physical function, and UI based on the assumption that pelvic muscle architecture decreases along with whole-body muscle mass. The investigators found that walking speed was the only independent risk factor for UI (HR 0.05, 95% CI 0.003–0.987, P ¼ 0.049) and sarcopenia has a non-significant association with UI [436].

3.4. Neurological disorders

Many specific neurological diseases may lead to UI [437]. DO is seen commonly in mengingomyelocele patients and spinal injuries, Parkinson's disease, and multiple sclerosis. Areflexic bladder dysfunction due to a cauda equina lesion or diabetes might cause overflow or a paralysed pelvic floor and hence SUI. A meta-analysis of 5 studies showed that men who suffered a stroke were at an increased risk for UI with a pooled odds ratio of 2.68 (95% CI 1.31-5.45) [403]. Another study reported that men who had suffered a stroke were at increased risk for UI with an odds ratio of 7.1 [406]. The Canadian National Population Health Survey showed that stroke in men increased their odds of having UI by 8x (OR = 8.26,

95%CI 3.63-18.8) [431]. A case-control study by Jorgensen [438], age-matched long-term stroke male survivors with controls showed a higher prevalence of UI among stroke survivors compared to controls (17% vs 9%). A retrospective observational study including 6327 men also showed an increased risk of UI with dementia (HR 1.68 95 % CI 1.43–1.98) and stroke diagnosis (HR 1.72, 95 % CI 1.35–2.19) [439].

In addition, among UI sufferers, the stroke survivors were found to have a higher frequency and more leakage than controls. In a study of 235 stroke patients, the occurrence of UI correlated with motor weakness (OR 5.4), visual defects (OR 4.8, and dysphagia (OR 4.0) [440]. In the UK, recent research involving a cohort of 1059 men from the Medical Research Council (MRC) National Survey for Health and Development showed that men diagnosed with previous stroke or TIA report more UUI (OR 2.6, CI 1.4-4.8) [435].

3.5. Diabetes

The results of studies on the association of diabetes mellitus with UI are conflicting. Several reports have not found diabetes as a factor significantly associated with UI in men. This includes the Canadian population-based study involving more than 25,000 men showing no increased risk for UI among men with diabetes [441]. However, the Japanese survey found that diabetics had twice the odds of having UI than non-diabetics [412]. Tsui and colleagues also reported an increased risk of UUI in patients diagnosed with diabetes (OR 1.94 CI 0.99-3.81) [435]. An earlier review reporting the pooled analysis of 6 studies showed that diabetic men were significantly more likely to have UI with an odds ratio of 1.36 (95%CI 1.14-1.61) [403].

3.6. Alcohol and Smoking

Two recent reports showed a significant association between alcohol consumption and UI in men. A Japanese survey showed an odds ratio of 1.84 (95%CI 1.2-2.82) [412], and a survey among Chinese men showed an odds ratio of 1.42 (95% 1.1-1.8) [423].

The prevalence of incontinence based on the Overactive Bladder Symptom Score (OABSS) and International Consultation on Incontinence Questionnaire-Short Form(ICIQ-SF) was reported to be higher among current and ex-smokers than non-smokers [442]. Smoking was also found to be significantly associated with UUI in non-obese men with an odds ratio of 1.79 (95% CI: 1.01-3.17) in a separate study [430].

3.7. Obesity

Previous studies did not reveal a significant association between increased BMI and UI [443]. However, a more recent prospective analysis of 1298 community-dwelling men, aged 70 to 79, in the multicenter Health, Aging, and Body Composition Study provided evidence of increased UI prevalence with higher BMI (OR 1. 49, 95% 1.21-1.83) and fat mass (OR 1.23, 95 % 1.05-1.45) [Bauer 2019]. In a study including a younger population in Australia, obesity was associated with UI with an odds ratio of 3.2 (1.2-9.0) [421]. A population-based survey in the UK involving 1059 participants from the National Survey for Health and Development also supports the increased risk of UI associated with increased BMI with an OR 1.26 (CI 1.12-1.4) [435]. Hence, contemporary studies are already consistent in identifying obesity as a strong risk factor for male UI.

3.8. Treatment for Benign Prostate Disease (monopolar TURP vs newer endoscopic treatment, open prostatectomy)

TURP has been associated with an incidence of stress incontinence of about 1%. A randomized controlled trial comparing TURP, laser prostatectomy, and vaporization of the prostate for benign disease showed comparable UI rates immediately and up to 12 months postoperatively [Van Melick 2003]. Resection and enucleation techniques using any modality have similar long-term UI rates but short-term transient UI was a concern in enucleation methods (odds ratio 1.92, 1.39 to 2.65) [446-447]. Holium laser enucleation which is commonly employed recently for large prostates (>100 g) was associated with 10% SUI rate postoperatively [448] while photoselective vaporization of the prostate was associated with 14.3 % de novo UUI after 6 months [449].

3.9. Treatment for Malignant Prostate Disease (radical prostatectomy and focal therapies)

Since the last edition of this text was published, significant progress in the study of post-radical prostatectomy UI has been made especially with the refinements in the techniques and technologies associated with the procedure. Radical prostatectomy seems to induce UI at a much higher rate than TURP. The most recent systematic review including 4 randomized controlled trials comparing RP and deferred treatment (watchful waiting and active surveillance) for localized prostate cancer showed a UI rate of 173/1000 men undergoing RP [450]. The overall prevalence of post-radical prostatectomy UI ranges from 2 to nearly 60% (Table 17). This wide range may be explained by many factors, including differences in study characteristics, population characteristics, study site, the definition used, and the timing of assessment of continence in relation to the surgery. The era in the development of the procedure has also been found to be associated with the prevalence rates [451], as well as the various procedural modifications of the surgery (see below).

Table 17. Examples of studies on the prevalence of post-prostatectomy incontinence

Author/Ref	Procedure	N	Follow up	Definition	Prevalence (%)
Mazariego 2020 [510]	RP	1642	15 yrs	needing to wear one or more pad per day owing to weak urinary control and frequent leakage	18.2 % (nerve-sparing RP); 27 % (non-nerve sparing)
Xu 2018 [511]	RP	1995	15 yrs	use of pads except for protection	12.80%
Schepens 2018 [579]	RP	1590		unknown	26.00%
Tienza 2018 [490]	RP	746	12 mo	complaint of any involuntary leakage of urine	23
Albkri 2018 [580]	RP	110	49.0 mo (5–160)	not explicitly stated	34.5% 26.8% (RRP) 46.3% (lap RRP) 28.5% (RARP)
Steentjes 2018 [581]	RP	842	2–18 yrs	Unknown	Early 14.9% Late 19.6%
Tyson 2018 [489]	RP/ RARP	1291	3 yrs	any urine leakage	Low risk PCa: 63 % Intermediate risk Pca: 68 % High risk PCa: 78 %
Leow 2017 [582]	RP	5082	30 days	unknown	7.3-7.9 %
Barocas 2017 [583]	RP	1523	3 yrs	EPIC questionnaire; any urinary leakage	14.00%
Wilt 2017 [584]	RP	731	19.5 years	use of absorbent pads	17.3
Daugherty 2017 [585]	RP	136	Not stated when the assessment for UI done in relation to the treatment	Validated 2-item incontinence severity index Incontinence based on an index value of 3 or greater (scale of 1-12), corresponding to moderate or severe incontinence	23.2 (14.0-35.9)
Carlsson 2017 [586]	RP	338	1 yr	Urinary continence was defined as less than one pad changed per 24 hour ; otherwise, incontinent	16.00%
Tasci 2015 [587]	RARP	1499	1 yr	Continence was defined as the use of no pads or only a safety pad usage; otherwise, incontinent	11.30%
Gavin 2015 [588]	RP	934	≥24 (2-18 yrs)	Unknown	27.8% (95%CI 24.9–30.8)
Kumar 2015 [481]	RARP	800	34.1 months in <70 years 37.2 months in >70 years	based on the EPIC questionnaires	8.7 % in <70 years 12.7 % in >70 years
Geiger-Gritsch 2015 [589]	RP	253	12 months	International Consultation on Incontinence Questionnaire(ICIQ)	Mild UI : 29.9% Moderate UI : 18.1% Severe UI :15.0 %
Holm 2014 [478]	RP	844	12 months	used pads daily/ occasional dribbling without pads	74.0% (40 % used pads daily, 34 % occasional dribbling)
Schiavina 2014 [465]	RRP	778	1 yr	use of 1 or more pads	7.70%
Kopp 2014 [589]	RP	362	Mean 6.3 (SD 4.8) years since diagnosis	Any UI UI < 1 /week UI 1 /week UI 1 /day Pad use	79.0% 21.8% 15.5% 41.7% 21.7%
Resnick 2013 [491]	RP	1164 842	24 60 180 (5 yrs)	No control or frequent leakage	9.6% 13.4% 18.3%
Peterson 2011 [508]	RP	1618	> 12	Self-report of UI in every followup	9.70%

Author/Ref	Procedure	N	Follow up	Definition	Prevalence (%)

RRP: radical retropubic prostatectomy
RPP : radical perineal prostatectomy
RP: radical prostatectomy, unspecified or combined
Lap RRP: laparoscopic retropubic prostatectomy
RARP : Robotic-assisted radical prostatectomy

Post-prostatectomy incontinence rates based on symptoms reported by patients are generally 2-3x higher than those based on physicians' observations. Studies that have performed both assessments in the same population confirm this observation that doctors underestimate postprostatectomy UI by as much as 75% [452-455]. This was conflicting to the recent report of Wagner and associates where practitioners significantly overestimate UI at 3 months post-RARP (48% vs 39%) [456]. A higher UI rate is also seen after self-reported questionnaire assessment compared to pad testing [457-458].

Incontinence rates after prostatectomy seem to steadily decline with time and plateau 1 - 2 years after surgery [459-465] (Table 18). This emphasizes the need for a long follow-up period to establish continence status postprostatectomy. An actuarial study among 647 postprostatectomy men estimated an UI rate of 13% at one year and 7% at two years postsurgery [466]. The Prostate Cancer Outcomes Study reported that the 5-year postprostatectomy incontinence rate among 1, 288 men was 14%, which was higher than the 10% rate reported after 2 years [467]. After 3 years of follow-up, a large nationwide population-based study found that 3% of the cohort studies eventually underwent post-prostatectomy UI surgery [468].

Table 18. Examples of studies on postprostatectomy UI rates at different times of assessment

Study	Type of Prostatectomy	N	UI Rates by Time of Assessment of Continence (%)				
			1 mo	3 mo	6 mo	12 mo	24 mo
Chen 2017 [608]	RP	469	-	45.6	-	32.3	33

[1] – continence defined as 0 pads
[2] – continence defined as <= 1 pad daily

Several preoperative patient characteristics and intraoperative factors postulated to influence the risk of UI post-radical prostatectomy have been investigated.

Older age at the time of surgery has been associated with a higher prevalence of post-prostatectomy UI [461,469-478]. One study showed a doubled risk for every 10 years of age beginning at age 40 [479]. Another showed that age at surgery predicted % per year [477]. However, other studies failed to demonstrate that age is an independent predictor for incontinence [454,480]. Kumar also conducted an age-stratified comparative analysis of functional outcomes among those who underwent robot radical prostatectomy and found that UI rates are comparable in younger and older men with the average time to continence also similar to both groups (3.1 vs 3.2 months, respectively) [481]. Other studies suggested that rather than age affecting final continence, elderly men need a longer time to achieve continence after surgery [462,482].

The weight and body mass index of patients has been identified as a risk factor for postoperative UI [469,483] or as a predictor of a longer interval before return to continence [461,473]. A meta-analysis [484], which included 6 trials with 2890 participants, showed that obesity (BMI ≥ 30) increases UI risk at 12 months in patients who underwent robotic-assisted laparoscopic radical prostatectomy (OR 2.43, 95% CI 1.21, 4.88, p-value = 0.01) but not in those who underwent laparoscopic radical prostatectomy.

Other factors have been associated with a higher prevalence of post-prostatectomy UI, although not consistently. These include preoperative LUTS and sexual dysfunction, ECOG status, severity of cancer, clinical stage, PSA, prostate volume, bladder neck size, Gleason score, and the hospital volume where the RP is done [469,471-472,475,485-486-491]. The effect of prior TURP on post-prostatectomy UI has also been variable [492-494]. A retrospective analysis of 156 patients who underwent preoperative MRI of the prostate and were followed up post-prostatectomy showed that time to return to continence was associated with the variation in the shape of the prostatic apex. The prostatic apex that does not overlap with the membranous urethra was found to be significantly associated with an early return of continence [486]. The preoperative thickness and length of the membranous urethra were also considered influential in post-prostatectomy UI [490]. Multiple prostate biopsies have not been shown to significantly affect mid to long-term UI after prostatectomy [495]. The 5-year cohort study of the Prostate Cancer Outcomes Study found that among prostatectomy patients, race and ethnic differences were related to UI, with African-Americans having better recovery compared to non-Hispanic whites and Hispanics [496].

The technique of radical prostatectomy impacts UI rates. Modifications associated with lower UI rates in early reports include the perineal approach [470,497] and sparing of the neurovascular bundle [469, 471,484,498]. Bladder neck preservation affords an earlier return to continence compared with bladder neck resection, but with similar UI rates after one year [499-500]. One study showed earlier recovery of UI after tennis racquet reconstruction and bladder neck preservation compared with bladder neck resection with puboprostatic ligament preservation, but with similar UI rates at one year [501-504]. However, continence status assessed more than 12 months after surgery showed even lower rates of UI after bladder neck preservation (11.6%) compared to resection (4.9%) in one study [502]. These longer-term difference in continence rates was further supported by the more recent randomized controlled trial [505] of 208 men with 3,6 and 12- month continence rates of 55.3% vs 84.2% (p <0.001), 74.8% vs 89.5% (p = 0.05) and 81.4% vs 94.7% (p = 0.027) in the control and bladder neck preservation group, respectively. Bladder neck intussusception was found to be associated with earlier return to continence in prospective studies [506]. The literature on the impact of neurovascular preservation on postprostatectomy continence rates is conflicting [507-508]. Present literature reports decreased UI was associated with increased neurovascular bundle preservation with 18.2 % UI rate among patients receiving nerve-sparing RP vs 27 % in the non- nerve sparing RP group [509,570]. An unprecedented ligation-free technique of the dorsal venous complex during laparoscopic radical prostatectomy done in 180 patients showed lower UI of 60% vs 75.5 %, 45.6% vs 62.3%, and 26.1% vs 28.3 %, at 3, 6 and 12 months, respectively compared to standard ligation technique [511]. Simforoosh introduced a sutureless vesicourethral anastomotic technique based on the assumption that a reduction in the number of sutures utilized in the vesicourethral anastomosis improves continence recovery by causing less disturbance in the intrapelvic urethra. Promising low UI rates were achieved: 10 % at 3 months, 4.1 % at 6 months, and 3.6 % at the last follow-up visit [512]. Other technical aspects of the surgical procedure including the use of cautery when resecting the seminal vesicle; the degree of bundle preservation; excision of lymph glands; use of cautery near the urethra; and observation of a cutting suture in the bladder neck were not associated with UI [509].

Since the inception of laparoscopic and robotic surgeries and with the increasing performance of these minimally invasive procedures, several studies have investigated their impact on postoperative continence rates. Early systematic reviews with metaanalysis of studies comparing continence rates for open, laparoscopic, and robotic radical prostatectomy did not show any significant difference in the postoperative continence rates between the 3 techniques [513-515]. However, a prospective study of 239 men showed that UI after laparoscopic procedures seems to be higher initially but approximates that of open techniques by one year [516]. A larger population retrospective study with 12092 localized prostate cancer patients compared UI rates among those who underwent minimally-invasive RP (technique not specified) and open radical prostatectomy. Higher rates of UI (53.9 % vs 43.2 % in the younger age group and 56.5 % vs 51.8 % among the older age group) were seen after minimally-invasive RP [517].

A systematic review that focused on robotic radical prostatectomy showed better continence recovery after robotic prostatectomy compared with open retropubic prostatectomy (OR : 1.53, p=0.03) or laparoscopic radical prostatectomy (OR : 2.39, p=006) [518]. However, more recent large multicenter prospective non-randomized controlled trials reported a non-statistically significant difference in UI at 2-3 years (UI rate of 21.3 % for RARP vs 20.2 % for RRP in the study of Haglind; UI score for RARP 76 + 21.3 vs 78 + 21.7 for RRP in the study of Harlemann) [519-521]. These conclusions were further supported by a randomized controlled trial assigning 326 men to RARP and RRP. Both approach yielded similar functional outcomes at 24 months [522]. Immediate continence defined as no pad usage after catheter removal was also not significantly influenced by the surgical approach (robot vs open) but by surgeon volume (>100 procedures), preoperative erectile function and ECOG status, bilateral nerve-sparing, less blood transfusion, and Gleason score [521]. The global evaluative assessment of robotic skill (GEARS) score, whereby a higher score was associated with superior surgical skill, was utilized as a tool to validate the relationship of surgeon technical performance and early continence after robot-assisted laparoscopic radical prostatectomy. Higher scores were associated with better continence rates [523].

Several recent multicenter prospective studies, randomized controlled trials, and meta-analysis have compared the Retzius-sparing technique and the conventional RARP [524-526]. These studies demonstrated superior early continence up to 6 months, and quality of life in the Retzius-sparing group compared to the standard RARP group with UI rates of 38.9 % vs 66.5 %, 8.9% vs 32 %, and 5.4 vs 15 % at 1 week after foley catheter removal, 3 months post-surgery, and 6 months post-surgery, respectively [526]. Robot-assisted radical prostatectomy has also been done extraperitoneal with UI rates of 69.8 %, 49.7 % and 11.2 % at 1, 3 and 12 months post-RP, respectively but these comparable rates to intraperitoneal RARP were attributed to the nerve-sparing technique done [527]. The use of Rocco suture has not been shown to predict the time of continence recovery in robot prostatectomy [528]. Kováčik and colleagues introduced Advanced Reconstruction of Vesicourethral Support (ARVUS), a novel post-prostatectomy reconstruction technique involving anterior and posterior reconstruction of the pelvic structures during RALRP. Unfortunately, the technique performed worse in continence rates compared to the control group [529].

Additional observation worth mentioning is that men who underwent salvage radical prostatectomy after either EBRT or brachytherapy were found to have worse urinary continence outcomes than after focal therapy [530]. Conversely, salvage brachytherapy was associated with 18.3 % UI in a small retrospective cohort study [531]. Adjuvant radiotherapy has not been found to affect post-prostatectomy UI rates when assessed beyond 1 year [532-533].

With the well-established association of radical prostatectomy and UI, interest in focal therapies for localized prostate cancer has emerged and research endeavors have been set in motion to understand the effect of different focal therapies on UI. Despite reports of having superior functional outcomes compared to radical prostatectomy, He and associates conducted a systematic review and meta-analysis on the oncologic and functional outcomes of high intensity focused ultrasound (HIFU) and was able to observe incidences of 10 % (95% CI 0.06–0.14), and 2 % (95% CI 0.01–0.03) UI among men after whole gland and partial gland ablation, respectively [526]. These rates were consistent with later reports, limited to observational cohort studies [535-537]. No randomized controlled trials (against radical prostatectomy and other treatment options for localized prostate cancer) have been reported as of the writing of this text. 3dRT monotherapy as a form of focal therapy confers 7% UI rate [538] while EBRT and/or high dose brachytherapy was reported to have 14 % UI rate.

3.10. Factors with unclear association with UI in men

A diagnosis of hypertension was associated with an increased UUI risk in men OR 1.52 (CI 1.0-2.33) based on recent research in the UK involving a cohort of 1059 men from the Medical Research Council (MRC) National Survey for Health and Development [435].

Those with sleep apnea were more likely to have UI than those without (OR=2.73, 95% CI=1.51-4.95) [539]. Li and associates evaluated the association of major depression and vitamin D deficiency, and UUI in 1293 non-obese men in the National Health and Nutrition Examination Survey. Odds ratio of 2.60, (95% CI: 1.33-5.09) and 1.61, (95% CI: 1.01-2.59) were obtained, respectively [430]. These risk factors have not yet been validated in other studies.

4. SUMMARY POINTS:

- The epidemiology of UI in men has not been investigated to the same extent as for females. But it appears that UI is at least twice as prevalent in women as compared with men. There seems to be a more steady increase in prevalence with increasing age than for women.
- Most studies find a predominance of UI, followed by mixed forms of UI and SUI the least. Most studies have a large fraction of other/unclassified types.
- Literature on incidence and remission of male UI is still very scarce.
- Clear risk factors are more seldom scientifically documented, but several medical correlates have been reported. Established risk factors predisposing men to UI include increasing age, presence of LUTS, UTI'S, functional and cognitive impairment, diabetes, alcohol intake, obesity, neurological disorders, and prostatectomy.
- Substantial gains have been achieved on the study of the epidemiology of UI in men compared to the previous years. The conduct of more population-based prevalence studies permitted a better understanding of the problem of UI among men.
- UI after radical prostatectomy is frequent, ranging from 2-57%. Rates steadily decline from the time of surgery and plateaus at 1 to 2 years postoperatively.
- Factors affecting post-prostatectomy UI include the age at surgery, obesity, type of prostatectomy, and certain modifications in the technique.
- There is not enough evidence to demonstrate any significant difference in continence rates between open, laparoscopic and robotic-assisted radical prostatectomy.
- Modifications in the surgical technique of radical prostatectomy have variable impact on postoperative continence rates.
- Comparative studies of surgical procedures and focal therapies to address prostate disease and their various modifications should be performed to better assess their impact on postoperative continence rates.

VI. EPIDEMIOLOGY OF OVERACTIVE BLADDER AND NOCTURIA

1. GENERAL COMMENTS AND DEFINITIONS

OAB and nocturia were previously neglected topics in the medical literature [617-619]. Earlier research on epidemiology of LUTS focused either on LUTS suggestive of BPH and BPO in men or SUI in women [620]. However, there has been increased research interest in OAB and nocturia during the last quarter century [618-619,621].

OAB can be bothersome [622-624], and is associated with comorbidity [322], impaired quality of life [8], and reduced emotional well-being and work productivity [625]. Nocturia is a common cause of sleep maintenance insomnia [626-628]. Nocturia can be bothersome [629-636], and is associated with impaired mental health, physical health and quality of life [636-638]. Systematic reviews and meta-analyses found that nocturia is associated with increased risk of falls, fractures and mortality [639-640]. Also OAB has been suggested to be associated with increased risk of falls and fractures [641-642]. Indeed, urinary urgency and urgency incontinence, the cornerstone symptoms of OAB, and nocturia are among the most

bothersome urinary symptoms both on an individual and population-level [643].

In general, the definition of any condition is a critical factor in evaluating its epidemiology: OAB and nocturia are not exceptions to this rule [619,644]. To facilitate discussion and research related to LUTS, the International Continence Society (ICS) has produced standardisation reports [645-648]. We will use the ICS definitions as basis of this chapter. However, we acknowledge that these definitions are not perfect and we encourage further research and discussion [621,644-651].

OAB is a term to describe the clinical problem of urgency and UUI from a symptomatic rather than from a urodynamic perspective. Previously various terms, such as 'irritable bladder' or 'unstable bladder' have been used. According to the ICS, OAB is a symptom-defined condition characterised by urinary urgency, with or without UUI, usually with increased daytime frequency and nocturia [645-646]. The ICS defines *urinary urgency* as sudden compelling desire to pass urine, and the term OAB is appropriate if there is no proven infection or other obvious pathology [645].

It has been known for a long time that among healthy people urine production is lower during the night than during the day [652]. Urologists have traditionally defined nocturia as frequency of micturition at night without reference to urine amount, while internists have assumed that nocturia results from an increased amount of urine produced with less focus on other LUTS [653]. According to the ICS definitions, *nocturia* refers to waking at night one or more times to void, and *nocturnal polyuria* (NP) is the production of an abnormally large volume of urine during sleep [647]. Nocturnal UI or nighttime bed wetting (enuresis) differs from nocturia.

According to the ICS, as stated earlier, nocturia is also a component of OAB. However, there is a debate on the definitions, especially regarding urinary urgency and OAB [621,650-651,654-664].

Sometimes OAB has been divided into 'OAB wet' (OAB with UUI) and 'OAB dry' (OAB without UUI). In this part of the chapter we focus on the epidemiology of OAB – without distinction between OAB 'wet' and 'dry' – and nocturia. 'OAB wet' (i.e., UUI) is covered separately in UI sections (Epidemiology of UI in Women and Epidemiology of UI in men).

2. PREVALENCE OF OVERACTIVE BLADDER

Prevalence estimates from as low as 2% [665] up to 53%[666] have been reported. Many studies on OAB have reported prevalence estimates between 10% and 20% [667-674]. However, many of the studies have been limited by not measuring bothersomeness.

Table 19 summarized population-based studies that assessed prevalence of OAB in adults of both genders. To identify these studies, a Medline search (English-language articles published before June 2016) was carried out on with the strategy (((Overactive bladder.mp) or (OAB$.mp)) and ((prevalence.mp). Non-population-based (i.e. based on doctor attendances or similar) studies or studies not conducted among both sexes were not included in Table 19.

Among these population-based studies identified, different populations, different sample selection and different data collection methods were often used (Table 19). Sample sized varied between 913 and 162,906, median being 3,366 individuals. Nine (39%) out of 23 studies did not report any response proportion. Among those 14 studies which reported, as many as eight (58%) had response proportion less than 50%. There was significant heterogeneity in symptom assessment, exclusion criteria, case definitions (some studies used grading of symptom severity whereas others did not), and in the time period during which the occurrence of symptoms was asked (Table 19). Hence, dissimilarities in study procedures likely explain the differences in prevalence estimates. Overall, median prevalence estimate of the studies was 16.5% (range 2-35% in men, and 3-41% in women) (Table 19). However, estimates of the prevalence of OAB have been smaller in many recent studies compared to earlier estimates (Table 19).

Table 19. Overview of published population-based studies assessing prevalence of OAB in both sexes (PubMed indexed English-language articles as of June 2016, in chronological order).

Origin	Data collection method	Sample source	Respondents (response proportion, %)	Age range (years)	2002 ICS Consensus Definition of OAB	Definition of normal - abnormal occurrence	Time period	Prevalence, %: Men/women
European [667]	Telephone interview / in person interview[a]	Telephone registry / electoral census[a]	16,776 (unreported)	40 – 75+	N/A	N/A	Undefined	**16 / 17**
USA [669]	Telephone interview	Telephone registry	5,204 (44.5)[b]	18 – 75+	N/A	N/A	Past 4 weeks	**16 / 17**
Canada [675]	Telephone interview	Telephone registry	3,249 (43.4)[c]	35 – 75+	N/A	N/A	Past month	15 / 21
Japan [671]	Mailed questionnaire	Not reported	4,570 (45.3)	40 – 100	N/A	N/A	Past month	14 / 11
Brazil [676]	Unreported	Not reported	913 (unreported)	15 – 55	Yes	Unreported	Undefined	14 / 23
Taiwan [677]	Questionnaire administered by nurse	Population registry	1,921 (67.0)	30 – 79	No	N/A	Past 4 weeks	16 / 18
International [674]	Telephone interview	Telephone registry	19,165 (33.0)	18 – 70+	Yes	No – Yes	Undefined	11 / 13
Finland [678]	Mailed questionnaire	Population registry	3,727 (62.4)	18 – 79	Yes	Rarely – often	Past 2 weeks	7 / 9
Korea [679]	Telephone interview	Telephone registry	2,005 (13.8)	40 – 89	No	N/A	Past 4 weeks	21 / 31
Canada [680]	Telephone interview	Telephone registry	1,000 (unreported)	18 – 90	No	N/A	Undefined	13 / 15
USA [681]	Mailed questionnaire / Telephone interview	Consumer panel	162,906 (62.7)	18 – 85+	No	N/A	Undefined	24 / 29
Portugal [682]	Telephone interview	Telephone registry	1,934 (59.6)	40 – 80+	No	N/A	Past 4 weeks	35 / 29
International [683]	Web-based interview	Consumer/ voter panel	30,000 (49.5)[d]	40 – 99	Yes	Rarely – sometimes (Sometimes – often)	Past 4 weeks	22 / 36 (5 / 11)
USA [684]	Web-based interview	Consumer/ voter panel	2,000 (42.1)[e]	40+	Yes	Rarely – sometimes	Past 4 weeks	26 / 41
USA [69]	In person interview	Community registry	3,483 (63.3)[h]	30 – 79	Noi	N/A	Past month[i]	9 / 14
Korea [685]	Telephone interview	Telephone registry	2,000 (22.1)	18 – 96	Yes	Unreported	Undefined	10 / 14
Korea [686]	Telephone interview	Post/address registry	2,000 (unclear)	30 – 60+	No	N/A	Past week[j]	19 / 27
China [687]	Interviewer assisted	Unreported	14,844 (69.0)	18 – 70+	Yes	<1 a week – ≥1 a week	Past week	6 / 6
USA [688]	Web-based interview	Consumer/ voter panel	10,000 (unknown)[f]	18 – 70	No	N/A	Past 4 weeks	16 / 30
Japan [689]	Web-based interview	Consumer/ voter panel	Unknown	20 – 60+	No	N/A	Past week[j]	10 / 9
Brazil [690]	In person interview	Local census tract	3,000 (unclear)	30 – 70+	Yes	Unreported	Undefined	5 / 10

Origin	Data collection method	Sample source	Respondents (response proportion, %)	Age range (years)	2002 ICS Consensus Definition of OAB	Definition of normal - abnormal occurrence	Time period	Prevalence, %: Men/women
China [691]	In person interview	Local census tract	9,805 (unclear)	40 – 70+	No	N/A	Past week	3 / 2
International [692]	Telephone interview	Unreported	3,130 (unknown)[g]	18 – 60+	Yes	No – Yes	Undefined	18 / 28

[a] In the European study, in five out of six countries, telephone interview was used (excluding Spain, where direct interviews were conducted due to lower proportion of households with telephone). Study sample was obtained from telephone number listings (except Spain, where electoral census data was used).
[b] Out of 11,740 participants (of 17,231 households contacted), 5,539 were considered ineligible. To calculate response rate, the number of respondents was divided by eligible participants (the former response rate). If same proportion of non-participants, as there were ineligible among participants (47%), were also considered ineligible, response rate was greater (the latter response rate).
[c] Out of 7,487 individuals, 3,239 completed the questionnaire (response proportion 43.4%).
[d] Invitation to complete email survey was sent to 88,150 members of the Internet-based panel. Of the members, 51,546 responded but 7,947 were excluded due to high rates of missing or inconsistent data, or discontinuation of the survey. Finally, 30,000 participants were randomly selected from the pool of respondents with completed surveys.
[e] Invitation to complete email survey was sent to 5,002 members of the Internet-based panel. Of the members, 3,058 responded, but only 2,106 members completed the survey. Finally, 2,000 participants were randomly selected from the pool of respondents with completed surveys.
[f] Invitation to complete email survey was sent to 38,469 members of the Internet-based panel. Of the members, 18,591 responded, but number of members completing the survey was not reported. Finally, 10,000 participants were selected from the pool of respondents with completed surveys.
[g] Authors reported that a large proportion of individuals asked to participate declined. However, the number of individuals asked to participate was not reported.
[h] Out of 5,503 individuals, 63.3% completed the questionnaire (n=3.483).
[i] In this study, individuals "were considered to have urgency if they reported difficulty postponing urination, had a strong urge to urinate (fairly often, usually or almost always) in the last month or a strong urge to urinate in the last 7 days (4 or more times)."
[j] Time period was not reported in the article. However, authors cited the original OABSS articles, which states that "patients were instructed to circle the score that best applied to their urinary condition during the past week" (Homma et al. Urology 2006).
[f] ICS, International Continence Society; OAB, overactive bladder; UTI, urinary tract infection.
[g] Cut-off point (threshold) used for normal vs. abnormal symptom occurrence. Reviewed only for studies using current ICS definition of OAB.1
h Time period during which the occurrence of symptoms was asked.

Only few population-based studies have evaluated OAB prevalence using the ICS definition *and* reported bother. Assessing perceived bother associated with OAB substantially decreases the prevalence estimates. In the FINNO Study (conducted in Finland among aged 18-79) [624], as many as 54% of men and 57% reported *any* (at least rarely) urinary urgency. However, prevalence of at least moderate bother from urgency was 7% for men and 9% for women. Overall, more than 96% of individuals with *rare* urgency reported no or small bother from it whereas 65% of individuals with urgency *often* and more than 70% with urgency *always* reported moderate or major bother (scale: none-small-moderate-major) [624]. These results are in concordance with two international studies [622-623]. In the EpiLUTS study (conducted in the US, UK and Sweden among people aged 40–99) [623], 22.4% of men and 35.7% of women reported urinary urgency at least sometimes (in scale: never-rarely-sometimes-often-almost-always) (Table 19). However, prevalence estimates were substantially lower when bother was taken into account. Only 6% of men and 12% of women reported "quite a bit" or more bother from urgency (in scale: not at all-a little bit-somewhat-quite a bit-a great deal) [623]. Bother analysis from the EPIC Study [622, 664] showed also that infrequent urinary urgency is not considered as very bothersome by most individuals. Out of OAB cases, 46% did not report symptom bother from it [622]. More recent studies [693-694] have had similar findings: i) definition of disease has strong impact on prevalence estimate, and ii) the more strict definition used, the bigger bother and quality of life impact. Overall, all these results suggest that i) bother measurement is essential in estimating the clinically relevant prevalence of OAB, and ii) most studies have overestimated the prevalence of patient-important OAB [5-8] (Table 18).

3. INCIDENCE OF OVERACTIVE BLADDER

The natural history of OAB has been systematically reviewed (English articles published between January 1, 1990, and September 20, 2009) [695]. Authors identified 7 longitudinal studies of OAB. OAB incidence varied between 3.7% and 8.8%; and included studies provided evidence for dynamic nature of OAB [80]. Indeed, longitudinal studies have confirmed not only that OAB prevalence increases with age but also that OAB is a dynamic condition [696-702].

In a population-based study (conducted between 1991 and 2007 in Gothenburg, Sweden) [693], the number of women with OAB with UUI ("OAB wet") increased from 6% to 16%, however, the proportion of women with OAB without UUI (OAB dry) did not differ significantly (11% vs. 10%). Among women with OAB dry in 1991, 23% remained OAB dry, 28% reported symptom progression to OAB wet and approximately half reported remission of OAB by 2007, supporting the concept of the dynamic nature of OAB. The rate of remission of OAB symptoms was greater for women who were OAB dry (49%) compared with those who were OAB wet (26%).

Finding that OAB is a dynamic condition was also reported in studies from Australia and Japan [701-702]. In the CHAMP study conducted among 1,705 men aged 70 or more living in metropolitan Sydney [701], one in three older men with OAB had sustained remission of symptoms without medical or surgical interventions. Of the men with OAB at baseline, 29% received treatment for OAB or benign prostatic enlargement over 5 years. In the Japanese longitudinal community-based "Fujiwara-kyo study" among more than four thousand people aged 65 years or more [702], the incidence rate of OAB was 12% and remission rate 30%.

4. RISK FACTORS FOR OVERACTIVE BLADDER

The causes of urinary urgency and/or OAB remain poorly understood. Identified risk factors are summarized below.

4.1. Age

In numerous cross-sectional studies older individuals reported more OAB than younger ones (Table 19). Furthermore, longitudinal studies have confirmed that OAB increases with age [695]. Besides increasing age, also having urgency in childhood predicts having urgency in later life [703-704].

4.2. Gender

In Table 19, we summarized population-based studies assessing prevalence of OAB among both genders. In most studies, OAB was more common among women (Table 19). Out of 23 listed studies, in only three (13%) the prevalence estimate of OAB was larger in men than in women. However, none of these studies [671,682,691] included younger age group. This is probably important as OAB is typically more common among women especially in younger ages.

4.3. Obesity

In a British, prospective study, obesity was a risk factor for the onset of OAB (OR 1.5, 1.0-2.1) in women [322] but not among men [688]). Ten studies were included in a systematic review examining the link between OAB and obesity [705]. There was a statistically significant link between obesity (measured by BMI) and OAB in eight studies. However, four of the studies that found a positive correlation were found to have low methodological quality. Three studies examined relation of OAB with waist circumference, two found relationship whereas one did not. Overall, unfortunately most studies were cross-sectional and did not often adjust for major confounders. A systematic review and meta-analysis of 33 observational studies (2190 patients, median follow-up 12 months) found that bariatric surgery is associated with improvement or resolution of any UI in 56% (95% CI 48-63%), SUI in 47% (95% CI 34-60%), and UUI in 53% (95% CI 32-73%) of patients [706].

4.4. Life-Style

In a prospective study among British women, neither alcohol, coffee nor tea consumption were risk factors for the onset of OAB (defined as having either urgency, UUI, or a combination of these) but use of carbonated drinks was [322]. Among men, neither tea, coffee nor wine consumption were associated with onset of OAB onset, but a negative association between beer intake at baseline and subsequent OAB onset was found [692]. However, this may be explained by a *systematic misclassification error* (individuals decrease or cease alcohol consumption due to ill health) [707-708], *residual confounding* (moderate drinkers have many other favouring lifestyle factors) [709-710], or direct biological effects. In a Swedish population-based study in young female twins [168], tea (but not coffee) drinking was associated with an increased risk for both OAB and nocturia. However, after controlling for confounders (including zygosity of twins) these associations did not remain significant. Concurring with these studies, among non-care seeking women [105], coffee or alcohol consumption was not associated with OAB. In a population-based study among women in Southern Sweden [306], OAB was not associated with alcohol consumption.

In a prospective British study, smoking was a risk factor for the onset of OAB (defined as having either urgency, UUI, or a combination of these) in women but not in men [696]. In a population-based study among Finnish women aged 18-79 [711], urgency was approximately three times more common among current and twice as common among former than never smokers. Parallel associations for urgency with smoking intensity suggested a dose–response relationship [99]. Other supporting findings have also been reported [712-714]. However, some other studies did not find smoking as a risk factor for urgency [168,682,306].

A prospective study among British men did not provide evidence of any specific dietary patterns as a risk factor for onset of OAB [697]. Furthermore, physical activity was not significantly associated with OAB onset in men [697]. Contradictory results were found among non-care seeking women [716] where physical activity was associated with decreased OAB.

4.5. Race/Ethnicity And Socioeconomic Status

Evidence regarding the role of race/ethnicity on OAB prevalence is emerging. In a small Taiwanese study [717], higher prevalence of urgency (7.7% vs. 4.3%, p=0.02), was found in indigenous woman than in non-indigenous women. In the US part of the EpiLUTS study [137], OAB was reported by 26% of White, 33% of Black, 27% of Asian and 28% of Hispanic men. In the multivariate analysis, OAB was significantly more common among African-American (OR 2.0, p<.001) and Hispanic (OR 1.7, p<.001) male participants. The authors reported no statistically significant differences among women after multivariate analysis, despite wide variation in crude prevalence (27% for Asian women, 43% for White, 46% for African-American and 42% for Hispanic) [137]. Hospital-based studies have reported conflicting results regarding prevalence of OAB by race/ethnicity [718-720].

4.6. Reproductive Factors And Pelvic Surgery

Urinary urgency is a common symptom during pregnancy [721]. In a Taiwanese study [722], only 1% of women reported having urgency before pregnancy, whereas corresponding estimates were 16% in the first, 25% in the second, and 31% in the third trimester. Other studies have also found increasing prevalence of urgency with advanced gestational age [723-724]. However, in a Nigerian study, women in the 3rd trimester did not report more urgency than women in 2nd trimester [725]. Although one quarter of pregnant women reported urgency, it was associated with moderate or severe bother for only 5% of symptomatic women.

The association of parity and urinary urgency is controversial. Some studies reported no association for parity with urgency or OAB [105,322,726-727] whereas others found increased prevalence of urgency among parous women [717,728-731]. However, there were substantial differences in methodologies between these studies. Regarding delivery mode, most studies demonstrated no effect on prevalence of urgency or OAB [682,726,730-733]. On the other hand, contrary findings have also been reported [734-735]. In a Swedish prospective study, weekly urgency was reported by 2.6% of women with a vaginal delivery and by 2.7% of the women with a cesarean section [715]. Corresponding figures were 7.9% for vaginal delivery and 2.7% for cesarean section groups at 9 months post-partum [734] concurring the results of a cross-sectional US study [734]. In a US study [715], for women with a history of at least one operative vaginal birth, the adjusted odds of OAB was more than quadrupled (OR 4.9, 95% CI 2.2-11; women who had delivered all their children by pre-labor cesarean as reference). A systematic review pooled estimates from 8 studies suggested an elevated risk of UUI after vaginal delivery versus cesarean section (adjusted OR: 1.30; 95% CI, 1.02-1.65; absolute risk difference: 2.6%) [736]. Similar findings were found for OAB in a prospective US cohort study following women for median time of 5 years post delivery [737].

The association of postmenopausal period with increased urgency or OAB has been reported in several studies [687,728,730-731,738-740]. Impact of hormone therapy on OAB is unclear [741]. The Cochrane Incontinence Group review of UI and estrogens (urgency or nocturia not as the primary objective of the study) found that there were less nocturnal voids and urgency episodes among women treated with local (but not systemic) estrogen [742]. There were no significant differences in OAB prevalence among women using either oral contraceptives or a levonorgestrel-releasing intrauterine device, in comparison to noncontraceptive users in a population-based study among young, Swedish women [743].

Radical hysterectomy is related with increased prevalence of pelvic floor problems [744]. For instance, patients treated for cervical cancer reported 2-3 times more commonly urgency than the matched controls: 36% of those with history of radical hysterectomy and pelvic lymph node dissection, 49% of those with surgery and adjuvant radiotherapy, and 48% of those with primary radiotherapy reported experiencing urgency [745]. However, the relation of urgency and hysterectomy for benign indications is less clear. Many studies did not find a significant association between hysterectomy with urgency [726-727,746-750]. However, some studies reported less [739,750-752] and some more [682, 728-729,753] urinary urgency after hysterectomy. No difference by route of hysterectomy on urgency has been found [750,752,754-755]. Both POPand stress incontinence surgery are associated with risk of (de novo) urgency or UUI in both hospital based, and population based studies [714,727,756-758].

4.7. Specific Conditions

There is a paucity of studies concerning conditions and co-morbidities that may be associated with OAB, and clear causal risk factors are even more seldom documented. Few available studies have identified potential risk factors, which are described below.

Benign prostatic hyperplasia. Instead of OAB/urgency, observational, clinic-based studies have assessed relation of DO with BPH/BPO. Although patients with DO are less likely to get symptom improvement after BPH surgery than those without DO, many patients report less urgency after BPH surgery [759]. Similar findings were found in a prostatectomy study among men aged 47-85, 32% (n=49) reported urgency pre-operatively and 13% post-operatively (n=20) [760]. In another study, DO was present in 68% of patients (n=21) at baseline and in 31% (n=10) at follow-up (mean 2 years) in the prostatectomy group [761]. However, many patients remain symptomatic after prostate surgery, and prognostic factors for success remain largely unknown [762].

Pelvic organ prolapse. In community-based studies [730,763-765], POP was associated with 2-6 times higher risk of having UUI. Concurrent with this findings, hospital based studies have also found POP as a risk factor for UUI, and in interventional studies UUI is often (but not always) relieved [766].

Mental health. In the BACH survey [767], urinary frequency, urgency, and nocturia were associated with previously experienced sexual, physical, and emotional abuse for both genders and for all ethnic groups of the study (White, Black, Hispanic). Concurring results were found in a German, clinic-based study where 31% of women with OAB reported almost twice as often earlier physical or sexual abuse as did the women with SUI (18%) or women without

LUTS (18%) [768]. In an Iranian study, individuals with OAB had a higher prevalence of anxiety (28.2 vs. 8.8%; p=0.001) and depression (38.2 vs. 18.2%; P = 0.02) [679] concurring with findings from multinational EpiLUTS study and a longitudinal Japanese where increased depression and anxiety were found among individuals with OAB [707,7699]. Furthermore, postpartum depression has also been reported to be associated with UUI [770].

Other conditions. In the BACH survey [771], urgency was associated with almost double the risk of hypertension and heart disease in women and with more than double the risk of diabetes in men. However, In a Japanese study among the elderly, OAB was not associated with diabetes or kidney disease but was associated with depression, alcohol use, and increasing BMI [772]. In a UK prospective cohort study within a random sample of 19,241 women aged 40 or more identified from Health Authority lists of 108 general practices [322], predictors of OAB included bowel urgency, imbalance, osteoporosis, ankle swelling, diabetes, DVT and cystitis [322]. Urgency/OAB has also been reported to common among patients with irritable bowel syndrome [773-774], functional dyspepsia [775], diabetes [776-778], including gestational diabetes [779], stroke [780] and asthma [689].

5. PREVALENCE OF NOCTURIA

Most earlier studies assessing nocturia prevalence were conducted among elderly men [781-788]. They consistently found that nocturia 1) is a very common symptom and 2) increases with ageing. These finding have been confirmed in numerous comparative studies conducted in both sexes [629-630,635,673,680,789-802] (Figure 8).

Population-based studies assessing prevalence of nocturia in adults of both sexes included. A Medline search of the English-language articles published before June 2016 carried out with the search strategy ((nocturia.mp) and ((prevalence.mp)). Non-population-based (i.e. not based on doctor attendances or similar) studies, studies not conducted among both sexes of adults, studies with narrow age range (<40 years), or studies with percentage data unavailable not included.

In the FINNO Study, conducted among men and women aged 18 to 79 [793], approximately one out of eight men and women reported at least two voids per night. In addition, one in three reported one void per night. Young women reported more nocturia than young men, prevalence of nocturia in men and women equalized in the sixth to seventh decade of life, and in elderly men had more nocturia than women. Many other studies have supported these findings: higher prevalence of nocturia among young women than young men, and an equalization of prevalence in middle age [188,635,649,681,687,802-804] (Figure 8). As the gender difference has been found across different continents (Europe, Asia, Australia, North America, and South America) it probably not due to specific country, lifestyle or cultural factors. The reasons for the excess of nocturia among older men remain unknown, but prostatic enlargement is likely to be the predominant factor.

The Krimpen study, conducted in the Netherlands among elderly men [805], is one of the few studies where nocturia was assessed by using frequency-volume charts. One and a half or more voids/night (average of information on two to three nights) was present in 60% of men aged 70-78 years, whereas at least 2.5 voids per night was present in 20%, respectively. These estimations are comparable to questionnaire studies: most elderly people void at least once per night [803] (Figure 8).

6. INCIDENCE OF NOCTURIA

A comprehensive systematic review and meta-analysis summarized the incidence and remission of nocturia [806]. Authors conducted a search of PubMed, Scopus, and CINAHL databases as well as abstracts of major urological meetings until end of August 2015 and found 16 eligible studies [807-823]. Of the 16 included studies, 10 (62%) were at high risk and six (38%) at low risk of bias. Of these 16 studies, 14 (88%) accurately assessed noctu-

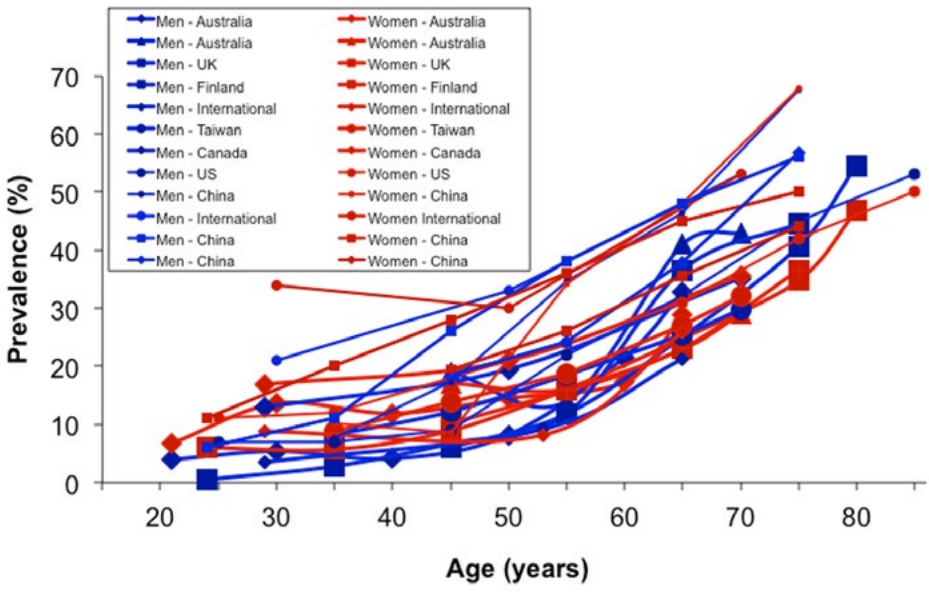

Figure 8. Prevalence of at least two voids per night across age groups by sex in population-based studies conducted among both sexes with wide age-range [14, 15, 20, 58, 65, 179-191].

ria both at baseline and at follow-up, nine (56%) had little missing data in the follow-up, and eight (50%) used representative source populations. Pooled estimates from 13 studies [810-823] with 114 964 person-years of follow-up demonstrated that annual incidence was strongly associated with age: 0.4% (0–0.8%) for adults aged less than 40 years; 2.8% (1.9–3.7%) for adults aged 40–59 years; and 11.5% (9.1–14.0%) for adults aged at least 60 yr. Of those with nocturia, each year 12.1% (9.5–14.7%) experienced remission.

7. RISK FACTORS OF NOCTURIA

The causes and risk factors of nocturia are not very well understood [650,785]. Available studies, that aimed to identify potential risk factors, are summarized below.

7.1. Age

There have been numerous studies showing that elderly subjects have more nocturia than younger people- age is one, if not the most important correlate of nocturia. For instance, in a community-based US study, less than 5% of those aged 18-24 reported two voids per night while the corresponding figures were approximately 15% and 25% for those aged 45-54 and 65-74 respectively [630]. Besides increasing age, also childhood nocturia and enuresis has been suggested to predict nocturia in later life [708,824].

7.2. Gender

Although there is no remarkable difference in overall prevalence of nocturia between genders, in more detailed age specific analyses differences have emerged between the genders (Figure 8). Many studies found higher prevalence of nocturia among young women than young men, and an equalization of prevalence in middle age [635,674,680,777,803,883]. Prostatic enlargement has been suggested as predominant factor for potential nocturia excess among elderly men [803].

7.3. Obesity

Several studies have shown the relation of overweight/obesity and nocturia. Obesity was associated with more than three-fold risk of nocturia in a Swedish study among middle-aged women [825], and with more than two-fold risk in the FINNO Study [826]. Confirmatory findings have been reported in numerous studies [804,827-834]. In the longitudinal TAMUS study among men aged 50 or more [835], obese men had double the risk for nocturia compared with normal weight men. The frequency of nocturia at baseline did not increase the incidence of obesity at follow-up.

7.4. Life-Style

Many studies have not found an association between nocturia and either alcohol [629,808,829,836-839] or coffee/caffeine [788,825,835,839-840] consumption. In some studies moderate alcohol consumers had less nocturia than abstainers [835,841-842]. However (as discussed earlier in 'Risk factors of overactive bladder'), these findings may be due to systematic misclassification error or residual confounding [707-710].

Many studies have not found an association between nocturia and smoking [788,805,829,835,838-839,843]. Some conflicting results have also been reported: in Swedish and Chinese studies [825,832] smoking was associated with increased nocturia but in Austrian [629] and Japanese [837] studies, with decreased nocturia.

Physical activity has been reported to be protective against LUTS in men [844.846], and against nocturia in both genders [801,825]. In an Austrian study [629], no relation was found between nocturia and physical activity. However, exercise programme has been shown to improve nocturia in non-randomised trial [847].

7.5. Race/Ethnicity And Socioeconomic Status

In several US studies, African Americans were approximately twice as likely to report nocturia as other groups [827,830,848-850]. This effect was attenuated, although remained significant [830,849], with adjustment for socioeconomic status and comorbidity. Furthermore, care-seeking black women reported also more commonly nocturia than other groups [8512-853]. Conflicting results were found in a Kaiser Permanente study [854]. In the EpiLUTS study conducted in the USA, UK and Sweden [823] and in a Kaiser Permanente study [855], Blacks and Hispanic had more nocturia when compared to White. Less is known about the relationship between ethnicity and nocturia outside the US. In small studies in Taiwan [717,856] and Scotland [857], associations of nocturia and ethnicity have been found. In the Scottish study, nocturnal polyuria was more common in the Caucasian men compared to Asian men.

7.6. Reproductive Factors And Pelvic Surgery

Nocturia is a very common symptom during pregnancy. In all studies most pregnant women report nocturia at least weekly, in many studies most women report having nocturia every night [721-725,732,858-860]. Typically the occurrence of nocturia increases during pregnancy. In an Indian study [859], nocturia (defined as more than one void per week) was reported by 51% of women before pregnancy (retrospective information), by 59% of those in the first, 72% in the second and 77% in the third trimester. In Finnish and Chinese studies [727,821], parous women reported slightly more nocturia than nulliparous women, contradicting earlier reports (conducted among perimenopausal women) of no association [729,861]. The relation of nocturia with parity has been suggested to be more likely due to pregnancy itself than trauma to the urinary tract during delivery [862] supported by finding of no difference in nocturia between primi- and multiparous women in the same Finnish study [727] and by a finding of no difference between vaginal delivery and caesarean section in a Swedish prospective study [734]. In these studies, the postpartum period was also associated with increased nocturia [727,734].

In a population-based Swedish study among young women, no difference in nocturia was found among oral contraceptive users and non-users, however, levonorgestrel-releasing intrauterine device (compared with non-contraceptive users), reported less nocturia (OR 0.53, 95% CI 0.32-0.89) [743].

Danish and Finnish population-based studies have reported more than double the risk of nocturia after menopause [727,729], consistent with other studies [738,821,861]. One study attributed this to aging rather than to menopausal transition [863]. In the Finnish and Swedish studies [727,861], there were indications of increased nocturia among women using menopausal hormone therapy, but the findings were statistically insignificant. In a small randomised trial [864], there was no difference in nocturia among those with menopausal hormone therapy or placebo. Similar findings were reported in a randomized trial of vaginal estradiol and placebo after sling surgery [865].

The relationship of nocturia and hysterectomy is unclear, with hysterectomy being protective factor [866-868], risk factor [729,855], or not associated with nocturia [727,739]. Surgery for SUI was not associated with nocturia in a population-based study [727].

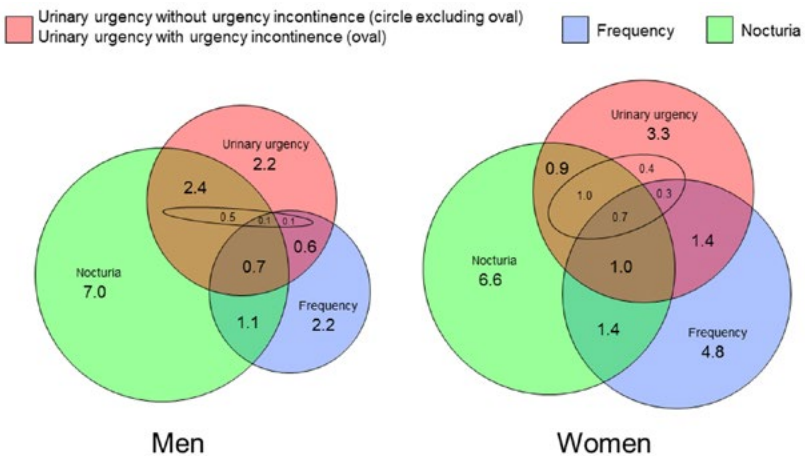

Figure 9. Age-standardized prevalence of nocturia, urinary urgency (with or without urgency incontinence) and urinary frequency among Finnish people aged 18–79 years.

The red circle represents individuals with urinary urgency (often or always in scale: never-rarely-often-always) without urgency incontinence (often or always in scale: never-rarely-often-always) excluding the area of the red oval representing individuals with urinary urgency with urgency incontinence. The blue circle represents individuals with urinary frequency (defined as more than eight voids/day) and the green circle nocturia (defined as at least two voids/night). Age-standardization performed using the age structure of Finland. Modified from "Tikkinen KA et al. Is the prevalence of overactive bladder overestimated? A population-based study in Finland. PLoS ONE 2007; Feb 7;2:e195" which is an Open Access article distributed under the terms of the Creative Commons Attribution Non-Commercial License which permits unrestricted non-commercial use, distribution, and reproduction in any medium, provided the original work is properly cited

7.7. Specific Conditions

BPH and prostate cancer. BPH constitutes a well-recognised risk factor for nocturia [805,839,869]. In the FINNO Study [839], half of the subjects with physician-diagnosed BPH reported at least two voids per night; however, only a third of the men with nocturia reported BPH. However, nocturia is the least specific LUTS associated with BPO and medical treatment to relieve BPO has less effect on nocturia than on other LUTS [870-871]. Furthermore, nocturia has been reported as one of the most persistent LUTS following prostate surgery [760,872], and in a study on men with bothersome LUTS, those receiving finasteride had an effect indistinguishable from placebo [873]. Many men with LUTS express a fear of prostate cancer [874], however, whether LUTS (including nocturia) are suggestive of prostate cancer is not clearly established [875]. In the large HUNT-2 study [876], LUTS severity was positively associated with the subsequent diagnosis of localised prostate cancer but not with advanced or fatal disease. More than 70% of men with physician-diagnosed prostate cancer reported at least two voids/night, while 7% of men with nocturia reported prostate cancer in the FINNO Study [839]. Whether men with nocturia are only more vulnerable to be diagnosed with prostate cancer (due to use of prostate-specific antigen), prostate cancer causes nocturia, or nocturia is a side-effect of various prostate cancer treatments remains unclear [636,877]. Impact of radical prostatectomy on nocturia has been neutral or negative (i.e. increased nocturia) [878-880].

Nocturnal polyuria. A systematic review and meta-analysis summarized the relationship between nocturia and nocturnal polyuria [881]. Authors conducted a search of PubMed and Embase databases for studies written in English, German, French or Dutch with original data on adult participants in an investigation of the relationship between nocturia and nocturnal polyuria. Fifteen studies met the inclusion criteria. Quality scores of studies were generally high for internal validity but low for external validity. Standardized mean difference of 0.6 (95% CI 0.3-0.9) for nocturnal voids between nocturnal polyuria and non-nocturnal polyuria cases was found. Risk ratio for nocturnal polyuria in individuals with nocturia was 1.41 (1.37-1.44). Authors concluded that "the association between nocturia and nocturnal polyuria is apparent and robust. However, the clinical importance of the association appears to be less obvious than previously suggested based on single studies. The observed high prevalence of nocturnal polyuria, as a result of the applied International Continence Society definition, may be responsible for this discrepancy." The ICS defines nocturnal polyuria as an increased proportion of the 24-hour output of urine volume occurring at night [645,647]. However, there is a paucity of studies providing reference values. The Krimpen study authors suggested that nocturnal urine production exceeding 90 ml/hr is abnormal [805,882] but concluded that "nocturnal urine production as an explanatory variable for nocturnal voiding frequency is of little value." Another systematic review aimed to determine population-based evidence of the diagnostic accuracy of proposed definitions of nocturnal polyuria based on data from frequency-volume charts [883]. Authors identified 13 studies which suggested that diagnostic performance characteristics for proposed nocturnal polyuria definitions show poor to modest discrimination, therefore more data is needed ffrom both women and men of all adult ages and various backgrounds. Finally, in many cases the fundamental pathogenesis of nocturnal polyuria remains largely unknown [884].

OAB. Urinary urgency was a clear risk factor for nocturia in the FINNO Study (OR 7.4, 95% CI 4.5-12 for men, and OR 4.9, 95% CI 3.2-7.7 for women) [839]. However, while half of subjects with urgency also reported at least two voids per night, only one in three with nocturia reported urgency [678]. The finding that most people with nocturia do not report frequent urinary urgency (Figure 9), has been reported also in the EPIC and EpiLUTS studies [623,676].

Diabetes. An association between diabetes and nocturia has been noted in most [792,817,823,827,832,839,842,869,885-889], but not

all reports [681,805,812]. In the BACH Survey [837] and in a Danish study at ages 60-80 years [839], nocturia was associated with double the risk of diabetes. In these surveys, however, it remained unreported whether there were gender differences. In the FINNO Study, diabetes was associated with nocturia after adjustment for other factors only in women. On the contrary, in a Chinese study, association was found for men, but not for women [801].

Hypertension. It has been suggested that essential hypertension and nocturnal polyuria are part of the same pathophysiological process [889]. In Japanese, US, Chinese and Malaysian studies [792,812,830,832,890], hypertension was associated with nocturia, although effect sizes were generally modest (ORs between 1.5 and 1.6). In another Chinese study [801], association of nocturia and hypertension was found in women, but not in men. In studies conducted in Europe [791,805,839], neither nocturnal polyuria nor nocturia were associated with hypertension. In a secondary analysis from the BACH survey, monotherapy with calcium channel blockers in women, and combination therapy with loop diuretics in men was associated with nocturia but no other associations for nocturia with any other antihypertensive was found [891]. While the treatment for hypertension may cause [620,891-892] or alleviate nocturia [893] in some cases, appropriate methods are of particular importance when trying to assess the relation between hypertension and nocturia.

Coronary disease. Earlier (male) studies [791-792,805] did not find a relation between nocturia and cardiac disease. However, in these studies, an association between cardiac symptoms/disease and nocturia was found in the preliminary analyses before multivariate modelling. In more recent studies [801,827,839,842-843,894-895] coronary disease has been shown to be associated with nocturia.

Depression. In Swedish and US population-based studies [638,896], depression and antidepressant use were both associated with increased prevalence of nocturia whereas in a Finnish study a relationship was found only among men using antidepressants after adjustment for other factors [839]. In another Finnish study (among men aged 50 or more), those with depressive symptoms at study entry were at almost triple risk for moderate or severe nocturia than those without depressive symptoms but nocturia had no effect on depressive symptoms during 5-year follow-up [897]. In a Kaiser Permanente study [855], increasing anxiety/depression scale was associated with increasing nocturia. In a longitudinal Japanese study (The Nagahama Study) of more than 9,700 individuals, authors found a clear dose-relationship between baseline nocturnal voiding frequency and new onset depressive symptoms and a weak association between baseline 5-item Mental Health Inventory and new onset nocturia [898].

Sleep apnea and snoring. In clinic-based studies [887,899-902], nocturia was associated with sleep apnea. In US studies conducted among community-dwelling older adults, subjects with increased apnea-hypopnea index had greater mean nocturia episodes, nighttime urine production and atrial natriutretic peptide excretion [903-904]. Snoring was one of the three most important nocturia population-level risk factors for both sexes in the FINNO Study [839] concurrent with a Swedish urology clinic study [294]. Overall, a systematic review and meta-analysis identified 13 studies (406 patients and 9518 controls) and found association (RR 1.41, 95% CI 1.26-1.59) between sleep apnea and nocturia [905].

Neurological diseases. Most patients with multiple sclerosis have bladder dysfunction, which may also lead to nocturia [907-908]. Nocturia was also associated with stroke and cerebrovascular disease [842,885,909]. Moreover, in a study among Parkinson´s patients, severity of disease was also associated with increased nocturia [910]. Furthermore, a relationship of nocturia with restless legs syndrome has been reported [910].

8. SUMMARY POINTS

- OAB has been defined as urinary urgency, with or without UUI, usually with increased daytime frequency and nocturia (in the absence of infection or other obvious pathology).
- Prevalence of OAB has been estimated from as low as 2% up to 53%.
- Recent population-based studies have shown that less than 10% of people have OAB with at least moderate bother, suggesting that bother measurement is essential in estimating the clinically relevant prevalence of OAB.
- Longitudinal studies have shown that OAB increases with age, and that OAB is a dynamic condition, with not only substantial progression but also remission rates.
- OAB may be associated with an increased risk of falls, fractures, and impaired quality of life.
- While age is a clear risk factor for urinary urgency and/or OAB, other risk factors have not been that well studied.
- Individuals with BPH, POP and mental health problems typically report urinary urgency more often than those without.
- Nocturia is one of – if not the - most common LUTS with similar overall prevalence in both genders.
- The prevalence of nocturia is higher among young women than young men, but the prevalence increases more strongly with age in men.
- The literature on the incidence of nocturia remains relatively sparse. The incidence of nocturia has been shown to increase with age but also remarkable fluctuation has been identified.
- Two episodes of nocturia constitute meaningful nocturia, affecting quality of life and perceived health, while a single episode does not.
- Nocturia has been associated with an increased risk of falls, fractures, and death.
- Risk factors for nocturia include conditions of the lower urinary tract, but also a range of systemic conditions, including but not limited to BPH, urinary urgency/OAB, obesity, sleep apnoea, parity, and the postmenopausal state.

9. FUTURE NEEDS

- Due to the relatively recent research in OAB and nocturia, most data currently available are cross-sectional, hence, more prospective studies are needed
- Natural history of OAB and nocturia need more research – progression and remission of these symptoms is not yet well understood.
- Better understanding of relationship of different ‘overactive bladder symptoms’ would be beneficial.
- With prospective studies examining risk factors for incident OAB and nocturia will be possible, however, definition of incident OAB and nocturia may be challenging due to fluctuating character of these symptoms.
- Overall, further studies should be conducted with proper study designs and population-based sampling in order to decrease the risk of bias.

VII. EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

1. GENERAL COMMENTS AND DEFINITIONS

POP refers to the loss of support for the uterus, bladder, colon or rectum leading to prolapse of one or more of these organs into the vagina. POP is thus a continuous condition when measured by visual inspection of the vaginal wall during valsalva. For clinical purposes, the degree of POP is commonly described as above the introitus, at the introitus, or beyond the introitus with or without valsalva. The International Continence Society first developed a standardised definition for the condition of POP in 1996 [911-912]. The ICS Pelvic Organ Prolapse Quantification (POPQ) examination defines prolapse by measuring the descent of specific segments of the reproductive tract during valsalva strain relative to a fixed point, the hymen. The POPQ system describes the anatomic findings of pelvic organ prolapse without consideration for symptoms and bother perceived by the woman. Validation of this system has shown it to be highly reliable [913]. The stages of prolapse severity are arbitrarily defined, and there is no clear differentiation between normal anatomic variation and mild POP. For research purposes there is consensus for use of the POPQ system until further evidence might clarify the distinction between normal variation and mild prolapse [913].

Determining POP based on self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms attributed to pelvic organ prolapse [914] and the fact that prolapse above the level of the hymeneal ring is usually asymptomatic [915]. The only exception appears to be a sensation of bulging into the vaginal [916] which is most strongly associated with prolapse at or below the hymeneal ring. A recent study of 110 women found that a question asking about a feeling of something bulging in or dropping out of their vagina had a sensitivity of 84% and a specificity of 94% for POP at or beyond the hymeneal ring on examination [916]. Seeing prolapse would presumably be even more specific, but is too uncommon to be useful as a definition.

2. PREVALENCE OF POP

Several studies have reported the prevalence of POP in a general population [916-924]. Reports from the Women's Health initiative (WHI) Oestrogen Plus Progestin Trial, and randomized controlled trial, have been included. While not actually population-based, the women in the trial were recruited from the community rather then from women seeking gynaecological care, and provide important information on the prevalence of POP based on pelvic examination.

The prevalence of POP based on a sensation of a mass bulging into the vagina was remarkably consistent, ranging between 5 and 10 percent. The prevalence of observed prolapse in women enrolled in the WHI trial is similar to the prevalence found in the one population-based study that also used pelvic examination [917], although the prevalence of each type of prolapse was higher in the WHI study. In both studies, prolapse occurs most frequently in the anterior compartment, next most frequently in the posterior compartment, and least in the apical compartment.

Two studies that examined POP by race found the that Black women had the lowest prevalence and Hispanic women the highest after controlling for multiple other factors in multivariate analysis [917-918]. The study reported by Rortveit et al based on symptoms found adjusted odds ratios of 0.4 (95% CI=0.2-0.8) for Black and 1.3 (95% CI=0.8-2.2) for Hispanic women, with White women as the referent group [924]. Hendrix et al reported adjusted odds ratios of 0.6 (95% CI=0.5-0.8) for Black and 1.2 (95% CI=1.0-1.5) for Hispanic women compared to White women for POP based on genital examination [918].

Table 20. Prevalence of pelvic organ prolapse (POP) defined by symptoms or observed on pelvic examination in the general population .

First author	Country	Definition of POP	Ages (years)	N	Prevalence Subgroup: %
Kumari [771]	India	a mass of flesh in the vagina or equivalent using local terminology	15+	2990	15-24: 5 25-34: 10 35-44: 8 45-54: 6 55-64: 9 65+: 3

**** Denominator is women with a uterus***

***** Stages defined as 0: no prolapse, 1: prolapse to 1 cm above hymen, 2: prolapse to between 1 cm above and 1 cm below hymen, 3: prolapse between 1 cm below hymen and 2 cm above introitus, 4: prolapse beyond 2 cm above introitus.***

Note: Studies reported by Handa, Nygaard and Bradley are all subsets from study reported by Hendrix.

3. INCIDENCE

Only two studies could be located that reported the incidence of new POP. Both studies were done on sub-groups of women enrolled in the WHI Oestrogen Plus Progestin Trial. The first study of 412 women enrolled at the University of California, Davis site, used a standardised pelvic examination repeated every 2 years over 8 years [917]. The incidence of new cystocele, rectocele and uterine prolapse was 9%, 6% and 2%, respectively. Annual rates of remission from grade 1 (prolapse to above introitus) was relatively common for each type of POP (24%, 22% and 48%, respectively) but less common from grade 2 or 3 (prolapse to or beyond introitus) (9%, 3% and 0%, respectively). In a second study of 259 women post-menopausal women with a uterus were examined using the POP-Q at baseline and annually for 3 years. POP was defined as prolapse to or beyond the hymeneal ring. The incidence of new POP was 26% at 1 year and 40% at 3 years, with remission rates of 21% at 1 year and 19% at 3 years [920].

Several studies have reported the annual incidence of surgery for POP in the US and at least one in the UK. A longitudinal study of over 17,000 women in the U K, age 25 to 39 at baseline, reported an annual rate of POP surgery of 0.16% [919]. This rate is consistent with the rate of approximately 0.2% per year reported in the US [919-920]. One US study reported an annual incidence rising with age from 0.05% in women age 30-39 to 0.5% in women age 70-79 with an estimated lifetime cumulative risk of surgery from prolapse of 7% to 11%. A recent US study reported similar surgical rates: 0.07% for women 18-39, 0.24% for women age 40-59, and 0.31% for women age 60-79 [922]. Surgical rates drop substantially after age 80 [921-922]. Estimating rates of prolapse surgery has the advantage of use of hospital discharge data on procedures, which is highly accurate for the procedure performed, but less accurate for the indications for the procedures, particularly when a procedure may have more then one indication.

4. RISK FACTORS

4.1. Bowel dysfunction and pelvic organ prolapse

Bowel dysfunction is highly prevalent among women in general and it has been estimated that up to 27% of the female population in industrialised countries is affected by constipation [926]. It is a commonly held notion that women who seek urogynecologic care report a high prevalence of bowel symptoms [927]. The overall prevalence of constipation and associated symptoms in women with POP ranges between 20-53% [928-930[. Although the definitions of dysfunction differ between studies it is widely acknowledged that bowel dysfunction is a complex condition with a multifactorial etiology. Bowel dysfunction comprises a wide variety of symptoms including constipation, rectal emptying difficulties, incomplete defecation, manually assisted defecation, fecal urgency and IBS. Neurophysiologic assessments have shown that damage to pelvic floor musculature innervation can occur as a result of chronic constipation [931]. Other predisposing factors comprise low socio-economic status, pelvic floor surgery, depressive disorders, thyroid dysfunction, physical disability and inactivity, and food habits [932].

Current epidemiological evidence on the association between bowel dysfunction and pelvic organ prolapse are at odds. A number of studies suggest that women with POP are significantly more likely to experience constipation and other symptoms of bowel dysfunction [930,933-936] whereas others show a weak or non-existent association [129, 937-939. A recent review of the literature based on 50 studies evaluating the association between POP and bowel dysfunction found that approximately 40% of women with POP have complaints of bowel symptoms but a similar frequency was reported by women without POP [940]. In a case-control study, manually assisted defecation was present in 19.7% of women with prolapse compared to 4.4% of control subjects (p<0.001) [930]. In a randomly selected population based study, IBS and constipation were both strongly associated with POP (OR 2.8 95% CI 1.7-4.6, and OR 2.5 95% CI 1.7-3.7 respectively) [935]. Varma et al. [931] suggested that among randomly selected women, having symptomatic POP more than doubled the risk for obstructed defecation (OR 2.3 95% CI 1.5-3.7). A retrospective questionnaire based survey of women with and without prolapse concluded that constipation as a young adult was an important factor in the development of POP [933]. In a case-control study, women with prolapse were at increased risk for constipation also after adjustment for dietary fiber intake (OR 2.9, 95% CI 1.1-13.5). when compared to women without POP[934]. Also in a low income setting constipation has been identified as a risk factor for symptomatic POP [941].

In the cross-sectional Women´s Health Initiative (WHI), cysto- and rectocele was only weakly associated with constipation (OR 1.1 95% CI 1.0-1.2).(10) Similar weak associations between prolapse and bowel dysfunction have been observed in other large cross-sectional studies [929,938-939]. In a clinical and ultrasonographic study of 279 patients, symptoms of obstructed defecation were significantly correlated with having a rectocele. Having a rectocele was positively correlated with straining at stool, digitation, incomplete emptying and requirement of laxatives or enema [942].

Overall severity and prevalence of bowel dysfunction has shown poor correlation with findings of POP at radiological imaging [943-945]. Also at clinical examination, increasing vaginal descensus and prolapse severity, show a generally weak (or absent) association with symptoms related to bowel dysfunction [928,946-949]. In a substudy to the WHI, no specific bowel symptom was associated with increasing loss of pelvic organ support in any vaginal compartment [930]. When considering compartment-specific pelvic floor defects, most studies suggest that increasing posterior vaginal wall prolapse and perineal descent are correlated to more symptoms of obstructive defecation [931, 945, 947]. In a cross-sectional study of 260 women with pelvic organ prolapse, women with posterior vaginal wall prolapse were more likely to incomplete emptying (41% vs 21%, P=0.003), straining at defecation (39% vs 19%, P=0.002), and splinting with defecation (36% vs 14%, P<0.001) compared with women without posterior vaginal wall prolapse. But there was no significant association bowel symptom and increasing severity of prolapse [950].

The association between bowel dysfunction other than specifically obstructive symptoms and POP is scarcely investigated. In a random population-based study of 2109 racially diverse women women with IBS (prevalence =9.7%) had higher odds of reporting symptomatic POP (OR 2.4; 95% CI, 1.4-4.1) compared to those without IBS [951]. It has also between suggested that anal sphincter dysfunction such as paradoxical anal sphincter reaction is more common in patients with rectocele as compared to women without rectocele at defecography [952].

4.2. Pelvic surgery and POP

Even though the notion that hysterectomy increases the risk for POP has wide acceptance, longitudinal studies confirming a temporal association are few and previous studies often do not differentiate between various types of hysterectomy. A number of cross-sectional and retrospective studies implicate hysterectomy as an independent risk factor for POP. However, due to a delay of

onset, large population samples and a sufficiently long duration of follow-up are required to determine an association with adequate certainty.

In a nationwide cohort study, Altman et al. [953] reported that 3.2% of women with hysterectomy had POP, compared with 2.0% in non-hysterectomized controls, corresponding to a risk of 1.7 (95% CI, 1.6-1.7). In this Swedish study, vaginal hysterectomy had the highest risk for subsequent POP surgery (HR 3.8, 95% CI, 3.1 to 4.8) in comparison to non-hysterectomised controls. These results were corroborated by Cooper et al. in a large study from Scotland showing an increased risk for POP surgery among women after hysterectomy, compared to endometrial ablation [954]. These register-based data are largely in agreement with the longitudinal Oxford Family Planning Association study by Mant et al. [955] reporting increased overall incidence rates for prolapse surgery following hysterectomy. Although not separating various hysterectomy techniques, Mant el al. determined that the risk of POP following hysterectomy was 5.5 times higher (95% CI 3.1-9.7) in women whose hysterectomy was performed for POP as opposed to other benign conditions. In a large register-based assesment from Denmark (n=154,882) it was determined that the highest cumulative incidence of subsequent POP surgery 32 years after hysterectomy was found among women where POP was the indication for hysterectomy and also that the posterior compartment was the predominant location for prolapse occurrence post-hysterectomy [956]. In a follow up study it was determined that there were only minor differences in risk of POP repair between different hysterectomy techniques [957]. A history of hysterectomy has also been identified to increase the risk for prolapse in several cross-sectional and retrospective studies [958-959].

Specific risk factors for posthysterectomy POP have been assessed in two case-control studies. Both Dällenbach et al. [960] and Forsgren et al. [961] reported that pelvic floor surgery before hysterectomy was the strongest risk factor for developing posthysterectomy POP (OR 7.9, 95% CI 1.3-48.2 and OR 2.8, 95% CI 1.0-7.7 respectively). The risk of prolapse repair was 4.7 times higher in women whose initial hysterectomy was indicated by POP [960]. Vaginal vault prolapse involves the loss of vaginal apical support and may per definition only occur after hysterectomy [962]. Marchionni et al. reported a 4.4% overall incidence of vaginal vault prolapse after hysterectomy but in women where uterine prolapse was the indication for hysterectomy the incidence was 11.6% [963]. In a register-based study Forsgren et al. showed that the greatest risks for prolapse surgery (HR 4.9, 95% CI 3.4-6.9) were observed subsequent to vaginal hysterectomy for pelvic organ prolapse but having a vaginal hysterectomy also for other indications significantly increased the risk for subsequent POP surgery compared to other modes of hysterectomy [964]. Similar observational results were shown by Cooper et al. [954]. A Danish register-based, matched cohort study focusing on nullipara entailed 809,435 person-years in risk and a 42 year observational period. 9535 nulliparous women who underwent a hysterectomy were matched individually with 47,370 nulliparous women without hysterectomy. The risk of POP surgery increased by 60% in women who underwent a hysterectomy compared with women in the reference group [965].

It has also been suggested that pelvic surgery other than hysterectomy may predispose women to subsequent genital prolapse including: rectopexy for rectal prolapse (OR 3.1; 95% CI 1.4-6.9) [966]; gynaecologic surgery in general (OR = 3.9, 95% CI 1.8-8.8) [967]; and retropubic colposuspension procedures are associated with a near 30% risk of subsequent vaginal vault and posterior vaginal prolapse at long-term evaluations [968-969]. In a prospective cohort study of 374 women, the 10-year re-operation rate was 17% after traditional POP or incontinence surgery [970]. Having undergone POP or UI surgery prior to the index operation increased the risk of re-operation to 17% compared with 12% for women who underwent a first procedure (p=.04)[970].

4.3. Obstetrical factors and POP

Observational studies will remain the main source of knowledge on the association between childbirth and POP later in life. For obvious ethical and practical reasons, randomised controlled trials to study the causal effects of vaginal and caesarean delivery on the pelvic floor will never be performed. Nonetheless it is widely accepted that childbirth is a important risk factor for POP, presumably due to overt or occult pelvic floor tissue trauma. Controversy does, however, remain with regard to the protective effect of cesarean section and if specific obstetrical events should be considered as risk modifiers. Due to a delayed onset of POP in relation to giving birth, studies on the subject need a long duration of follow-up as well as large study populations to be able to elucidate on the possible causative events. Therefore, the majority of studies on the subject are typically designed a cross-sectional surveys or retrospective cohort or case-control studies. It is, however, encouraging that long term longitudinal data are starting to emerge and in recent years several studies with follow-up periods extending beyond 10 years have been published.

Pregnancy in itself has been established as a risk factor for SUI. With regard to POP, the association is however, less well substantiated. In a clinical case-control study, all 21 nulliparous non-pregnant women had POP-Q stage 0 or 1, whereas 47.6% of 21 nulliparous pregnant women had pelvic organ descent corresponding to stage II (p<0.001) [971]. Overall POP-Q stage was higher in the third trimester than in the first (p=0.001). Also Sze et al. [972] found that in 94 nulliparous women evaluated at the 36 antepartum visit and six weeks postpartum, POP-Q staging increased.

A large number of studies identify childbirth as one of the strongest predictors for developing POP later in life [935,937,955-956,973-978. It is also a recurrent observation that number of childbirths is associated with the risk for POP although there are data to suggest the contrary [979]. In the prospective Oxford Family Planning Association study [955] childbirth was the single strongest risk factor for developing POP in women under 59 years of age and the risk increased by every childbirth. Similar findings derived from the WHI [937] where a parity of one conveyed an overall two-fold risk increase for POP compared to having no children, after which each additional childbirth added a 10-20% risk increase. In a case-control study, Tegerstedt et al. [977] found that the risk for symptomatic POP increased with number of childbirths and were 3.3-times higher among mothers of four than among mothers of one. Similarly, Rortveit et al. [935] found that the risk for prolapse increased in women with one (OR 2.8 95% CI 1.1-7.2), two (OR 4.1, 95% CI 1.8-9.5), and three or more (OR 5.3, 95% CI 2.3-12.3) vaginal deliveries compared with nulliparous women. In a questionnaire based cross-sectional study among 2,640 middle-aged women the number of vaginal deliveries was a risk factor for past or present symptomatic POP [978]. In a nationwide matched cohort survey of 14,335 women unexposed to childbirth, having had one cesarean section and one vaginal delivery the investigators found that the prevalence of symptomatic prolapse was relatively similar and below 5% across ages 40-64 years. In contrast, in women after vaginal delivery, there was an accelerating increase in the prevalence of symptomatic POP up to 65 years of age. The observed delay of onset period associated with 1 vaginal delivery seemed to be at least 20 years among women giving birth in their early 20s. At

age 64 years, the estimated probability of symptomatic POP was 12 times higher after vaginal delivery compared with caesarean delivery (13.4% [95% CI 9.4-18.9] vs 1.1% [95% CI 0.4-2.5]). The calculated reduction of symptomatic POP by cesarean delivery at 64 years of age was thus 92% [980].

Whether or not cesarean section prevents loss of pelvic organ support has been debated but today the vast majority of studies show that elective cesarean section does indeed decrease the risk for POP later in life [973-978, 981-985. In 4,458 randomly selected women, vaginal childbirth increased the risk for POP by 1.82 (95% CI 1.04-3.19).(66) In a nested case-control study, Uma et al. [986] found that cesarean section was associated with a significantly reduced risk of pelvic floor surgery compared with spontaneous vaginal delivery (OR 0.16, 95% CI 0.05-0.55). In a case-control study, Chiaffarino et al.(40) found that women who were delivered by cesarean section were at significantly lower risk for POP (OR 0.3 95% CI 0.1-1.0). In a register-based cohort study of women having their first and all subsequent deliveries by cesarean (n = 33,167), and an age-matched sample of women only having vaginal deliveries (n = 63,229) between 1973 and 1983, Leijonhufvud et al. found that women only having vaginal deliveries had a significantly increased overall risk of subsequent POP(hazard ratio, 9.2; 95% CI 7.0-12.1) compared with women only having cesarean deliveries [982]. (Figure 10). Among women with vaginal deliveries only the incidence rate for POP surgery increased steadily, reaching its peak close to three decades after first delivery. This corresponds with data from other long-term studies with more than a decade of follow-up (see below). In women with cesarean deliveries only the incidence rate for POP surgery showed very little variation over time and being notably lower compared to the vaginal delivery cohort 10 years after first birth for the duration of the observational period. There are some reports suggesting that in the long term, caesarean delivery do not provide a significant risk reduction pelvic floor morbidity compared with vaginal delivery [987-988]. These studies belong to an overwhelming minority and most long-term longitudinal studies published in recent years, with follow-up times ranging between 10 and 23 years, commonly show that cesarean section provides a significant reduction in risk for pelvic organ prolapse. Volløyhaug et al. [983] showed that caesarean delivery was associated with decreased risk of POP 15-23 years after first delivery (OR 0.42, 95% CI 0.21-0.86). Compared with women whose births were all spontaneous vaginal deliveries, women who had all births by caesarean section were the least likely to have prolapse (OR 0.11, 95% CI 0.03-0.38) 12 years after first birth according to Glazener et al. [985]. Gyhagen et al. [984] reported that 20 years after birth singleton primiparae with no further births (n = 5236) had a significantly higher prevalence of POP after vaginal delivery compared with caesarean section (14.6 versus 6.3%, OR 2.55, 95% CI 1.98-3.28) but was not increased after acute compared with elective caesarean section.

A number of specific obstetrical events and interventions have been implicated as risk factors for the development of POP. In one study, maternal age and use of epidural analgesia was associated with an increased need for POP surgery.(65) Handa et al. [989] found that operative vaginal birth significantly increased the risk for all pelvic floor disorders and POP in particular (OR 7.5, 95% CI 2.7-20.9). In a long term longitudinal study Volløyhaug et al. [983]found that operative vaginal delivery was associated with increased risk of POP (OR 1.73, 95% CI 1.21-2.48) when compared with non-instrumental vaginal delivery. There were no differences in the risk for POP when comparing forceps and vacuum delivery.

In a case-control study, Chiaffarino et al. [981] found that after forceps delivery women had an OR of 3.6 (95% CI 1.0-13.5) for developing pelvic organ prolapse, but after adjustment for vaginal delivery the odds were no longer significant (OR 1.3 95% CI 0.6-3.1). Also Moalli et al. [967] concluded that forceps delivery posed a risk for POP and a case-control study found no significant association with maternal age, instrumental delivery (forceps or vacuum), or length of delivery when comparing women with POP to randomly selected controls.(68) On the other hand, Uma et al. [976] found no significant association between POP and forceps delivery (OR 0.9, 95% CI 0.7-1.2); infant birthweight >4.0 kg (OR 0.9, 95% CI 0.5-1.7); episiotomy (OR 1.46, 95% CI 1.0-2.10); and labour prolonged >12 hours (OR 1.51, 95% CI 1.00, 2.27). Similarly both Gyhagen [984] and Glazener [985] found no significant association of increased risk between instrumental delivery and POP compared with spontaneous vaginal delivery.The inconsistency and wide variety in the magnitude of the risk estimates suggest that most studies so far lack sufficient statistical power for valid conclusions.

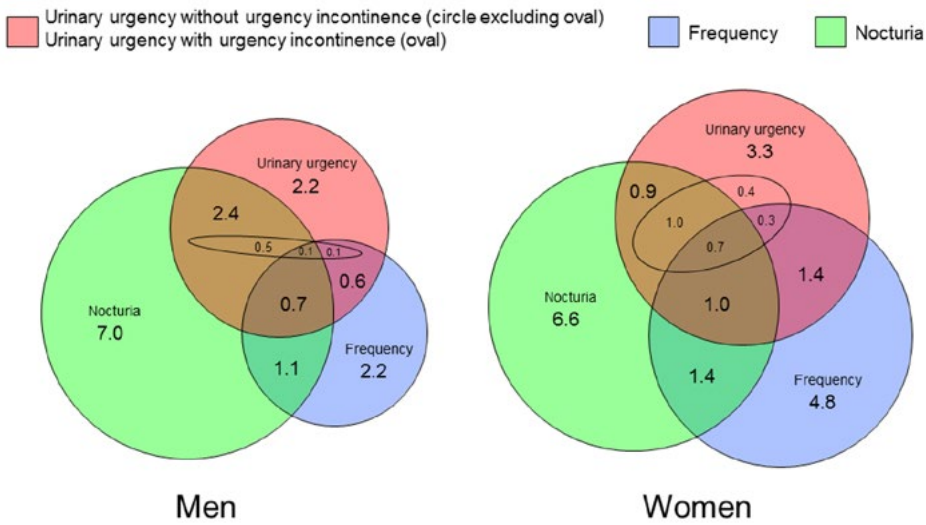

Figure 10. Rate of pelvic organ prolapse surgey in relation to mode of delivery and time from first childbirth [821].

4.4. Miscellaneous risk factors and POP

A wide variety of risk factors for POP, others than those addressed above, have been identified in the literature. Most of these have been investigated as part of larger multivariate analyses based on cross-sectional surveys or retrospective case-control studies. Overall, these associations are largely of level III-IV evidence and further research is needed to disentangle the effects and interactions of environmental risk factors for prolapse.

Several somatic risk factors for POP have been identified. Generalised connective tissue disorders such as Ehlers-Danhlos disease and Marfans syndrome [990-991] have been linked to an increased risk for POP. In a community-based study of prolapse in rural West Africa, chronic anemia was the strongest risk factor for prolapse after parity and age (OR 2.1 95% CI 1.1-3.4).(48); and chronic obstructive pulmonary disorders. Skeletal abnormalities such as thoracic kyphosis, lumbar lordosis and pelvic dimension changes have been associated with an increased risk for POP [992-993]. Women with joint hypermobility have a significantly higher prevalence of genital (and rectal) prolapse in comparison to women with normal mobility [996-997]. Weak associations have also been shown for osteoporosis and rheumatoid arthritis.(69) Obesity may be associated with increased pelvic floor symptoms and more severe symptomatic POP [978,998-999] yet increasing body mass index and obesity has not consistently been identified as risk factors for POP as compared to stress urinary incontinence [1000-1001]. Other factors that has not convincingly demonstrated any significant linkage to prolapse includes the presence of chronic obstructive pulmonary disease and diabetes mellitus [941,958,1001]. Pulmonary impairment has been shown to be more common in women with loss of pelvic organ support compared to those without [1002] whereas others suggest no association with asthma and smoking [1003]. In a study by Rogowski et al. [1004] the diagnosis of metabolic syndrome was associated with the severity of pelvic organ prolapse in urogynecological patients (OR 3.5, 95% CI 1.5-8.2) as compared to those without.

A low educational level (OR 2.16, 95% CI 1.10-4.24)[1005] and low annual income [1006] are socio-economic factors which have been associated with an increased risk for POP. Among 21,449 non-hysterectomized Italian women, higher education was a protective factor for uterine prolapse [988]. However, despite significant differences in educational level, smoking habits, alcohol consumption, and socio-economic indices, the prevalence of POPdid not differ between Croatian urban and rural women [1007]. Interestingly, risk factors for pelvic floor disorders including POP among women in developing countries were similar to those in industrialized countries (increased age and parity). In a review study across 16 low-income and lower middle-income countries the mean prevalence for POP was 19.7% (range 3.4-56.4%) but risk factors were similar to those described in studies from more affluent countries but additionally POP and other pelvic floor disorders were associated with other factors including poor nutrition and heavy physical work [1008-1009].

A physically strenuous occupation has also been shown to influence the risk for POP. In a register based study of 28,000 Danish assistant nurses exposed to repetitive heavy lifting, the risk for prolapse was higher among the nurses compared to controls (OR 1.6 95% CI 1.2-2.2) [1010]. Women who were laborers/factory workers had significantly more severe prolapse than other job categories ($p < 0.001$) in a cross-sectional study of women presenting for routine gynecological care [1006]. This notion is supported by a retrospective study of 662 women referred to a urogynecology unit for pelvic floor symptoms. Heavy lifting was associated with sonographic POP (OR 1.71, 95 % CI 1.2-2.4), confirmed on multivariable analysis and positively associated with symptoms and clinical signs of POP) on univariate analysis. It was concluded that heavy lifting may be a potential risk factor, in particular for posterior compartment POP [1003]. Also, hard physical training may increase the risk for POP as women attending paratrooper training, were more likely to present stage II prolapse compared to controls (RR=2.7 95% CI 1.4-5.4) [1011].

5. SUMMARY POINTS

- Most studies have used a cross-sectional design and there is limited longitudinal data to suggest a causal relationship between symptoms of obstructed defecation and POPor vice versa.
- Posterior vaginal wall prolapse and perineal descent are the specific pelvic defects most frequently associated with symptoms of obstructive defecation.
- Large epidemiological studies suggest that hysterectomy increases the long-term risk for subsequent pelvic organ prolapse
- Vaginal hysterectomy and hysterectomy performed for uterine prolapse are the strongest risk factors for having secondary pelvic floor surgery
- Childbirth is associated with an increased risk for POP later in life and increasing number of childbirths is positively associated with the risk.
- Long-term prospective studies data consistently show that caesarean section decreases the risk for POP and that caesarean section is associated with a decreased risk for subsequent pelvic floor morbidity in comparison to giving vaginal birth.
- Current understanding of how specific obstetrical interventions influence the risk for pelvic organ prolapse is poor but instrumental delivery may increase the risk for development of pelvic organ prolapse.
- Life style factors and socio-economic indices may be associated with the risk of POP in both industrialised and non-industrialised countries.
- A number of somatic diseases and conditions have been linked to the occurrence of POP but the cause-effect relationship is undetermined.

VIII. EPIDEMIOLOGY OF FAECAL INCONTINENCE

1. GENERAL COMMENTS AND DEFINITIONS

FI is the involuntary loss of feces – solid or liquid. AI includes these events as well as the involuntary loss of flatus, which is felt by many patients to be an equally disabling disorder. These terms will be used to a degree interchangeably throughout the chapter. A third cause of soiling or embarrassment is anal mucoid seepage, a troubling condition that cannot be deferred even by an able sphincter and intact cognition. It is most often caused by an organic colonic disease or dietary sensitivity, and more rarely by fecal impaction. This is the loss of fluid, sometimes feculent, often following a normal continent defecation. Seepage is an important condition to distinguish from other manifestations of incontinence because most authors that report very high prevalence rates of AI include leakage in their questionnaires. However in these individuals there is often no detectable sphincter abnormality [1012]. It is not treatable by any of the standard therapies for incontinence of feces: such as sphincter repair, neuromuscular re-education or even fecal diversion. It is in fact why we wear underclothes.

1.1. Ascertainment of Anal Incontinence

Older reports of AI prevalence have come from single institutions, and the patients described therein have been subject to referral bias when demographics and etiology are discussed and widely varying definitions of AI. The accuracy of AI prevalence estimates may also be diminished by difficulty in ascertaining those figures due to patients' reluctance to report symptoms or to seek treatment [1013]. It has been shown that women are more willing to report AI than men [1014]. In addition, the character (incontinence of solid feces, diarrhea, or flatus, or merely anal seepage) and frequency (daily versus episodic) and duration of reported AI varies greatly in each report. So, prevalence depends heavily on the definition of AI.

To determine accurately who has AI and who does not has resulted in the development of many scoring tools and publications that compare these tools. [1015-1020]. In an insightful tool, the authors studied adults, not excluding those in custodial care [1017]. Acknowledging the difficulty in prevalence estimation, they used three different questionnaires. The first simply asked if the participant had incontinence and if they were troubled by it, the second was a well known quantitative instrument and the third a quality of life instrument specific to fecal incontinence. In the cohort examined there were those who were totally continent, those that exceeded thresholds in all three instruments and were undeniably incontinent and those who had positive responses on only one or two of the questionnaires. The authors surmised that two out of three positive responses constituted clinical AI, though the threshold for the quality of life instrument was very high (i.e. perhaps too sensitive). The prevalence of AI varied from 12.6% to 26.8% for each individual instrument, 4.6% were positive for all three and 13.2% were positive for two of three, which was the authors' definition of AI. The remainder of the studies in this group are systematic reviews of published tools, the most thorough being Gray et al. [1018].

Two more tools are widely used or referred to: Rome IV criteria and NHANES 2010 Bowel Health Survey BHQ_F [1021-1022]. NHANES was the only publication to present data on seepage.

1.2. Data Sources and Level of Evidence

Since ICI 6, new studies were sought using a search strategy for Medline and EMBASE and the Cochrane data base of clinical trials from 1966 to April, 2021.

Because therapeutic interventions are not the subject of this chapter, the epidemiology is descriptive and in almost all cases not derived from clinical trials (aside from the pre-partum intervention described below, Cesarean delivery and surgery for anal fissure, all discussed below), the level of evidence will be at best 2 for the rest.

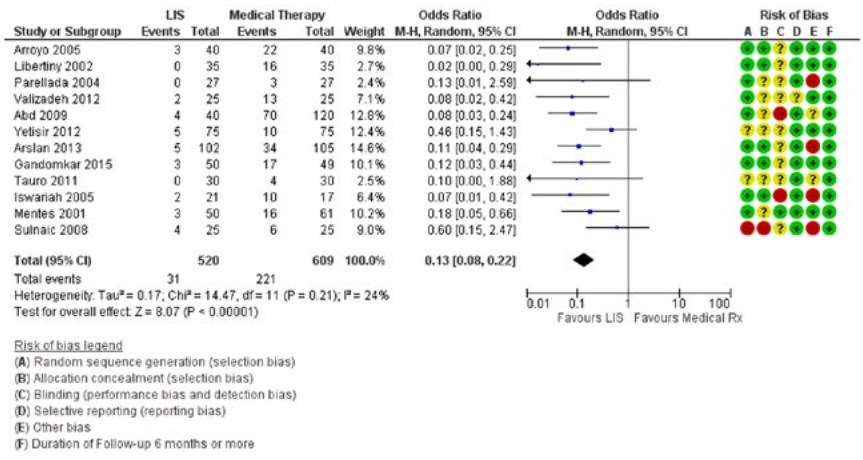

Figure 11. Forest Plot Comparing the Sustained Cure (> 6 Months Post Therapy) of Lateral Internal Sphincterotomy (LIS) With Any Medical Therapy. Medical therapy has about a 50% cure rate compared with > 90% for LIS.

2. PREVALENCE

Is FI a disease or a dysfunction? Is it reported with any accuracy, like cancer? No. Is there a broadly accepted means for assessing its prevalence? No. So reports are very idiosyncratic and very difficult to merge with other reports.

2.1. Adults

In an effort to resolve the widely varying reported prevalence figures five systematic reviews of the published frequencies have been done of community dwelling adults (Table 21) [1023-1027]. All five established a protocol for searching in advance that stressed a number of quality criteria among which the following were included: A defined search strategy. Each study presented a PRISMA statement. Quality of the included studies was assessed using variously the following variables:

1. Response rate > than 50%
2. A validated continence assessment tool.
3. A representative community based population, with selection procedures that minimize selection bias.
4. Appropriate outcome reporting.
5. Optimal data acquisition from participants

Not every included study in these five systematic reviews found a large number of reports that adhered to these criteria, but the risk of bias in each study was assessed in some of these reviews and the highest quality studies described separately. None of the five were able to find a study that did prospective cohort assembly and data collection. A summary frequency was not calculated in the second review (Table 21) [1024] because of the marked clinical heterogeneity between reports. The three reports that the authors judged most free of potential biases in this review [1024] had frequencies between 11% and 15%, though only one of these three used a validated FI assessment instrument. The degree of disability present in these 11%-15% is not known, nor even if a portion of them that had only anal seepage. These high prevalences were obtained in surveys that employed anonymous self-administered questionnaires, which may not allow objective confirmation of AI or assessment of degree of disability associated with AI.

Quality assessment was presented in Table 21 in various ways in systematic reviews 2 through 5 The authors in each systematic review were interested in estimating a prevalence that is without the massive range descriptions from individual studies in Table 21. In that regard each one was successful, with prevalences ranging from 3.5 to 7.7. Because these are systematic reviews, to varying degrees these 5 authors were assessing the same studies but had some different results.

There are two more studies that need to be mentioned regarding adult prevalence: the first is a series of publications by the Rome Society which has developed a series of assessment tools for FI among other GI disorders. The most recent is Rome IV. The criteria have changed with each iteration of this tool. A study is published of FI in 3 English speaking countries and the data pooled [1021]. 5931 participants were questioned about various aspects of FI and 957 were found to have FI, 16.1%. Using Rome III criteria, only 412 (6.9%) were categorized as having FI and with Rome IV, 196 (3.3%). Both these changes from the original 957 of Rome III and

Table 21. Systematic Reviews of Prevalence of FI

Author Search Years	Number of Studies	Children	Principal Outcomes	Prevalence	Range	?Quality?

Table 22. NHANES 2010 Report of FI Prevalence and Risk Factors

Population	Prevalence	Age	Significant Associations Odds Ratio & 95% Confidence Interval	Non Significant risk Factors of Fecal Incontinence
14,759	8.39 %	2.91 % in 20 year olds	Age > 70 2.05 (1.19-3.73)	BMI Ethnicity
NHANES 2005-2010	95% CI; 7.76 to 9.05	16.16 % in over 70s	Poor General Health 1.32 (1.02-1.71)	Marital Status Poverty
			Gender: women 1.49 (1.12-1.96) but only if the woman has UI too. Otherwise non significant	Education Physical Activity Vaginal Deliveries Pregnancies
			Urinary Incontinence 1.63 (1.27-2.14)	
			Diabetes 1.63 (1.22-2.71)	
			Stool Character 2.52 (1.79-3.56) and Frequency >21 per week 2.46 (1.41-4.29)	
			>2 Chronic Illnesses 1.74 (1.25—2.42)	

Rome IV were due principally to a change in the frequency of FI episodes. The entire 957 wrote that they had a significant reduction in their quality of life because of their FI.

Last but not least is NHANES. The National Health and Nutrition Examination Survey of the National Center for Health Statistics and the Center for Disease Control. Selection of the participants is more thorough, and results in a group more representative of the United States population than any of the heretofore mentioned and the studies. The examination of each participant is also more thorough than those studies [1028]. Examination for specific organ or disease is periodic, the most recent for FI being in the Bowel Health Survey in 2010 [1022]. Data from that survey on specific subjects and questions have been published since then, including FI [1029]. 14,759 people participated, 49% women, all over 20 years old and 8.39% had FI (95% CI; 7.76-9.05). Specific risk factors were also investigated (Table 22) and will be discussed below.

2.2. Children

The reported prevalence of AI in children can be broadly divided into two facets: those children born with congenital anomalies of the anus and rectum – either congenital aganglionosis (Hirschprung's Disease) or imperforate anus – and those children with functional disorders and without congenital anomalies. These congenital disorders are not horribly rare, occurring in 3 to 5 per 10,000 live births [1030]. The functional disorders are more common but often not referred to as incontinence, but retentive or non-retentive soiling Males are more common than females in both, 3.5 to 1, [1031]. The reported range of retentive varies from 0.5 to 19.2 % and for non-retentive, 0-1.8% [1032]

Among children without congenital defects of the anal canal, bowel control has been found to be complete in one Swiss cohort in 33% by age 1 year, 75% by age two and 97% by age three. Nevertheless in this longitudinal study, a quarter of the boys and one tenth of the girls had a major period of incomplete bowel or bladder control between the ages of 6 and 18. At least annual encopresis occurred in 2-3% of these children, boys more frequently than girls [1033].

Among those children and adults who were born with congenital anomalies, despite surgical correction of the defect, lifelong defecation difficulties are common, occurring in roughly half of affected children [1034-1035]. Problems with psychological health and development because of the defecation disorder are also common in this group, as is a generally depressed quality of life [1036-1037].

3. INCIDENCE

Characterizing new incidence of FI or AI at the time of onset and noting what preceded it gives a different perspective on causation. This has been reported in five different publications. The first included patients with new onset FI [1038-1042] and assessing risk factors at that time.

The second monitored 435 patients admitted to an acute care hospital, mean age 72 [1039]. 11% had FI. 21.1% developed AI, principally in those patients over 85. The largest number were on the orthopedic ward, were the most frail and had the longest length of stay [1042].

The third recruited a population of 1000 participants in several communities, rural and city, with equal numbers of male and females and white and African/American races , all in equal numbers [1040]. They were all examined and interviewed on day one, phoned 6 monthly thereafter and reexamined four years later, all over 65 years old. Some died, some were lost to follow up, 79 had FI at recruitment. 557 had no FI at recruitment and it is this group that was monitored for development of FI. 93 developed FI, 17% (95% CI 13.7-20.1). Table 23 shows the regression analysis of four key variables.

Table 23 Multivariable Logistic Regression Analysis Comparing Risk Factors for Incident Fecal Incontinence (FI) in Women and Men

Variable	Odds Ratio (95% Confidence Interval) for Any FI	
	Women, n =293	Men, n =259
African American	0.5 (0.2- 1.0) *	0.9 (0.5- 1.8)
Depression symptoms	3.2 (1.1 - 9.1) *	1.2 (0.2- 6.1)
Urinary incontinence	2.0 (1.0-3.9) *	2.3 (1.1-4.7) *
Chronic diarrhea	3.5 (1.0-12.5) *	0.9 (0. 1- 1.1)

Multivariable logistic regression models controlled for age, comorbidity count, and body mass index.
**** P<.05.***

Two more studies were in patients living in geriatric care facilities. Chassange followed 234 previously non-FI residents in France for 10 months, during which 20% had FI episodes, but only 7.5% developed long lasting FI [1041]. The others had acute episodes due to diarrhea or impaction. The factors associated with the development of long lasting FI were UI (2.9, 1.8-4.6), decreased mobility (1.8, 1.1-3.0), and cognitive defects: either as seen in an MMSE score <15 (2.5,1.4-4.4) of history of dementia (2.1, 1.2-3.5). Neither gender nor age were risk factors. Nelson reported, in a cohort of 18,000 nursing home residents in Wisconsin, a subgroup of 3,850 continent of both urine and feces in 1992 and were assessed one year later [1042]. 15% developed FI. Positive associations were seen for ADL loss (3.4, 2.4-4.5), trunk restraints (2.5, 1.7-3.6), dementia (1.7, 1.4-2.0), African American race (2.1,1.3-3.4) and age (1.02, 1.0-1.0). UI was not investigated as a risk factor because it was felt to be a co-morbidity.

4. RISK FACTORS

4.1. Age

Systematic reviews and NHANES have analyses of the association of age and anal incontinence and found advancing age to be the most consistent of all assessed associations [1043].

4.2. Gender

Most discussions of the etiology of AI have been based upon the assumption that women, particularly for individuals under the age of 65 years, are far more at risk for FI than men. Injury to the pudendal nerve or sphincter muscle from prior obstetric trauma is described as the primary risk factor [1044], followed by irritable bowel syndrome (a disease thought to be more prevalent in women) [1045], and other etiologies such as diabetes a distant third [1046]. Yet a population based-survey by the National Center for Health statistics of the prevalence of FI has shown a surprisingly high prevalence in males (Fig 12), [1023,1025-1026,1029]. In the most interesting finding in this review, in the NHANES list of potential risk factors for FI, in the age controlled bivariate analysis, women with urinary incontinence (UI) were significantly at risk of FI but in the multivariate analysis the risk flips to a significant risk of FI for men when UI is included in the regression model [1029]. UI is a significant risk factor for FI in women in both the bivariate and multivariate analyses, with almost identical risk in each.

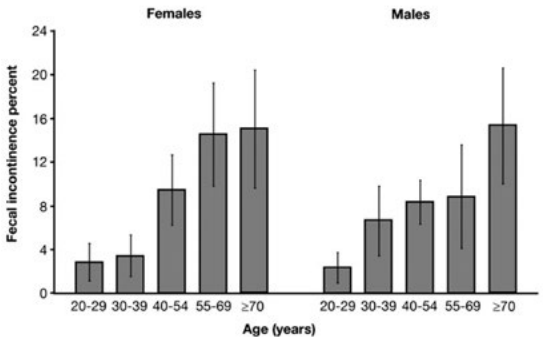

Figure 12. Prevalence of FI grouped according to age and sex

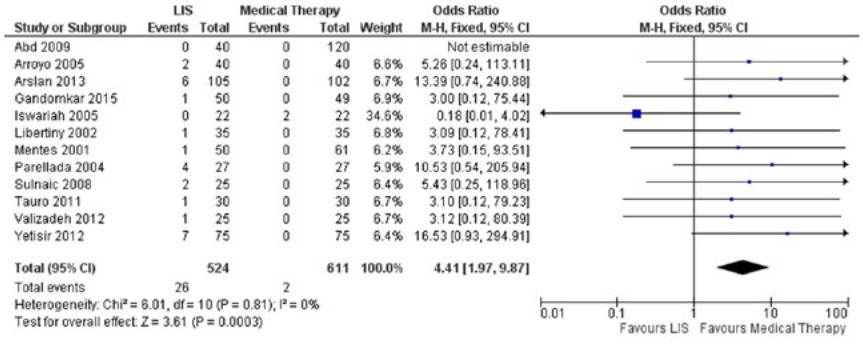

Figure 13. Forest Plot of Studies Comparing of The Risk of AI (usually to flatus alone) more than 6 Months Post Therapy of Lateral Internal Sphincterotomy versus Any Medical Therapy See Table 3

In the scoping search for this updated review, 26 publications assessed prevalence of AI, two included both genders and 24 included only women, vaginal childbirth being the risk factor of interest. Yet many women never have a vaginal delivery and of course half the population at risk are men (Figure 12). This represents a rather gross imbalance in research on this topic. Clearly, etiologies in pregnancy other than childbirth must be sought.

4.3. Obesity

Four reports have demonstrated an increased risk of AI in obese women, a Kaiser cohort, a cross sectional survey in a specialty clinic and two case control studies [1047]. One longitudinal study found a reduction in anal leakage (again not necessarily a direct correlate with incontinence) in women after bariatric surgery and weight loss, though other factors including diet and activity change may have been responsible for the improvement [1048]. A more recent SR of weight loss surgery and FI was a bit equivocal in deciding on the benefit of this surgery [1049]. However NHANES and a later Kaiser report found no significant association of FI with obesity [1029,1050].

4.4. Urinary incontinence

UI is generally regarded as a comorbidity with FI, sharing common etiologic factors [18].

4.5. Nursing home residence

The most prominent association with AI by far is nursing home residence, a post morbidity rather than comorbidity or risk factor. A very thorough discussion of this is [1051] which combines data from NHANES, The National Study of Residential Care Facilities (NSRCF), the National Home and Hospice Care Study (NHHCS) and the Minimum Data Set (MDS). Whereas the prevalence of AI is reported able to be 7-8% for community-dwelling persons, and may rise with increasing age to greater than 10%, among nursing home residents the prevalence approaches 50% [1043,1052]. This is explained by FI being one of the most common reasons for nursing home admission. In a large survey of 18,000 Wisconsin nursing home residents, risk factors for fecal incontinence (FI) were directly observed by nursing home personnel [1044]. Urinary incontinence (UI) was the greatest association with FI (OR= 12.6, 11.5-13.7), followed by the loss of ability to perform daily living activities (6.0, 4.7-7.7), tube feeding(7.6, 5.6-10.4), physical restraints (3.2, 4.7-7.7),diarrhea (3.3, 2.7-4.2), dementia (1.5, 1.4-1.7),impaired vision (1.5, 1.4-1.7), constipation (1.4, 1.3-1.6), fecal impaction (1.5, 1.1-2.1), stroke (1.3, 1.2-1.5) male gender (1.2, 1.1-1.3), age and body mass index. Inverse associations were noted with heart disease, arthritis and depression.

4.6. Diarrhea

The importance of diarrhea of liquid stool in FI cannot be overemphasized [1052-1053]. One case series noted that 51% of individuals with chronic diarrhea were incontinent [1013]. Non-infectious causes of diarrhea must also be considered, such as inflammatory bowel disease and those initiated by sports activities such as running [1051].

4.7. Constipation

Constipation may alternate with diarrhea in irritable bowel syndrome making defecation chaotic and often very urgent and result in retentive incontinence [1032,1045], seen most often in Children**.** Often retained feces lead to anal seepage that cannot be held. In the New Zealand survey, the 2 of 3 rule for categorizing an individual as incontinent when excluding constipated patients, which was also assessed in their survey [1017], the positive rate fell from 13.2% to just over 9%. This further demonstrates the frequent co-existence of constipation and AI .

4.8. Diabetes

There are two factors leading to FI in diabetics. The disease itself [1055-1057] and the medication used most commonly in its treatment [1058].

4.9. Neurological and other diseases

Several specific diseases have been associated with AI in case series, and mechanisms to explain the associations have been investigated [1059]. Examples are stroke, multiple sclerosis, Parkinson's disease, systemic sclerosis, myotonic dystrophy, amyloidosis, spinal cord injury, imperforate anus, procidentia, and any illness causing diarrhea (HIV, IBD, radiation, infection). Many of these conditions directly affect patient mobility and ability to perform daily living activities or they cause diarrhea or fecal impaction**.**

4.10. Surgery

AI originating from surgery would seem fairly insignificant in the general population, since prior anal surgery has not been an apparent risk factor in any of the larger surveys cited herein. Several operations nonetheless are thought frequently to result in AI. Examples are midline internal sphincterotomy for fissure in ano, lateral internal sphincterotomy, fistulectomy, fistulotomy, hemorrhoidectomy, and ileo-anal reservoir reconstruction, low anterior rectal resection, total abdominal colectomy, and ureterosigmoidostomy.

An example of how interventions can get a bad reputation before the definitive studies are done is the history of anal fissure [1060]. Prior to 1989, the accepted treatment for a painful chronic anal fissure was lateral internal sphincterotomy (LIS). However in 1989 everything changed. A large case series of follow-up after LIS was published in which 36% of the patients were incontinent to flatus and 5% to solid stool. In 1996 from the University of Minnesota, which had reported such low incontinence rate in 1985, in a retrospective comparison of open vs. closed LIS, it was found in a new study that 30.3% of their patients were incontinent to flatus and 11.8% to solid stool. The age of GTN (glyceryl trinitrate ointment), Botox (botulinum toxin injection) and CCBs (calcium channel blockers) as medical therapies for fissure was born. In many countries it appears that LIS had been abandoned in favor of medical therapy. Yet patient satisfaction with LIS has been reported to be high. The often crippling pain of fissure is almost immediately relieved [1059], and at surgical meetings many of us (colorectal surgeons who never encountered such a patient) wondered: "Where are all these incontinent patients?"A systematic review of all treatments for anal fissure, which included 148 randomized trials, was published in 2017 [1060]. The data in studies included in this review were reviewed by ethics committees, which are very sensitive to potential harms in clinical trials and their recording, and the trials themselves had, especially in trials with an LIS component focused on incontinence risk. The often used words permanent incontinence are particularly unfortunate, since virtually all AI is eminently treatable. Retrospective review numbers are certainly subject to selection bias, but even that doesn't seem to explain the disparity with what is described here (Figures 11) and those publications. More likely is that outcomes were measured way too early, which was found in

many studies in this systematic review, when a healing wound was perceived by patients, and or examiners as incontinence. In the patients having LIS after 2000, the risk of incontinence was 3.9% (Table 24), not radically different from what is seen after medical therapy with GTN, Botox or CCBs. The certainty for the evidence in this review in GRADE is High.

Table 24. Adverse Events After Treatment of Anal Fissure, Reported in a Systematic Review of 148 Randomized Trials. Note how close the FI rate for LIS after 2000 is to the rates of GTN, Botox and CCB (48).

Studies	Headache rate	Incontinence rate
GTN all studies	504/1801; 28%	7/634; 1.1 %
LIS all studies; both reviews	3/253; 1.2%	138/3093; 4.4%
LIS with 6-month follow-up		27/623; 4.3%
LIS in surgical studies published after 2000		31/803; 3.9%
Arginine	0/30	
"Healer Cream"	1/20; 5%	
Botox	7/138; 5.1 %	8/354; 2.3%
Oral CCB	9/24; 37.5%	
Topical CCB	27/169; 16%	4/287; 1.4%
Indoramin	7/14; 50%	
GTN patch	25/73; 34.2%	
Lidocaine	4/45; 8.9%	
Dilator; speculum 4.8 cm, balloon 3.0 cm, repeated dilation at home	0/20	0/128
Manual dilation		32/264; 12.1 %
Placebo	36/428; 8.4%	

LIS lateral internal sphincterotomy, CCB calcium channel blockers, GTN glyceryl trinitrate

The reason for this lengthy description of the systematic review of all randomized trials of anal fissure is first, the volume of publication related to surgery and FI is the greatest for fissure of all operations. Second, the best data show the concern described above is not supported by the data (Table 24) [1060]. It is important to look carefully at the quality of the data in other operations that have been associated with FI. For anal fistula, in the randomized trials, the FI rate also was in the range of 4%. There are no randomized trials of hemorrhoidectomy and FI risk. Association of hemorrhoidectomy with FI is ridiculous. No muscle is touched. Anterior resection syndrome in colorectal cancer is real, but in a very long career doing this operation, though often offered, I have had one patient ask for surgical therapy. And so on.

5. PREVENTION

5.1. Childbirth: mode of delivery

A meta-analysis of published reports that assessed anal sphincter integrity after vaginal delivery and correlated this with continence stated that 77%-83% (depending on parity) of AI in parous women was due to sphincter disruption [1044]. Another systematic review that looked only at post partum factors in prospective cohorts found that the only predictor of AI was 3rd-4th degree sphincter rupture during birth [1061]. Three things are implied by the conclusion of the first review: first, that incontinence in men, children, and in nulliparous women, or women having Caesarean delivery are not exposed to this risk factor, and so should have a lower risk of FI than parous women who have vaginal delivery. There is scant epidemiologic evidence that this is the case (Fig 14). Second, it is implied that sphincter repair would be effective treatment for anal incontinence in parous women. Yet repair of disrupted sphincter has less than a perfect track record. Even more importantly, there is a reported rapid decay in function after repair that is far too great to be explained by age alone [1062-1063]. Third, if direct trauma to the anal sphincter (and not intra-pelvic nerves) were the major cause of anal incontinence, then caesarean delivery should be effective in preventing incontinence. However an SR has shown that this is not the case [1064].

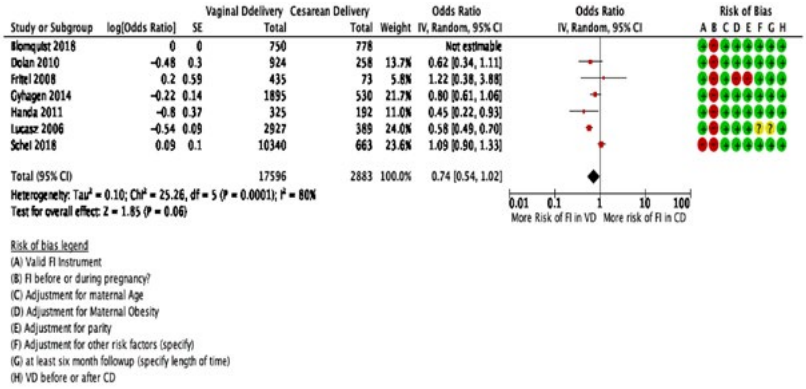

Figure 14. Forest Plot of Studies Comparing Risk of AI (Combined Fecal and Gas Incontinence) after Vaginal Delivery and Cesarean Delivery

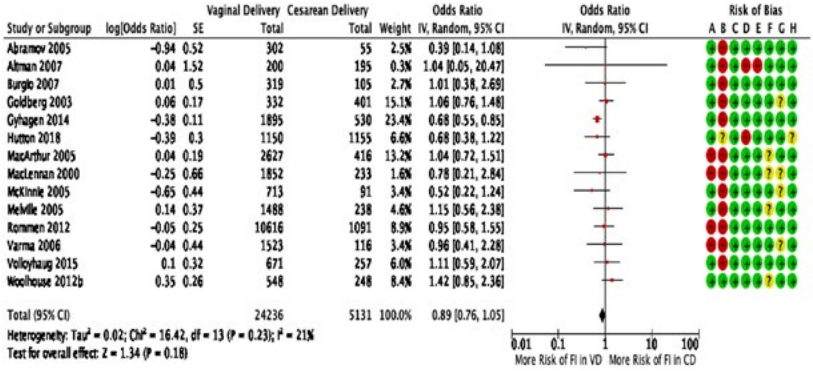

Figure 15. Forest Plot of Studies Reporting Comparison of FI alone after Vaginal Delivery and Cesarean Delivery

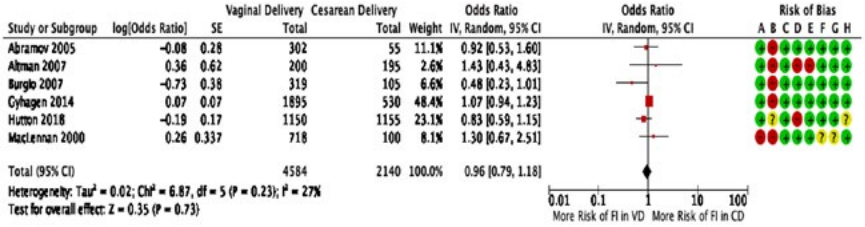

Figure 16. Forest Plot of Studies reporting Flatus Incontinence Alone after Vaginal Delivery and Cesarean Delivery

2526 titles and abstracts were found from which 24 eligible studies were analyzed that compared AI risk, vaginal delivey versus caesarean delivery. These included 39,937 vaginal delivery women and 7,484 caesarean delivery women. Forest plots of the results are in Figures 3a (combined FI and Gas I), 3b (FI), and 3c (Gas I alone). Only one of the eligible studies was a randomized trial, with significant crossover. None of the three comparisons showed a significant difference between vaginal delivery and caesaran delivery The strength of the GRADE evidence for each of these was Low for combined AI and Moderate for FI and GasI. Time Trend FI showed incontinence at three months was largely resolved after one year. As with anal fissure above, many studies measured continence too soon after delivery. This is an unresolved issue that needs clarification. Randomized trials of vaginal delivery vs. caesarean delivery of average risk pregnancies have been performed for other outcomes and need to be performed that assess continence to strengthen the evidence shown in these results.

5.2. Pelvic Muscle Training

There is another intervention that has been shown to diminish post partum incontinence: prepartum and post partum muscle training [1065]. A book on this topic was published in 2007 entitled “Prevention of Fecal Incontinence”. Not too much else other than this method was offered. A follow up Cochrane review [1066], which in 49 trials does not strongly support this intervention.

6. SUMMARY POINTS

- AI and UI commonly coexist, particularly in the elderly and in nursing home residents (2 for evidence, C for Grade).
- The prevalence of AI increases with age, but is present in all age groups in both genders varying from 1.5% in children to more than 50% in nursing home residents (2, C).
- AI is almost as common in men as in women (2, C).
- Mode of delivery does not seem to be a significant factor in the development of obstetric AI, i.e., AI develops after caesarean delivery almost as often as after vaginal delivery in non-randomized trials (2, C).
- Obesity may be the most modifiable risk factor for AI (2, C), but the data associating obesity with AI are weak.
- Prepartum pelvic floor education has been studied to determine if it can decrease the risk of subsequent development of post partum AI (2, C)
- As populations age, co-morbid disease becomes a significant component of fecal incontinence risk. Surgery, neurological diseases, and stroke are examples. (2, C)
- Cognitive and activities of daily living impairment are associated with fecal incontinence. (2, C)

7. FUTURE NEEDS

- As populations age, co-morbid disease becomes a significant component of fecal incontinence risk. Surgery, neurological diseases, and stroke are examples. (2, C)
- Prevention, and policy, are still a great distance away.
- Randomized trials are needed of AI (and UI) in average risk pregnancy comparing vaginal delivery and caesarean delivery with minimal cross over and sufficient follow-up to adequately assess FI and UI

IX. WHY DO PREVALENCE ESTIMATES DIFFER?

The discussion here relates to UI only, as data and literature for FI and POP are very scarce. However, many of the principal arguments will be relevant to these conditions as well.

1. GENERAL PROBLEMS IN SURVEY RESEARCH

The well documented variation in prevalence estimates is thought to result at least in part from several confounders common to survey and epidemiological research. Herzog and Fultz,[1012] in a review of the prevalence and incidence of UI in community-dwelling populations, proposed that past investigations were plagued by sampling and non-response issues, by self selection and attrition, by definitional, conceptual, and measurement issues. Comprehensive reviews about measurements and methodological aspects of investigating UI are provided. It is clear that there are large methodological challenges to rigorous research in this field. In general, quality of recent large studies has undoubtedly improved, but the scientific community must continue to deal with methodological challenges in order to achieve progress.

2. DIFFERENT DEFINITIONS AND MEASUREMENT

A major problem in research on UI has been the use of different definitions and measurements, and this might contribute to the wide range of reported prevalence estimates. The former ICS definition of UI – as a condition in which involuntary loss of urine is a social or hygienic problem and is objectively demonstrable - included objective demonstration of urine loss as one critical component. This aspect limited the ICS definition for community based epidemiological investigations, because objective demonstration of UI is difficult to achieve outside of the clinical setting, and studies which were able to include this aspect in their assessment might have produced different prevalences. In addition, a social or hygienic aspect of the definition was problematic in epidemiologic studies because it added a subjective aspect to an objectively defined condition and therefore confounded the investigation of prevalence, incidence, and risk factors. In our previous report we argued for reconsideration of the definition of UI, and we emphasized that the core of the definition should be ”any involuntary loss of urine”. In accordance with this view, ICS changed its definition in 2001 to UI being ”the complaint of any involuntary leakage of urine”.

The new definition makes epidemiological research easier. But three consequences should be addressed:

1. Epidemiological studies should not be based on this definition alone, and all studies should include a minimal additional data set, standard confounders, and questions specific to the aim of the study. This is discussed in the Section on Recommendations for further research.
2. The number of persons fulfilling the definition will increase. This should not be interpreted as an increase in the number potential of patients.
3. Public awareness, case finding of health care personnel, and help seeking behaviour may be affected of a new and more extensive definition.

Studies have used different severity levels and time frames for defining UI. A further factor complicating the conceptualization and measurement of UI in epidemiologic studies lies in the nature of the condition. UI is a chronic condition (or set of conditions) that often starts slowly and comes and goes for a considerable time period before it become fully established. If people get used to their UI or notice it less, this can interfere with valid assessment.

Ideally self-report measures are validated by clinical evaluations. However, clinical and even urodynamic investigations should be regarded as other measures, not necessarily as gold standards, because it is known to be difficult to demonstrate all LUTS in the clinical setting.

Low response rates may further bias prevalence estimates. Known differences between responders and non-responders can be compensated during the analysis. The major problems is unknown differences in response rates and other characteristics. Incontinent women may not answer (or deny UI) because of embarrassment or related handicaps. But incontinent women may also find the subject particularly relevant and therefore respond to a greater extent than continent women. At present, we do not know much about how these factors may affect the comparison between incontinent and continent women.

One paper explored the problem of underreporting incontinence and how it can be altered with the use of an introduction to the UI

questions and probing [178]. Another paper explored the issue of selection bias in mailed surveys. The first wave had higher prevalence of UI than follow-up mailings, and thus individuals with UI tended to respond on the first wave. In an English mailed survey on UI and other LUTS, a sample of non-responders were traced, and those eligible were asked questions from the survey [1013]. Compared with the responders, the non-responders overall showed little differences in reporting of urinary symptoms. However, non-responders >70 tended to be of poorer general health, and they reported certain LUTS more frequently.

3. SUMMARY POINTS:

- The lack of epidemiological data from populations underrepresented in research limits the world wide application of the present information.
- Many investigations are plagued by sampling and non response issues, by self selection and attrition. Many early studies were obtained from sampling patients seeking care.
- A major problem is the use of different definitions of incontinence. The new ICS definition makes epidemiological research easier.
- There are large methodological challenges to research in the field of UI. Unless the scientific community deals with these issues, progress will be difficult to make.

X. HELP SEEKING BEHAVIOUR

1. URINARY INCONTINENCE

A majority of people with UI have not sought help [540]. Reasons given by people for not seeking help include: not regarding UI as abnormal or serious, considering UI to be a normal part of ageing, having low expectations of treatment and thinking they should cope on their own. Some studies also confirm the notion that embarrassment may be an important reason for not seeking help. There is an association between help seeking and condition-specific factors like duration, frequency and amount, and people's perceptions of the impact of UI but other more personal characteristics like individual health care behaviour and attitudes may also play a role.

In a Norwegian study 4.4 % of all women >20 years old in a community consulted their general practitioner for UI during a 3 year period [1014]. Mentioning the symptoms to a physician may not be enough. There are reports of doctors not responding, either by ignoring the statement of symptoms or by providing a dismissive explanation, and people interpreting a lack of response from the doctor as an indication that no treatment is available. In a study of management of UI in general practice, 30% of the women who had told their doctor about their symptoms perceived that they were offered no help. It is probable that many primary health care providers lack confidence in managing UI, and that this contributes to under treatment in those seeking help.

Only a small proportion of incontinent community-residing women have had surgery, medication, or exercise regimens. In addition to seeking help from the formal health care system, common responses to symptoms of illness are self-management and self-treatment behaviour. The major method of actively managing UI among community residents is the use of absorbent products.

It is obvious that millions of men and women suffer from their UI, and that for many of them good treatment options are available. However, for many persons with very mild or occasional UI it is probably adequate not to seek help from the health care system. Others are satisfied with just information and understanding about the causes and in many cases self care may be quite appropriate. A Danish study has shown that simple information and advice was adequate " treatment" for 23% of the women attending an open access incontinence clinic [1015]. A Swedish study found that among 136 women with UI, 36% wanted clinical evaluation, and only 24% subsequently started treatment [649].

Both epidemiological and qualitative research in this field should be encouraged in order to understand cultural, religious, and personal factors for help seeking behaviour world wide. Specifically, other than condition-specific factors should be further explored, e.g. persons' health care behaviour, perceptions and attitudes.

2. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

There are indications of underreporting also of FI and patients' reluctance to report symptoms or to seek treatment. It has been shown that women are more willing to report FI than men. For POP we have no information.

3. SUMMARY POINTS:

- Recent publications confirm that a majority of people with FI, UI, and POP have not sought help.
- Only a small proportion of community-residing people with UI have had surgery, medication, or exercise regimens.
- Increasing severity, increasing duration, and urge/mixed type of UI are related to consulting a health care provider.
- Associations other than condition-specific factors should be further explored in future research, e.g. persons' health care behaviour, perceptions and attitudes.
- Health care personnel should be encouraged to approach persons at risk for FI, UI and POP. People with such symptoms should be assessed so services and treatment can be offered and targeted. The patient's view of management, even denial, should be respected.

XI. EPIDEMIOLOGY AND CLINICAL WORK: FROM RESPONDENT TO PATIENT

We have emphasised some major and important differences between epidemiology and clinical work. These differences may have several implications. A selection process is most often accomplished first by self-selection (help seeking), then a referral system, which provides specialist physicians to a patient population with higher prevalence of disease, more severe disease, and often skewed type distribution, thus obtaining test results with fewer false positives, better diagnostic accuracy, and more efficient use of resources. However, such intended and purposeful selection bias has its drawbacks. There is growing evidence that this selection process introduces bias into research and hampers our ability to generalize hospital based research back to general or primary care

populations. Furthermore, it may result in recommendations and guidelines for diagnosis or therapy derived from tertiary care centres that are inappropriate at the primary care level. Often guidelines, review articles or teaching material do not take into account the varying prevalence and variation in clinical picture between community and hospital. They may also emphasise use of tests or equipment that are not appropriate or relevant for primary health care, thus leading to over utilisation of referrals. Data from hospitals or specialist level may also overestimate level of burden, costs and number of persons in need of treatment if such data are used for extrapolation back to community level. Therefore it is important that this Consultation uses different algorithms for initial and specialised care (see other relevant chapters).

One study provides substantial empirical evidence to support the existence of selection bias for UI [125]. The analyses were based on three populations of incontinent women: Community level (epidemiological survey), primary care level (prospective study), and secondary care level (university hospital, prospective study). The general practice patients were older and the hospital patients younger than those in the community. From community via general practice to hospital, there was an increase in duration, frequency of leakage, amount of leakage, severity and perceived impact of UI. Help-seeking at the primary care level was associated with increasing age and severity, and with urgency symptoms and impact. Referral from general practice to hospital was only associated with (lower) age and urgency symptoms.

Under the subtitle Severity and impact we have given examples of how the prevalence estimates for women change dramatically when bothersomeness and severity are considered. Taken together with selection bias, this emphasises caution when epidemiological data are used in a clinical context. It concerns " level of care" in several ways; there is a large transitional zone from healthy to diseased, there is a danger of medicalisation, and there is a danger of treating patients at a higher level than necessary. Risk factors, predictors and correlates discovered in epidemiological studies are probabilistic of nature and may not be decisive in the clinical assessment of an individual patient. In addition, the attributable risk due to some known risk factors may be statistically but not clinically significant.

1. WORLDWIDE ESTIMATES OF LOWER URINARY TRACT SYMPTOMS

In order to effectively plan health care resources it is necessary to estimate the prevalence and incidence of illnesses to know to what extent resources require to be allocated to a specific illness health care condition. This chapter has dealt with three major global problems, UI and FI as well as POP, that affect women and men throughout the world. Irwin and coworkers [539] have published data estimating the current and future worldwide prevalence of lower urinary tract symtoms.

The objective of the study was to estimate the current and future number of people with LUTS, including OAB and UI utilising the current ICS definitions. Age- and gender-specific prevalence rates from the EPIC study [417] were applied to the worldwide over 20 year old population (4.2 billion) with males and females stratified into five-year age groups (20-24 to 80+). Projected population estimates for all worldwide regions were based on the United States Census Bureau International Database (IDB).

Estimates were presented for 2008, 2013 and 2018 and are summarised in Tables 25 and 26. Table 25 summarises the estimated number of individuals with certain LUTS symptoms by year and sex in the world population and Table 26 describes the estimated number of individuals of LUTS and OAB over 10 years across the world regions.

Table 25. Estimated Number of Individuals with Certain LUTS By Year & Sex - World Population (In Millions) [539]

LUTS Symptoms	Male 2008	Male 2013	Male 2018	Female 2008	Female 2013	Female 2018
Incontinence						
Any Incontinence	98	109	120	250	275	301

Storage + Voiding + Post Mic Symptoms (Noct ≥2)	130	144	158	119	142	142

Table 26. Estimated Worldwide Number of Individuals with LUTS including OAB and Incontinence by Region (In Millions) [539]

Region	Estimated Number of individuals with any LUTS			Estimated Number of Individuals with OAB			Estimated Number of Individuals with Incontinence		
	2008	2013	2018	2008	2013	2018	2008	2013	2018
World	1,930	2,106	2,277	455	500	545	346	383	420
Africa	203	231	263	46	53	60	33	38	43
North America	167	180	193	40	44	48	32	34	37
South America	111	122	133	26	29	32	20	22	24
Asia	1,166	1,284	1,396	272	302	332	206	231	256
Europe	273	278	280	68	70	71	54	56	57

Estimates and projections featured in this analysis were based on prevalence rates of LUTS described in the EPIC study – based primarily on a European population. The prevalence rates featured in the EPIC study are similar to other prevalence rates of LUTS that were found in others studies across other countries [284,537]

The projections in this report assume the prevalence rates of LUTS will remain throughout the year 2018 for all age and sex groups

Prevalence of LUTS will also increase as other factors related to LUTS, such as obesity, increases. The estimated number for present and future years are not true numbers but are based on a projected population configured by the International Database (IDB). The IDB's estimates and projections are drawn by Census Bureau demographers and are based on reviewed censuses, surveys, and vital statistics provided by National Statistics Offices[9]. Data on international migration and refugee movements, public health efforts, socio-political circumstances, and historical events such as natural disasters and conflict are all considered when the IDB calculates the estimates and projections.

It is anticipated that with the overall aging of the population the prevalence of LUTS will also increase

It has been shown that LUTS are burdensome to individuals [202,485] and the likely increase in the number of individuals experiencing. LUTS has implications on healthcare resources and overall health burden. This analysis is an estimate of the number of individuals with LUTS based on a conservative prevalence rate, and so the future number of those with certain LUTS may surpass those of this report.

Table 27. Summary of major findings regarding the estimated worldwide prevalence figures for lower urinary tract symptoms LUTS [539]

46% of the 4.2 billion of the adult world population (≥ 20 and over) experience any LUTS
455 million individuals or 11% of the world population estimated to experience OAB symptoms
346 million individuals or 8% of the world population estimated to experience some type of UI
SUI is the most common type of incontinence in 2008 and 2018 (Fig 1.)
136 (3%) and 164 (4%) million individuals are estimated to experience SUI in 2008 and in 2018 respectively
49 (1%) and 60 (1%) million individuals are estimated to experience UUI in 2008 and in 2018 respectively
53(1%) and 65 (1%) million individuals are estimated to experience MUI in 2008 and in 2018 respectively
108 (3%) and 131 (3%) million individuals are estimated to experience Other Incontinence in 2008 and in 2018 respectively Assuming LUTS prevalence rates remain stable for the next ten years, 2.3 billion individuals are estimated to experience LUTS by the year 2018 An increase of 18% from 2008
Storage symptoms has the highest burden in both the male and female population than other LUTS (Fig 2.)
Male: estimated 597 million in 2008, 713 million in 2018
Female: estimated 760 million in 2008, 901 million in 2018
Asia region is estimated to carry the highest burden of LUTS. Estimated 1.2 billion individuals in Asia regions may experience any LUTS

2. SUMMARY POINTS:

- The spectrum of severity of AI and UI, as well as POP, and the symptom profile of patients referred to specialist centres do not necessarily reflect the spectrum of disease seen in the community.
- The selection and referral process may introduce bias into research and hamper the ability to generalise hospital-based research back to primary care populations.
- One should be very careful with calculating numbers of patients in need of therapy based on epidemiological data.

XII. RECOMMENDATIONS FOR FURTHER RESEARCH

Much biomedical research is observational and the reporting of such research is often inadequate which hampers the assessment of its strengths and weaknesses and of a study´s generalisability. The STROBE (Strengthening of the Reporting of OBservational studies in Epidemiology) statement was introduced [1016]. It is a a checklist of items that should be addressed in articles reporting on the three main study designs of analytical epidemiology: cohort, case-control, and cross sectional studies. The use of this checklist is highly recommended.

1. URINARY INCONTINENCE

It is recommended that more sustained research on measurement of UI should be performed including, its types and severity to move the research ahead. Longitudinal study designs are needed to estimate incidence of UI and describe the course of the condition and its different forms and to investigate its risk factors and possible protective factors.

There is still little knowledge with regard to prevalence, incidence, and other epidemiological data in developing countries. A recent review on the global prevalence of UUI clearly showed that prevalence rates are largely unknown for many countries in the world [1017]. It is recommended that fundamental research regarding prevalence, incidence and other epidemiological data in developing countries should be encouraged, and tailored to the cultural, economic and social environment of the population under study.

Crude prevalence studies (descriptive epidemiology) from USA and Europe are abundant, and further studies should be done only with recommended and validated questionnaires or in order to combine data from the prevalence study with studies of co-factors and predictors (analytical epidemiology). Control for confounders, stratification, and multivariate techniques should be increasingly used because of the need for more advanced epidemiological analyses of risk factors and comorbidity. Strength of associations should be determined by relative risks and odds ratios, and confidence limits should be given. We have still very little knowledge of the absolute and relative importance of several risk factors, and almost no information about the attributable risk of the factors in the society.

Some potential risk and protective factors deserve more attention. For example, the role of pregnancy and childbirth in the development of UI must be studied in a fashion that links population-based methods to clinical assessment of pregnancy, delivery and the birth trauma and follows women over many years. Such a design is necessary because the effect of pregnancy and childbirth may become clear only years later when the woman is older and because the woman will not be able to report the exact nature of the tear or episiotomy, etc. There should be more emphasis on the associations between UI and specific diseases like stroke, diabetes, psychiatric disease and genital prolapse. Genetic components should be investigated.

Primary prevention is the main goal in the management of human disease. An important strategy would thus be to identify the individuals at risk, and then take measures to reduce the risk among those individuals or in certain risk groups. A predictive modelling system based on risk factors identified in population studies has been put forward [1018]. Primary prevention studies should be encouraged, but the epidemiological basis for choosing appropriate interventions is weak.

In surveys based on questionnaires or interviews symptoms can be registered. There are convincing data suggesting that the different types may reflect quite different pathologies and risk factors. Differentiating the types in future research might therefore prove very fruitful. Methodological work has still to be done in this area, but typical type descriptions should be included in new studies. Likewise, studies of risk factors should include important and known confounders such as age, parity, and weight.

Variations in definitions and measurement issues are fundamental and lead to problems with assessing the findings in epidemiological studies. We need to improve epidemiological studies by including variables that better characterise UI, so that more advanced and in-

Table 28. Elements in a minimum data set recommended for all epidemiological studies

• Screening question for any involuntary urine loss
• Frequency measure. For example, classification into categories of none, less than once a month, one/several times a month, one/several times a week, every day/nigth, all the time
• Quantity of urine loss for a typical episode. For example, classification into categories of none, drops, small amounts, moderate amounts, much/a great deal
• Duration. For example months, years
• Type. Based on typical description; stress, urge, mixed and other
• Severity. Either by combining excisting questions or by a validated index

formative analyses may be conducted. It is therefore recommended that all epidemiological studies include a minimum data set (Table 28), including elements of screening question, frequency measure, quantity of urine loss, duration, type, and severity. In addition, it is recommended that validated measures of bother/quality of life and LUTS other than UI should be included. We here also refer to the chapter from the committee on symptom and quality of life assessment.

In addition, it is recommended that validated measures of bother/ quality of life and LUTS other than UI should be included.

2. FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE

In these areas there is a need for more epidemiological research in all areas; prevalence, incidence, and risk factors. Many of the fundamental methodological issues relevant to UI discussed above are highly relevant to the fields of FI and POP.

The committee emphasises that uniform definitions of FI and POP should be used in studies, and there should be a move towards a standardization of measurement instruments in community surveys that can be used worldwide. Developing definitions is a scientific process requiring careful conceptualization of the condition in light of its many clinical presentations and underlying mechanisms. This will require a multi-method approach and consideration of issues such a reliability and validity.

CHAPTER 2

NEURAL CONTROL AND CELL BIOLOGY

ABBREVIATIONS 135

INTRODUCTION 137

I. AFFERENT SIGNALLING AND PAIN IN THE LUT 137
1. The Structural Basis of Bladder Nociception 137
1.1. Organisation of Bladder Afferent Innervation. 137
1.2. Complexities of Bladder Innervation and Sensation. 138
1.3. Bladder Afferent Fibres and Receptive Endings. 138
2. The Functional Basis of Bladder Nociception 139
2.1. Bladder Pain, Nociceptors and Sensitisation. 139
2.2. Bladder Nociception – Mechano-reception. 140
2.3. Bladder Nociception - Chemoreception. 142
2.4. “Silent”, Mechanically Insensitive Endings. 143
2.5. Contemporary Research Approaches. 143
3. Bladder Sensitisation 144
3.1. Afferent/Cellular Sensitisation. 144
3.2. Cross-organ Sensitisation. 145
4. Additional Considerations 147
4.1. What Constitutes a Visceral/Bladder Nociceptor? 147
4.2. Translation of Research to Humans. 147

II. INTEGRATIVE FUNCTIONS OF THE BRAIN IN LUT CONTROL 149
1. Background and Overview of the Control Network 149
1.1. Neural Control. 149
1.2. The Working Model of Forebrain Control. 149
1.3. Midbrain Involvement 149
2. Continent Adults: Human Studies of Bladder Storage, Filling and Voiding 150
2.1. Overview. 150
2.2. The Voiding Phase 150
2.3. The Storage Phase 151
2.4. The Filling Phase. 152
3. Non-neurogenic LUTD: Human Studies of Bladder Storage, Filling and Voiding 153
3.1. The filling phase. 153
3.2. The Storage Phase. Resting state functional connectivity (RSFC). 154
4. Neurological Treatment of Urgency Urinary Incontinence (UUI) 154
4.1. Deep Brain Stimulation (DBS). 154
4.2. Sacral Neuromodulation (SNM). 154
5. Studies of Neurogenic LUTD 155
5.1. Multiple Sclerosis (MS): Structural and Functional Considerations. 155
6. Structural Considerations for LUTD 156
6.1. Overview. 156
6.2. White Matter. 156
6.3. Brain volume. 156
6.4. Summary. 156
7. Conclusion 156
7.1. The Working Model. 156
7.2. Future Work. 156
7.3. Summary. 157

III. EFFERENT NERVOUS CONTROL OF THE LUT – A TARGET FOR NEUROMODULATION 157
1. Introduction 157
2. Efferent Innervation of the Lower Urinary Tract 157
3. Neuromodulation of Peripheral Nerve Activity 158
3.1. Sacral Nerve Activity to Elicit Voiding. 158
3.2. Sacral Nerve Stimulation to Inhibit Voiding. 158
4. Distal Stimulation Sites 158
4.1. Pudendal Nerve Stimulation. 159
4.2. Hypogastric Nerve Stimulation. 159
4.3. Pelvic Nerve Stimulation. 159

ABBREVIATIONS

Chemical and some other specific terms used only once are not included. Please also refer to figure legends as appropriate

8-AG	8-aminoguanine
a(p)MCC	anterior(posterior) midcingulate cortex
ABC	ATP-binding cassette (transporter)
ABMA	α,β-methylene ATP
ACC	anterior cingulate cortex
ACh	acetylcholine
AHS	acidic hypertonic solution
AITC	allyl isothiocyanate
ALFF	amplitude of low frequency fluctuations
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (glutamate) receptor
ASIC	acid-sensing ion channel
AT(D)P	adenosine tri-(di-)phosphate
BAC	bacterial artificial chromosome
BK	large-conductance Ca^{2+}-activated K^+ current
BNST	bed nucleus of the stria terminalis
BPH	benign prostatic hyperplasia
BPS	bladder pain syndrome
BTX-A	botulinum toxin A
C-MiHi	mechano- and heat-insensitive ('silent') nociceptors
CaCC	Ca^{2+}-dependent Cl^- channel (Ano1)
cAMP	cyclic adenosine monophosphate
CB1,2	cannabinoid receptor 1, 2
CEN	central executive network
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
ChAT	choline acetyltransferase
ChR2	channel rhodopsin-2
CICR	Ca^{2+}-induced Ca^{2+}-release
CNG	cyclic nucleotide-gated
CNS	central nervous system
CO	carbon monoxide
CPA	cyclopiazonic acid
CPPS	chronic pelvic pain syndromes
CRF	corticotrophin releasing factor
CSF	cerebrospinal fluid
CTFG	connective tissue growth factor
CYP	cyclophosphamide
dACC	dorsal anterior cingulate cortex
DAN	dorsal attention network
DAPI	4′,6-diamidino-2-phenylindole, nuclear label
DAPR	decerebrate arterially perfused rodent
DBS	deep brain stimulation
DFV	discoidal fusion vesicle
DGN	dorsal genital nerve
DL	dorsolateral column
dlPAG	dorsolateral PAG
DMN	default mode network
DMSO	dimethyl sulphoxide
DO	detrusor overactivity
DRG	dorsal root ganglion
DTI	diffusion tensor Imaging
ECM	extracellular matrix
EFS	electrical field stimulation
EGF(R)	epidermal growth factor (receptor)
eGFP	enhanced green fluorescent protein
EJP	excitatory junction potential
EMG	electromyograph(y)
ENaC	epithelial Na^+ channels
EUS	external urethral sphincter, rhabdosphincter
FAAH	fatty acid amide hydrolase
FiMH	type-1 pilus adhesin of uropathogenic *Escherichia coli*
fMRI	functional magnetic resonance imaging
GABA	γ-amino butyric acid
GAG	glycosaminoglycan
GIT	gastro-intestinal tract
GMV	grey matter volume
GPCR	G-protein coupled receptor
GPi	globus pallidus pars interna
GRK	G-protein-coupled receptor kinase
H_2O_2	hydrogen peroxide
HCN	hyperpolarisation-activated, nucleotide-gated (channel)
HGN	hypogastric nerve
HIF-1α	hypoxia-inducible factor 1-α
IC(C)	interstitial cell (of Cajal)
IC/BPS	interstitial cystitis/bladder pain syndrome
IFG	inferior frontal gyrus
IL	interleukin
IMD	inter-mediodorsal nucleus
IMG	inferior mesenteric ganglion
IP_3	inositol trisphosphate
IPar	intra-parenchymal injection
IS	inflammatory soup
IUS	internal urethral sphincter
Ives	intravesical instillation
IVP	(bladder) intravesical pressure
KCl	potassium chloride
Kv	voltage-dependent K^+ channel
L-NA	nitro-L-arginine
LC	locus coeruleus
LP	*lamina propria*
LPS	lipopolysaccharide
LS	lumbosacral
LSN	lumbar splanchnic nerve
LUT	lower urinary tract
LUTS(D)	lower urinary tract symptoms (dysfunction)
LVDCC	L-type voltage-dependent Ca^{2+} channel
MCC	maximum cystometric capacity
MIA	mechanically insensitive afferent
MLC(P)	myosin light chain (phosphatase)
MM	*muscularis mucosae*
MMP	matrix metalloproteinase
mPFC	medial prefrontal cortex
MPO	medial preoptic area of hypothalamus
(m)RNA	(messenger) ribonucleic acid
MS	multiple sclerosis
mTOR	mechanistic (or mammalian(target of rapamycin
MVB	multivesicular bodies
N(I)DO	neuropathic (idiopathic) detrusor overactivity
NaCl	sodium chloride
NADPH	nicotinamide adenine dinucleotide phosphate
NANC	non-adrenergic, non-cholinergic
NCX	Na^+-Ca^{2+} exchange
NGF	nerve growth factor
NMDA	N-methyl-D-aspartate (glutamate) receptor
nNOS	neuronal nitric oxide synthase
NO(S)	nitric oxide (synthase)
OAB	overactive bladder
OCT	organic cationic transporter
OP	parietal operculum
P2X, P2Y	purinergic receptor classes
PAG	periaqueductal grey
(p)BOO	(partial) bladder outflow obstruction

PD Parkinson's disease
PDE5(I) phosphodiesterase type-5 (inhibitor)
PDGFR platelet-derived growth factor receptor
PFC prefrontal cortex
PFM pelvic floor muscles
PG pelvic ganglion
PHC parahippocampal area
PKA (PKG) protein kinase-A (-G)
PLC phospholipase-C
PMC pontine micturition centre
PN pelvic nerve
PoCG postcentral gyrus
PPARγ peroxisome proliferator-activated receptor-γ
PPN pedunculopontine nucleus
PRF pulsed radio-frequency (stimulation)
PuN pudendal nerve
PUV posterior urethral valves
qRT-PCR quantitative reverse transcription polymerase chain reaction
ROK Rho-associated protein *kinase*
ROS reactive oxygen species
RSFC resting state functional connectivity
RTX resiniferatoxin
RyR ryanodine receptor
SARS sacral anterior root stimulation
SCI(T) spinal cord injury (transection)
SCN suprachiasmatic nucleus
SCN10A gene that provides instructions for expression of Na^+ channels
SDAF sacral deafferentation
sGC soluble guanylate cyclase
SHH (protein) sonic hedgehog
SMA supplementary motor area
SMA(α) smooth muscle actin (type α)
SMC smooth muscle cell
SK small-conductance Ca^{2+}-activated K^+ current
SMN salience and sensorimotor network
SN salience network
SNM sacral neuromodulation
SR (ER) sarcoplasmic (endoplasmic) reticulum
STD spontaneous transient depolarisation
STO(I)C spontaneous transient outward (inward) current
SUI genuine stress incontinence
TEA tetraethylammonium chloride
TEM transmission electron microscopy
TGF-β transforming growth factor-β
TH tyrosine hydroxylase
TIMP tissue inhibitors of MMPs
TL thoracolumbar
TLR_4 toll-like receptor 4
TNBS trinitrobenzenesulphonic acid
TNP-ATP 2'(or 3')-O-(2,4,6-trinitrophenyl)-ATP
TrkA tyrosine kinase A
TRPA transient receptor potential ankyrin receptor
TRPM transient receptor potential melastatin receptor
TRPML transient receptor potential mucopilin receptor
TRPV transient receptor potential vanilloid receptor
TTX (-r) tetrodotoxin (-resistant)
TVDCC T-type voltage-dependent Ca^{2+} channel
UCP urethral closing pressure
UDIF urothelial-derived inhibitory factor
UIC urethral interstitial cells
UPEC uropathogenic *Escherichia coli*

UTI urinary tract infection
(U)UI (urgency) urinary incontinence
VD voiding dysfunction
VIP *vasoactive intestinal (poly)peptide*
VL ventrolateral column
VNUT vesicular nucleotide transporter
VSM vascular smooth muscle
WAS water avoidance stress
WB western blot
XO xanthine oxidase

INTRODUCTION

Two chapters (Cell Biology and Neural Control) offered in previous editions of the consultation have been combined into a single compilation of fundamental research that underpins an understanding of lower urinary tract function in normal and pathological situations. Such a fusion is beneficial so that afferent and efferent nervous information can be integrated, not only within the central nervous system but also with sensory transduction processes and motor effectors in the lower urinary tract (LUT). This chapter starts with a consideration of how the nervous system integrates the functionality of the lower urinary tract: how information from the lower urinary tract is coded into afferent signalling; how sensitisation and cross-sensitisation with other organ systems occurs; to upgrade the current working model whereby the brain integrates sensory and motor nervous signalling. Efferent control of LUT activity is considered from the point of view of neuromodulation and how more effective control may be artificially achieved with a view to alleviate pain and motor disorders. A more detailed consideration is then given as to how component parts of the LUT, including the outflow tract, urothelium and detrusor muscle, act as sensory transducers and effectors of motor activity. Of importance also it to recognise that advances in experimental methods facilitate our understanding of this integrative approach and a section on the development of some novel animal models is included. Finally, such information as gained will be discussed in the context of developing better pharmaceutical therapies for managing LUT disorders.

Such a consultation cannot cover all elements of scientific activity to understand LUT function. The chosen topics have been selected to provide an upgrade of some noteworthy areas that have seen advances since the last edition and also some that have not had more detailed coverage for a longer time. There are no specific research suggestions at the end of the Chapter as individual researchers will have their own interests to pursue. However, each section highlights areas for future study that different contributors find of interest.

I. AFFERENT SIGNALLING AND PAIN IN THE LUT

Chronic pelvic pain syndromes (CPPS), including chronic prostatitis and bladder pain syndrome, are often characterised by complaints of painful bladder filling or urgency, typically in the absence of overt bladder pathology to explain the pain. CPPS are also associated with negative cognitive, behavioural, sexual, and/or emotional consequences and reduced quality of life. Typically, men with chronic pelvic pain and voiding complaints are diagnosed as having chronic (usually non-bacterial) prostatitis whereas women with chronic pelvic pain and voiding complaints are commonly diagnosed as having bladder pain syndrome (BPS). Urinary CPPS (UCPPS) is an umbrella term incorporating urinary tract symptoms (frequent urination, urgency, dysuria) with chronic pain complaints localised to lower abdominal/pelvic areas. Estimates of prevalence of chronic (non-bacterial) prostatitis range from 8.4% to 25% (1). Estimates of prevalence for BPS in women vary with diagnostic criteria, ranging from 2%-17.3% among the general population (2). Commonly, female BPS patients report that their pain is worse with bladder filling (3) and that the urge to urinate is primarily due to pressure, discomfort, or pain (4). In addition, co-morbidities such as irritable bowel syndrome, dysmenorrhoea, dyspareunia, fibromyalgia and chronic fatigue syndrome are common in UCCPS (5,6) revealing both increased pelvic visceral and widespread non-visceral somatic pain sensitivity.

Management of UCCPS is challenging in part because our understanding of the mechanisms that contribute to pain is incomplete. The physiology and mechanisms of visceral pain continue to be comprehensively reviewed (7-10). Pain is typically initiated by activation of sensory afferent endings, or “nociceptors”, in all tissues and transmitted by afferent nerves to the central nervous system, which has an obligatory role in pain perception and reaction. Whereas the role of the central nervous system (CNS) increases in complexity in chronic pain conditions (e.g., amplification of afferent input, structural alterations to the brain), the contribution of ongoing, persistent afferent input to the maintenance of chronic pain is increasingly evident (11-16), including in bladder pain conditions (17-24). Thus, blockade of bladder nociceptive input into the CNS can effectively relieve or markedly attenuate discomfort and pain. Accordingly, we focus here on the organisation, complexity, sensitivities, heterogeneity and sensitisation of bladder afferent neurons, including bladder nociceptors. What constitutes a bladder nociceptor is considered more at the end of this section. Fundamentally, bladder nociceptors are afferent endings that encode the intensity of stimulation (usually bladder filling/stretch) in the noxious range and undergo an increase in excitability after organ ‘insult’. With respect to inflammation, it is important to appreciate that the mechanism(s) by which experimentally applied inflammogens activate the innate immune system differ, thus potentially affecting interpretation and comparison of experimental outcomes.

1. THE STRUCTURAL BASIS OF BLADDER NOCICEPTION

1.1. Organisation of Bladder Afferent Innervation.

The urinary bladder is innervated by efferent autonomic sympathetic and parasympathetic (‘motor’) and afferent (‘sensory’) nerves. The dual afferent innervation of the bladder, like that of other lower abdominal and pelvic organs, originates from two independent sources with neuronal cell bodies (somata) located in spinal dorsal root ganglia associated with thoracolumbar and lumbosacral (or sacral in humans) spinal segments (25,26; see (7) for an illustration of human viscerotomes). In rats, vagal afferents extend to the urinary bladder (27), but this has not been established in humans. Because visceral afferent fibres course anatomically within the same nerve (e.g., lumbar splanchnic nerve) as efferent fibres of sympathetic (thoracolumbar) and parasympathetic (lumbosacral/sacral) nerves (28), an earlier literature described them as “sympathetic afferents” and “parasympathetic afferents - a confusing self-contradiction in terminology that unfortunately continues to be used. To avoid ambiguity in meaning and presentation, visceral afferents here are described by nerve name.

Initially, the presumed function of ‘sympathetic’ afferent fibres was transmission to the CNS of conscious sensations, including discomfort and pain. Conversely, the ‘parasympathetic’ afferent innervation was associated with autonomic control rather than sensation and perception (e.g., vagal afferent innervation of thoracic and abdominal organs). This assumed functional distinction with respect to the bladder, however, was not supported when investigated. For example, studies of the function(s) of bladder afferent nerves revealed that the pelvic (i.e., ‘parasympathetic’) nerve was important for transmission of conscious sensations (e.g., fullness, distension/urgency, discomfort, and pain). Transection or blockade of the pelvic nerve abolished bladder contractions in response to

repetitive filling and relieved pain in patients suffering bladder pain (8,29,30). This was unexpected because It was commonly held that pain arising from internal organs was transmitted in afferent nerves associated with sympathetic efferent pathways (i.e., lumbar splanchnic/hypogastric nerves for the urinary bladder). While the early proposition that 'sympathetic afferents' convey sensations of discomfort and pain to the CNS may apply generally to organs in the upper abdomen and thorax, subsequent studies in rodents as well as humans confirmed that pelvic nerve afferents were the main conveyers of painful sensations from lower abdominal and pelvic organs (e.g. 30,31). Contemporary evidence documents that the function(s) and modality-selectivity of an organ's innervation changes with organ insult and disease states. For example, lumbar splanchnic/hypogastric nerve afferents activated by mechanical and chemical stimulation of the bladder contribute to the regulation of micturition and transmission of painful sensations in the presence of bladder irritation/damage (32,33).

1.2. Complexities of Bladder Innervation and Sensation.

Three common characteristics of visceral innervation and sensation apply to the lower urinary tract: low density of afferent innervation; referral of sensations; and cross-organ sensitisation. The bladder afferent innervation is complex and broad, with bilateral input from both thoracolumbar and lumbosacral/sacral spinal nerves, but the density of innervation (i.e. the number of afferents innervating the bladder) is relatively low compared with the afferent innervation of non-visceral somatic tissues. It is estimated that only 5-15% of the total afferent input into the spinal cord arises from the viscera (e.g. 8,10). In contrast, it is estimated that up to 50% of second or higher order spinal neurons respond to visceral stimulation because visceral afferent terminals extensively arborise within the spinal cord, including to the contralateral side (34). Further, the rostro-caudal spread of accessible visceral afferent spinal terminals increases in the presence of visceral insults (e.g. 35,36).

An additional complexity of the visceral innervation is the referral of sensation to non-visceral sites (referred pain). Virtually all second order spinal neurons that receive a visceral input also receive convergent non-visceral inputs from skin and/or muscle, as well as convergent inputs from other visceral organs. Accordingly, spinal viscero-receptive neurons, located principally in Rexed's *laminae* I, V and X, and in the dorsal grey commissure of the lumbosacral spinal cord, receive multiple convergent inputs that influence responses to diverse afferent inputs. Spinal somato-visceral convergence has long been considered as the underlying basis for referral of visceral sensations to non-visceral tissues (i.e., convergence-projection, 37). Likewise, spinal viscero-visceral convergence is a factor in cross-organ sensitisation between multiple organs (38).

A third complexity of the bladder innervation that may contribute to both referred sensation and cross-organ sensitisation is that a single afferent dorsal root ganglion (DRG) soma can give rise to what has been described as dichotomising or bifurcating axons that innervate two different tissues and/or organs. Experimental evidence from anatomical, behavioural and physiological studies supports the concept of pelvic organ cross-organ innervation and sensitisation. A single DRG soma may innervate both the bladder and colon in rat and mouse (39) and the bladder and prostate in rat (40,41) and mouse (42). Anatomical evidence is generated by injection of different fluorescent retrograde tracers into the bladder wall and another organ and counting DRG neurons that contain one or both tracers (see Cross-organ Sensitisation below). The physiological or clinical relevance such dichotomised axons remains to be determined. However, with rodents' distal colon irritation increases the frequency of bladder contractions and altered micturition reflexes (43-45). Similarly, prostate inflammation leads to bladder overactivity and hypersensitivity to bladder filling (41,42) while bladder inflammation in rodents leads to hypersensitivity of colon distension (43,44).

A final complexity of bladder innervation relates to interpretation of results from different species, most clearly in recent studies of rodent bladder DRG somata. In sequential studies, mouse bladder somata in the L6 DRG (46) and rat bladder somata in L6-S1 DRG (47) were labelled and studied after intra-parenchymal (IPar) injection or intravesical (IVes) instillation of fluorescently tagged retrograde tracers. The route of tracer administration, IPar or IVes, exposed two anatomically distinct groups of lumbosacral bladder afferents. IPar labelling was distributed throughout non-urothelial layers of the rodent bladder, whereas IVes labelling was confined to the urothelium, and occasionally the submucosa. Subsequent whole-mount, *in situ* patch-clamp recordings from labelled DRG somata revealed significant differences between rat and mouse. In the mouse (46) IVes labelled, 'urothelial' DRG somata exhibited greater excitability relative to IPar labelled, non-urothelial DRG somata. These electrophysiological differences between anatomically distinct urothelial and non-urothelial bladder DRG somata, however, were not replicated in the rat, (47). The translation of findings in non-human animals to humans is considered in the closing comments.

1.3. Bladder Afferent Fibres and Receptive Endings.

Centripetal axons of DRG somata travel to the lower urinary tract in lumbar splanchnic/hypogastric and pelvic nerves (Figure 1), terminating in bladder and urethra muscle, sub-urothelium and urothelium. Pudendal afferent nerve endings, arising from sacral DRG, innervate the bladder neck and urethra. Because the urinary bladder is derived from midline structures, it has bilateral afferent inner-

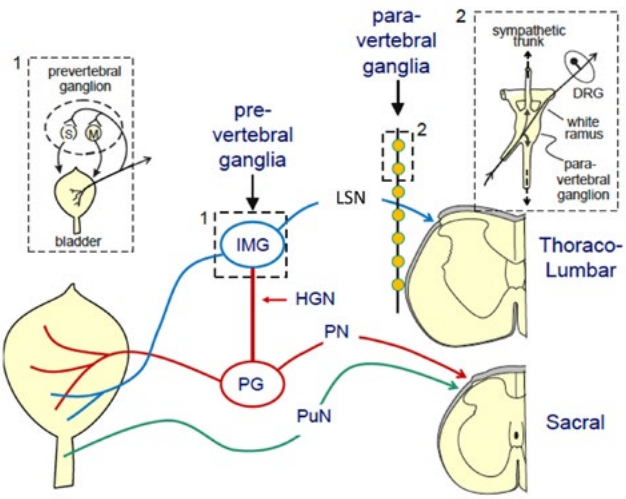

Figure 1. Afferent innervation of the urinary bladder. *Pelvic (PN, red) and pudendal (PuN, green) nerves, with afferent terminals from the bladder and urethra terminate in lumbosacral (most animals) or sacral (humans) spinal cord segments. PG, pelvic ganglion/plexus. Lumbar splanchnic nerve (LSN, blue), with many terminals at the bladder base, and hypogastric nerve (HGN, red) fibres pass through pre- (box 1) and para- (box 2) vertebral ganglia before reaching thoracolumbar spinal segments: IMG, inferior mesenteric ganglion. S,M (Box-1) represent secretory and motility functions of neurons in prevertebral ganglia. From (61,74-76).*

vation from both lumbar splanchnic/ hypogastric and pelvic nerves. Discomfort and pain often occur during voiding in individuals with urethritis (inflammation of the urethra) or urinary tract infections, but normally activation of pudendal afferents is not nociceptive.

The urinary bladder afferent innervation is comprised largely, if not exclusively, of thinly myelinated Aδ- and unmyelinated C-fibres. Unmyelinated C-fibres are slower conducting (0.5-2.0 $m.s^{-1}$), while myelinated Aδ-fibres conduct at 2.5-30 $m.s^{-1}$. Fibre myelination is related to conduction velocity and is not a reliable indicator of function, although function has been assigned to fibre type. For example, it was thought previously that Aδ-fibre endings were excited by mechanical stimuli and thus transmitted information about bladder filling, whereas C-fibre endings were excited by chemical stimuli and transmitted nociceptive information leading to discomfort and painful sensations. As discussed below, bladder Aδ- and C-fibres respond to several stimulation modalities. Receptive endings of bladder afferents in detrusor, sub-urothelium and urothelium are assumed to be unencapsulated ("free") endings - largely based on parallels with non-visceral somatic Aδ- and C-fibres. These receptive endings express multiple transducer molecules (e.g., G protein-coupled receptors, ligand- and voltage-gated ion channels, etc.) that respond to specific mechanical, chemical, and/or thermal stimulus modalities.

Bladder afferent terminals that respond to mechanical and/or chemical stimuli give rise to conscious sensations, including fullness, urgency, discomfort and pain (i.e. are *sensory* afferents). Bladder afferent terminals also respond to mechanical and chemical stimuli that are *not* consciously perceived (i.e. are not sensory), including responses to interoceptive stimuli (48). Non-sensory bladder afferents play important roles in conjunction with sympathetic and parasympathetic efferent nerves in the reflex control of urine storage and micturition. Some bladder afferent terminals are also thermosensitive (49). Thus, some are multi-modal, as are other pelvic visceral afferents that respond to thermal, chemical and/or mechanical stimuli.

Most electrophysiological studies of bladder afferents have focussed on mechano-sensation, as bladder filling is a physiologically relevant stimulus and hollow organ distension is commonly used as an experimental, noxious visceral stimulus (50-52). Bladder afferent terminals that respond to filling or distension are presumed to be in the detrusor smooth muscle, initially classified as 'in-series' tension receptors (8,53). Based on studies primarily in rats and mice, mechano-sensory bladder signalling has been assigned to several functionally distinct afferent endings, as discussed below. Until recently, detailed information about the location and morphology of bladder afferent terminals was unavailable. Spencer et al. (54,55) described morphologically distinct types of pelvic nerve afferent endings in mouse bladder. After unilateral injections of an anterograde tracer into the L5-S2 DRG, four morphologically distinct types of spinal afferent endings in urinary bladder tissue sections were distinguished: three were located in the detrusor muscle and one in the sub-urothelium and urothelium. The detrusor muscle endings comprised 81% of the total and had a "simple", "branching" or "complex" morphology; the majority (75-89%) were calcitonin gene-related peptide (CGRP)-immuno-positive, confirming their classification as 'afferent'. Sub-urothelial and urothelial endings generally had a "simple" morphology with single, fine varicose or non-varicose axons. They lacked a specialised terminal ending and were also CGRP-immuno-positive.

On a morphological basis, "complex" endings were most common (44% of labelled endings) and terminated in detrusor, with some also in the sub-urothelium. Such endings developed from a single axon that bifurcated extensively near the fibre terminal, spreading within detrusor muscle but without uniform orientation to either muscle fibres or other afferent fibres. They were distributed throughout the bladder with no preferred topography. "Simple" endings in detrusor and sub-urothelium (25% of labelled endings) terminated as single, straight axons with varicosities along terminal endings. The least common (12%) were "branching" endings, occasionally with multiple endings arising from one parent axon and typically coursed in alignment with detrusor muscle fibres. The distinctive functional properties of these four morphological types remain to be established.

2. THE FUNCTIONAL BASIS OF BLADDER NOCICEPTION

2.1. Bladder Pain, Nociceptors and Sensitisation.

Noxious stimuli that are algogenic (give rise to pain) do so only if they are "adequate" excitants of nociceptive receptive endings that are typically unencapsulated/"free" Aδ- or C-fibre nerve endings in skin, bone, joints, muscle, and internal organs. In addition, rapidly conducting Aβ-fibres have been associated with nociceptive endings (56), but they are not common in the rodent visceral innervation. Whether a nociceptive stimulus is adequate depends on the tissue to which it is applied and the modality of the applied stimulus (57,58). For example, cutting, crushing/pinching, or burning reliably excites nociceptors in skin, whereas they generally do not evoke pain or other conscious sensations when applied to hollow organs (7). Rather, stretch or distension of hollow organs, traction on intestinal mesenteries, organ hypoxia/ischemia/inflammation and chemical stimuli, such as endogenous inflammatory mediators, activate visceral nociceptors. Nociceptors are receptive endings which, when excited by an adequate stimulus, are associated with an action (a withdrawal reflex, guarding behaviour) or sensation (discomfort, pain) and thus are defined by their function. Designation of sensory neurons with slowly conducting or unmyelinated axons and small-diameter DRG somata as nociceptors, in the absence of evidence of their function, has become common but is not reliably accurate.

Nociceptors were initially thought to have high thresholds for response to applied stimuli and then to encode stimulus intensity throughout the noxious range. It is now appreciated that response threshold is not a distinguishing characteristic of nociceptors. Many skin, muscle, joint, and visceral mechano-nociceptors respond to low stimulation intensities, with respect to response threshold, are indistinguishable from non-nociceptive mechano-receptors. There are two defining properties of nociceptors: they encode stimulus intensity in the noxious range; and they sensitise (59). Most mechano-sensitive bladder endings have low response thresholds and have these properties (60-61).

Sensitisation represents an increase of nociceptor excitability and is operationally established as a leftward shift of afferent behavioural or psychophysical stimulus-response functions (Figure 2), i.e. a reduced response threshold and an increased response magnitude to a nociceptive stimulus (59,62). Note that as response threshold decreases, previously non-nociceptive intensities of stimulation or previously inadequate or subthreshold stimuli, including other modalities of stimulation, may become effective excitants; spontaneous activity may also develop. Examples of sensitisation at different levels of the neuroaxis are given in Figure 2.

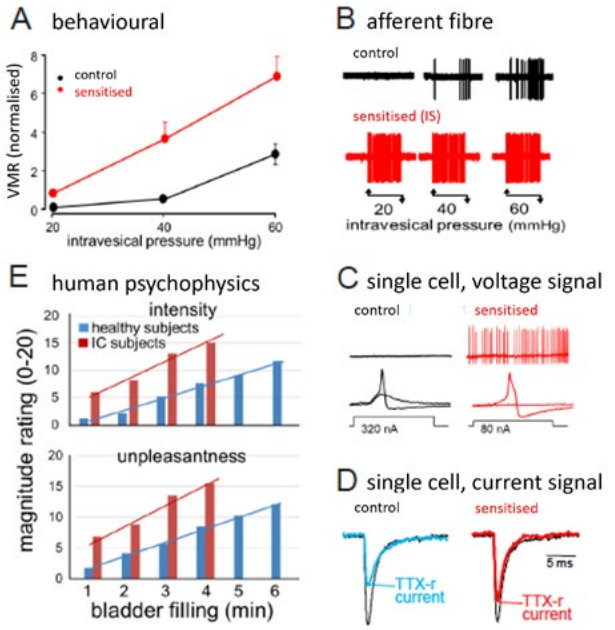

Figure 2. Examples of sensitisation. *A: behavioural; viscero-motor responses to bladder distension seven days after bladder inflammation (red). B: afferent fibres; increased responses to bladder distension of a detrusor afferent fibre after 5-min inflammatory soup exposure (red, 99). C: DRG soma responses before and after (red) cyclophosphamide exposure. D: ionic current before and after cyclophosphamide exposure – TTX-r: current resistant to tetrodotoxin. E: human psychophysics; intensity (top) and unpleasantness (bottom) scores during bladder filling in healthy subjects and IC/PBS patients. *2.2. Bladder Nociception – Mechano-reception***.**

Most studies of bladder afferents focused on mechano-sensitivity and multiunit recordings of afferent fibre responses to bladder distension were first reported in the 1930s (63,64). Most afferent fibres in the pelvic and hypogastric nerves responded to bladder distension. For afferent fibres with high response thresholds, it was suggested their function was related to painful sensations. Subsequently, it was proposed that pelvic nerve bladder afferents responsive to detrusor contractions and distension were tension-sensing afferents “in series” with detrusor smooth muscle and associated primarily with regulatory reflexes (53).

Subsequent studies in cats (65-69) led to promotion of a functional distinction between Aδ- and C-fibre bladder afferents. Aδ-fibre mechano-sensitive afferents, mostly associated with the pelvic/sacral bladder innervation, responded to both bladder distension and detrusor contractions. These mechano-sensitive afferents had low response thresholds and slowly adapted to phasic increases of wall tension from either active detrusor contraction or passive bladder filling/distension. Because of their mechano-sensitivity and low thresholds for response, they were assumed to be in series with bladder detrusor muscle and associated with voiding. In contrast, C-fibre bladder afferents were mostly mechano-insensitive or chemo-sensitive (e.g. to capsaicin, 300 mM-K^+), and thus had a nociceptive function. Consistent with this, those C-fibre afferents that were mechano-sensitive tended to have higher response thresholds (25-30 mmHg) to filling.

The association of bladder function with axon myelination and conduction velocity in cats was not found in rodents. In rats, *in vivo* recordings from lumbosacral dorsal roots, from which fibre bundles were teased to record from individual bladder afferents, documented mechano-sensitive Aδ- and C-fibre pelvic nerve afferents with low or high thresholds for response to bladder distension (60,70,71). Most (70%-80%) distension-responsive afferents had response thresholds in the physiological range (<5 mmHg); the remainder had high response thresholds (~25-30 mmHg), in the noxious range (Figure 3). Bladder afferents that responded to very noxious urinary bladder distension (80 mmHg) included unmyelinated C-fibres (mean conduction velocity 1.8 $m.s^{-1}$) and thinly myelinated Aδ-fibres (mean conduction velocity 8.1 $m.s^{-1}$) (60,70). Both low and high threshold afferents, demonstrated slowly-adapting responses during phasic isotonic distension or slow bladder filling. Afferent discharge frequency increased monotonically during phasic isotonic bladder distension. During slow bladder filling, afferent activity more closely correlated with increases of intravesical pressure. Evidence of a significant proportion of stretch/distension-responsive bladder afferents with high response thresholds was proposed to confirm the existence of bladder mechano-nociceptors. This has also been documented in other visceral organs and in different species (10). However, when it was established that low-threshold mechano-sensitive afferents in the bladder and other visceral organs (stomach, colon) sensitised (see below), the notion that high threshold afferents are “the” bladder/visceral nociceptors was reassessed.

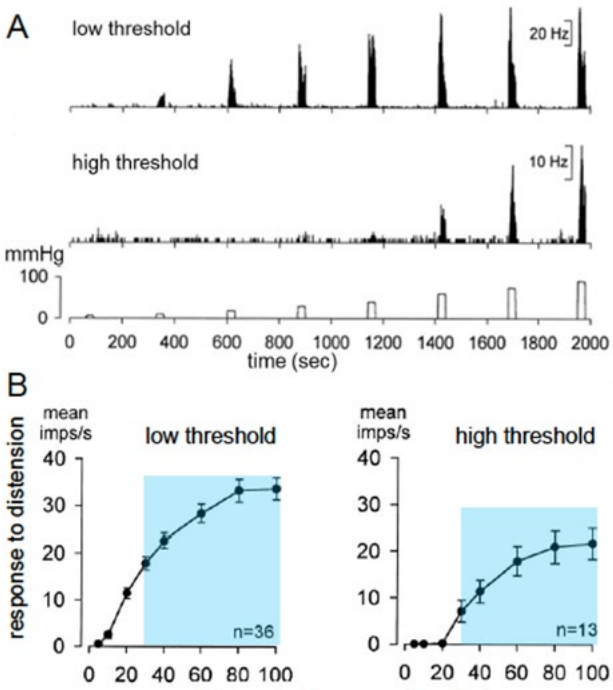

Figure 3. Responses of mechano-sensitive rat bladder pelvic nerve afferents. *A: examples of a low threshold and high threshold afferents to bladder distention (5-100 mmHg, 30 s each at 4-min intervals). B: mean stimulus-response functions of low- and high-threshold afferents with mean extrapolated response thresholds of 6.0±0.5 mmHg and 31.1±1.2 mmHg. Shaded areas represent the range of noxious intensities of bladder distension: note the greater magnitude responses of low- relative to high threshold afferents. Adapted from (70).*

Studies in mice and guinea pigs subsequently characterised mechano-sensitive classes of bladder afferents and clarified their ability to sensitise. With an *ex vivo* flat-sheet urinary bladder preparation with nerves attached, fine filaments can be teased to record from single afferent fibres. Four functionally distinct mechano-sensitive afferent types have been characterised. In the guinea pig, bladder afferent fibre recordings distal to the pelvic ganglia (thus including afferents in both the lumbar splanchnic/hypogastric and pelvic nerve innervations) were classed as: i) muscle mechano-receptors responding to bladder stretch, with low or high response thresholds; ii) tension-mucosal afferents responding to both stretch and mucosal stroking with monofilaments; iii) mucosal mechano-receptors responding only to mucosal stroking; iv) chemoreceptors responding mucosal application of acid (pH 4), high-K (50 mM), or in about 25% of fibres to capsaicin (3 μM) (72,73).

With a similar mouse preparation, four functionally distinct mechano-sensitive afferent types were also characterised in the lumbar splanchnic/hypogastric nerve (LSN) and in pelvic nerve (PN) bladder innervations (61). Here, with the urothelial side facing up, all afferents responded to probing with monofilaments. In the LSN bladder innervation, fibre types were classed as muscular/urothelial, muscular, or serosal; in the PN innervation, the same fibre types were found, as well as endings that responded to urothelial stroking (Figure 4). Of interest, there were significant differences between

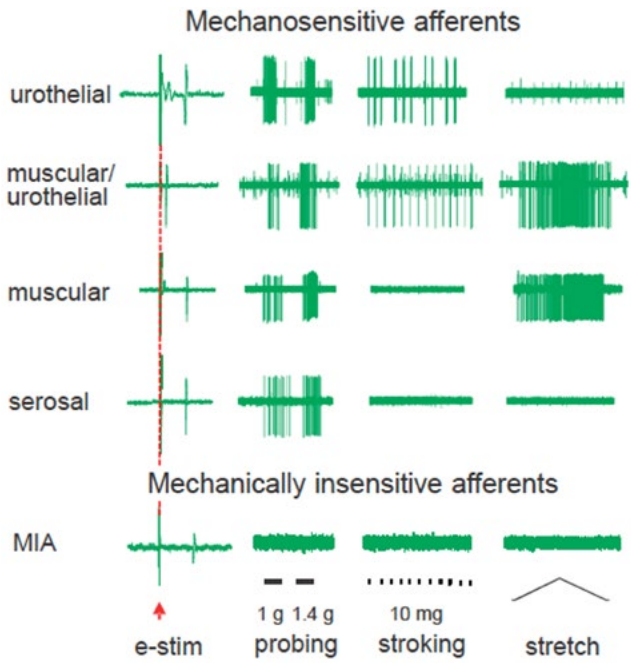

Figure 4. Classes of afferent endings in the mouse bladder. *Endings located by electrical stimulation of a bladder sheet, urothelial side up (e-stim; left column; red arrow, vertical line stimulus artifacts). Classes based on responses to different mechanical stimuli. All mechano-sensitive endings responded to blunt vertical probing by 0.4-1.4 g monofilaments. Urothelial endings also activated by stroking the urothelial surface (10 mg). Muscular/urothelial endings additionally activated by stroking and circumferential stretch (0-170 mN, 35 s). Muscular endings also activated by circumferential stretch. Serosal endings activated only by blunt probing. MIA (mechanically insensitive afferents) endings did not respond to any mechanical stimuli. From Feng B and Gebhart GF, unpublished.*

the two innervation pathways of the mouse bladder with respect to the topographical distribution of receptive fields on the bladder sheet and in the proportions of afferents that responded to these different stimuli.

LSN afferent endings typically had a single, small (typically 0.5 mm) punctate receptive field, clustered at the base of the bladder, from which responses could be reliably evoked. Muscular afferents, which comprised 30% of the LSN mechano-sensitive fibre types, responded to probing and to stretch but not to urothelial stroking. A small (3%) proportion of LSN afferent endings were designated muscular/urothelial because they responded to stroking of the urothelium, and also to graded bladder stretch. No 'urothelial' afferent endings were found in the bladder LSN innervation. The largest proportion (67%) of LSN afferent endings were designated as serosal; they had receptive fields that were reproducibly activated in a graded fashion only by perpendicular, blunt monofilament probing of the bladder sheet and not by bladder stretch or urothelial stroking.

With the PN bladder innervation the four types of afferents from their receptive fields (urothelial, muscular/urothelial, muscular and serosal: Figure 4) also had single, punctate fields. Muscular afferents (63% of fibres) that responded to graded bladder stretch, but not urothelial stroking, were the most common fibre type. Muscular/urothelial PN afferents (14%) responded to both urothelial stroking and graded bladder stretch. A similar proportion of PN afferents (14%) responded only to probing of their receptive field and were classed as serosal afferents. The fourth class of PN afferents (9%) were classed as urothelial afferents as they were responsive only to stroking of their receptive fields. Unlike LSN afferents, PN afferent receptive fields were distributed throughout the bladder (Figure 5). However, none of the PN urothelial afferents had receptive fields at the base of the bladder, where most LSN mechano-sensitive receptive fields were located. These differences in the topographical distribution of LSN and PN receptive endings in the mouse bladder are consistent with the anatomical distribution of LSN and PN terminals in the cat bladder. In the cat bladder it was found that PN/sacral axons were distributed equally to all areas of the bladder whereas LSN/lumbar axons were most numerous in the trigone (74-76). With respect to response thresholds to bladder stretch, 64% of PN mus-

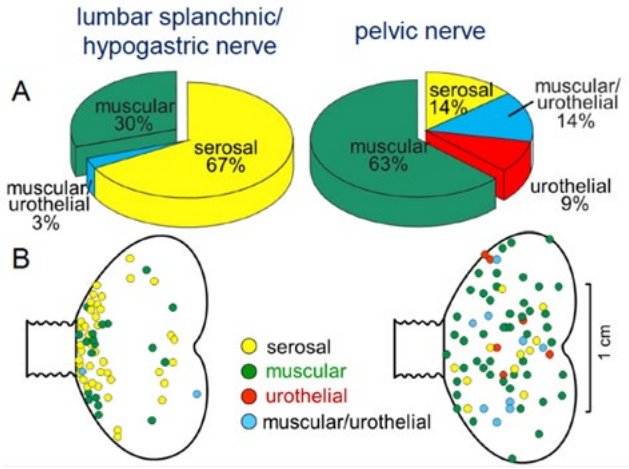

Figure 5. Mechano-sensitive lumbar splanchnic/hypogastric and pelvic nerve bladder mouse afferents. *A: Proportions of different classes. B: Topographical distribution of receptive endings. Adapted from (61).*

cular afferents had low response thresholds, two-thirds of which encoded stretch over the range of applied loads (61). The residual one third were 'non-encoding'; i.e., response magnitude to stretch did not increase as the applied load was augmented. PN muscular afferents with high response thresholds to stretch (36% of the sample) encoded stretch throughout the range of applied loads. There was no differential topographical distribution of receptive endings on the bladder sheet between low and high threshold muscular PN afferents.

An underlying assumption about the dual innervation of internal organs is that different innervation pathways communicate unique aspects of afferent transmission, both sensory and non-sensory. The foregoing comparisons between afferent responses to identical stimuli in LSN and PN pathways innervating the bladder reveals that there is some overlap, as well as distinct differences in functionality between these pathways - see also with the mouse colon (77). It is apparent that all afferent types in both pathways encoded the intensity of stimulation. The bladder PN pathway is primarily comprised of stretch responsive low and high threshold muscular and muscular/urothelial endings distributed throughout the bladder (77% of all afferents, 61). By contrast, the bladder LSN pathway is primarily comprised of 'serosal' endings (67%) that respond only to blunt probing; with receptive endings clustered mostly near the bladder base. The designation "serosal" is not a histological assignment; it simply denotes a mechano-sensitive ending for which a potential function is not apparent. About 10% of the PN innervation were classed as urothelial; no urothelial afferent endings were found in the LSN innervation.

PN afferent endings were detected using a search strategy of focal electrical stimulation and their receptive fields noted (77). These were subsequently tested for mechano-sensitivity using probing, stretch and stroking stimuli. The proportions of muscular/urothelial (20%) and urothelial (9%) afferent endings (Feng B, Gebhart GF, unpublished data) were comparable to proportions where mechanical probing was the search stimulus (61). The proportion of muscular afferents (37%) was less and of serosal afferents (30%) was greater than previously reported (61). Endings that did not respond to these mechanical stimuli were called mechanically insensitive afferent (MIA) endings (Figure 4). MIAs constituted 5% of the total, 37.5% of which were Aδ-fibres; this is smaller than the proportion (~25%) in the LSN and PN innervations of the mouse colorectum (77).

2.3. Bladder Nociception - Chemoreception.

Fewer studies have examined chemical activation of bladder afferents. Additionally, these studies have often been models of bladder inflammation without attention to nociception. Bladder afferent endings contain neuropeptides, including substance P and CGRP, and also express a wide variety of voltage-gated and ligand-gated receptors, including the capsaicin activated transient receptor potential vanilloid receptor 1 ($TRPV_1$), the mustard oil activated transient receptor potential ankyrin 1 receptor ($TRPA_1$), the nerve growth factor receptor tyrosine kinase A (TrkA), and adenosine triphosphate (ATP) activated purinergic receptors (P2X, P2Y). Accordingly, these and other substances have been used to interrogate bladder afferent chemosensitivity.

With *in vivo* cat studies, low and high threshold mechano-sensitive afferents in the pelvic/sacral innervation of the bladder are also responsive to intravesical instillation of mustard oil or turpentine oil, which also led to spontaneous activity and a change in mechano-sensitive properties (78,79). In a succeeding study, it was shown that mechano-sensitive pelvic/sacral bladder afferents were activated at short latency by intravesical instillation of mustard oil or turpentine oil. Thus, a large proportion of mechano-sensitive pelvic/sacral bladder afferents are also chemo-sensitive (80). Subsequently, in a rat study, whereas bladder filling with isotonic NaCl increased multiunit afferent hypogastric nerve activity two-fold, there was a five-fold increase with isotonic KCl infusion (32). In contrast, pelvic nerve bladder afferents exhibited no chemosensitivity as responses to NaCl and KCl bladder infusions did not differ.

With a guinea pig preparation, the chemo- and thermo-sensitivity of two classes of low-threshold mechano-receptors (stretch-responsive muscular/urothelial afferents; and stretch-insensitive urothelial afferents), as well as high-threshold, stretch-responsive afferents were compared (81,82). With low threshold stretch-responsive afferents serotonin (100 μM) and bradykinin (10 μM) and a high concentration of the $TRPA_1$ receptor agonist, allyl isothiocyanate (AITC, 100–300 μM) activated sub-populations of afferents. However, capsaicin (3 μM), substance P (100 μM), prostaglandin E2 (10 μM), H_2O_2 (300–1000 μM), or low pH solution (pH 4) were without effect. Heated Krebs (46-65°C) activated about 50% of afferents tested. With low threshold stretch-insensitive afferents virtually all (95%) responded to heated Krebs, capsaicin and bradykinin, but were unresponsive to serotonin, substance P, and prostaglandin E2 at the same concentrations as above. With high-threshold, stretch-responsive afferents capsaicin (3 μM) excited 86% of fibres, of which most were also activated by H_2O_2, or AITC. H_2O_2-induced activation was significantly attenuated by the $TRPA_1$ receptor antagonist HC-030031, but not by a $TRPV_1$ receptor antagonist.

Purinergic signalling in the bladder has long been a topic of interest. Exogenously applied or endogenously released ATP, acting on P2X ligand-gated ion channels is excitatory and mediates non-cholinergic bladder contractions (83). During bladder distension, ATP is released from urothelial cells to act on P2X-expressing bladder afferent endings below the urothelium where ATP is thought to signal changes in fullness, as well as pain (84). In an *in vitro* mouse bladder PN preparation, intravesical application of the P2X receptor agonist α,β-methylene ATP (ABMA; 0.03–1 μM) increased multifibre discharges and both low and high threshold PN afferent fibre responses to bladder distension in a receptor-selective manner; the effects of ABMA were antagonised by the $P2X_3$-$P2X_{2/3}$ receptor antagonist 2'(or 3')-O-(2,4,6-trinitrophenyl)-ATP (TNP-ATP; 85).

Responses of bladder thoracolumbar (TL) and lumbosacral (LS) afferent DRG somata to purinergic agonists, low pH and capsaicin were compared (86). The majority of LS neurons (93%) but only 50% of TL neurons responded to ABMA; most LS and TL bladder neurons also responded to low pH (>75%) and capsaicin (>90%). Most TL (85%) and LS (61%) DRG somata bound isolectin B4 (IB4) - a marker for neurons associated with unmyelinated C-fibre axons - consistent with reports that >90% of LSN bladder afferents and 50-70% of PN bladder afferents conduct in the C-fibre range (26,60,87). Although purinergic signalling in the bladder has been well-documented in rodents, its contribution in humans, particularly with respect to nociception, has yet to be confirmed. However, it may play a role in those with pathological bladder conditions (e.g., detrusor overactivity, interstitial cystitis; 83). It is noteworthy that mRNA for the $P2X_3$ receptor is expressed in ~70% of mouse bladder DRG somata (88) and its expression is highly correlated between human and mouse DRG somata (89). This suggests that the $P2X_3$ receptor is a reasonable target for drug development (see also below).

Importantly, these studies of bladder mechano-sensitive afferents reveal a variety and mixture of sensitivities with respect to mechan-

ical, chemical and thermal modes of activation. Low- and high-threshold stretch/distension-sensitive bladder afferents exhibit mixed chemical and/or thermal sensitivities, revealing significant heterogeneity with important clinical implications. It is important also to realise that afferent sensitisation to mechanical activation also leads to sensitisation by other modalities. Thus, modest acidification of urine, for example, may stimulate sensitised low-threshold mechano-sensitive afferents when such a chemical intervention would otherwise have no effect.

2.4. "Silent", Mechanically Insensitive Endings.

Silent (or sleeping) afferents more accurately designated as mechanically-insensitive afferents (MIAs, 90), constitute a significant proportion of the afferent innervation in many tissues. MIAs acquire mechano-sensitivity after tissue insult and are important contributors to the development and maintenance of hypersensitive states (e.g., UCPPS) and were first characterised in the knee joint of the cat (91). These endings are electrically excitable but insensitive to mechanical stimulation. After experimental inflammation of the knee joint, however, they became spontaneously active and acquire mechano-sensitivity. MIAs have been reported in the visceral innervation, but because mechanical search stimuli were employed in these studies, the designation MIA was inferred p*ost hoc* by their appearance in electrophysiological recordings following an inflammatory or chemical insult to the tissue (92-95). In the cat, following *in vivo* bladder filling with irritants, the estimated proportion of bladder MIAs ranged greatly, between 6 and 97% (78,79,80). An unbiased electrical stimulation search strategy to locate receptive endings in the mouse colorectum found that that MIAs comprised 23-33% of the PN and LSN innervations (77). An unpublished study of the mouse urinary bladder, also using an unbiased electrical search strategy, found a much smaller proportion of MIAs in the PN bladder innervation (5%). For reference, the proportion of C-fibre MIAs in human skin is ~24% (96). The differences in estimated proportions of bladder MIAs summarised here may reflect how bladder afferents were studied (e.g., *in vivo* bladder filling with irritants), species differences (cat *vs* rodents), or that the urinary bladder simply differs from other organs/tissues.

The chemosensitivity of MIAs is usually associated with irritant chemicals or tissue inflammation related to MIA sensitisation, and thus acquisition of mechano-sensitivity. A recent study, using an optogenetic strategy to examine the contribution of action potential initiation to afferent encoding, described two distinct chemo-sensitive populations of PN MIAs in the mouse colo-rectum (97,98). MIA endings were stimulated and then tested for activation/sensitisation by application to the receptive ending of an inflammatory soup (IS, containing bradykinin, serotonin, histamine and prostaglandin E2 in pH 6.0 Krebs solution, 99) and/or an osmotic stimulus (acidic hypertonic solution (AHS); pH 6.0, 800 mOsm.l^{-1}). Both interventions activated and sensitised MIAs. The optogenetic strategy revealed that IS-sensitive and AHS-sensitive MIAs represent two discrete afferent groups: one group was inflammation-sensitive and the other osmo-sensitive.

A different approach was used to characterise in mouse DRG a subset of peptidergic MIA somata. Specifically, retrogradely labelled bladder DRG somata that expressed the nicotinic acetylcholine receptor alpha-3 subunit (nAChRα3) were sensitised by the inflammatory mediator nerve growth factor (NGF) and mechanically-activated currents recorded by whole-cell patch-clamp (100). The underlying reasoning in this study was that mechanical stimuli applied incrementally to the cell soma by the patch pipette was equivalent to mechanical stimuli applied to receptive endings in the bladder and thus sufficient to classify DRG somata as "mechano-insensitive 'silent' nociceptors". nAChRα3-expressing DRG somata accounted for up to 40% of the CGRP-immuno-positive somata population in T12-L1 and L6- S1 DRG, from which the lumbar splanchnic/hypogastric and pelvic nerves that innervate the bladder are derived, respectively. It was concluded that mechano-insensitive nAChRα3-expressing afferents account for ~50% of all peptidergic somata innervating the bladder (and colon) and after sensitisation, the mechanically-gated ion channel Piezo2 mediates NGF-induced mechano-sensitivity.

2.5. Contemporary Research Approaches.

Newer optogenetic and molecular profiling strategies have been applied to study urinary bladder afferents and their function. An optogenetic approach bypasses the process of transduction of stimulus energy (mechanical, thermal, chemical) and focuses on the process of action potential initiation at the receptive ending. Archaerhodopsin (Arch), a light-activated proton pump, hyperpolarises neurons in which it is expressed when activated by a specific wavelength of green light to an extent sufficient to suppress neuronal firing. This optogenetic approach was employed to target bladder afferent neurons by expressing Arch in a sensory neuron-specific Cre BAC transgenic mouse line, where Cre is under the regulation of SCN10A (Na^+ channel Nav1.8) promoter elements. Optogenetic Arch-induced inhibition of mouse bladder afferents suppressed the bladder distension-provoked visceromotor response (a nociceptive guarding response) and significantly increased detrusor inter-contraction intervals (101). Light activation of Arch also reduced both ongoing nociceptive behaviour, as well as referred cutaneous hypersensitivity in mice with experimentally induced cystitis. In a related study, light-activated excitatory channel rhodopsin-2 (ChR2) was expressed in two distinct populations of afferent neurons: Nav1.8-positive neurons (as above) and $TRPV_1$-lineage neurons (102). Excitatory stimulation of ChR2-expressing bladder afferent terminals by blue light significantly increased viscero-motor responses to bladder distension in both transgenic mouse lines and produced phasic detrusor contractions in the Nav1.8/ChR2 mouse line. However, it must be appreciated that nociceptors are not selectively targeted by this approach (102) and not all mouse bladder C-fibre afferents express the Nav1.8 sodium channel. In addition, nearly one-third of sensory neuron specific-Cre lineage neurons express a neurofilament protein (NF200) present in myelinated Aδ-fibres (103) and are not targeted by Nav1.8 or $TRPV_1$ promoters. Thus, interpretation of results with respect to nociception *per se* requires additional validation.

With a different approach, a recent study examined 32 selected genes expressed in thoracolumbar and lumbosacral mouse bladder DRG somata to assess their potential role in bladder function and bladder nociception (88). The genes chosen for study were based on their previously-validated roles in stimulus detection (e.g., TRP receptors, mechano-sensors, purinergic receptors, acid-sensing ion channels, cytokine receptors) or neuronal excitability (opioid receptors, neuropeptides, Na^+ channels). The objective was to correlate the molecular phenotype of individual neurons, or clusters of neurons, with the physiological properties of their afferent endings (responses to mechanical and/or thermal stimuli, nociceptive signalling). From retrogradely labelled bladder DRG somata and single-cell qRT-PCR, bladder DRG somata were sorted into distinct clusters (peptide, non-peptide, neurofilament expressing thoracolumbar [TL], lumbosacral [LS] or mixed TL/LS clusters). The principal conclusion was that bladder afferents from different portions of the neuraxis have overlapping functions, consistent with the earlier literature.

Currently, such contemporary research approaches, all using mouse models, do not provide coherent results with respect to targets and nociception. Because of the large number of genes expressed in DRG bladder somata, as well as genes not included for evaluation, it is unclear at present if afferent function based on molecular characteristics of the cell soma can be reliably defined, but improvements in bioinformatic analysis may improve this situation.

3. BLADDER SENSITISATION

Virtually all chronic pain conditions are associated with increased sensitivity to multiple modalities of natural and applied stimuli. In such visceral pain states, sites to which sensation is referred exhibit characteristic hypersensitivity; reduced thresholds to applied stimuli, often with complaints of discomfort to normally non-painful palpation; referred sensation areas are increased in size. More broadly, patients suffering from chronic pelvic pain conditions (bladder pain syndrome, primary dysmenorrhea, non-bacterial prostatitis) experience generalised somatic hypersensitivity and enhanced negative perception of both innocuous and noxious stimuli. Underlying bladder hypersensitivity is increased neuron excitability (sensitisation), initially localised to afferent endings in the bladder but rapidly including spinal and then supra-spinal neuronal excitability. There is considerable evidence that ongoing, persistent afferent input often contributes to maintenance of chronic visceral pain states.

3.1. Afferent/Cellular Sensitisation.

As indicated above, sensitisation represents a change in neuronal excitability that is expressed and evident at both the cell soma and afferent ending. Mechano-sensitive bladder afferent sensitisation has been documented in cat, rat, and mouse. In the cat, intravesical instillation of 2.5% mustard oil initially (30 min) sensitised pelvic/sacral mechano-sensitive afferents to bladder distension, after which (120 min) afferent responses were desensitised (80). In studies with rats, responses to bladder distension of pelvic nerve afferents from the L6 and S1 dorsal roots were recorded before, 30 min after intravesical exposure to 10% DMSO, and then again after filling the bladder with a solution of human recombinant NGF in DMSO (104). Nearly all myelinated Aδ-fibre afferents and ~50% of unmyelinated C-fibre afferents were mechano-sensitive, responding to graded distension of the bladder (0-60 cm H_2O) at low pressure thresholds in the innocuous range and encoding responses into the noxious range. Within 30 min after NGF instillation, most mechano-sensitive Aδ- and C fibre afferents were sensitised (response threshold was reduced, and response magnitude increased) that persisted up to 3 hr. Furthermore, some afferents, initially unresponsive to bladder filling, developed mechano-sensitivity. Similarly, intravesical instillation of xylene or mustard oil into the rat bladder sensitised responses of pelvic nerve afferents in the L6 dorsal root to bladder distension with isotonic fluids (70).

In addition to establishing purinergic chemo-sensitivity of mouse bladder mechano-sensitive pelvic nerve afferents (85), responses to bladder distension of almost all high threshold afferents and most low threshold afferents were sensitised after intravesical instillation of 1mM ABMA. As noted above (11), afferents that did not respond initially to bladder distension did so after exposure to ABMA. In a study of muscle, stretch-sensitive PN mouse bladder afferents (61), sensitisation to bladder stretch was tested by applying directly an inflammatory soup (IS, 99) to the receptive ending. The response magnitude to stretch of both low (encoding) and high threshold PN muscle afferents increased significantly when tested five minutes after washout of the IS, and the response threshold of high threshold muscle afferents decreased (see examples in Figure 6). Sensitisation to stretch was selective in that responses to monofilament probing of the same afferent endings were not sensitised by application of IS. In addition, about 60% of muscle PN afferents tested responded directly to application of IS, revealing chemosensitivity to one or more component chemicals.

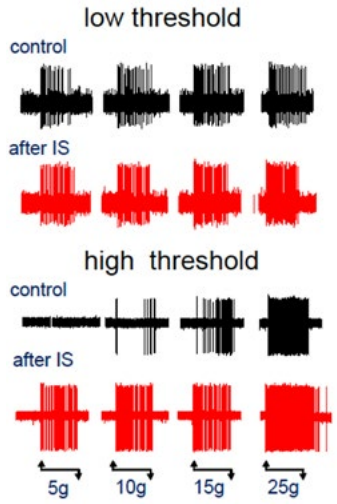

Figure 6. Sensitisation of mouse low- and high-threshold pelvic nerve bladder afferents. *Sensitisation (red) after 5-min exposure to an inflammatory soup (99) applied directly to the receptive ending. Adapted from (61).*

An alternative approach to bladder sensitisation showed afferent sensitisation in the absence of bladder inflammation (105). Bladder permeability was increased by *in vivo* instillation of protamine sulphate (100 µl, 1 $mg.ml^{-1}$) and PN multiunit responses to bladder filling were examined 1, 7, and 28 days after treatment. One day after treatment, mechano-sensitive PN bladder afferents were sensitised to bladder filling, the activation threshold of afferents was decreased and afferent peak firing rates increased. In particular, only low-threshold afferents were sensitised, and sensitisation was no longer apparent 7 or 28 days after instillation. It was further concluded that MIAs were not recruited by protamine sulphate treatment, leading to the hypothesis that such bladder afferent sensitisation is functionally distinct from inflammation-induced bladder sensitisation.

In studies of rat bladder DRG somata, identified by retrograde tracer injection, cellular properties and P2X receptor involvement were examined after bladder inflammation, induced by cyclophosphamide (CYP) (106). Neuronal excitability, spike frequency during current injection and current density, were all significantly increased in both thoracolumbar (TL) and lumbosacral (LS) bladder DRG somata after CYP treatment. Peak inward current, as well as the proportion of TL neurons (>80%) activated by purinergic receptor agonists, were also increased. In addition to sensitising bladder neurons, bladder inflammation also led to a selective increase in the functional expression of heteromeric $P2X_{2/3}$ and homomeric $P2X_3$ receptors in LS and TL bladder neurons, respectively (Table 1).

In a related study with mouse bladder DRG somata (107), CYP-induced bladder inflammation also significantly increased mouse LS and TL bladder neuron excitability. However, in contrast to the rat study, no bladder DRG somata from CYP-treated mice exhibited spontaneous activity. Moreover, whilst inward currents generated by purinergic agonists are changed in both rat and mouse bladder

Table 1. ABMA-evoked currents and P2X transcripts in bladder DRG somata

	current type	Saline-treated	CYP-treated
Rat LS somata (n=52 sal, 56 CYP)	slow	87%	100%
	fast	6%	0%
Rat TL somata (n=27 sal, 44 CYP)	slow	15%	9%
	fast	22%	43%
Mouse LS somata (n=28 sal, 24 CYP)	slow	100%	100%
	fast	0%	0%
Mouse TL somata (n=22 sal, 29 CYP)	slow	73%	79%
	fast	27%	21%
Mouse P2X transcripts			
	LS P2X2 only	6.7 ± 3.8%	14.0 ± 7.3
	LS P2X2/3	82.2 ± 2.2%	76.8 ±9.8
	LS P2X3 only	4.5 ± 2.2%	4.6 ± 2.3%
	TL P2X2 only	0	0
	TL P2X2/3	51.2 ± 8.0	73.3 ± 6.7
	TL P2X3 only	49.8 ± 8.0	26.7 ± 6.7

Proportions of bladder DRG somata with slowly (slow) and rapidly desensitising (fast) inward currents on ABMA exposure. Slow currents associated with heteromeric P2X2/3 receptors; fast currents with homomeric P2X3 receptors. "n" is number of DRG somata in lumbosacral (LS) and thoracolumbar (TL) DRG from saline (sal)- and cyclophosphamide (CYP)-treated rats and mice. The bottom part of the table presents the proportions of P2X receptor transcripts in mouse bladder DRG somata. Each group consisted of 45 bladder LS and TL DRG somata. Adapted from (106,107). The vertical connector in the top of the table indicates the difference of slow currents in rats and mice. Note the significant increase in the proportion of rat TL DRG somata exhibiting a fast current with CYP treatment (red arrow) and the absence of change in mice TL counterparts (black arrow). The vertical connector in the bottom part of the table shows the difference in P2X3 transcripts between LS and TL mouse DRG somata.

DRG somata after CYP-induced bladder inflammation, they are associated with different P2X receptor subunits and also different bladder afferent pathways.

The differences between rat and mouse bladder neurons with respect to P2X receptor gene transcripts and purinergic-evoked inward currents reinforces differences between rats and mice with respect to electrophysiological properties of urothelial and non-urothelial L6-S1 DRG somata (46,47). This raises questions about which, if either, rodent species best represents bladder physiology and pharmacology in humans. As previously stated, the contribution of purinergic signalling in humans with respect to the lower urinary tract is uncertain at present. The broader issue about translation of research data obtained in non-human animals to humans is discussed further at the end of this section.

3.2. Cross-organ Sensitisation.

Cross-organ sensitisation represents a different, indirect mode of sensitisation (i.e. the bladder is not the primary afferent sensitiser) and has significant implications for understanding and managing chronic pelvic pain conditions. Potential mechanisms underlying cross-organ sensitisation have been considered elsewhere (38,108,109) and will not be discussed at length here. Rather, the focus will be on sensitisation of bladder afferents initiated by events in other pelvic organs (e.g., colon to bladder, prostate to bladder, and uterus to bladder cross-sensitisation).

Colon-to-bladder. It has been appreciated for some time that patients with irritable bowel syndrome (in the absence of a diagnosis of endometriosis) complain of genitourinary problems and exhibit signs of bladder overactivity, including nocturia, frequency and urgency (110-112). Experimentally, colorectal irritation in rodents (43-45) induces increased contraction frequencies, reduced inter-contraction intervals and altered micturition reflexes.

In the rat, colorectal inflammation sensitises bladder function and bladder afferents. One hour after intracolonic instillation of trinitrobenzenesulphonic acid (TNBS), responses of PN C-fibre bladder afferents were significantly enhanced at distending pressures ≥30 mmHg, as were responses to administration of intravesical capsaicin, bradykinin, and substance P (113). In a subsequent study of rat PN bladder afferents three days after intracolonic instillation

of TNBS, enhanced afferent fibre responses to bladder distension were accompanied by mast cell infiltration and raised neuropeptides in the bladder, a further implication of colon-to-bladder sensitisation (114). In a behavioural study of rats 10 days after intracolonic instillation of TNBS, nociceptive behaviours attributed to the lower urinary tract were significantly increased, consistent with colon-to-bladder and colon-to-urethra cross-sensitisation by C-fibre afferent pathways (115). Similarly, in the mouse, the micturition reflex was significantly altered (increased voiding frequency) seven days after intracolonic instillation of TNBS (45). Non-visceral somatic hypersensitivity was also evident as responses to mechanical and thermal stimulation of both hind paws were sensitised. In a study of retrogradely labelled rat bladder afferent somata in lumbosacral DRG, colonic inflammation enhanced both the peak amplitude of a tetrodotoxin-resistant Na^+ current (see example Figure 2D) as well as neuronal responses to capsaicin, revealing increased excitability of bladder somata (116).

Prostate-to-bladder. Bladder sensitisation is also associated with other pelvic organs but has not been studied as extensively. For example, chronic non-bacterial prostatitis is characterised by genitourinary pain in the pelvic region. Greater than 90% of such patients report urological pain or discomfort associated with urinary symptoms and/or sexual dysfunction, revealing that the bladder is the main organ affected by prostatitis (117). A peripheral, afferent component associated with prostate-to-bladder sensitisation has been documented in rodents. In the mouse, prostate inflammation induced significant up-regulation in the bladder of pro-inflammatory and anti-inflammatory cytokines, NGF (nerve growth factor), as well as T-lymphocyte markers FoxP3, CD4 and CD8 (42). Prostatitis also produced significant functional changes and sensitisation of bladder afferents. After injection of zymosan into the dorsal lobe of the mouse prostate to generate inflammation, bladder function and PN afferent responses to bladder distension were measured after 7-28 days. Cystometry revealed increased bladder contraction frequency that persisted for the 28 days of testing. Similarly, visceromotor responses to bladder distension were significantly enhanced after prostate inflammation (Figure 7C) as were responses of PN afferents (Figure 7A), characterised by an increased response magnitude and a decreased response threshold. Normally, 20-25% of mechano-sensitive PN bladder afferents have high thresholds for response to stretch, but this proportion progressively decreased after generation of prostatitis (with a phenotypic switch from high to low threshold afferents; Figure 7B). In a rat model of non-bacterial prostatitis, produced by 5% formalin injection into each ventral lobe, prostate-to-bladder sensitisation was assessed by examining bladder activity and the functional properties of L6-S1 retrogradely labelled afferent bladder DRG somata (41). Bladder inter-contraction intervals were significantly decreased and the number of non-voiding contractions during the storage phase were increased. Whole-cell patch-clamp recordings confirmed hyperexcitability of bladder and dichotomised afferent somata (prostate and bladder double-labelled somata; see example in Figure 8) after prostate inflammation. Sensitisation was more robust in double-labelled DRG somata than in somata labelled only from the bladder, ascribed to be related to "direct" *vs* "indirect" sensitisation mechanisms.

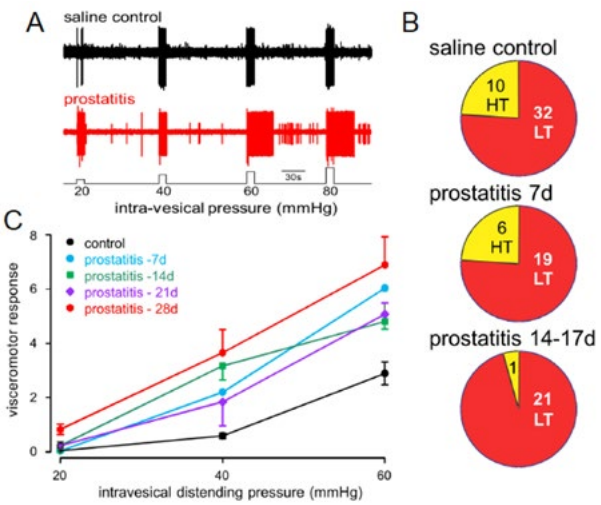

Figure 7. Prostatitis: sensitisation of bladder afferents and visceromotor responses after experimentally-induced prostatitis in the mouse. *A: representative pelvic nerve bladder afferent responses to bladder distension 7-10 days after intra-prostate saline or inflamogen (zymosan) injection. B: Numbers of low-threshold and high-threshold stretch-sensitive pelvic nerve bladder afferents from control and prostatitis (zymosan-treated for 7- or 14-days) mice. C: bladder visceromotor responses (normalised to control) at three distending pressures during zymosan-induced prostatitis. Adapted from (42).*

Uterus-to-bladder. Uterus-to-bladder cross-sensitisation is evident from the coexistence of UCPPS in women with dysmenorrhoea. Even in the absence of overt bladder pain syndrome, women with dysmenorrhoea experience bladder pain hypersensitivity (118). About 25% of women with dysmenorrhoea, when challenged by a non-invasive oral water ingestion test (118), reported bladder pain nearly as severe as those diagnosed with bladder pain syndrome (119); they also reported widespread non-visceral somatic hypersensitivity. The self-stated severity of their menstrual pain was predictive of the bladder pain evoked by water ingestion. They also reported more non-menstrual pain, including reduced vaginal pressure thresholds, dysuria, and dyspareunia. These findings of unappreciated bladder hypersensitivity in women with dysmenorrhoea suggest that an easy-to-administer water ingestion test may identify those at greater risk for development of UCPPS, and this provides an opportunity to examine whether early intervention could modify that risk (6,120,121). There is relatively little non-human experimental evidence at present regarding uterus-to-bladder afferent cross-sensitisation. It has been reported that two hours after administration of mustard oil into the rostral part of the right uterine horn, plasma extravasation in the bladder was significantly increased (108). Of interest, uterine horn-to-bladder cross-organ sensitisation occurred only in proestrus, not metoestrus, and sensitisation was absent with hypogastric nerve transection.

Dichotomising afferents. The potential contribution of so-called dichotomising afferents to cross-organ sensitisation is an appealing, but indeterminate underlying mechanism at present. The concept that dichotomising neurons (afferent endings of one DRG soma innervating two different tissues) contribute to referred visceral pain is not new (7,38). The concept re-gained currency with evidence from the primary afferent innervation of the rodent colon and bladder (122-124) and rodent prostate and bladder (Figure 8; 41,42,125). The reported proportions of double-labelled DRG somata range between 14-21% for colon and bladder and 7.5-18% for prostate and bladder. Given that the visceral innervation generally represents a relatively small proportion of all spinal afferents (5-10%; 10), and the proportion of dichotomising axons arising from DRG somata innervating the viscera comprise no more than a fifth of this fraction, only a limited role can be ascribed at present for dichotomising afferents in cross-organ sensitisation.

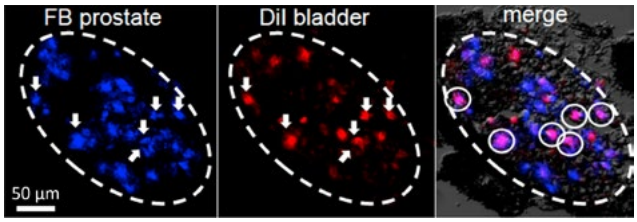

Figure 8. Dichotomising afferents. *Retrogradely-labelled somata in the same mouse L6 dorsal root ganglion (dashed line boundary). Left, fast blue label; middle, DiI label; right, merged image. Arrows in the left and middle panels identify somata that were labelled from both the prostate and bladder, circled in the right panel. From E Schwartz E, J-H La and GF Gebhart, unpublished.*

4. ADDITIONAL CONSIDERATIONS

4.1. What Constitutes a Visceral/Bladder Nociceptor?

Implied or explicitly stated in much of the literature on bladder afferents is that nociceptors are a component if not the focus of study. The conception and classification of an afferent receptive ending as a nociceptor derives from Sherrington's studies of stimuli that he described as "nocuous" (noxious) because they damaged or threatened damage to tissue and thus were "adequate" for the sense of pain (57,58). Specified as a receptive ending that responds to a noxious stimulus, the nociceptor was thus defined in a functional context (and not by axon myelination/conduction velocity, size of neuron somata, etc., although contemporary transcriptomic research approaches are clarifying the 'barcodes' of human nociceptors – see below). Two points of clarification are important: firstly, the tissue upon which Sherrington worked was skin; and secondly, Sherrington fully appreciated the distinction between pain (a conscious perception) and nociception (the neural process of encoding noxious stimuli). As the study of nociceptors grew, largely based on studies of skin, reconsideration of nociceptor properties, particularly visceral nociceptors, generated continuing discussion and debate, in part because the viscera had long been regarded as insensate (7,9,10). Subsequent clinical and experimental evidence documented the sensibility of the viscera and efforts continue to clarify the structural and functional basis of visceral sensation and pain.

Our view of what constitutes a visceral/bladder nociceptor has been informed by affirmation that afferent endings in the viscera/bladder possess two important, obligatory properties of nociceptors: 1; the ability to encode stimulus intensity into the noxious range and 2; to sensitise. Firstly, bladder afferents with low response thresholds to distension encode stimulus intensity well into the noxious range (Figure 3) and similar findings have been made in other tissues: e.g. group III (Aδ-fibres) and IV (C-fibres) skeletal muscle afferents (126); joint afferents (127), and C-fibre mechano-sensitive cutaneous afferents (128). Accordingly, despite existing definitions of nociceptors as high threshold sensory receptors, growing evidence establishes that the property of encoding into the noxious range is not limited to afferent endings with high response thresholds. Importantly, cutaneous, muscle, joint, and visceral mechano-nociceptors with low response thresholds are indistinguishable from non-nociceptor mechano-receptors, which do not encode stimulus intensity into the noxious range (61). Moreover, the slope of hollow organ visceral/bladder afferent encoding functions to organ distension is generally greater for low threshold afferents than for high threshold afferents. Similarly, the response magnitude to noxious intensities of bladder distension is greater for low threshold than for high threshold afferents (Figure 3B). Secondly, both low and high threshold visceral/bladder mechano-sensitive endings sensitise (Figure 6). In addition, spontaneous activity and previously ineffective stimuli may become effective (i.e. "adequate"), including other modalities of stimulation (chemical, thermal, etc.) as most visceral/bladder afferent endings are multi-modal in character. Collectively, these findings document that visceral/bladder nociceptors include those with thresholds for response in the physiological range. This is clinically relevant in patients with organ insult or inflammation as well as those diagnosed with so-called 'functional' disorders that exist in the absence of documentable organ pathology.

4.2. Translation of Research to Humans.

The broad issue about translation of research data obtained from non-human animals to humans requires consideration with respect to the relevance of what has been presented above. Regarding bladder afferents and nociception, the translation of results to humans requires consideration of the component parts of afferents: neuronal somata in DRG and receptive endings/afferent fibres.

Neuronal somata in the DRG. The use of dissociated DRG cell cultures to study nociceptive processing is based on two fundamental assumptions. The first assumption is that what is expressed and contained in the neuron soma is faithfully represented in the receptive ending, and this is generally accepted. The second assumption is that a dissociated cell culture represents *in vivo* conditions, and this is known to be incorrect. Moreover, the extent to which it is incorrect depends on many factors (culture medium, time in culture, presence of other cell types in the culture) that requires evaluation.

Furthermore, the above differences between rat and mouse bladder afferent DRG somata with respect to purinergic signalling and to the electrophysiological properties of urothelial and non-urothelial L6-S1 DRG somata raise concerns about which, if either, species better represents bladder physiology and pharmacology in humans. This is of considerable importance, given their widespread reliance as experimental animals. Initial studies suggested that gene expression of potential targets for development of analgesics was not dissimilar between mouse and human DRG somata. As noted above with respect to the $P2X_3$ receptor, the P2rx3gene is expressed in ~70% of mouse bladder DRG ganglion somata (88) and its expression correlates reasonably well in human and mouse DRG somata (89). This recent RNA-sequencing study of mouse and human DRG somata (89), found conserved enrichment of most transcription factors in mouse and human DRG somata, suggesting similarities between mouse and human. Accordingly, it was tentatively concluded that the mouse DRG was a reasonable model system for studying human DRG.

To return to the use of dissociated DRG cell cultures as model systems. It is appreciated that DRG somata removed and cultured acquire an injury-like transcriptomic phenotype. This is evident from the increased expression of genes associated with nerve injury or inflammation in cultured mouse and human DRG somata and has implications for use of DRG cultures to model sensory neuron physiology and pharmacology (129). In addition, when comparing expression profiles of putative pain-relevant genes in human and mouse DRG, the expression of G-protein-coupled receptor and ion channel gene families specifically expressed in neurons were markedly lower in culture, and also not all genes detected in intact DRG were expressed in culture.

In a study when RNAscope *in situ* hybridisation compared parallel neuron populations in mouse and human DRG, interspecies differences were apparent (130). Based largely on mRNA-expression studies of mouse DRG somata, putative nociceptor populations have been identified: peptidergic nociceptors (CGRP-expressing somata), non-peptidergic nociceptors and larger diameter somata that express NF200 and classed as mechano-nociceptors. This template, however, is not representative of human DRG somata, in which a large, overlapping subpopulation of CGRP and $P2X_3$ receptor co-expressing DRG somata is apparent (130). In addition, there were also significant differences between mouse and human DRG somata in the expression of mRNAs for $TRPV_1$ and $TRPA_1$ receptors, nicotinic cholinergic receptors, as well as Na^+ and K^+ channels. Although mRNA expression does not always reliably project protein expression, these findings challenged the translatability of findings in the mouse DRG to the human DRG.

The above findings were based on bulk sequencing approaches. More recently, a near-single DRG neuron spatial transcriptomic study of human lumbar cells has uncovered additional significant differences between mouse and human gene expression in DRG somata (131). At least ten clusters of human DRG somata, exhibiting distinct expression profiles were identified: six were classed as C-fibre nociceptors, one as an Aβ-fibre nociceptor, one as an Aδ-low threshold mechano-receptor and two as Aβ-low threshold mechano-receptors. Clusters of putative nociceptors included those classed as cold, itch or silent nociceptors. This granular analysis also evaluated sex differences, noting several that may be relevant for therapeutic drug development. Of interest, although many of the same G-protein-coupled receptors are expressed in both human and mouse DRGs, their cellular expression and distribution within DRG somata differ. Moreover, the distinction in mouse DRG somata between peptidergic and non-peptidergic nociceptors, upon which considerable weight rests relative to drug development, is non-existent in human DRG equivalents. Most human DRG somata classed as nociceptors express neuropeptide, $TRPV_1$ and $NTRK_1$ (NGF receptor), exposing a combination of several markers in the human that distinguish in the mouse putative peptidergic from non-peptidergic nociceptors. Collectively, these recent studies, employing increasingly advanced tools, reveal that the general translatability of findings in mouse DRG somata to human DRG somata is low, leaving open the question whether another animal species is a better model.

The studies performed to date in human DRG somata have used lumbar DRG which contain few, if any, visceral afferent somata. Thus, it is not known if visceral afferent somata are the same or in some way distinguishable from the results described above. One could imagine, given that stretch/distension is a common, natural noxious visceral stimulus, that mechano-sensitive channels/receptors might be expressed at a higher level in visceral afferent DRG somata. Alternatively, genes not included in the studies cited above may be important for visceral nociception. Future studies will clarify whether there are tissue-specific nociceptors whose 'adequate' stimulus is represented by a distinctive pattern of gene expression.

Receptive endings/afferent fibres. Electrophysiological studies of visceral afferents have a substantial history from which to draw inferences about translation to human afferents. Bladder afferent recordings in cats documented early-on that mechano-sensitive endings responded to bladder filling. Subsequent studies in rats, guinea pigs and mice described subsets of mechano-sensitive endings with low or high thresholds for response to bladder filling/distension/stretch. In rats and mice, C-fibre and Aδ-fibre axons were associated with both low and high threshold afferent endings. Moreover, when tested, many mechano-sensitive bladder afferent endings also exhibited chemo- and/or thermo-sensitivity and were thus revealed to be multi-modal. Finally, mechanically insensitive, silent afferent endings have been documented in the bladder. The studies on afferent endings from different species reviewed above suggest that findings in non-human animals translate well to human afferent physiology.

Although there have been no reported electrophysiological recordings of bladder afferents in humans, relevant information about mechano-sensation and nociception is available in the human microneurographic literature. Developed in the mid-1960s by Swedish investigators in Uppsala, microneurography is the technique of recording nerve action potentials in resting, fully awake humans using a metal microelectrode inserted percutaneously into a nerve (a personal history of microneurography has been published recently, 132). The great advantage of microneurography is the ability to easily switch between intraneural nerve recording and stimulation modes and thus incorporate psychophysical detection into the study. Accordingly, microneurography has successfully revealed functional properties of afferents subserving touch and pain (in addition to its application to the study of sympathetic efferent fibres). For example, intraneural stimulation of rapidly adapting low threshold mechano-sensitive afferents is associated with sensations of tapping, tickle and vibration, depending on the frequency of stimulation, and linked to Meissner's and Pacinian corpuscle end organs. Slowly-adapting low threshold afferents are associated with the sensation of pressure and linked to Merkel's disk (e.g. 133-135). Intraneural stimulation of Aδ-fibre mechano-nociceptors produce a sensation of sharp pain, whereas stimulation of C-fibre nociceptors produce sensations of itch or dull/burning pain (associated with C-mechano-sensitive endings or C-mechano-heat [C-MH] endings, commonly referred to as polymodal nociceptors, 136). C-MiHi (mechano- and heat-insensitive, or "silent' nociceptors) are also present in human cutaneous tissue (137). Importantly, there is close correlation between the number of action potentials evoked from human C-fibre nociceptors by intraneural stimulation and the temporal pattern of discharge with psychophysical estimates of stimulus intensity and perceived sensation, respectively. Similarly, intraneural stimulation of group IV (C-fibre) mechano-sensitive (deep pressure) skeletal muscle afferents produce a sensation of cramping pain (138,139). Microneurography has also documented the presence of C-fibre tactile receptors that respond vigorously to gentle skin stroking and, when stimulated intraneurally, produced hedonic ratings that subjects reported as pleasant at higher firing rates (140). Recently, A-fibre high-threshold mechano-receptors that encoded noxious skin indentations, but were unresponsive to gentle touch, were described in human skin (141). Of interest, the pain produced by intraneural stimulation was associated with thickly myelinated axons (i.e. Aβ-fibres) and described as an "ultrafast system for signalling mechanical pain", consistent with the presence of Aβ-fibre nociceptors in many non-human animal species (56).

The foregoing is the result of microneurographic studies of superficial nerves innervating the skin, typically the peroneal or superficial radial nerve, and knowledge about human visceral afferents in general or bladder afferents in particular is not available. However, what is known from human microneurographic studies and the study of visceral/bladder afferents in non-human animals suggests reasonable translation of studies of afferents in non-humans to humans. Rodent bladder afferents exhibit mechano-sensitivity, chemosensitivity, thermo-sensitivity, and multi-modality as well as mechanical insensitivity, as do human skin afferents. In an evolutionary context, one might consider innervation of human skin as highly developed with respect to sensibility and interaction with its

environment in comparison to the innervation of internal organs in non-human species. However, the same fundamental sensibilities are represented in both tissues, although the breadth of sensitivities and proportions of afferent types are certainly different.

The functions of human DRG somata classed as 'nociceptors' remains to be determined independently of expression profiles of receptors and channels, peptide content, etc. However, contemporary research approaches applied to human DRG somata and afferent fibre recordings in human tissue samples will contribute to and clarify our appreciation of the visceral/bladder innervation. Recent electrophysiological recordings of colon afferents from human tissue samples have already opened this avenue of research (142-144) for translation of findings from studies in non-human animals. It is anticipated that a similar approach could be applied to the study of human bladder afferents.

II. INTEGRATIVE FUNCTIONS OF THE BRAIN IN LUT CONTROL

1. BACKGROUND AND OVERVIEW OF THE CONTROL NETWORK

Loss of bladder control (urgency urinary incontinence, UUI) is a common and morbid condition that is often refractory to treatment by drugs, conservative measures, or electrical stimulation at spinal, peripheral, or brain sites. Regarding UUI, the neural control committee of the previous International Consultation on Incontinence (ICI-6) concluded that "The fact that voiding and continence are under forebrain control is now well established (145)." The elements of this control were summarised in a 'working model' showing the regions of the brain believed to be most important for bladder control, and their interconnections (Figure 9; 146,147). This section will concentrate on bringing the working model up-to-date by incorporating newly published knowledge. Furthermore, measurement of connectivity in the brain will be considered and will include sections on the effect of neurological disease (in particular, multiple sclerosis; MS) on brain maps and connectivity. Finally, there will be a consideration of what can be learned about UUI from deep brain stimulation (DBS) of patients with Parkinson's disease (PD), many of whom have concomitant UUI.

1.1. Neural Control.

The basis of control is a long-loop, spino-bulbo-spinal reflex (the voiding reflex) that acts as a switch between the two phases of micturition (148) - urine storage (or bladder filling) and voiding (bladder emptying). The rostral terminus of the reflex comprises two brainstem or midbrain nuclei: the pontine micturition centre (PMC) and the periaqueductal grey (PAG). The PAG has numerous forebrain and limbic projections, some of which enable bladder afferents to be relayed to regions of the forebrain where sensations such as desire to void or urgency are generated. Moreover, signals descending from cortical or limbic regions act on the PAG and modulate firing of the voiding reflex, thus maintaining continence or promoting voiding as appropriate. According to the current version of the working model, as the bladder fills signalling from bladder afferents increases, so progressively exciting the PAG. When PAG activity attains a critical trigger level, it excites the PMC, which is believed to send a descending signal to the sacral spinal cord and, *via* spinal circuitry, make the urethral sphincter relax and the bladder contract

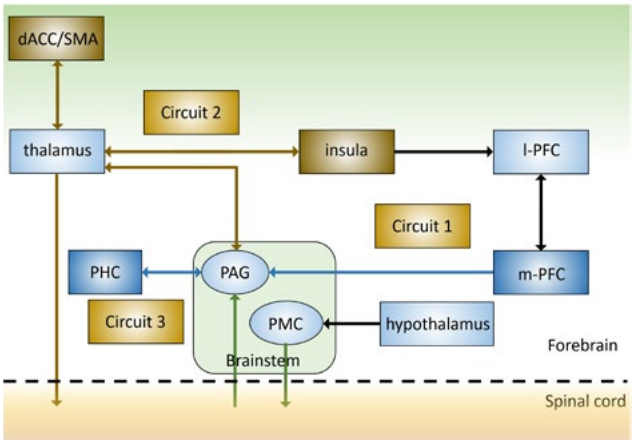

Figure 9. The bladder control network, working model of the forebrain. *The PAG and PMC form the rostral terminus of the voiding reflex and together act as a switch between the two phases of the reflex. The PAG receives ascending afferents from bladder. It also propagates into and receives signals from circuits-1, -2 and -3, to allow forebrain modulation of the switching action. Key - PHC: parahippocampal area; dACC/SMA: dorsal anterior cingulate cortex/supplementary motor area; PAG: periaqueductal grey; PMC: pontine micturition centre; l-PFC: lateral pre-frontal cortex; m-PFC: medial pre-frontal cortex.*

and empty, i.e. the reflex switches to the voiding phase. This basic automatic reflex behaviour is modulated by input to the PAG from cortical and limbic circuits, so enabling generation of sensations such as desire to void or urgency as well as voluntary control of voiding (148). Thus, according to this model the PAG is activated during bladder filling, and the PMC is quiescent, while the PMC is active during voiding and passive during filling.

1.2. The Working Model of Forebrain Control.

The working model described above relies to a considerable extent on the results obtained by a few research groups (149,150). Data have typically been generated by recording a functional magnetic resonance imaging blood-oxygen-level-dependent (fMRI BOLD, henceforth fMRI) signal during performance of a 'task' such as repeated infusion and withdrawal of fluid into and out of the bladder. Since ICI-6, other publications dealing with this topic have used a variety of methods or tasks (e.g. functional connectivity, regional homogeneity, resting-state fMRI, and diffusion-tensor imaging). Although this variety hinders direct comparison with the working model, the use of several different methods may disclose important complementary facts that otherwise would remain hidden. This section will examine whether and how the working model needs to be revised in the light of the continued development of methods that examine brain function and anatomy.

1.3. Midbrain Involvement

Periaqueductal grey matter (PAG). As explained above, the PAG modulates autonomic functions such as micturition, serving as a bridge between higher decision-making brain centres and lower centres responsible for reflex voiding. It may be affected in many disorders, including multiple sclerosis (MS), stroke, idiopathic normal pressure hydrocephalus, Parkinson's disease and multiple-system atrophy. It is critical for the basic understanding of voiding and storage disorders and is a potential candidate for diagnostic and therapeutic interventions. For example, deep brain stimulation in humans (DBS; section II.4.1) that targets the PAG increases bladder capacity. PAG involvement is discussed further in section I.2.2.

A review of PAG function (151) has provided more detail about how signals ascending from the bladder are processed in the PAG with the help of the PMC (Figure 10). The afferent bladder-distension signal first reaches the ventrolateral column of the PAG (vl-PAG), from where it may trigger excitation of the PMC and thereby induce bladder contraction without requiring any modulation from higher brain centres. In the rat the vl-PAG projects to a nucleus of the thalamus, and thence to the insula. The signal ultimately reaches the medial prefrontal cortex (mPFC) where, in humans, conscious, voluntary control can be exerted (Figure 10). The return projections from the medial prefrontal area reach predominantly the dorsolateral PAG (dl-PAG). Part of this pathway has been mapped out in the mouse (152). The medial preoptic area of the hypothalamus may provide additional signalling, ensuring a safe start to voiding. This network of connections provides continuous monitoring of incoming signals regarding the level of the bladder fullness and the state of the environment, and ultimately enables a decision about the feasibility of voiding (152). A recent study, using 7T-fMRI with human subjects, demonstrated a parcellation technique which showed the presence of within-PAG connectivity related to state of bladder fullness (153), setting the stage for future detailed investigations of this integral component of the model.

Thalamus, basal ganglia and limbic brain structures.
It has been suggested that electrical stimulation of the subthalamic nucleus and PAG inhibits micturition and improves urinary incontinence, whilst stimulation of the ventral intermediate and ventral posterolateral nuclei of the thalamus induced micturition (154). Other subcortical targets in the basal ganglia for modulating micturition and urodynamic parameters include the globus pallidus, where deep brain stimulation can ameliorate detrusor overactivity in some patients but can also worsen maximum flow rate and post-void residual volume. In patients with neuropathic pain, deep brain stimulation of the PAG dramatically increases maximum cystometric capacity (MCC; 155) - the volume at which patients ask for an artificial saline infusion to be stopped (urgency) - but it does not affect the volumes at which voiding is desired and where there are strong and very strong desires to void.

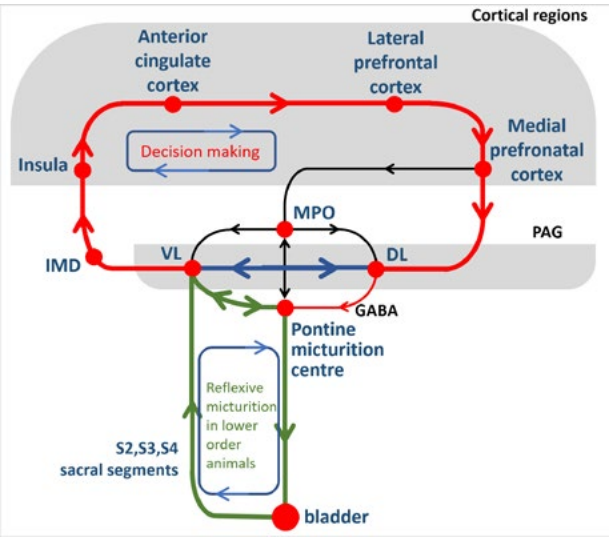

Figure 10. Schematic diagram of the organisation of the PAG. *Two loops, the decision-making and reflexive micturition feedback loops, are active in higher- and lower-order animals, respectively. Key – VL: ventrolateral column; DL: dorsolateral column; IMD: intermediodorsal nucleus of the rat thalamus (analogous to mediodorsal nuclei of the human thalamus); MPO: medial preoptic area of hypothalamus.*

The pedunculopontine nucleus (PPN).
The PPN is a brainstem nucleus in the rostral pons that differs from either the PMC or the PAG described in the working model. It may be identical to the "L-region" introduced by neurophysiological experiments in the cat (156,157) and is believed to be a "pontine continence centre". Stimulation of the PPN acts on the bladder in an inhibitory manner but does not appear to be a clinically useful as a target for treatment (158).

The L-region. The L-region first described neuroanatomically and later by its response to electrical stimulation, has an inhibitory effect on the bladder, probably mediated by stimulation of the urethral sphincter mechanism (156,157).

The bed nucleus of the stria terminalis (BNST).
The BNST is emerging as a critical region in disorders such as anxiety, post-traumatic stress disorder, panic disorder, as well as alcohol and substance misuse (159). It is also a region within which viscero-motor and viscero-sensory signals converge (160). Animal and human studies have examined connections of the BNST and their impact on BNST function. Structural connections between the BNST and insula (part of circuit-2, Figure 9) have been described in rodents, and recently by Pang et al (161), who found evidence of a BNST-insula structural connection in humans. It would be interesting to examine whether the BNST also mediates urinary tract disorders such as urgency urinary incontinence.

2. CONTINENT ADULTS: HUMAN STUDIES OF BLADDER STORAGE, FILLING AND VOIDING

2.1. Overview.
Since ICI-6 several papers have been published which have a bearing on the validity of the working model. Whether for historical reasons or for reasons of convenience, the filling phase has been more commonly investigated in females and the voiding phase in males. Studies generally require use of a 'task' that defines what is actually measured; for example, repeated bladder filling is a commonly used task. Alternatively, in some studies 'imagined voiding' has been used (150), whereby the subject imagines initiating voiding without actually doing so. Differences in these tasks, while hindering direct comparison of studies, may reveal subtle differences in the control mechanism related to different parts of the micturition cycle.

2.2. The Voiding Phase
Relatively few groups have investigated real voluntary voiding, most likely due to practicality. One group (150) investigated the central regulatory mechanisms activated during micturition in 22 healthy males. They used as the 'task' an alternating sequence of micturition phases: imaginary voiding, initiation of voiding (divided into early and late), and actual voiding. Despite the best of intentions, not all subjects were able to void in the scanner. Those who could (voiders) showed prominent supraspinal activity during the late phase of initiation, particularly in the brainstem (PAG, pons), insula, thalamus, prefrontal cortex, parietal operculum and cingulate cortex; with significant functional connectivity between the forebrain and parietal operculum (Figure 11). Subjects unable to void in the scanner (non-voiders) showed less activation during initiation of attempted micturition, particularly in the forebrain and brainstem. It

was deduced that micturition is controlled by a specific supraspinal network which is used for voluntary initiation. Once the network has been triggered, micturition normally continues automatically without further supraspinal input until the bladder is empty. This suggests that the micturition cycle may best be described not just by two phases (storage and voiding) but a more complicated switching action of storage, initiation of voiding and then maintenance of voiding. The network involved includes not only the brainstem (PAG, pons) but also the insula (the seat of interoception - or perception of sensations from inside the body, 162); the thalamus (a way-station); the prefrontal cortex (executive decision-making); and the cingulate cortex (functional connectivity between prefrontal regions and parietal operculum). Within the reflex pathway, projections from S2, the sensorimotor area in the parietal operculum, enter the temporal lobe and limbic structure via the insula (Figure 11). S2 is thought to be important in recognising the nature of a more-or-less painful stimulus such as 'urgency'. Most of the regions identified in this network are near to similar regions in the working model, thus providing some support for this revised model. Moreover, once voiding has been initiated by a barrage of descending bladder neurons, maintenance seems to require little or no further neural activity, but only myogenic elasticity or 'tone'.

Figure 12 shows that the difference between voiders and non-voiders is in fact real and significant. This suggests that the cortical sensorimotor area (in particular the parietal operculum) is part of the mechanism of voiding. Furthermore, brainstem regions such as PAG and pons (PMC) are more strongly activated in voiders than non-voiders.

2.3. The Storage Phase

Given the constraints of fMRI scanning, it is simplest to investigate brain control of the bladder in a steady state. As such, resting state fMRI analysis at discrete bladder volumes can give some insight into fundamental functional differences based on continence status, thereby establishing foundational knowledge of relevant mechanisms. While this technique lacks the ability to measure acute changes occurring with dynamic bladder stimulation, it might suggest regions of interest for further interrogation with additional techniques.

fMRI analysis in a single bladder state.

'Resting state' analysis has become popular and offers the opportunity to identify subtle differences between subgroups of individuals without the addition of a complex task, i.e. at rest. Additionally,

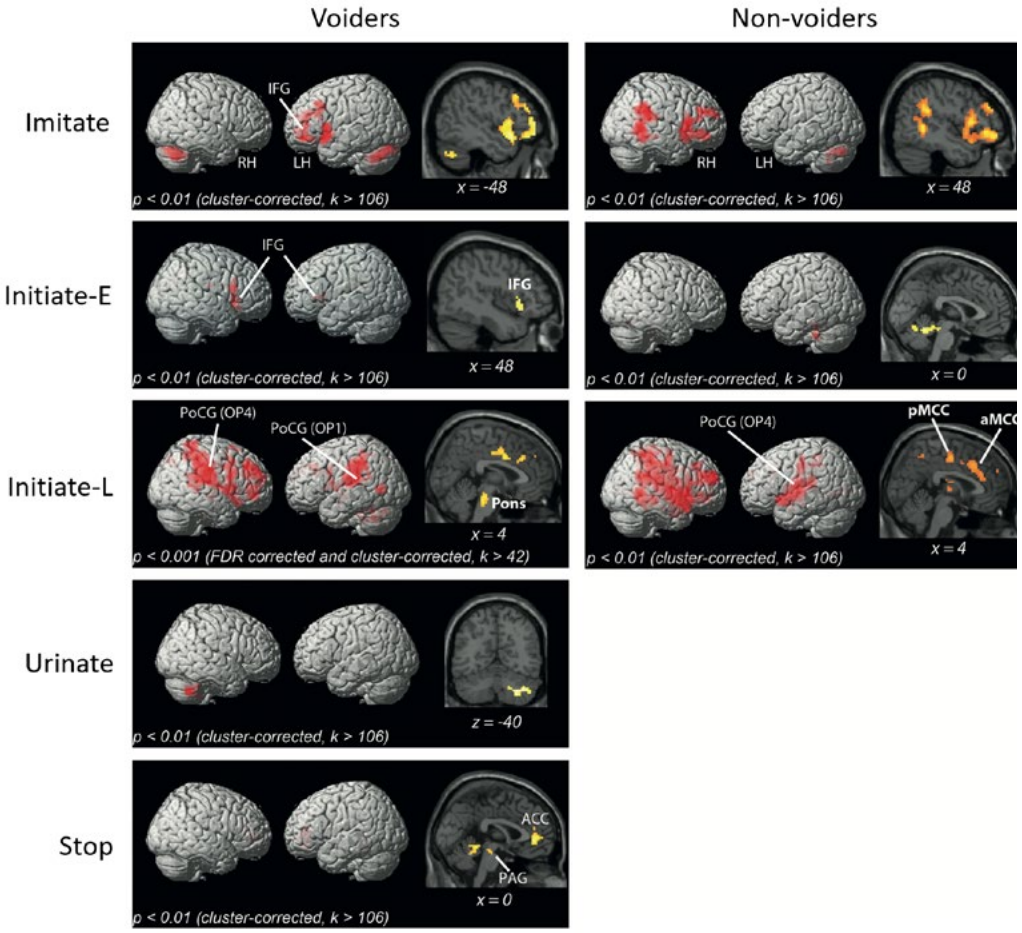

Figure 11. Bladder control in normal males during the voiding cycle. *Voiders (left, n=14) and non-voiders (right, n=7). Imagined voiding (Imitate) activates modestly parts of the forebrain in both voiders and non-voiders. During initiation of voiding there is at first (Initiate-E) minimal excitation, followed by (Initiate-L) strong excitation in cortex and pons in both voiders and non-voiders. Finally, during actual voiding (Urinate) there is very little excitation: voiding continues automatically, normally until the bladder is empty (Stop). Key – LH/RH; left/right hemisphere: IFG, inferior frontal gyrus: PoCG, postcentral gyrus: OP, parietal operculum: aMCC/pMCC, anterior/posterior midcingulate cortex: ACC, anterior cingulate cortex: PAG, periaqueductal grey. Figure 12. Bladder control in normal males, voiders and non-voiders. *Difference between voiders and non-voiders. During the late initiation phase (Initiate-L), there are significant differences between voiders and non-voiders in the parietal operculum, pons and PAG. The parietal operculum includes the secondary sensorimotor area S2 and is thought to be important in helping to recognise the nature of a potentially painful stimulus, possibly such as urgency. Key – LH/RH; left/right hemisphere: PoCG, postcentral gyrus: OP, parietal operculum: PAG, periaqueductal grey. From (150) with permission.*

evaluation of functional connectivity between identified regions or within established brain networks aligns with an increasingly network-focussed view of brain control mechanisms. Connectivity measures can be evaluated at rest and during stimulus tasks (such as filling) using generalised psychophysiological interaction analysis (section II.3.1 - *connectivity*). Connectivity is a measure of brain activity which evaluates the temporal connections between regions and has given rise to an understanding of networks such as the Default Mode Network (DMN), typically engaged at rest. Resting state functional connectivity (RSFC) is a measure of this connectivity at rest. In bladder studies this is typically performed with a full and/or empty bladder. One might evaluate the RSFC of seed regions known to regulate the bladder to identify baseline differences according to continence status: RSFC strength may be a predictor of the potential to activate the appropriate circuitry when necessary. Alternatively, connectivity measured during a bladder 'task', might highlight circuitry which fails or may be augmented with successful therapy.

Resting state and functional connectivity in continent adults.
Resting-state fMRI (rs-fMRI) has been used to identify brain areas related to bladder sensation in several studies of continent participants. Gao et al. (163) measured regional homogeneity (ReHo) in 30 participants at rest, with both an empty bladder and at 'strong desire to void'. ReHo is a voxel-based measure of brain activity which evaluates the similarity or synchronisation between the time-series of a given voxel and its nearest neighbours (164). In general, homogeneity was greater when there was strong desire to void, especially in the prefrontal cortex (PFC), anterior cingulate cortex (ACC), hypothalamus, temporal lobes and left caudate nucleus, indicating that these regions might play an active role in attending to the full bladder. The cortical areas (ACC and PFC) are similar to those in the working model, lending support to their involvement in the cerebral control of bladder storage.

The use of graph analysis found topological changes in the brains of continent women between empty and partially filled (after infusion of 100 ml fluid) bladder states (165). Specifically, reduced global efficiency in the Salience Network (SN), Dorsal Attention Network (DAN), Default Mode Network (DMN) and Central Executive Network (CEN) was found, as well as changes to local efficiency in the Salience and Sensorimotor (SMN) networks in a fuller bladder. This suggests a shift in focus to attend to bladder-associated networks. Similarly, Pang et al. (166) found decreased global efficiency in the full *vs* empty bladder state, with increased functional connectivity in the DMN, medial frontal cortex, inferior and superior frontal gyri, and the cingulate gyrus, known to be important regions of the continence mechanism.

Mawla *et al*. (167) evaluated changes in amplitude of low frequency fluctuations (ALFF) between an empty and 'fuller' (after ingestion of 350 ml) bladder state in 62 continent men and women. ALFF is a measure of regional spontaneous neuronal activity which may reflect pre-disposition to certain conditions. Anterior cingulate cortex, supplementary motor area and pre-frontal cortex showed ALFF decreases with increasing urinary urge. Additionally, PAG connectivity with the cingulate cortex, motor area, prefrontal cortex and right insula was associated with increasing urinary urge and bladder volume. Further linear regression of the brain networks revealed increased SN, SMN and DMN connectivity with bladder volume as seen by Pang *et al.* (166). Zhao *et al*. (168) used ALFF analysis to identify seed regions which changed between the empty and 'fuller' (200 ml infusion) bladder state to examine changes in connectivity. Their analysis confirmed that the connectivity between the pre-frontal cortex, insula, and cingulate gyrus, components of circuits-1 and -2 of the working model, plays a role in continence control of healthy bladders.

These resting state analyses suggest that throughout all stages of bladder filling in continent adults, from infusion of 100 ml to 'strong desire to void', the brain focus diverts from the default resting networks, which are active with an empty bladder, to regions and networks known to be involved in continence control and highlighted in the working model.

2.4. The Filling Phase.
Regular clinical studies allow for inter-subject variation, but not for variation between different trials, because they are performed in different centres, or use slightly different protocols. Meta-analyses can take into account this source of variation.

A meta-analysis based on 14 different studies of 181 healthy adults between 1997-2015, examined brain activation in response to experimental bladder filling (169). It revealed significant activation of the fMRI signal in brain regions that includes thalamus, right insula, cerebellum, brainstem and right PAG (Figure 13). These regions (apart from those in the cerebellum) belong to, or are located close to, circuit-2 of the working model. Among the six areas shown in Figure 13; the insula, thalamus, and PAG appear in similar locations in the working model, supporting the idea that they are activated during bladder filling (the storage phase). The case of the thalamus deserves special mention: it not only gives and receives signals to and from the PAG but may also have direct access to the spinal cord, as suggested in Figure 1. Of interest, of the cortical regions most important in the working model, the anterior cingulate cortex (ACC) was only seen in men and the medial prefrontal cortex (mPFC) was not replicated in this analysis of healthy subjects. This may reflect the type and variety of bladder filling tasks included. PFC activity may only occur when there is a desire to void that is less likely to be reached in those with good bladder control.

Comparison of bladder filling with rectal distension.
Adults with pelvic floor disorders commonly present with overlapping bladder and bowel symptoms. To further investigate this phenomenon a meta-analysis of responses to rectal distension has been carried out (170). It showed that different areas of the brain were activated by rectal distension and by bladder filling, apart from the right insula, which was activated by both. The insula is involved in interoception and sensory processing in general (162) and so it

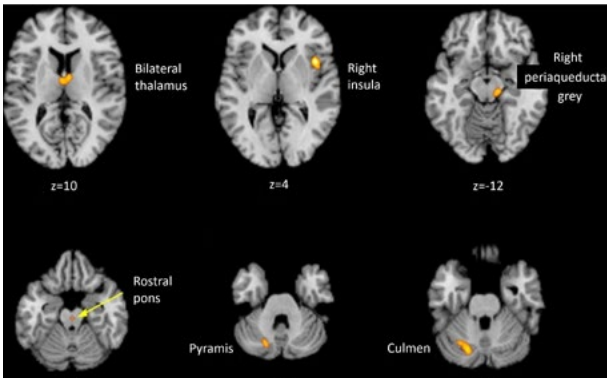

Figure 13. Areas of the brain activated during bladder filling in healthy adults. *Meta-analysis of 14 neuroimaging studies with 181 subjects showing regions activated during bladder filling: bilateral thalamus (4,-4,10; -2,-6,10); right insula (42,22,4); right periaqueductal grey (12,22, -12); rostral pons (0,-22,-20); pyramis (posterior lobe of cerebellum; -20,-72,-28); culmen (anterior lobe of cerebellum -28,-64,-26). Adapted from (169) with permission.*

is not surprising that it registers urgency of both bladder and rectum. Overlapping of activations in the insula may enable interaction between rectal and urinary function, in both motor and sensory aspects.

3. NON-NEUROGENIC LUTD: HUMAN STUDIES OF BLADDER STORAGE, FILLING AND VOIDING

3.1. The filling phase.

Several imaging studies of bladder filling have been published. A trial of biofeedback-assisted pelvic floor muscle training for urgency urinary incontinence in 62 older women (171) used a common 'infusion-withdrawal' bladder filling task. A small control arm (*n*=11) showed only weak activations of questionable significance. Of 62 women with UUI, 28 subjects responded to training (responders) and showed a reduction of dorsal ACC (dACC) activation after treatment, potentially a reduction of circuit-2 involvement upon reduction in symptoms. The remaining non-responders showed marked deactivation of the medial prefrontal cortex (mPFC) during rapid filling of the bladder. It was suggested that this unexpected observation might signify that the mPFC was the origin of a cortico-pontine pathway conveying executive control to the PAG - a part of circuit-1 that was revealed in a mouse model by optogenetic methods (172).

Nardos (173) and Ketai (149) used similar bladder filling tasks (multiple infusion/withdrawal cycles to induce a strong desire to void or urgency) to identify key brain areas involved in continence control. These regions were subsequently used as seed regions for resting state connectivity analysis (Section II.3.2). Differences in activation between those with UUI and continent controls were investigated (149). According to the working model this manoeuvre should activate typical regions of circuit-2, the interoceptive network. As anticipated, brain responses to infusion were greater in those with UUI than controls. In both, changes were greater when infusion was greatest and with a large amount in the bladder. Figure 14 shows differences in activation between UUI patients and controls during an infusion phase with a high fill rate. Infusion is associated with activation in the region labelled dACC in Figure 14, slightly anterior to the region with the same name in the working model. Similarly, infusion corresponds to activation in the anterior and posterior insula and ventrolateral PFC, which correspond to the insula in the working model. Thus, there is reasonable correspondence with circuit-2.

A main-effects analysis of UUI *vs* continent controls (173) identified 28 regions of interest that had significant differences in activity over an infusion-withdrawal cycle. These regions included the ACC and insula, also corresponding to circuit-2. Specifically, the ACC showed significant differences in how activity changed over the infusion-withdrawal cycle between different bladder volumes and continence status groups. The ACC may be the driver of, or main responder to, urgency within circuit-2.

Connectivity (the filling task).

An evaluation of functional connectivity between seed regions of interest (174) identified in previous studies (171) was carried out. Here, a small control group was compared with a larger study of pelvic floor muscle therapy. Significant connectivity changes between seed regions identified from the working model between groups were seen, but these did not survive multiple-comparison correction. Connectivity differences were seen at baseline (pre-therapy) and tended towards 'normal' in successfully treated UUI subjects, specifically there were connections between: the insula and primary motor cortex; insula/dACC and primary visual cortex; and prefrontal cortex and midcingulate. The reported changes in functional connectivity reveal a potential 're-training' effect in treatment responders, whereby brain activity becomes more like that of continent individuals. Conversely, the connectivity patterns in the non-responder group were either already similar to the continent group pre-treatment ('re-training' unnecessary) or did not change 'toward' the continent group after therapy ('re-training' unsuccessful). This led to the proposal that these changes may reflect therapeutic mechanisms associated with behavioural retraining of PFMT. The subgroup dif-

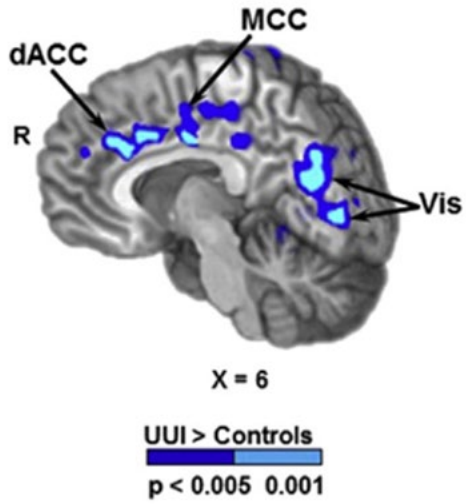

Figure 14. Bladder filling in patients with urgency urinary incontinence (UUI). *Differences in activation between controls and UUI patients during high fill rates. Magnitude of p-values denoted using dark blue (p<0.005) and light blue (p<0.001). Sagittal (X) slice locations according to the Talairach atlas. ferences in the changes may reflect the effect of underlying phenotypes of UUI which require different treatment approaches - e.g. brain re-training *vs* bladder-targeted approaches.

3.2. The Storage Phase. Resting state functional connectivity (RSFC).
RSFC has been evaluated in women with OAB/UUI, using a graph theory technique (175), or by studies that used seed regions identified from task-based studies (149,173): all compared OAB/UUI to continent controls. Changes in functional connectivity strength between OAB/UUI and continent patients in the superior frontal gyrus, middle frontal gyrus, anterior cingulate and precentral gyrus with an empty bladder (175) were also found to be predictive of UUI; using a Support Vector Machine (SVM) analysis (173) of connectivity differences between full and empty bladder states. A comparison of RSFC was carried out between responders and non-responders to pelvic floor muscle therapy, all with an empty bladder (174). The caudate, putamen and cerebellum/culmen had both significant differences in connectivity according to therapeutic success in this study and exhibited differing connectivity according to continence status in another study (173). By contrast another study (149) found differences in connectivity, dependent on continence state, between the mid cingulate cortex and dorsolateral and ventrolateral prefrontal cortices with an empty bladder. Methodological and analytical differences in these studies, such as selection of connectivity seeds and quantitation method, preclude making robust claims about their concurrence, but there is significant qualitative overlap in regions with connectivity differences dependent on continence state and treatment outcome. These regions could give insight into successful compensatory control mechanisms or mechanisms of treatment that would allow prediction of success.

4. NEUROLOGICAL TREATMENT OF URGENCY URINARY INCONTINENCE (UUI)

4.1. Deep Brain Stimulation (DBS).
The nuclei of the basal ganglia and their connections are often targetted by deep brain stimulation (DBS, 176). DBS is an emerging therapy for neurological diseases, especially Parkinson's disease, where it improves the motor symptoms found in severe disease. Specifically, stimulation of the subthalamic nucleus or the globus pallidus internus – parts of the basal ganglia – can improve urinary symptoms such as OAB or voiding difficulty. During the past few years, DBS has gained acceptance as an experimental treatment for intractable incontinence in patients with neurological diseases such as Parkinson's or multiple sclerosis (MS: 177,178) and animal models have also been developed (179).

DBS can improve conditions such as intractable incontinence, and the site of stimulation may indicate particular elements of the brain/bladder control system with possible lesions. However, the subject population exposed to DBS is biased towards patients with conditions such as Parkinson's, so that little can be discovered about normal function. Additionally, such invasive treatment may not be appropriate for those without concurrent neurological disease. DBS is typically performed using stimulation by electrical pulses delivered via a multi-lead electrode (180) implanted in defined regions of the basal ganglia – usually the subthalamic nucleus or the globus pallidus internus (178). The parameters of the stimulating pulses may continue to be adjusted for some months after implantation. This enables the clinical response to be optimised (176) but makes comparisons between studies more difficult, as standardised protocols cannot always be established.

The effect of DBS on urinary symptoms.
A review of the effect of DBS on autonomic function (154) emphasised that, depending on the specific target in the brain, DBS can raise or lower blood pressure, normalise the baroreceptor reflex, alter the calibre of bronchioles and eliminate abnormal excessive sweating – all through modulation of the sympathetic nervous system. In particular, DBS improves cortical control of the bladder and directly induces or inhibits the micturition reflex (178).

The effects of DBS on urinary function during voiding and storage in 416 patients with advanced Parkinson's disease (307 males and 109 females) were evaluated (178). With the use of standard symptom scales, the aim was to determine if DBS of the globus pallidus pars interna (GPi) or the subthalamic nucleus (STN) could improve lower urinary tract symptoms. Scores on LUTS items at baseline and after 12 months for the GPi DBS and STN DBS groups were separately evaluated, and any potential gender-associated differences were also sought. Significant improvement of urinary incontinence and frequency scores occurred in the STN DBS group, and in both men and women. Thus, it seems that the STN could be an important part of the working model. However, the role of GPi DBS is less convincing in this context.

A further clinical study of the effects of DBS on urinary dysfunction in patients with Parkinson's Disease was carried out (177) where the location of DBS was not specified but was presumably optimised at the time of, and in the period following, surgery. Symptoms such as urinary frequency, urgency, and incontinence were notably relieved by DBS treatment. Compared to male patients, DBS surgery significantly improved the AUA-SI (American Urological Association, Symptom Index) scores for urinary symptom and quality-of-life scores, as well as maximum urinary flow rate, detrusor pressure at peak flow, and residual urine volume. It was concluded that DBS surgery is effective in improving urinary function in Parkinson's Disease patients, as primarily reflected by the alleviation of symptoms such as urinary frequency, urgency, and incontinence.

A rat model was used to assess the feasibility of regulating bladder activity by DBS (179). Four potential targets were evaluated: the PAG, the locus coeruleus (LC), the rostral pontine reticular nucleus, and the pedunculopontine tegmental nucleus. DBS of the PAG region inhibited detrusor overactivity, whereas targetting the pedunculopontine tegmental nucleus slightly increased maximum bladder capacity measured during urodynamics. These observations are consistent with human investigations (158).

4.2. Sacral Neuromodulation (SNM).
Two studies have recently investigated the effect on brain function of sacral neuromodulation for treatment of urinary symptoms. Gill *et al*. (181) investigated the immediate effect by cycling a Medtronic Interstim II device on and off *during* fMRI signal acquisition at three different stimulation intensities (sub-, supra-, and at sensory threshold) in six participants. There were functional differences between on-stimulation and off-stimulation cycles at all three sensory levels. Sub-sensory stimulation predominantly generated deactivation throughout the brain, though specifically in the PAG and may suggest a role for SNM in suppression of the voiding reflex. Supra-sensory and at-sensory threshold stimulation predominantly produced activation in the insula and thalamus (Figure 15). While the implications of such results are speculatory, this data provides some evidence that neuromodulation has immediate effects on brain function.

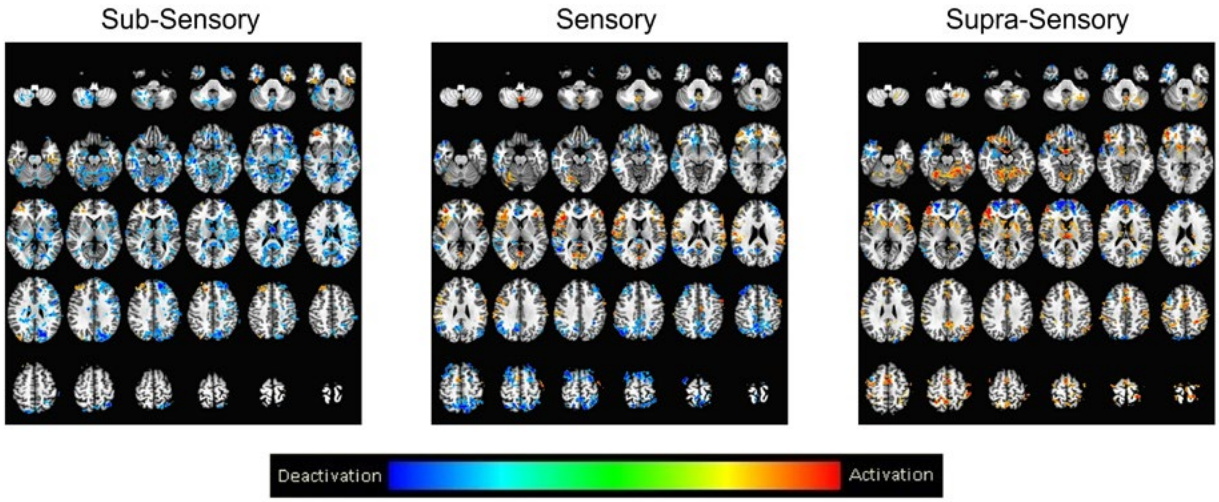

Figure 15. Changes in brain activity during sacral neuromodulation. *Stimuli are set at subsensory, sensory and suprasensory levels. Red areas indicate maximal activation, blue areas indicate maximal deactivation. Adapted from (181) with permission.*

Weissbart *et al*. (182) investigated the therapeutic effect of SNM on the brain by comparing functional brain changes during bladder filling associated before and after six weeks of SNM treatment. Data was compared between those who had successful responses to lead implantation (responders) with those who failed the SNM trial (non-responders). In post-implantation measurements the neurostimulator was 'off' when subjects were in the scanner. Pre-treatment, responders had significantly different activation patterns with bladder filling compared to non-responders; there was greater dACC, right insula, dorsolateral prefrontal cortex, orbitofrontal cortex and right supplementary motor area (SMA) activity. In those who responded, these areas (except the SMA) reduced in activity post-treatment. Because effects of SNM persist for a short time after sustained stimulation, this is a good indicator of a change in brain activity due to SNM itself. These observations are potentially suggestive of activation patterns which might be 'abnormal' and are returned to 'normal' after successful therapy. This is similar to that seen with biofeedback-assisted pelvic floor muscle therapy, where a reduction in dACC and PFC activity was seen in responders to therapy (171). This study did not identify any pontine activity changes. However, the overall reduction in brain activity with successful SNM treatment is consistent with a proposal that its mode of action is related to reduction in brain activity in key continence-related areas and that sub-sensory (the clinical therapeutic level) stimulation produces generalised deactivation (181). It is also consistent with a similar reduction of activity in the prefrontal cortex, cingulate gyrus, cerebellum after SNM (183). The mechanism of action of SNM remains unclear, but these studies suggest avenues for further exploration.

5. STUDIES OF NEUROGENIC LUTD

5.1. Multiple Sclerosis (MS): Structural and Functional Considerations.

Evaluation of urinary symptoms in multiple sclerosis may be a useful tool in addressing the relationship of brain lesion location and extent of the severity of urinary symptoms. Studies have assessed the location of brain lesions in MS patients with incontinence to understand which are more likely to induce deficits in the continence control mechanism. Comparison of the urinary symptoms of MS patients with and without pontine lesions showed no difference, despite the those with MS-related pontine lesions to those without, despite the importance of the pontine micturition centre plays in the voiding reflex (184). There was a weak statistical association between pontine lesion size and both a weak stream and urinary incontinence, but no effect of presence or absence of lesion, which may suggest a threshold size of lesion that might affect continence. A voxel-based lesion mapping system (185) was used to reveal those potentially related to UI symptoms. Lesions tended to affect the frontal and temporo-occiptal white matter, and included para-hippocampal areas, the posterior cingulate cortex, precuneus and cerebellum. A further study showed that specific locations of white matter plaques had an association with urinary symptom severity (186), whereby there was an increased volume of plaques in the cingulate gyrus in those with severe urinary symptoms.

Functional differences of continence control have also been assessed in those with MS compared to healthy controls during strong desire and initiation of voiding (187). MS patients showed increased activation of areas related to: executive function (frontal gyri); motor tone (lentiform nucleus); emotional recognition and attention (cingulate, insula, parietal lobules and precuneus); and anxiety and depression (subcallosal gyrus) at both strong desire and initiation of voiding. In general, there was more activation in those with MS during strong desire to void than healthy controls, and less activation during initiation of voiding. Those with neurogenic detrusor overactivity had increased activation in areas associated with executive function, as did those with detrusor sphincter dyssynergia, who also had increased activation in the cingulate gyrus, caudate and brainstem.

A further study (188) of MS patients compared those with and without voiding dysfunction (VD and non-VD). Multiple areas had reduced activation in those with VD, but of greater importance some regions, such as the PMC, right PAG, left thalamus and left cingulate gyrus, showed deactivation in those with VD and activation in the non-VD group. Overall, the non-VD group resembled healthy controls in activation pattern, though with reduced activity, whilst those with VD showed a distinctly different pattern of activity. A study of the effect of onabotulinumtoxin A therapy on LUTS in MS (189) showed increased activity in areas related to sensation (cin-

gulate, insula and pontine micturition centre) after therapy, but not a level seen in healthy controls.

Overall, MS patients exhibited lesions in brain areas associated with continence control, with different brain activation patterns to controls during voiding initiation and desire. The current literature does not allow us to assess the direct effects of structural damage on function, but further study of brain lesions and concurrent voiding dysfunction may shed light on this relationship.

6. STRUCTURAL CONSIDERATIONS FOR LUTD

6.1. Overview.
It is known that white matter damage causes incontinence by disruption of pathways critical to the continence mechanism as discussed above. Structural abnormalities occur in the forms of white matter hyperintensities (overt white matter damage); reduced structural integrity of white matter tracts (quantified by Diffusion Tensor Imaging, DTI; analysis of water diffusion along and perpendicular to white matter tracts – lower fractional anisotropy denotes poorer structural integrity); and hypertrophy or atrophy of grey matter (volume differences assessed by Voxel Based Morphometry, VBM). These differences may be caused by ageing or disease, and may be causal of, or contributory to, lower urinary tract dysfunction. Many fundamental studies of the relationship between structural brain damage and incontinence have been in those with neurological conditions such as multiple sclerosis (section II.5.1), where lesion mapping may provide insight into loss of function. Here we cover more recent non-neurological UUI-focused work assessing structural differences in those without overt neurological disease and which may provide insight into structural abnormalities that directly relate to bladder dysfunction.

6.2. White Matter.
In an attempt to relate white matter damage to urinary symptoms in non-neurological UUI, the Pittsburgh group (190) found that in women with UUI, after age adjustment, there is a significantly greater white matter hyperintensity burden compared with continent controls. This is true in the whole brain and specifically in the cingulate and superior longitudinal fasciculus. The cingulum itself, the nerve tract that forms the white matter core of the cingulate gyrus and connects components of the limbic system, exhibits lower fractional anisotropy, representing poorer structural integrity, in those with UUI compared to continent controls. Because the cingulum projects between the ventromedial pre-frontal cortex and the parahippocampal areas, this may be an integral structural connection within 'circuit-1' of the working model. Thus, the association between damage in this location and reduction in bladder control is plausible.

Of interest, in the same study (190), the burden of white matter damage was higher in those who responded well to behavioural therapy than those who did not. It was suggested that 'responders' may belong to a phenotype of incontinence caused by disruption of brain control of the bladder; successful re-learning of bladder and pelvic floor control may be associated with strengthening or re-routing of these pathways, specifically the superior longitudinal fasciculus.

6.3. Brain volume.
Assessment of grey matter volume (GMV) may provide an estimate of altered cellular structures (e.g. neuron number or dendritic complexity), potentially indicating reduced traffic to certain brain areas (atrophy), or increased usage of a particular area (hypertrophy). Comparison of GMV via voxel-based morphometry (190) showed relative atrophy of hippocampal and parahippocampal areas in those with UUI, compared to continent controls. Responders to pelvic floor muscle therapy showed hypertrophy pre-treatment in the mid-cingulate area compared to non-responders, potentially related to the poorer integrity of the white matter pathways. A similar grey matter volume comparison of those with OAB symptoms and those without (191) showed decreased volume in the anterior cingulate, hippocampus, left insula (plus caudate, middle frontal gyrus, superior temporal gyrus and cerebellum) in OAB patients compared to continent controls.

A pilot *post-hoc* analysis (192) of responders *vs* non-responders to anticholinergic therapy, assessed pre-treatment, showed non-responders had significantly smaller white matter volume in the anterior cingulate gyrus and parahippocampal areas. Thus, brain areas identified in the working model continue to show significant structural differences when stratified by continence status, and further, by potential continence phenotype.

6.4. Summary.
It is worth noting that structural differences between those with UUI/OAB and continent controls appear in biologically plausible brain areas, consistent with the working model. Incontinent subjects have more white matter damage and potentially related grey matter volume changes within 'circuit-1'. Since UUI and OAB are symptom-based diagnoses, the cause is generally unknown, and whether structural brain changes are causal or coincidental with a common cause cannot be ascertained by these studies. Future studies that evaluate structural and functional brain changes in responders and non-responders to brain (e.g. behavioural therapy) and bladder (e.g. anticholinergic medication) targeted therapies can offer valuable insight into potential causes of UUI and may allow for identification of disease phenotypes.

7. CONCLUSION

7.1. The Working Model.
The body of evidence presented here is largely in line with the working model of bladder control presented in 2.1.2. Variation between study designs, brain coordinate systems, spatial resolution limitations, and the image manipulation techniques required to facilitate group analyses of fMRI studies limits expectation of exact positional concordance in identification of brain regions. However, by incorporating established knowledge of brain function and fundamental science studies, the consensus is that of broad agreement. It is also clear that the identification of brain regions not presented in the working model and an increased focus on the 'network' model of brain control suggests that this working model is a simplification of a complex process, especially when considering the failure of LUT control. Despite this acknowledgement, many regions identified as significant in those with some level of LUT control failure are those outlined in this model; it still represents the integral components of the mechanism.

7.2. Future Work.
Studies thus far have concentrated on the voiding and storage/filling phases of the micturition cycle. It is likely that there are more complex processes regarding initiation and continuation of voiding and the role of sensation and psychological factors related to voiding. These should be considered in future work.

Further, UUI incidence increases with age, as do structural brain changes. It is difficult to identify those changes that may be causal of bladder symptoms, versus those that are coincidental. Careful study and subsequent consideration of the differences associated with UUI in younger people, in specific neurological disease and changes associated with successful and unsuccessful treatment, of different types, will help to parse out these subtleties.

In addition, evaluation of the basal ganglia and other midbrain components are largely missing from our current knowledge-base in humans. These should also be considered in further study of this process.

7.3. Summary.
Evaluation of LUT control is largely symptom-based; it is representative of a highly variable system which is affected by lifestyle factors and often driven by sensation, perception and socially conditioned processes. There are no objective, slow-changing measures that can be monitored to correlate with brain processes. As such, trying to understand the association of UUI with brain control is difficult and requires a careful, iterative process, considering all aspects of bladder function to map out the control mechanism and its associated failures. Here is presented a diverse array of studies which have provided robust foundational knowledge; this foundation should be used to plan confirmatory studies and those which seek to fill in the gaps in knowledge highlighted in this chapter.

III. EFFERENT NERVOUS CONTROL OF THE LUT – A TARGET FOR NEUROMODULATION

1. INTRODUCTION

The motor nerves supplying the detrusor and external urethral sphincter muscles act as a functional unit whose activity is co-ordinated at spinal and supraspinal levels to promote the storage and periodic release of urine. In the event that such control is lost, due to disease or traumatic injury, the ability to manipulate activity of the efferent nerves by electrical means (neuromodulation) presents a therapeutic target for restoring coordinated bladder function. Peripheral nerve stimulation to modulate voiding dysfunction has emerged as an effective alternative to help voiding dysfunction in patients who are refractory to drug treatment. Here the innervation of the lower urinary tract is considered, with a focus on how stimulation of peripheral nerves can be used to restore bladder control following disease or injury to the urinary voiding circuitry.

2. EFFERENT INNERVATION OF THE LOWER URINARY TRACT

The innervation the pelvic viscera has been the subject of several excellent comprehensive reviews (193-195). With subtle species-specific and strain-specific differences (196,197), innervation of the lower urinary tract (LUT) – comprising the bladder and the urethra - follows a basic pattern. Essentially, efferent axons are carried in three sets of peripheral nerves that exit the spinal cord at lower lumbar and upper sacral levels: sacral parasympathetic (pelvic nerves) and thoracolumbar sympathetic nerves (hypogastric nerves) which supply smooth muscle of the bladder and urethra, and sacral somatic nerves (primarily the pudendal nerves) that innervate external urethral sphincter (EUS) or the rhabdosphincter, which as the latter name implies is composed of skeletal muscle fibres (Figure 16). In each component of this circuit, the efferent fibres (sympathetic and parasympathetic) involved in bladder control are intermingled with other nerve types innervating both the LUT and other pelvic organs. Approximately one-third of all pelvic nerve axons are sensory, most of which are unmyelinated (198), with those innervating the bladder body, bladder trigone and urethra being completely segregated from those innervating the rectum (199). There is some evidence for sexual dimorphism: the pelvic ganglion of males contains more than twice the number of cell bodies of spinal preganglionic parasympathetic efferent nerves compared to males (200).

With the exception of the somatic motor neurones innervating the striated muscle of the EUS, which originate in Onuf's nucleus in the sacral cord, preganglionic axons (sympathetic and parasympathetic) carrying information from the spinal cord synapse with autonomic ganglion cells in the pelvic plexus, prevertebral sympathetic ganglia (inferior mesenteric ganglia), paravertebral sympathetic chain ganglia or ganglia on the serosal surface and in the wall (intramural ganglia) of the organs. As befits controlled synchronised contraction of the smooth muscle wall of hollow organs, the postganglionic efferent nerves distribute widely over the bladder surface (201).

Various neurotransmitters, including acetylcholine, noradrenaline, dopamine, serotonin, excitatory and inhibitory amino acids, adenosine triphosphate, nitric oxide and neuropeptides, have been implicated in the neural regulation of the lower urinary tract (194,202,203).

Current understanding of the detailed anatomy and transmitters utilised at the neuroeffector junctions has opened the way for development of pharmacotherapies to normalise bladder and voiding dysfunction. However, despite considerable success in pharmaco-

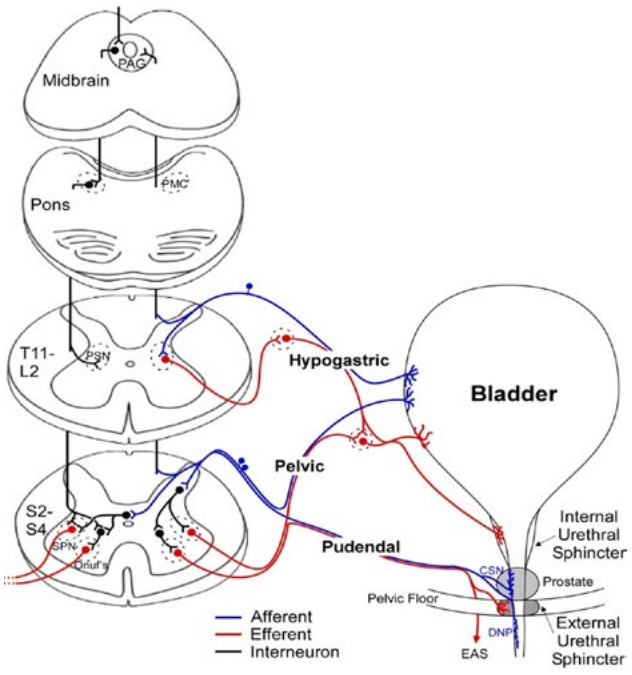

Figure 16. Innervation of the lower urinary tract in males. *Modified from (206) with permission.*

logical management of some disorders, there remains a significant number of patients who are refractory to drug treatment. Even in patients who are responsive, adverse side-effects, often due to actions at other organs, limit drug usage and necessitate a search for alternative therapies that could be tailored to target more specifically patient needs.

3. NEUROMODULATION OF PERIPHERAL NERVE ACTIVITY

3.1. Sacral Nerve Activity to Elicit Voiding.

Electrical stimulation of nerves offers the opportunity to influence storage and voiding by modulating the efferent supply to the bladder. One of the earliest targets for neuromodulation was the efferent outflow to the bladder as it exits the upper sacral cord. Studies in baboons with areflexive bladders following complete supra-sacral spinal cord injuries showed that stimulation of the anterior (ventral) sacral root, which contains efferent nerves supplying bladder and sphincter muscles (S1-S4 depending on species), could elicit emptying of the bladder (204). For efficient voiding to take place, and to avoid bladder sphincter dyssynergia, the urethra and sphincter muscles must relax whilst the detrusor contracts. Whilst sacral anterior root stimulation (Figure 17) activates efferent nerves to detrusor and EUS muscles, its functional effectiveness relies on the differential responsiveness of striated and smooth muscles to stimulation of their efferent nerve supply. A short period of stimulation of motor axons supplying the striated muscle of the EUS elicits a rapid contraction, followed by rapid relaxation once stimulation stops. In contrast, the response of the smooth muscle of the bladder follows a much slower time course so that contraction is still ongoing after the sphincter has relaxed, thereby allowing urine to flow. In this manner, repeated short bursts of stimulation can evoke coordinated voids. In the early stages following spinal cord injury the bladder is typically areflexive but later becomes hyper-reflexive (neurogenic bladder), leading to incontinence. A modification of the technique to include dorsal (posterior) root rhizotomy (Figure 17) to sever afferent inputs and reduce spontaneous reflex contractions of the bladder can improve continence (205).

Recent evaluations of sacral anterior root stimulation with sacral deafferentation (SARS-SDAF) in male and female users have concluded the procedure to be beneficial, with a high level of patient satisfaction, a decline in the need for intermittent catheterisation and fewer cases of involuntary urine leakage; importantly the treatment can remain effective for many years (206-208).

3.2. Sacral Nerve Stimulation to Inhibit Voiding.

Whilst early neuromodulation therapy focussed on efferent nerve stimulation to promote bladder contractions, the development of sophisticated stimulation paradigms now offers the potential to inhibit as well as activate different nerve types by electrical stimulation. In particular, the realisation that efferent nerve activity could be modified reflexly by activation of afferent nerve fibres has broadened the field of neuromodulation to restore control to patients with overactive bladder and urinary urge incontinence. Rather than evoking micturition, continuous stimulation targetting afferents running in dorsal (posterior) roots (Figure 17) is able to reduce bladder excitability and improve continence by reflexly influencing efferent activity (205). Preclinical studies in cats demonstrated that sacral neuromodulation-evoked inhibition of reflex bladder hyperactivity by activation of afferent nerves occurs primarily in the central nervous system, to inhibit the ascending or descending pathways of the spino-bulbo-spinal micturition reflex (209,210). Several recent

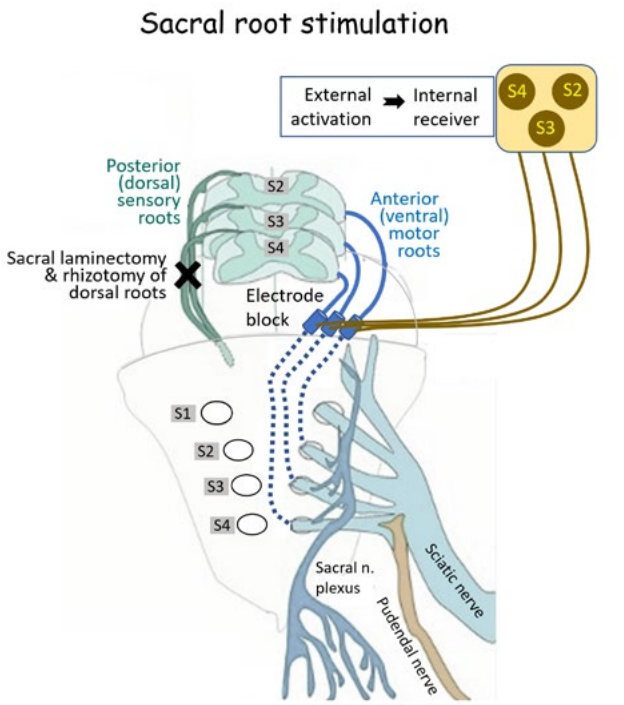

Figure 17. Anatomical arrangement of the sacral nerves. *Shown is the location of a stimulator for anterior root sacral neuromodulation. Adapted from (205).*

meta-analyses confirm the efficacy of sacral neuromodulation in patients with overactive bladder (211-213).

Notwithstanding the success of sacral root neuromodulation, there is still room for improvement. There is ongoing debate over the importance of stimulation parameter selection to optimise functional effectiveness: whether intermittent as opposed to continuous stimulation, or bilateral versus unilateral (214-216). Several recent innovations developed using animal models, may further improve clinical practice. For example, recent experimental work using a spinal injury model in minipigs (217) indicates that very early intervention after spinal cord injury may prevent the development of bladder sphincter dyssynergia without the need for dorsal rhizotomy. Transcutaneous Electrical Spinal Stimulation for LUT functional Augmentation (TESSLA) is a less invasive procedure that can be utilised in patients with spinal injury to either evoke voiding (218,219) or to improve symptoms of overactive bladder (220). The use of epidural stimulation, developed in spinal cord injured rats to elicit voiding, represents another promising minimally invasive procedure (219). Contemporary wireless-powered stimulation technology (221,222) is another innovation that obviates the need for repeated surgical interventions to replace batteries.

4. DISTAL STIMULATION SITES

Despite the considerable technological and surgical advances made since the introduction of the Brindley procedure, one major drawback associated with stimulating large mixed nerve trunks such as the sacral roots is the incidence of non-specific unwanted side effects due to activation of afferent and efferent axons supplying organs outside the LUT. By moving the stimulation site distally towards nerves supplying the target organ (pelvic, hypogastric and

pudendal nerves), the risk of unwanted side-effects should be reduced. It is worth remembering however, that even these peripheral nerves are mixed, at least in rats (198).

4.1. Pudendal Nerve Stimulation.

The pudendal nerve has proved to be one such effective target. This mixed nerve contains afferent and efferent fibres innervating the external urethral sphincter, although a branch to the urethra and external genitalia (the dorsal penile nerve in males) contains only afferent fibres. In humans, pudendal afferent fibres can be activated by stimulating the dorsal genital nerve (DGN) and the procedure has been adopted into clinical practice with some success. Importantly, it can be applied on-demand by the patient outside of the clinical environment. DGN stimulation has proved an effective means to engage and enhance bladder emptying in patients with retention and/or detrusor sphincter dyssynergia, or to normalise bladder function in patients with overactive bladder (OAB) (211,223-225). Although the primary action of DGN stimulation is activation of somatic afferent fibres, the functional outcome is suppression of bladder efferent activity and improvement in urodynamic outcomes in patients with overactive bladder following spinal cord injury (226,227). Indeed, there are indications that DGN stimulation may be superior to sacral neuromodulation for treatment of OAB (227-229). Limited evidence also reports excitatory bladder contraction can be evoked by pudendal nerve stimulation in patients with spinal cord injury (230).

In the cat and rat, electrical stimulation of the pudendal nerve trunk or the DGN at low frequency (5-10 Hz) promotes continence by suppressing bladder excitability, thus reducing spontaneous isovolumetric contractions, and by increasing bladder capacity. Of importance, this effect outlasts the initial stimulation period and also persists after spinal cord transection (231-234). Stimulating peroneal skin, which activates pudendal nerve afferents, inhibits isovolumetric bladder contractions in rats (235).

The effectiveness of pudendal nerve stimulation appears to be both intensity and frequency specific. Due to the electrical characteristics of different fibre types, it is possible to activate selectively different functional classes of axons. For example, low intensities of stimulation (twice the threshold for evoking the pudendal-anal reflex) were optimal to induce inhibitory effects, whereas stimulation at higher intensities facilitated voiding (236,237). In a similar way, low frequency stimulation (5-15 Hz) is optimal to inhibit micturition, whereas voiding can be facilitated in cats and rats by stimulation at higher frequencies (>20Hz), particularly when intermittent stimulation (33 Hz, duty cycle 1-s on, 0.2–0.3-s off) is delivered (231,232,238,239). Low-frequency effects are mediated via a supraspinal pathway whereas high-frequency effects are spinally-mediated (240). Analysis of the fibre types involved revealed that Aβ-fibre activation evoked a long latency, delayed onset effect over several minutes, whereas stimulation of Aδ-fibres evoked responses at short latency (235).

The pattern of activation is another variable which determines the functional effectiveness of stimulation. In humans, micturition is normally characterised by relaxation of the EUS (241) in order to permit urine to be expelled in a stream. In the rat the EUS undergoes a burst of contractions and relaxations during micturition, so urine is expelled in spurts. The pudendal efferent nerves have a median burst frequency of 40 Hz with 3-4 action potentials per burst in rats (242). By adjusting the pattern of pudendal nerve stimulation to evoke burst firing of the EUS, rather than sustained tonic firing, voiding efficiency was enhanced in cats which, like humans, expel their urine in a stream, as well as rats (239,240). The effect was mediated through activation of pudendal sensory pathways (243-244). Presumably the high resistance generated as the bladder contracts against the intermittently closed EUS would lead to a higher rate of pulsatile flow in the urethra during the periods of intermittent relaxation of the sphincter, rather than releasing urine in a continuous stream. Urethral flow at high bladder volumes relaxes the EUS by engaging the spinally-mediated augmenting reflex (245), which further facilitates urine flow.

The early studies of pudendal nerve effects were performed on animals with normal bladder function. However, stimulation has also been shown to be effective in rat and cat models of overactive bladder (234,246). In rats with reduced bladder capacity due to acetic acid-induced irritation of the bladder, pudendal nerve stimulation increased bladder capacity via a β-adrenergic mechanism involving the hypogastric nerves (246). Stimulation of pudendal afferents can also improve bladder emptying in rats with urinary retention following spinal cord transection (231,247), as well as improving voiding efficiency in diabetic rats (243). These studies in animal models provide insight into to the translational potential of amplifying the sensory feedback from pudendal urethral afferents to modulate efferent activity to the bladder and EUS.

4.2. Hypogastric Nerve Stimulation.

Whilst predominantly a sympathetic nerve, the hypogastric nerve also contains sensory afferent fibres which detect bladder distension at normal physiological pressures, as well as a population of nociceptor fibres that become sensitive after chemical irritation of the bladder and likely play a role in the facilitation of the nociceptive bladder activity induced by bladder irritation (248,249). In healthy individuals, activation of sympathetic efferent fibres in the hypogastric nerve evokes a β3 receptor-mediated relaxation of the detrusor in response to distension of the bladder – the guarding reflex (250). Of interest, reflex activation of these fibres by sensory pudendal nerve stimulation increased bladder capacity in rats and cats with irritated bladders, but not in normal animals (246,251). This intriguing finding suggests that the presence of bladder irritation may in some way unmask suppressed sympathetic reflexes, opening new avenues for therapeutic options to treat overactive bladder.

4.3. Pelvic Nerve Stimulation.

The pelvic nerve has recently been re-examined as a potential target for neuromodulation therapy. The nerve constitutes the major efferent supply to the bladder although a significant minority of its fibres are afferent (252). The postganglionic nerve bundles on each side distribute to the entire bladder musculature (201), which ensures that efficient voiding can take place even after unilateral denervation (253). There appears to be sexual dimorphism with respect to the pelvic nerve, at least in the rat where in males the preganglionic pelvic nerve ganglia contain approximately 2.5-times the number of cells compared to females (200). The functional significance of this sex difference is not clear. There is no evidence that ganglion cells modulate transmission of the efferent signal to the detrusor, at least in rats and pigs (254), but local reflex pathways exist between the bladder and the pelvic ganglia, which regulate non-voiding contractile activity (255) and may be involved in bladder fullness perception during urine storage (256).

Early studies using animal models with underactive or areflexic bladders were carried out to examine the potential of pelvic nerve stimulation to enhance bladder contraction and restore voiding function. This goal was thwarted by simultaneous activation of the external urethral sphincter (257). However, by incorporating a sophisticated stimulation paradigm, which permits efferent stimulation whilst blocking afferent activity, bladder-sphincter dyssynergia was

overcome and more than 75% voiding efficiency has been achieved in rats (258).

Stimulation of the pelvic nerve also has potential to normalise overactive bladder. In both rat and cat models of chronic overactive bladder, continuous pelvic nerve stimulation increased bladder capacity measured during single fill cystometry, effectively normalising urodynamic function (259,260). The stimulation was effective within only a very narrow range of parameters. In rats, stimulation at 10 Hz was effective, whereas 1 Hz was ineffective, but only when the intensity was raised to the threshold for evoking reflex activation of the EUS (259). On the other hand, in cats, stimulation at 1 Hz and twice threshold was required to produce a similar effect (259,260).

Promising effects have also been produced by adopting low voltage, pulsed radiofrequency (PRF) stimulation of the pelvic nerve in an acute acetic acid model of OAB (261). Pre-treatment with 5-minutes of nerve stimulation produced an increase of bladder capacity that persisted for at least 3.5-hours. The effective PRF stimulation parameters were 80 ms biphasic pulses at 2 Hz frequency; each pulse comprising 500 kHz sinusoid radiofrequency waves, intensity ±3 V. It has been proposed that PRF stimulation produces extremely high electric fields (E = 45-200 kV.m^{-1}, 37-44°C) that may disturb the neuronal membranes and function, inhibiting abnormal bladder contractions by blocking afferent signals from the bladder to the spinal cord (261). Of interest, in this study the effect could not be reproduced by PRF stimulation of the pudendal nerve, even though conventional low frequency stimulation at this site has been shown to be effective in inhibiting bladder excitability (see above).

A further development in rats is the use of high-frequency stimulation (in the kHz range) of the pelvic nerve to suppress voiding on-demand. In anaesthetised animals 30-s of high frequency (1-3 kHz) stimulation instigated at the onset of an imminent void, suppressed the void by aborting the detrusor contraction and increasing tonic activity in the EUS. Importantly, the effect was rapidly reversible so that voiding resumed within minutes of ceasing stimulation (253,262). The stimulation regimen was similarly effective in conscious rats (263). There were no signs of discomfort to the animal during stimulation or any evidence that long-term implantation compromised normal nerve functionality (263,264). It is not clear how such high frequency stimulation produces functional blockade of the voiding circuitry. Efferent fibres within the nerve seem not to be engaged since stimulation at this frequency range did not evoke bladder contractions (253). A modelling study of the effects of kHz stimulation in small, myelinated nerves predicts that transmission occurs, but the stimulation likely evokes a non-physiological pattern of firing (265). This might lead to transmission failure of efferent activity through the pelvic ganglion as well as functional blockade of afferent transmission through the micturition reflex circuitry at spinal or brainstem level, so that the neural network is prevented from generating a co-ordinated void (253).

Although still at an early stage, pelvic nerve stimulation may have translational potential for management of OAB. In cases of urinary urge incontinence, the ability to suppress rapidly an unwanted imminent void on demand could restore volitional control. However, in humans the pelvic nerve is diffuse and does not lend itself to easy surgical access, unlike the rat where the pelvic nerve is a discrete entity. Advances in laparoscopic techniques and robotic-assisted surgery (the LION procedure, (266-267)) may however, overcome these limitations in humans.

4.4. Tibial Nerve Stimulation.

Activation of somatic afferents in the tibial nerve to therapeutic advantage has emerged as another means to indirectly influence the efferent supply to the bladder. Tibial nerve stimulation has the advantage of ease of access and a lower incidence of side effects and complications compared to sacral nerve modulation (268,269). Patients with refractive overactive bladder and/or pelvic floor dysfunction report a decrease in daytime and night-time voiding frequencies and a reduction in the incidence of urge incontinence following tibial nerve stimulation (270). Tibial nerve stimulation has also undergone limited trials for non-obstructive urinary retention, but results obtained so far are not compelling (271).

Tibial nerve stimulation normally requires visits to the medical practitioner in an out-patient setting to allow percutaneous insertion of a needle above the medial malleolus in order to activate afferent fibres in the tibial nerve. Unlike other neuromodulation therapies, the effects of tibial nerve stimulation persist after the stimulation session (272) but even so, treatment with percutaneous tibial nerve stimulation (PTNS) typically involves 12 weekly treatment sessions followed up with a monthly maintenance programme (81). However, a new generation of minimally invasive implantable stimulators is evolving which employ wireless power transfer (273). By offering non-invasive transcutaneous stimulation with associated cost and safety benefits and allowing patients the ability to stimulate at home and on a daily basis if required, this procedure shows considerable promise in terms of improved outcomes compared with traditional office-based PTNS (274-275).

How activation of somatic afferents produces significant effects on bladder function is still not fully understood; the effect is exceptionally dependent on stimulation frequency. In cats with healthy bladders tibial nerve stimulation at 5-6 Hz, but not at 15 or 30 Hz, induced bladder underactivity by significantly increasing bladder capacity and reducing contraction amplitude (276-278). Studies using rat models also report frequency specificity of effective tibial nerve stimulation, but the optimal frequency ranges differ between different centres (279,280). Both tibial and pudendal nerve stimulation at 5 Hz reduced the frequency of firing induced by bladder distension in spinal cord neurons (281) but only tibial nerve-evoked effects persisted following termination of the stimulation suggesting that the underlying mechanisms are not identical (280,281). Indeed, tibial nerve stimulation is known to engage supraspinal brainstem pathways, in contrast to pudendal nerve-evoked effects, which are spinally-mediated (282).

Of interest, the effectiveness of tibial nerve stimulation may actually depend on activation of fibres in the saphenous nerve (283), which is probably co-activated when electrodes are positioned for tibial nerve therapy (284). In fact, selective saphenous nerve stimulation evoked frequency-dependent inhibition of bladder function in anaesthetised cats (279,285). A pilot study in humans indicates that the procedure offers a promising new intervention for treating overactive bladder (286).

5. NOVEL STIMULATION PARADIGMS

Studies with animal models have considered not only alternative targets for neuromodulation of bladder function but also the optimisation of stimulation parameters. Within a mixed nerve adjusting intensity, frequency, pulse duration, pulse waveform, pattern of stimulation (continuous of intermittent) can lead to selective ac-

tivation of different fibre types and different functional outcomes. Optimal stimulation parameters to evoke the same functional outcome may differ depending on the site of stimulation. Thus, bladder contractions evoked reflexly by stimulating the dorsal nerve of the penis (pudendal nerve afferents) in cats were optimal in response to trains of single pulses or doublets at 33Hz (233). However, bladder contractions evoked by direct stimulation of the spinal outflow to the bladder (pelvic nerve efferent fibres) were optimal in response to lower (5Hz) frequency stimulation (287,288).

At present, stimulators available for clinical use offer only a limited range of stimulation parameters and there is relatively little information available about the impact of programming changes on clinical effectiveness (289). However, investigations in preclinical models suggest that the efficacy of such devices could be improved by increasing the range of available stimulation parameters**.** A more in-depth understanding of the neurophysiological effects produced by different stimulation parameters also has the potential to allow tailoring of stimulation paradigms for specific patient needs and to optimise therapeutic outcome.

Another property of peripheral nerve electrical stimulation, which deserves more attention, is its ability to inhibit rather than excite nerve axons. High frequency stimulation in the kHz range blocks conduction in mammalian nerves, including pudendal nerve efferent fibre supplying the EUS (290-292). Combinations of low frequency (multiples of 10 Hz) stimulation and kHz frequency stimulation can activate some fibre types whilst inhibiting others. Low frequency stimulation of the S2 sacral roots combined with high frequency-induced block of transmission in the pudendal nerve enabled co-ordinated micturition in cats (293). Another elegant study (258) showed it was possible to prevent the development of bladder-sphincter dyssynergia in rats by combining distal low frequency (10 or 20 Hz) pelvic nerve stimulation to evoke detrusor contraction, with high frequency (20 kHz) stimulation at a more proximal site along the pelvic nerves to block afferent fibre-induced activation of the EUS. A similarly imaginative strategy to promote continence in cats with complete spinal cord injury utilised continuous bilateral 5 Hz stimulation of the pudendal nerve to excite afferents and reflexly inhibit bladder overactivity during storage to promote continence. This was combined with periodic 20-30 Hz stimulation to induce reflex bladder contraction and 10 kHz stimulation to block conduction in efferent nerves to the sphincter, thereby enabling low pressure voiding to empty the bladder (294).

Until recently, a major limitation of all implantable stimulation devices has been the finite lifespan of the batteries, with the requirement of surgical intervention for battery replacement. This problem may soon be overcome by the new generation of stimulators driven by wireless-powering (30), or which can be recharged by wireless power transfer (295). The use of time-interfering current technology for non-invasive stimulation, which delivers higher penetration efficiency than transcutaneous methods (296) is another potential refinement. The development of optogenetic technology, which can excite or inhibit the bladder nerve supply (297), and transcutaneous ultrasound technologies for stimulation (298) represent further developments that are paving the way towards a new era of clinically effective neuromodulation devices.

A recent development of great interest is ‘on demand’ or ‘conditional’ stimulation. Sensory feedback-based closed-loop stimulation may offer greater clinical benefit by driving bladder relaxation to increase bladder capacity or inhibit imminent unwanted voids only when bladder contractions are detected. In rats, dorsal penile nerve stimulation, triggered automatically by an increased frequency of bladder non-voiding activity, resulted in bladder inhibition, and a consequential increase in bladder capacity (299). This study demonstrates the feasibility of using the frequency of non-voiding contractions as a trigger event for conditional inhibition of detrusor contractions. In a similar vein, the application of stretchable electronics technology to detect bladder fullness (297) and drive optogenetic stimulation to inhibit bladder excitability and suppress voids is another exciting development.

In the past decade advances in understanding the neurophysiological mechanisms underlying neural control of the bladder, combined with technological advances in stimulation technology mean that therapeutic manipulation of activity in peripheral nerves of lower urinary tract by non-invasive means is becoming an attainable goal for management of LUT dysfunction. This is set to revolutionise neuromodulation therapy to normalise dysfunctional bladder storage and voiding control mechanisms.

IV. THE TISSUES OF THE URETHRA

1. INTRODUCTION (STRUCTURE & FUNCTION)

The muscular tissues of the urethra are composed of an inner longitudinally arranged and an outer circularly-arranged layers of smooth muscle and an outermost striated muscle layer. Inside this muscular tube is the mucosa, that contains a dense distribution of blood vessels, containing vascular smooth muscle cells (SMCs) as well as scattered SMCs in the *lamina propria* (SMC-LP). The contractility of these smooth muscles is enhanced by noradrenaline released from sympathetic nerves supplied via the hypogastric nerves, while smooth muscle relaxation is predominantly mediated by nitric oxide (NO) released by the action of parasympathetic nerves that are conveyed by pelvic nerves (300). In contrast to these autonomic innervations of the urethral smooth muscle, contractions of the striated muscle fibres are mediated by acetylcholine (ACh) released from somatic motor neurons via pudendal nerves (Figure 18).

During the bladder storage phase of the micturition cycle a sustained urethral closing pressure (UCP), that is greater than bladder intravesical pressure (IVP), is generated to maintain urinary continence. The highest closing pressure of 100–120 cmH_2O occurs approximately 3 cm from the bladder neck in the female urethra and approximately 5 cm from the bladder neck in the membranous region of the male urethra (301). Upon sudden rises in IVP due, say, to an increase of abdominal pressure, reflex increases in the UCP known as the ‘guarding reflex’ are developed to prevent urine leakage (250). Prior to the voiding phase, UCP starts to decline so that the bladder can void urine, with a minimal rise in the IVP (Figure 19). Such active opening of the urethral lumen preceding the bladder contractions is nicely visualised using transrectal or transvaginal ultrasound scanning (see supporting information in (302). Such urethral opening results not only from a decline of striated muscle tone, associated with a cessation of bursts in external urethral sphincter (EUS) electromyography (EMG) signals, but also the active relaxation of the smooth muscles.

All muscular components contribute to the closure of the urethral lumen. Animal studies report that the relative contribution of the striated muscle to the UCP is one-third or even less of the smooth muscle (303,304), suggesting a predominant role of the smooth muscle

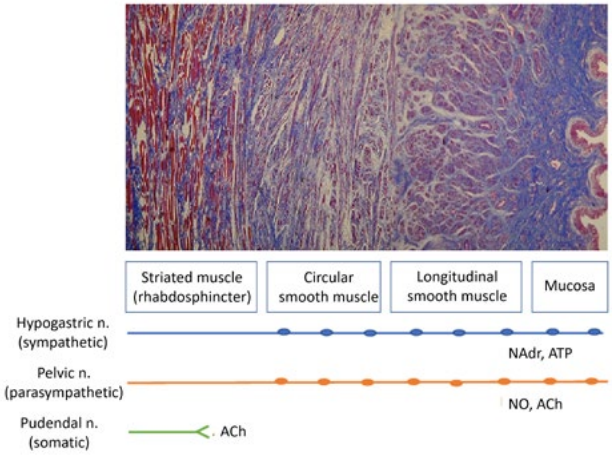

Figure 18. Muscular layers in the urethral wall. *The urethral wall has four major layers. Innermost (right) is the mucosal layer, made up of epithelial cells (urothelial cells in the proximal urethra) and lamina propria. The muscular layer consists of inner longitudinal and an outer circular smooth muscle layers and outermost striated muscle layer. The mucosa and smooth muscle layers receive efferent innervation from sympathetic hypogastric nerves, releasing noradrenaline (NAdr) and ATP, and parasympathetic pelvic nerves releasing NO or ACh. Striated muscle receives innervation from somatic, pudendal nerves releasing ACh. With acknowledgement to the late Prof. Alison Brading, University of Oxford, UK*

layers in developing UCP. This includes the mucosal smooth muscle component of vascular and non-vascular components (305). In humans, the striated muscle layer, the organised smooth muscle layers and the mucosa components are each estimated to contribute approximately equally to the final UCP (306). In contrast, the paramount importance of striated muscles to development of the UCP, both at rest and during physical activity, has also been proposed (307). Such contrasting reports are likely to be due to the difficulty of selectively inhibiting the individual components *in vivo* and therefore estimating their individual contribution.

Because a large proportion of male patients restore urinary continence after radical prostatectomy, smooth muscle, the dominant contractile component in the internal urethral sphincter (IUS)/bladder neck, is often considered to contribute little to urinary continence. Female patients who display an incompetent IUS are also capable of maintaining continence upon rises of abdominal/intravesical pressure, and thus the EUS is considered to play a predominant role in urethral closing (308). Nevertheless, at rest urine is normally stored at a level superior to the IUS in both men and women and preservation of the IUS results in an earlier recovery of urinary continence after radical prostatectomy (309). Therefore, both the 'smooth muscle predominant' internal sphincter and the 'striated muscle predominant' external sphincter contribute to the generation of the urethral closing pressure (310). Because of the differing contractile properties of smooth and striated muscles, the smooth muscles have a larger contribution to generation of a resting urethral pressure, whilst striated muscles play a predominant role in developing transient pressure rises.

Here, the morphological and contractile properties of urethral striated and smooth muscles, as well as the muscular components in the urethral mucosa will be described. Pathological changes, in particular with ageing, and their relevance as a therapeutic target will also be discussed.

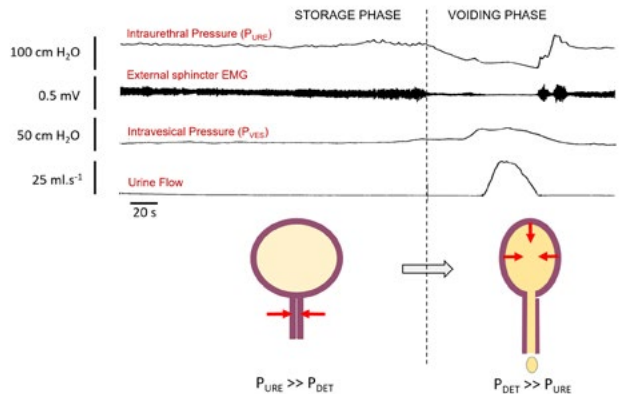

Figure 19. Functions of the urethra during storage and voiding phases. *Four traces from a urodynamic study on an awake subject from top to bottom are: urethral pressure (PURE), external sphincter EMG, intravesical pressure (PVES) and urine flow. The vertical dotted line indicates the timing of 'ask to void'. With thanks to Dr Sarah Knight and Prof Michael Craggs, the London Spinal Cord Injury Centre, Stanmore, UK.*

2. STRIATED MUSCLE

2.1. Morphological properties.

In the human, striated muscles exist along the length of both the male and the female urethra and constitute the EUS, or rhabdosphincter. With the male urethra, striated muscles inferior to the caudal prostate form an omega-shaped dense aggregation of circular fibres in the region of the membranous urethra. This structure runs longitudinally and becomes less apparent towards the bladder (310). With the female urethra, the relatively thick striated muscle fibres begin at the bladder neck and are in a horseshoe-shaped configuration with the opening on the dorsal side (311). Starting at the midpoint of the urethra, the EUS continues to the compressor urethrae and the urethrovaginal sphincter. With the use of immunohistochemical techniques, 3D reconstructions of the muscle structure in the foetal urethra demonstrated different compositions of muscular structures along the urethral length (311). Thus, the proximal third consists of predominately circular smooth muscle fibres, with the middle third of both smooth and striated muscle fibres arranged in circular orientation. The distal third consists of circular smooth muscle fibres surrounded by an omega-shaped layer of striated muscle fibres.

Several animals have provided important models for physiological studies of the urethra. With the male pig, the striated muscle component is less evident cranially, towards the bladder, but forms a thick sphincter caudal to the prostate body that almost completely surrounds the urethra (312). With the female pig, the striated muscle layer starts at the midpoint and becomes dominant in the distal one-third of the urethra (301). In female rats, striated muscle fibres start at the end of the proximal third of urethra and increase to a maximum density in the middle third of the urethra to make up the EUS (313). Thus, the arrangements of striated muscles in the urethrae of the animal models are basically similar to that of human urethra.

2.2. Contractile properties.
In the human urethra, slow-twitch, aerobic, oxidative (type-I) muscle fibres are predominant, whilst fast (type-II) fibres are distributed throughout. Fast (type-II) fibres are subdivided into type IIA (fast, fatigue-resistant) and type IIB (fast, fatigable) fibres distinguished by their differential staining with myofibrillar ATPase or myosin heavy chain isoforms (314). Type I and types IIA fibres are adapted to develop the resting UCP in coordination with smooth muscles, whilst types IIB fibres are recruited on sudden rises if the abdominal/intravesical pressure. In contrast to the human urethra, striated muscle fibres in rat and mice predominantly express fast myosin heavy chains, with a smaller proportion of slow myosin heavy chain fibres (315). This predominance of fast fibres (Figure 20) is consistent with the behaviour of the EUS during voiding which demonstrates oscillatory bursts of EMG activity consistent with a staccato voiding pattern. This differs considerably from that of humans by in whom EUS activity ceases during the voiding period (316).

Contractile activity of the EUS is exclusively regulated by somatic motor neuron inputs from S2-S4 nerve roots originating in Onuf's nucleus, via the pudendal nerve. EUS motor units are highly excitable and easily recruited allowing tonic, synchronous contractions of EUS fibres to efficiently close the urethral lumen (317). The EUS motor pool consists of both fast and slow motor units, and their mode of recruitment depends on the size principle, that becomes evident in spinally-transected animals (242).

In the isolated lower urinary tract of the greyhound dog, pudendal nerve stimulation triggers rapid, transient rises of urethral pressure, while pelvic or hypogastric nerve stimulation causes more slowly-developed and prolonged pressure increases (318). In isolated EUS muscle strips, electrical field stimulation (EFS) at a frequency of greater than 20 Hz develops smooth tetanic contractions that are sensitive to d-tubocurarine, indicating that the contractions are mediated by the activation of nicotinic receptors from neurally-released acetylcholine. In the membranous urethra where fast, fatigue-resistant (type IIA) fibres predominate, the contraction amplitude is well maintained during a prolonged stimulation (319), suggesting that type IIa fibres can contribute not only to phasic activity but also to maintenance of sustained urethral tone.

Striated muscle fibres of the greyhound membranous urethra have a resting membrane potential of -75 mV and are capable of generating action potentials with amplitudes of over 90 mV – i.e. a significant overshoot (318). In myoblast cultures established from the human or porcine EUS, voltage-gated Na^+ channels, that play a fundamental role in action potential generation, have been identified (320). Voltage-gated Ca^{2+} channels, that function as a voltage sensor rather than a Ca^{2+} influx pathway, have also been identified (320). The activation of sarcolemma voltage-gated Ca^{2+} channels would trigger the opening of ryanodine receptor Ca^{2+} release channels located in the sarcoplasmic reticulum, resulting in voltage-induced Ca^{2+} release to contract the muscle fibre. However, detailed descriptions of intracellular Ca^{2+} dynamics in excitation-contraction coupling of EUS muscle fibres, including Ca^{2+} release and sequestration by sarcoplasmic reticulum and/or mitochondria is very limited to date (Figure 21) and deserves greater investigation. Fluorescently-labelled reporter mice have confirmed that T-tubular plasma membrane also express Piezo1 mechano-sensitive Ca^{2+}-permeable cation channels in EUS muscle fibres (321). Thus, Piezo1 channels may well sense urethral wall tension and allow Ca^{2+} influx

B: Ca2+ transient induced by single 20 µs electrical field stimulation (EFS). C: tetanic Ca2+ transients triggered by 20 µs EFS pulses at 10, 20 or 50 Hz for 1-s. D: D-tubocurarine (5 µM) abolished EFS (50 Hz for 1s)-induced Ca2+ transients but increasing pulse duration from 100 µs restored Ca2+ transients. E: abolition of Ca2+ transients by tetracaine (1 mM) – EFS stimulation (50Hz, 1s, pulse duration = 100 µs) in the presence of D-tubocurarine. Increasing ∆F/F0 represents a rise of the [Ca2+]i. Prof Hikaru Hashitani, Nagoya City University, Nagoya, Japan; unpublished data.*

into EUS muscle fibres, independently of α-motor neuron-mediated excitation-contraction coupling.

2.3. Nitric oxide (NO).
In EUS muscle fibres of the male membranous urethra, nitric oxide synthase (NOS) immunoreactivity and NADPH diaphorase activity have been detected in the sarcolemma of about 50% of muscle fibres, particularly fast-twitch fibres (322). Although neuronal NOS (nNOS) is also localised in nerve trunks and fibres of pudendal motor neurons innervating EUS, skeletal muscle itself, in general, contains high concentrations of potent NO scavengers that could limit any neurohumoral action of NO. Therefore, NOS located in the sarcolemma or sarcoplasm of EUS muscle fibres could produce NO that acted particularly on closely-neighbouring target proteins.

In healthy males, sublingual administration of an NO donor, reduces not only the resting UCP but also the maximal urethral pressure induced by magnetic stimulation of the sacral roots (323). Nevertheless, since NO functions as a major inhibitory neurotransmitter causing the relaxation of urethral smooth muscles, the site of actions of systemically administrated NO should be carefully considered. In the EUS of the guinea-pig urethra where β-NADPH-diaphorase activity is preferentially expressed at the neuromuscular junction, NO donors reduce peak UCP evoked by pudendal nerve stimulation (324), although NOS inhibition or cGMP blockade fails to enhance resting urethral pressure. In sheep EUS, where distinct nNOS-positive and cGMP immunoreactive striated muscle fibres are distributed, basal cGMP immunoreactivity is strongly enhanced by a PDE5 inhibitor and reversed upon inhibition of guanylate cyclase activity (325). This suggests that nNOS-positive fibres could be the source of endogenous NO, that stimulates cGMP production in neighbouring cGMP immunoreactive fibres. However, pharmacological manipulation of cGMP again failed to modulate nerve-evoked contractions. Overall, cGMP appears not to play a significant role in NO-mediated regulation of the EUS contractile function. In skeletal muscle in general, nNOSμ, the splice variant of nNOS located in the sarcolemma or the inner membrane of the nuclear envelope, plays a fundamental role in NOS signalling via S-nitrosylation of target proteins (326).

2.4. Age-related changes.
In the urethra, the relative volume of striated muscles and blood vessels decline with age and is associated with an increase in connective tissue. However smooth muscle relative volume does not undergo any significant change (327). In both males and females, the density of striated muscle in EUS declines with age, from 87% to 30% over 0 to 90 years, and due to apoptosis and subsequent replacement by connective tissues (328). This indicates that striated muscle in the urethra displays the age-related deterioration known as sarcopenia. However, unlike sarcopenia seen in musculo-skeletal striated muscles (329), mean fibre diameter is not significantly changed, and may reflect the slow twitch fibre dominance in the EUS. Indeed, in the EUS from nulliparous rabbits, in which the proportion of fast and slow myosin fibres is about 4:1, there was a selective decrease in the volume of type-II (fast) muscle fibres and/or conversion of type-II to type-I (slow) muscle fibres, as occurred in the EUS of old multiparous animals (330). In the human female EUS, the density of nerves also declines with age and displays a close correlation with the reduction of muscle fibre numbers (331). Considering the fact that EUS plays a predominant role in preventing genuine stress incontinence (SUI), an age-related decline, particularly in motor neurons and fast muscle fibres may be an important causal factor

The volume and/or strength loss of EUS function in association with SUI has also been demonstrated by clinical measurements. Intraurethral ultrasound examination in combination with urodynamic studies in patients with SUI have demonstrated that reduction of the thickness and contractile function of the EUS correlates well with the severity of SUI (332). Studies using magnetic resonance imaging have reported that patients with SUI have thinner urethral striated muscle than continent subjects, while the thickness of the smooth muscle layers and mucosa are not different between continence and incontinence groups (333). This further suggests a dominant role in the decline of striated muscle volume and function in the pathogenesis of SUI. EUS needle biopsies have confirmed that muscle fibres are largely replaced by connective tissue in the EUS of patients with SUI (334,335). Abnormal EMG recordings of patients are characterised by a reduced number of motor unit potentials and decreased maximum voluntary electrical activity. This indicates that muscle atrophy results from a denervation of α-motor neurons. Older women who have suffered UI symptoms also developed a generalised sarcopenia indicated by a significant decline in their physical performance, specifically standing and balance (336).

In females, the decline in oestrogen levels during peri-menopause and post-menopause periods is a possible aetiological factor in development of SUI. In rats, ovariectomy was associated with a decline in both baseline and active urethral pressure induced by sneezing associated with SUI. Oestrogen replacement partially restores baseline pressure values, but not active pressure or improvement of continence (337), suggesting that oestrogen enhances smooth muscle tone rather than EUS mediated urethral contractile function. However, in humans, oestrogen receptors are predominantly expressed in the squamous but not transitional cell epithelium in the female urethra, while no significant amount of receptor expression is found in the muscle layers (338). Systemic hormone replacement therapy generally worsens SUI, while local vaginal oestrogen treatment may improve SUI (339).

2.5. Plasticity and therapeutic strategies.
Myostatin, a negative regulator of skeletal muscle mass and satellite cell proliferation inhibits proliferation of myotubes developed from EUS satellite cells (340). Inhibition of myostatin, caused an increase of EUS muscle fibre and elastin fibre number, associated with a rise in leak point pressure in rats that had undergone pudendal nerve crush and vaginal distention (341). This suggests that inhibition of myostatin could be a therapeutic strategy for treatment of SIU.

In aged mice, injection of recombinant insulin-like growth factor-1 (IGF-1) into the urethral wall activated satellite cells that became incorporated into existing striated muscle bundles (342). The IGF-1/Akt/PKB pathway controls skeletal muscle growth via mechanistic (or mammalian) target of rapamycin (mTOR), a conserved serine/threonine kinase that forms a multiprotein complex (mTORC1) (343). Since mTOR/mTORC1 plays a critical role in resistance exercise-induced muscle hypertrophy independently of the IGF-1/Akt/PKB pathway, an exploration of the role of this pathway in maintenance and improvement of EUS function would be of great interest.

For women with SUI, pelvic floor muscle (PFM) training increased EUS cross-sections in ultrasound imaging (344) or EUS thickness, cross-sectional area and volume imaged with MRI (345). Thus, PFM training appears to effectively induce hypertrophy of EUS. PFM training may also trigger the release of myokines from trained individuals, as some myokines positively increase skeletal muscle mass (346). If this is the case, a combination of PFM training with

systemic resistance training would be beneficial for the conservative treatment of SIU.

Downstream targets of the protein sonic hedgehog (SHH) that plays a critical role in the development and maintenance of smooth muscle have also been identified in human EUS tissue (347). Nanofibre-based delivery of SHH protein increases the growth of EUS muscle cells, while SHH inhibition results in a reduction in the cell growth, and thus such an approach also offers a strategy to improve regeneration of muscle mass. Several other regenerative strategies for the treatment of SUI have been introduced. Injection of autologous myoblasts and fibroblasts into EUS increases its thickness and contractility resulting in a better improvement of SUI in women compared with collagen injection (348). Periurethral injection of autologous adipose-derived regenerative cells reduces the urine leakage in patients with post-prostatectomy SUI (349).

3. SMOOTH MUSCLE

3.1. Tone development.

There is no doubt that contractions of circular smooth muscle generate a concentric force to narrow the urethral lumen. In contrast, the roles of longitudinal smooth muscle contraction in maintaining the UCP is less readily recognisable. In rabbit urethra, longitudinal smooth muscle cells (SMC) have a higher sensitivity to ACh and demonstrate less pronounced nitrergic relaxations compared with circular SMCs (350). In addition, longitudinal SMCs, compared to circular SMCs, have a three-times greater shortening which suggests a phasic nature of longitudinal SMC contraction (351). Based on such characteristics of longitudinal SMCs, it has been suggested that their contractions result in urethral shorting, which in turn would promote opening of the proximal urethra upon the micturition and reduces overall urethral hydraulic resistance. Nevertheless, because sympathetic nerves project to both circular and longitudinal muscle layers, neurally-released noradrenaline should contract longitudinal SMCs during the bladder filling phase.

In the gastrointestinal (GI) tract, longitudinal muscle is considered to concentrate circular muscle fibres within a fixed longitudinal segment. Such an effect increases the total force available to maintain closure for the same individual fibre force by increasing the number of circular fibres within the segment (352). Conversely, for a given total closure force required to maintain closure of a fixed longitudinal segment, the force per circular muscle fibre is reduced allowing more energy efficient muscle work. Therefore, longitudinal urethral SMCs could also indirectly contribute to the UCP during the storage phase.

Smooth muscles of the urethra, particularly those in the proximal urethra, develop spontaneous sustained tone contributing to the resting UCP (353). With pig urethral smooth muscle, phasic contractile activity is not consistently evident during sustained tone, but phasic contractions become evident during the relaxing phases. Since urethral muscle strips taken from several species develop phasic rather than sustained contractile activity, it was envisaged that the UCP results from the summation of several phasic contractions (Figure 22).

The urethral tone is largely diminished upon the blockade of L-type voltage-dependent Ca^{2+} channels (LVDCCs; Cav1.2) (354,355), indicating that influx of Ca^{2+} via LVDCCs has a fundamental role to generate smooth muscle tone. Consistently, LVDCC, as well as T-type voltage-dependent Ca^{2+} channel (TVDCC)-currents have been demonstrated in SMCs of human and rabbit urethra (356,357).

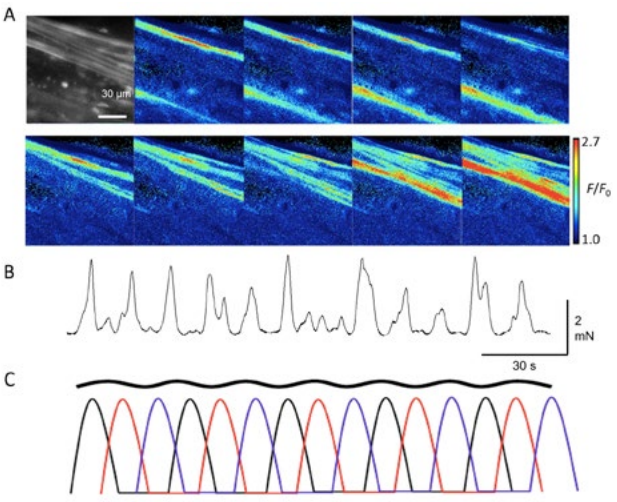

Figure 22. Basis of urethral smooth muscle tone. *A: rabbit urethra smooth muscle bundles; spontaneous Ca2+ transients generated as either 'non-propagating' Ca2+ transients (upper) or intercellular Ca2+ waves (lower): frame interval 100 ms. Modified from [404]. B: spontaneous phasic contractions of muscle fibres exhibit varied amplitudes. C: schematic of spontaneous phasic contractions generated independently in different muscle bundles (black, red, blue). Urethral smooth muscle tone (upper thick black wavy line) is maintained by spatio-temporal summation of the contraction of multiple muscle bundles.*

Ca^{2+}-activated Cl^- channels (CaCCs), anoctamin-1 (Ano1), and also known as transmembrane member 16A (TMEM16A), are expressed in urethral SMCs of sheep, rat and mouse, and their pharmacological blockade diminishes EFS- or noradrenaline-induced contractions (358). This suggests that depolarisation due to the opening of CaCCs depolarises the resting membrane potential to the threshold of LVDCC opening. However, spontaneous Ca^{2+} waves in isolated mouse urethral SMCs appear to arise from release of Ca^{2+} from sarcoplasmic reticulum Ca-stores. This release occurs via type 1 inositol trisphosphate ($InsP_3$) and ryanodine (RyR)-receptor Ca^{2+} release channels, maintained by Ca^{2+} influx through store-operated Ca^{2+} entry but not VDCCs (359).

Sex differences in development of spontaneous tone may be contributed by differential activity of some of the above components. Spontaneous contractile activity was more readily developed by in vitro preparations from female patients and rats than male counterparts (360). The expression level of Ano-1(CaCC) and Ano-1 inward current, as well as dependent increase of $[Ca^{2+}]_i$ were higher in tissue from females compared to males. By contrast, in pig SMCs, where spontaneous tone is predominantly generated by Ca^{2+} influx via LVDCCs, Ano-1 blockers have no effect on the urethral tone, while store-operated Ca^{2+} entry contribute to the tone generation (355).

In pig urethra, the blockade of Rho kinase (ROK) or the inactivation of Rho GTPase diminishes spontaneous tone without reducing $[Ca^{2+}]_i$, suggesting the additional role of ROK-dependent Ca^{2+} mechanisms in developing spontaneous tone (354). RhoA-ROK dependent Ca^{2+} sensitisation in SMCs may arise from inhibition of myosin phosphatase (MLCP) resulting in greater phosphorylation of myosin light chain (MLC). Alternatively, the ROK/LIM kinase/cofilin pathway could cause actin polymerisation to develop smooth muscle contractions. However, in rabbit urethral SMCs, ROK ap-

pears to play a role in developing muscle contractions neither via the inhibition of MLCP or actin polymerisation (361).

3.2. Electrical properties.

Urethral SMCs have a resting membrane potential ranging between -70 mV and -35 mV that varies amongst species and/or circular/longitudinal muscle layers (357,362-364). Urethral SMCs develop individual or bursting spike-like action potentials (357,362). Urethral SMCs also generate spontaneous transient depolarisations (STDs) and electrical slow waves (363,364). In isolated sheep urethral SMCs in which fast-activating LVDCC current and slowly-developing CaCC currents were recorded, the blockade of LVDCCs prevented action potential generation leaving STDs that were abolished after the blockade of CaCCs (365). Thus, CaCCs function as pacemaker currents and the resultant depolarisation triggers the opening of LVDCCs to contract urethral SMCs. Unlike sheep urethral SMCs, in isolated SMCs of rabbit urethra that display LVDCC currents, CaCC currents are seldom recorded, whilst urethral interstitial cells exhibit CaCC currents or STDs (366), see also section IV.5). Similarly, only fast-activating LVDCC currents but not slowly-developing CaCC currents are observed in isolated human urethral SMCs, while interstitial cells display slowly-activating inward currents upon depolarisation and prominent tail currents upon repolarisation, characteristic of CaCC currents (367). In rabbit urethra, slow waves are developed in circular SMCs, while longitudinal SMCs generate action potentials (368). Such differences in the form of electrical activity between the two layers may partly explain the fact that shortening velocity of contraction of the longitudinal SMC layer is greater than the circular SMC layer (351). By contrast, slow waves but not action potentials are generated in the longitudinal smooth muscles of the guinea-pig urethra (364). Thus, there are considerable differences between species differences in urethral electrical activity (Figure 23). Of importance is to demonstrate which animal models provide the greatest translational potential to human urethral activity.

The blockade of LVDCCs diminishes or abolishes action potential discharge (357,368), indicating a predominant contribution of LVDCCs to action potential configuration. LVDCC blockade also inhibits the plateau phase of slow waves to shorten their duration without affecting the initial depolarising phase (363,364). Thus, both action potentials and slow waves permit Ca^{2+} influx via LVDCCs resulting in smooth muscle phasic contractions. In contrast, the blockade of TVDCCs reduces the frequency of action potentials without diminishing their amplitude (357). Thus, TVDCCs may be activated at resting membrane potentials of around -50 mV (351) and any resultant depolarisation would increase the probability of LVDCC-dependent action potential generation (356,357).

In isolated sheep urethral SMCs, blockade of large-conductance Ca^{2+}-activated K^+ (BK) current abolishes the depolarisation-evoked early transient outward currents and also diminishes sustained outward currents, however small-conductance Ca^{2+}-activated K^+ (SK) current has only a marginal contribution (369). BK channel blockade abolishes transient repolarisation of action potentials and increases their amplitude and plateau duration, indicating a fundamental role of BK channels in stabilising urethral SMC excitability. In rabbit urethral SMCs, BK currents are suppressed by the blockade of LVDCCs or RYRs but not $InsP_3$-induced Ca^{2+} release. This suggests that Ca^{2+} influx through LVDCCs triggers Ca^{2+}-induced Ca^{2+} release (CICR) via RYRs to activate BK channels (370). In urethral SMCs taken from mice in which transient receptor potential mucolipin-1 (TRPML1) channels are genetically deleted, spontaneous Ca^{2+} sparks and resultant BK-STOCs are impaired (371). TRPM1 channels localised to the membranes of late endosomes and lysosomes may allow Ca^{2+} release that triggers CICR via RYRs in close vicinity. After suppression of the BK channel currents in USMCs, the blockade of voltage-sensitive K^+ (Kv) channels, predominantly Kv2.1 subtype, increases the amplitude and duration of action potentials of urethral SMCs (356,372). This suggests that Kv2.1 channels function as a backup mechanism to ensure action potential repolarisation. The blockade of ATP-sensitive K^+ (KATP) channels causes a membrane depolarisation (373), and thus a small propor-

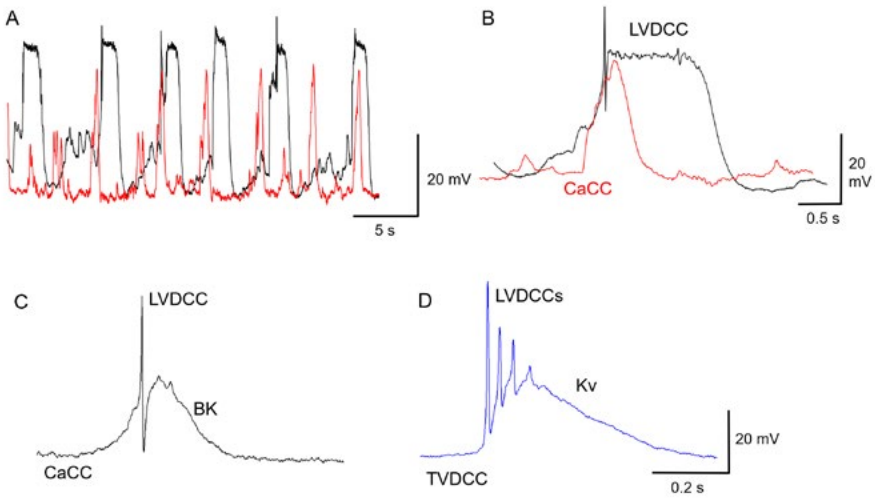

Figure 23. Spontaneous electrical activity in urethral smooth muscle cells (SMCs). *A: guinea-pig longitudinal layer SMCs; slow waves (black) and spontaneous transient depolarisations (STDs, red) on a slow (left) and fast (right) time-base. B: rabbit longitudinal layer SMCs in the absence (left, black) and presence of cyclopiazonic acid (CPA, 10 μM) to block the sarcoplasmic-endoplasmic reticulum Ca pump (right, blue). CPA prevents the transient repolarisation and prolongs action potential repolarisation. Ion channels contributing to different components of slow waves or action potentials are shown: CaCC, Ca2+-activated Cl- channel; LVDCC/TVDCC, L/T-type voltage-dependent Ca2+ channel; BK, large-conductance Ca2+-activated K+ channel; Kv, voltage-sensitive K+ channel. Modified from: A; [364], B [368].*

tion of KATP channels appear to stay open at rest and contribute to the maintenance of the resting membrane potential.

4. SMOOTH MUSCLE NEURAL MODULATION

4.1. Excitatory innervation.

In human urethral smooth muscle, in which the density of cholinergic nerves is much greater than adrenergic nerves noradrenaline causes contractions by activating α-adrenoceptors, whilst in comparison ACh activating muscarinic receptors has no or relatively little contractile effect compared with noradrenaline (374,375). In dog urethra, contractions induced by hypogastric nerves are largely diminished upon the blockade of α-adrenoceptors but not muscarinic receptors, indicating the predominant role of neurally-released noradrenaline to generate urethral contractions (376). In rabbit urethra, EFS-induced contractions in the circular smooth muscle layer are predominantly mediated by α-adrenoceptors activation from neurally-released noradrenaline. The blockade of muscarinic receptors largely diminishes nerve-evoked contractions in the longitudinal smooth muscle (350). Thus, the relative contribution of noradrenergic and cholinergic contractions varies between the circular and longitudinal muscle layers. In addition, there is a regional variation in the neural control of urethral smooth muscle contractility along the length of urethra. In pig urethra, in which the density of sympathetic nerves is higher in the distal than the proximal urethra, sympathetic nerve-mediated contractions are more pronounced in the distal urethra (377). Distribution of cholinergic nerves is uniform along the length of urethra, but larger muscarinic contractions are developed in the proximal than distal urethra (377) (Figure 24).

With circular smooth muscles of the rabbit proximal urethra, EFS evokes an initial excitatory junction potential (EJP) followed by a late depolarisation (378). The initial EJPs are mediated by the activation of α-adrenoceptors, whilst late depolarisations are mediated by neural-released acetylcholine that activate muscarinic receptors. Consistently, noradrenaline depolarises the membrane and increases the frequency of spontaneous slow waves, indicating that neurally-released noradrenaline contracts urethral smooth muscle at least partly by enhancement of depolarising electrical activity resulting in Ca^{2+} influx via LVDCCs (363). In longitudinal smooth muscle of the guinea-pig urethra, EFS evoked EJPs that could sum to trigger the generation of slow waves (364). Both EJPs and evoked slow waves are non-adrenergic, non-cholinergic (NANC) in nature and mediated by neurally-released ATP. In the rabbit urethra, where EFS-induced NANC contractions are mediated by P2X purinoceptor activation, bath-applied ATP induces inward currents in isolated SMCs arising from activation of these receptors (379). Of interest, bath-applied ATP can also generate smooth muscle contractions via activation of P2Y purinoceptors. These appear to be attributable to increases of spontaneous Ca^{2+} transients and inward currents in urethral interstitial cells but not urethral SMCs (380). In the urethra of hamster, ATP induces relaxation of precontracted smooth muscles via the activation of P2Y receptors, predominantly $P2Y_1$, but not P2X receptors (381). Thus, the effects of ATP on the contractility of urethral smooth muscle are complex and may depend on basal muscle tone, as well as vary between species.

With circular smooth muscle of the rabbit urethra, EFS-induced increases of spontaneous Ca^{2+} transients are prevented by α-adrenoceptor blockade, while α-adrenoceptor agonist increases the frequency of spontaneous Ca^{2+} transients (363). Thus, neurally-released noradrenaline contracts urethral smooth muscle at least partly by increasing intracellular $[Ca^{2+}]$. In rabbit urethral smooth muscle, EFS- or α-adrenoceptor stimulation-induced contractions

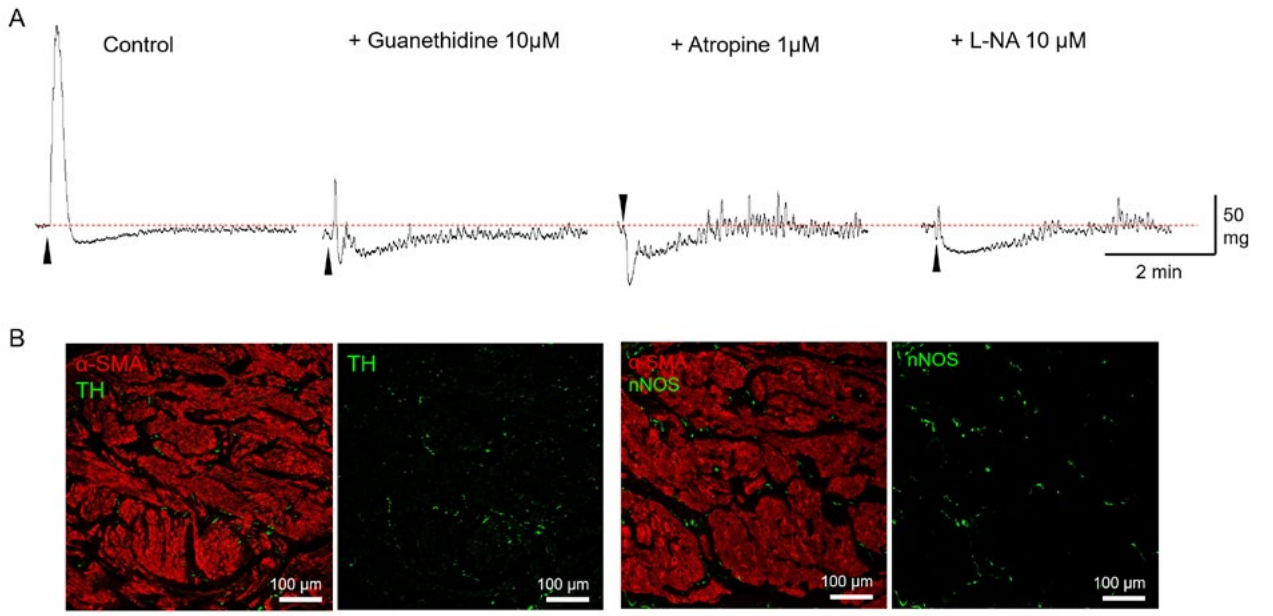

Figure 24. Excitatory and inhibitory innervations of urethral smooth muscle. *A: guinea-pig longitudinal smooth muscle; contractile responses to EFS (20 Hz, 50 μs pulses, 1-s train) in control and in the presence of guanethidine (10 μM), atropine (1 μM) and nitro-L-arginine (L-NA,10 μM). Note: guanethidine almost abolishes the contraction and unmasks a transient relaxation; atropine abolishes the small residual contraction and enhances the transient relaxation; L-NA blocks only the transient relaxation. B: tyrosine hydroxylase (TH)-positive sympathetic nerve fibres (left) and nNOS-positive nitrergic nerves (right) are distributed in the circular smooth muscle layer. Modified from [415].*

are suppressed by ROK inhibitors but not an inhibitor of PKC that can cause Ca^{2+} sensitisation via CPI-17 (361). This suggests the involvement of ROK-mediated Ca^{2+} sensitisation in α-adrenoceptor mediated contractions. However, α-adrenoceptor stimulation fails to induce phosphorylation of myosin light chain (LC20), MYPT1 or cofilin, and thus the mechanism underlying α-adrenoceptor induced contractions remain to be elucidated.

4.2. Inhibitory innervation.

Nitric oxide (NO), released from nitrergic nerves that are identified by their NOS-immunoreactivity or NADPH diaphorase activity (382,383), functions as a predominant inhibitory neurotransmitter causing relaxations of urethral smooth muscle. In precontracted urethral smooth muscles, relaxations induced by EFS, particularly at low frequency, are blocked by inhibitors of NOS (382,384). The relaxant action of NO is further supported by the findings that NO or NO donors induce a potent smooth muscle relaxation. During nerve-evoked relaxation of urethral smooth muscle, guanosine 3':5'-cyclic monophosphate (cGMP) is increased (384), consistent with cGMP functioning as a second messenger of nitrergic signalling. A fundamental role of cGMP in the relaxation of urethral smooth muscle is corroborated by the finding that the NO-dependent relaxations are abolished in mice lacking a soluble guanylate cyclase – PKG pathway (385). *In vivo* recording of urethral pressures in rats has demonstrated that reflex urethral relaxations during the voiding phase are abolished or diminished by an NOS inhibitor, indicating physiological relevance of NO as an endogenous relaxant of urethral smooth muscle (386). In the proximal urethra where a greater spontaneous tone is generated, EFS induces greater relaxation than other urethral regions, suggesting the role of inhibitory nitrergic innervation is to open the bladder outlet on micturition (377).

In circular smooth muscle of rabbit urethra, in which EFS evokes NANC inhibitory junction potentials (IJPs) (378), an NO donor or cGMP analogue reduced the frequency of spontaneous slow waves without hyperpolarising the membrane (363). Thus, neurally-released NO may cause relaxation of urethral smooth muscle by mechanisms other than membrane hyperpolarisation. Nevertheless, neurally-released NO or NO donor inhibits spontaneous Ca^{2+} transients associated with a reduction in basal Ca^{2+} level, indicating that NO-mediated relaxation of urethral smooth muscle is at least partly attributable to a reduction of intracellular Ca^{2+} concentration (368). In mouse urethral SMCs, spontaneous Ca^{2+} transients are also reduced by an NO donor (359). ROK inhibitors greatly suppress spontaneous or α-adrenoceptors-mediated contractions, involvement of Ca^{2+} desensitisation in NO-mediated relaxations remains to be determined (354,361).

Relaxations of urethral smooth muscle induced by high frequency electrical field stimulation consists of an initial, fast relaxation followed by a slowly-developing, prolonged component (384). The initial component, but not the slowly-developed component, is abolished by blockade of NOS, suggesting that slowly-developing relaxations are mediated by a neurotransmitter other than NO. Nerve-evoked relaxations are not inhibited upon the blockade of β-adrenoceptors, VIP receptors or the depletion of sensory neurotransmitters with capsaicin (387). In addition, blockers of several K^+ channels, including BK, SK, intermediate conductance Ca^{2+}-activated K^+ (IK) channels or KATP channels, failed to inhibit non-NO, nerve-evoked relaxations. In rat urethra, in which calcitonin gene-related peptide (CGRP)-containing nerve fibres originating from L6-S1 ganglia are distributed (388), capsaicin or CGRP induces relaxations of precontracted urethral preparations in a manner partially inhibited by CGRP antagonist. Thus, CGRP released from afferent nerves can function as an inhibitory neurotransmitter (389).

With pig urethral smooth muscle, in which neuronal and non-neuronal carbon monoxide (CO)-forming enzymes, namely haem oxygenase isoenzymes, are expressed CO causes a relaxation associated with an increase in cGMP, but not cAMP production (390). This suggests that CO may act as an inhibitory neurotransmitter in the urethra. In human urethra, haem oxygenase-2 immunoreactivity is colocalised with neuronal NOS immunoreactivity in ganglionic cell bodies, while some haem oxygenase-2 positive nerve trunks also appear to express nNOS (391). Nevertheless, urethral smooth muscle relaxation induced by neuronally-released CO has not been proven.

5. URETHRAL INTERSTITIAL CELLS (UICS)

UICs are variable in their morphology, typically being shaped, characterised by a varying numbers of branches or processes (366). UICs are easily distinguished from urethral SMCs by their abundant vimentin intermediate filaments and little α-smooth muscle myosin. In rabbit urethra, UICs expressing Kit immunoreactivity are distributed in both circular and longitudinal layers where they are individually scattered preferentially in parallel with the SM bundles without forming an extensive network (392). In rat or sheep urethra, where UICs are identified as cGMP immunoreactive cells, they also express vimentin and Kit (393).

The question of UICs acting as pacemaking cells to smooth muscle myocytes has remained contentious. Pacemaking functions of Kit-positive UICs, with respect to mouse cells, has not been directly shown, by their lack of associated Kit immunoreactivity, in spite of their ability to generate spontaneous Ca^{2+} transients and spontaneous transient depolarisations (STDs) (394). Sustained tone generated by urethral smooth muscles arises from the temporal summation of spontaneous phasic contractions that are tonically accelerated and augmented by neurally-released noradrenaline through the activation of α1-adrenoceptors (see section V.3.1). Spontaneous phasic contractions are driven either by action potentials or slow waves that trigger Ca^{2+} influx into SMCs via LVDCCs. Such spontaneous electrical activity has been considered to be generated within the SMCs themselves as shown in sheep myocytes expressing 'pacemaker currents', namely CaCCs, to develop spontaneous electrical activity (365). Thus, this has been termed as 'myogenic' activity.

It is now recognised that myogenic activity could also originate from a population of UICs, at least in those from rabbit urethra. Isolated rabbit UICs develop spontaneous transient inward currents (STICs) and corresponding STDs arising from the opening of CaCCs, whilst isolated urethral SMCs lacking CaCCs are electrically quiescent (366). Thus, UICs function as pacemaker cells to electrically drive SMCs that are capable of generating LVDCC-dependent action potentials with the depolarising input from UICs. Expression of TMEM16A (or Ano1)/CaCCs has been demonstrated by single-cell RT-PCR, and TMEM16A inhibitors suppress CaCC currents, STICs and STDs (395). By contrast, in mice, rat and sheep urethra TMEM16A/Ano1 is expressed in urethral SMCs but not UICs (396).

Generation of STICs/STDs in UICs are triggered by spontaneous Ca^{2+} oscillations that primarily depend on Ca^{2+} release from SR/ER intracellular Ca^{2+} stores via $InsP_3$ and ryanodine receptors (397,398). Ryanodine receptors (RyR2 and RyR3 subtypes) function as primary Ca^{2+} release channels, while $InsP_3$ receptors ($InsP_3R1$ and $InsP_3R2$ subtypes) are required to convert localised Ca^{2+}

release to propagating intercellular Ca^{2+} waves (399). Maintenance of spontaneous Ca^{2+} oscillations also depends on extracellular Ca^{2+} influx via or reverse mode the sodium-calcium exchanger (NCX), rather than capacitative Ca^{2+} entry (399-401). Similar to the role of $InsP_3$-mediated Ca^{2+} release, Ca^{2+} influx via NCX converts localised Ca^{2+} release to propagating waves Ca^{2+}, presumably by increasing cytosolic and/or luminal SR/ER Ca^{2+} levels, resulting in the facilitation of Ca^{2+} release.

Blockade of LVDCCs reduces the amplitude and duration of spontaneous Ca^{2+} oscillations and corresponding slow waves in UICs, with little effect on their frequency (398,402). It was originally thought that summed STDs generated in UICs are transmitted to urethral SMCs presumably via gap junctions to activate LVDCCs and generate the plateau phase of slow waves. However, slow waves appear to be generated in UICs themselves that then propagate to the urethral SMCs. However, UICs are scattered amongst the urethral SMCs without forming an extensive network (392), so that the close similarity in the shape of slow waves in UICs and urethral SMCs is probably due to the high input resistance of the SMCs. Indeed, spontaneous Ca^{2+} transients in urethral SMCs are often generated in individual cells independently of each other rather than forming intracellular Ca^{2+} waves (403), indeed suggestive of poor intercellular coupling between individual urethral SMCs. Thus, scattered UICs may be capable of driving only adjacent urethral SMCs, resulting in asynchronous Ca^{2+} transients and associated SMC contractions. (Figure 25).

Mitochondria, in addition to the SR/ER, also have a role in the generation of spontaneous Ca^{2+} oscillations by buffering cytoplasmic Ca^{2+}, rather than merely producing ATP to drive the SERCA Ca^{2+} pump that plays a fundamental role in ER/SR store refilling (404,405). Spontaneous Ca^{2+} waves preferentially originate from the perinuclear region where clusters of mitochondria and ER/SR surround the nucleus. Perinuclear Ca^{2+} dynamics are characterised by a gradual rise of basal Ca^{2+} that precedes each regenerative Ca^{2+} wave. In addition, small Ca^{2+} fluctuations are generated in the cell periphery where short filamentous mitochondria are scattered (405). Inhibition of mitochondrial Ca^{2+} uptake reduces the frequency and amplitude of spontaneous Ca^{2+} waves, while increasing small, non-propagating Ca^{2+} fluctuations. Thus, mitochondria Ca^{2+} buffering may prevent 'premature' CICR from the ER allowing sufficient ER Ca^{2+} sequestration that is to initiate regenerative Ca^{2+} waves (405). Inhibition of mitochondrial Ca^{2+} efflux slows spontaneous Ca^{2+} waves by suppressing the initial gradual rise in perinuclear Ca^{2+} and eventually prevents Ca^{2+} waves. This suggests that Ca^{2+} efflux through the mitochondrial NCX may be transferred to the ER/SR stores.

In isolated UICs, two types of spontaneous transient outward currents (STOCs) are also developed by the opening of BK channels (397). Generation of large STOCs with a long duration (slow STOCs) that are usually coincident with STICs appear to require spontaneous Ca^{2+} release involving $InsP_3$ receptors, whilst smaller STOCs with a fast time-course (fast STOCs) depend on RyR-mediated Ca^{2+} release. At a membrane potential more negative than -40 mV, namely within the range of resting membrane potentials in UICs, STICs predominate over the slow STOCs, and thus UICs preferentially fire STDs. Since UICs are capable of generating fast STOCs at a membrane potential of -50 mV, STOCs could contribute to the maintenance of the cell resting membrane potential.

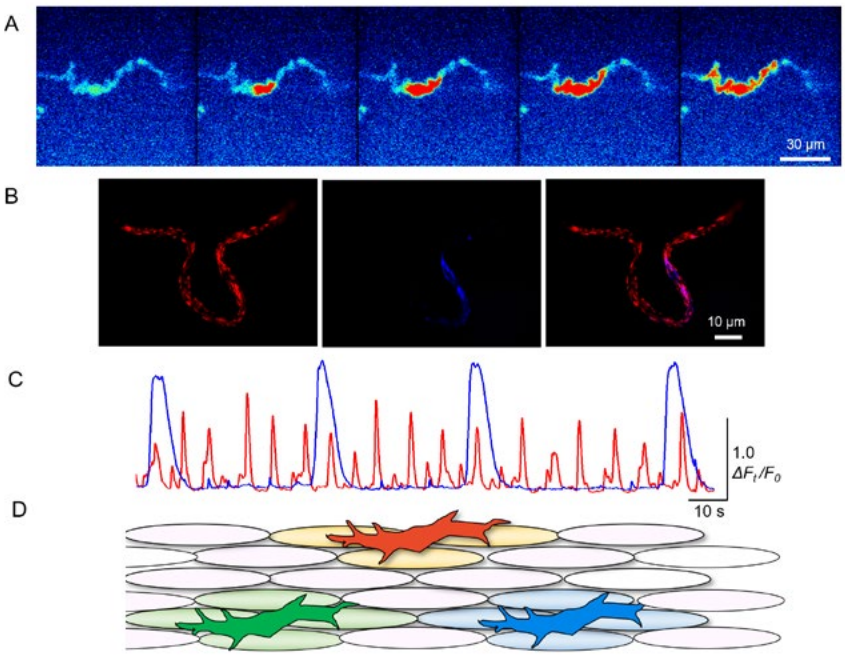

Figure 25. Spontaneous activity in urethral interstitial cells (UICs). *A: rabbit urethra: Isolated UICs develop spontaneous Ca2+ transients that preferentially originate from the perinuclear region. B: mitochondria (red, MitoTracker-Red) are clustered around the nucleus, while short filamentous mitochondria are scattered in the non-nuclear area. Endoplasmic reticulum (ER, blue, ER-Tracker) are also clustered around the nucleus. Merged image on the right. C: spontaneous Ca2+ transients in UICs (blue) do not exhibit a close temporal correlation with those in neighbouring urethral SMCs (red). D: because of poor intercellular coupling between urethral SMCs, spontaneous activity in SMCs triggered by UICs (green, orange, blue) is often restricted to adjacent urethral SMCs. Traces in A-C modified from [403,405]*

Bath-applied noradrenaline increases the frequencies of STDs or STICs recorded in isolated urethral UICs of the rabbit, via the activation of α1-adrenoceptors. This results from an increase of $InsP_3$ production to trigger Ca^{2+} release from SR/ER Ca^{2+} stores with subsequent opening of CaCCs (366,406). Stimulation of α1-adrenoceptors also accelerates spontaneous Ca^{2+} transients in UICs *in situ* (403). In isolated rabbit UICs, ATP also induces CaCC inward currents to increase STIC frequency or spontaneous Ca^{2+} oscillations by activation of P2Y purinoceptors (380). Thus, UICs may act as intermediaries of noradrenergic and/or purinergic excitatory neuromuscular transmission in urethral smooth muscles.

NO donors or cyclic GMP (cGMP) diminishes the spatial spread of spontaneous Ca^{2+} transients in isolated rabbit urethral UICs by inhibiting $InsP_3$-induced Ca^{2+} release (407). NO donors also diminish spontaneous Ca^{2+} transients in UICs *in situ*, suggesting that UICs may also play a role in inhibitory, nitrergic neuromuscular transmission in the urethra. This hypothesis is morphologically supported by the frequent points of contact between Kit-positive UICs and nerves, particularly nitrergic nerves (392). While cGMP acts as an inhibitory second messenger, activation of cAMP/PKA does not affect spontaneous Ca^{2+} transients in UICs, although PKA inhibitors diminish the generation of spontaneous Ca^{2+} transients (408). Of interest, in rabbit UICs that express cyclic nucleotide-gated (CNG) channels, a CNG channel inhibitor attenuates spontaneous Ca^{2+} transients or STOCs. Thus, non-selective cationic CNG channels allowing Na^+ or Ca^{2+} influx may contribute to maintenance of spontaneous activity by inducing depolarisation or increasing Ca^{2+} (409). Such roles of CNG channels will act in contrast to the inhibitory actions of the NO/cGMP pathway, unless CNG channels are preferentially activated by constitutively activated PKA but not NO-induced production of cGMP.

In rat or sheep urethra, where UICs express connexin43, a gap junction protein, neither the contractile effects of noradrenergic nerve stimulation, nor the relaxations induced during nitrergic neurotransmission are modified by gap junction blockers, questioning the role of UICs as an intermediary of neuromuscular transmission (410).

6. MUCOSA

6.1. Mucosal blood vessels.

Coaptation of the urethral mucosa forms a watertight seal contributing to urethral closure during the bladder storage phase and help to maintain urinary continence. Different components of the urethral mucosa, including the epithelium, blood vessels, SMCs in the *lamina propria* and connective tissue, are involved in the development of mucosal sealing. Because filling of urethral vascular bed contributes to about one-third of closing pressure (305,306), it is reasonable to assume that the mucosal vasculature contributes substantially to mucosal sealing.

In the *lamina propria* of dog urethra, the vascular plexus with inflow from small arteries is composed of interconnected longitudinal tubular vessels in the proximal urethra, while a network of sinusoidal vessels are located in the distal urethra (411). With the rat urethra, a pronounced venous plexus, lying immediately below the *lamina propria*, is distributed in the distal urethra where both smooth and striated muscles are only sparsely located, suggesting a predomi-

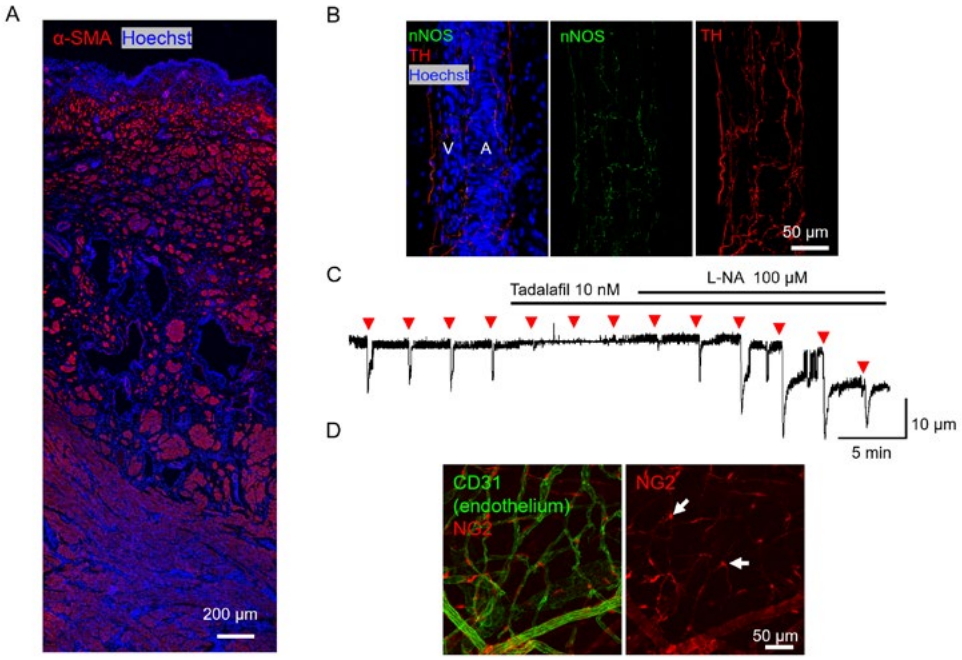

Figure 26. Microvasculature of the urethral mucosa. *A: the pig lamina propria is highly vascular with large venules, a-SMA (red, a-smooth muscle actin; Hoechst, blue, nuclear label). B: Both arterioles (A) and venules (V) receive dense innervation of TH-positive sympathetic and nNOS-positive nitrergic nerves. C: reduction of mucosa arteriole diameter with EFS (20 Hz, 100 μs pulses for 2-s, at arrowheads), tadalafil (10 nM) and L-NA (100 μM) added where shown – tadalafil abolished responses, reversed by L-NA. Modified from[415]. D: NG2-DsRed mouse urethral mucosa; the vascular network is visualised by endothelium labelling with CD31 (left). A network of capillary pericytes (arrows) expressing DsRed, a red florescent protein (right). Dr Retsu Mitsui, Nagoya City University, Nagoya, Japan; unpublished data.*

nant role of vascular plexus in the closure of urethral lumen (412). Clinical evaluation of urethral mucosa vascularity using colour Doppler has demonstrated that the mucosal vascular dimension correlates with the increases of maximal UCP and its decreases with age (413). It has also been demonstrated that continent multiparous women demonstrated a significant reduction in urethral vascularity parameters compared with continent nulliparous women (414). Nevertheless, the function of mucosal blood vessels in the urethra is less well understood compared to those in the bladder (Figure 26).

In mucosa of the pig urethra, double immunostaining for tyrosine hydroxylase (a label for dopaminergic neurons) and nNOS revealed that perivascular sympathetic fibres around mucosal arterioles and venules are intermingled with, but distinct from, nitrergic nerves (415). CGRP-containing primary afferent nerves are also distributed around both arterioles and venules, in close apposition with but distinct from perivascular nitrergic nerves, and thus there are at least three different innervations to mucosal blood vessels. This finding is consistent with a previous study demonstrating that chemical denervation of sympathetic nerves with 6-hydroxydopamine or primary afferent denervation with capsaicin did not diminish nitrergic relaxations in the rat urethra (416). This indicates that nNOS-containing nerves originate from neither sympathetic nor afferent nerves. In the rat major pelvic ganglion, NOS immunoreactive cell bodies also display choline acetyltransferase immunoreactivity (417). Moreover, nitrergic relaxation of the rat urethral smooth muscles are abolished by bilateral cryo-ganglionectomy of the major pelvic ganglia (417), suggesting that nitrergic nerves projecting to the urethra are predominantly parasympathetic in origin. In the mucosa of rat urethra, blood vessels receive vesicular acetylcholine transporter-positive cholinergic, nNOS-positive nitrergic nerves and CGRP-immunoreactive afferent nerves (412).

In the pig urethra, a reduction of urethral pressure during voiding is accompanied by greater mucosal blood flow (303). Because in parasympathetic neural activity to the lower urinary tract is dominant during voiding, the increased blood flow could result from arteriolar dilatation, mediated by NO released from parasympathetic nerves. Considering that emptying the mucosal vascular plexus would reduce mucosal sealing, while its expansion with blood would help luminal occlusion, the increased mucosal blood flow during voiding seems contradictory. This paradoxical phenomenon may result from the increased blood flow velocity due the simultaneous rise in arteriolar inflow and venular drainage.

In mucosal arterioles of the pig urethra, EFS-induced vasoconstriction is abolished by tetrodotoxin and largely suppressed by guanethidine (10 μM), and thus is predominantly mediated by sympathetic nerves (415). EFS-induced vasoconstriction is suppressed by tadalafil, a PDE5 inhibitor, in a manner sensitive to L-NA (L-nitro arginine, a NOS inhibitor). This indicates that NO released from nitrergic nerves act as an inhibitory neurotransmitter. Since L-NA also reduces the basal vessel diameter, NO may also be continuously released from the endothelium. The vasorelaxant effects of NO is possibly due to its inhibitory actions on arteriolar SMCs, mediated by cyclic GMP. In addition, the proximity of nitrergic and sympathetic nerve fibres in the mucosal vasculatures may allow NO-induced presynaptic inhibition of sympathetic transmitter release. Neurohumoral regulation of the contractility in different vascular segments in the urethral mucosa needs to be explored further.

6.2. Smooth muscle cells in the lamina propria (SMC-LP).
In the urethral mucosa, sparsely distributed, longitudinally-arranged SMCs in the *lamina propria* (SMC-LP) have been described (418). Rabbit urethral *lamina propria* contracts upon activation of α-adrenoceptors with EFS or bath-applied noradrenaline (418),

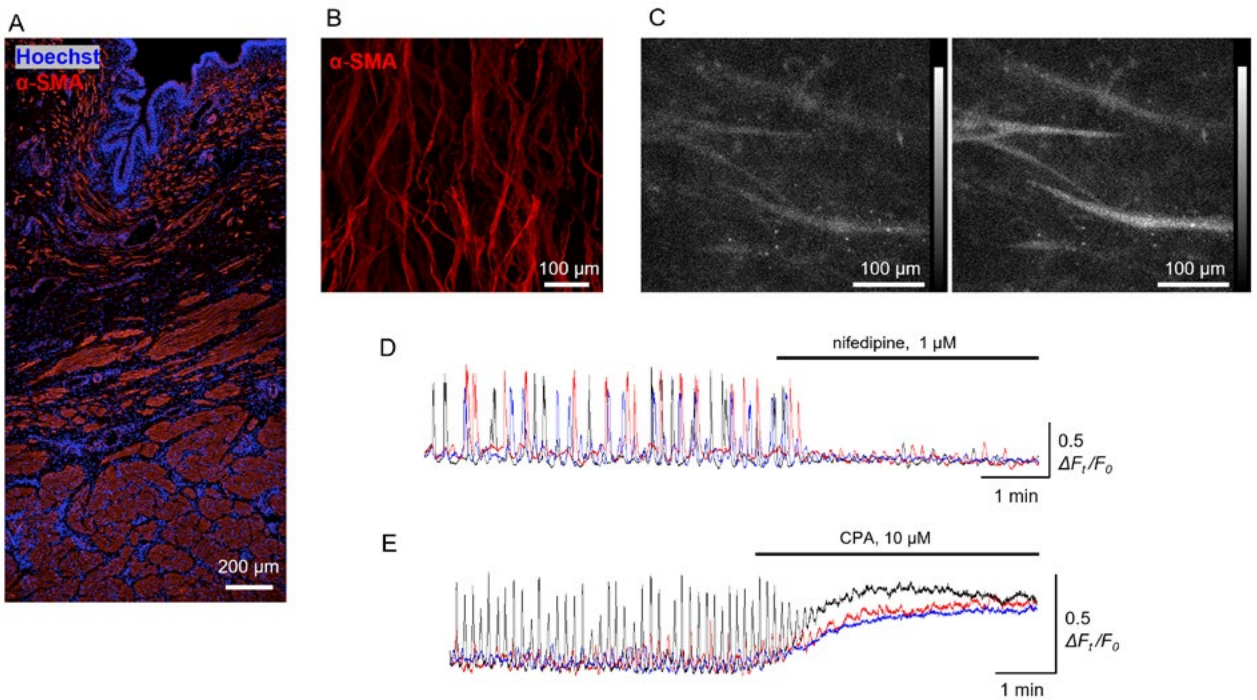

Figure 27. Ca2+ dynamics of pig lamina propria SMC (SMC-LP). *A: SMC-LP visualised by α-smooth actin (α-SMA) immunoreactivity. B: mucosa whole-mount, α-SMA positive SMC-LPs are loosely arranged predominantly along the longitudinal urethral axis. C: SMC-LPs develop asynchronous spontaneous Ca2+ transients independently of each other and largely suppressed by 1 μM nifedipine. D: residual Ca2+ transients abolished by the blockade of the SR with 10 μM CPA. Modified from [415].*

although it was not determined whether this was ascribed to the SMC-LP or vascular smooth muscle. In pre-contracted rabbit urethral *lamina propria*, neurally-released NO or bath-applied ACh, that triggers NO release, induces relaxation (419), suggesting that the contractile properties of SMC-LP are similar to those of urethral SMCs (Figure 27).

In the *lamina propria* of pig urethra, α-SMA-immunoreactive SMC-LP are sparsely scattered throughout but predominantly arranged in the longitudinal direction (415,420). However, they do not form muscle bundles comparable to the *muscularis mucosae* in the bladder. SMC-LP develop spontaneous Ca^{2+} transients associated with weak contractions in individual cells. These transients are often generated in individual SMC-LP independently of each other, although a few adjacent SMC-LP can display near synchronous behaviour, suggesting that the summed contractility of multiple SMC-LP is not very vigorous. Spontaneous Ca^{2+} transients in SMC-LP are largely diminished or abolished after the blockade of LVDCCs, suggesting that they generate LVDCC-dependent action potentials or slow waves. Transients are prevented upon the blockade of SR Ca^{2+} ATPase, and thus spontaneous activity in SMC-LP appears primarily to depend on SR Ca^{2+} handling.

Unlike SMC-LP in the rabbit urethra, SMC-LP in the pig urethra do not respond to EFS, indicating that they lack a functional innervation. This is consistent with the absence of sympathetic, nitrergic or CGRP-containing afferent innervation to SMC-LP. Nevertheless, noradrenaline suppresses spontaneous Ca^{2+} transients or abolishes their generation with a reduction in the basal Ca^{2+} level in a manner sensitive to propranolol, a β-adrenoceptor antagonist. ACh first accelerates spontaneous Ca^{2+} transients, and then causes a sustained raise in the basal Ca^{2+} level, that is sensitive to atropine, a muscarinic receptor antagonist. Thus, SMC-LP in the pig urethra have a contractile phenotype similar to bladder *muscularis mucosae*, although SIN-1, an NO donor, fails to affect their spontaneous Ca^{2+} transients. Because of anatomical proximity of SMC-LP to the epithelium, they may be readily affected by epithelium-derived factors that inhibit urethral smooth muscle contractions induced by muscarinic or adrenergic stimulation (421).

V. THE UROTHELIUM

The urothelium can be thought of as a first responder to various types of stress that can include physiological, psychological and disease-related factors. The urothelium is an interface between the urinary space and underlying tissues (Figure 28A) and as such, forms a high resistance barrier. Beside this necessary function, the urothelium can modulate the volume and composition of urine (422) and actively participates as an integral part of what has been termed a 'sensory web' where it receives, integrates, amplifies and transmits information about the external environment to underlying nervous and muscular systems. Alterations of bladder urothelium at the molecular and structural levels have been reported in both patients and animals modelled for various bladder disorders. It is likely that many therapies currently used in the treatment of bladder disease may target urothelial receptors and/or their release mechanisms.

1. INTRODUCTION TO THE ANATOMY AND BARRIER FUNCTION OF THE UROTHELIUM.

The urothelium is the epithelial lining of the lower urinary tract between the renal pelvis and the urinary bladder. Adult urothelium is composed of at least three layers with distinct cell types (the exact number of layers is species dependent) and can be distinguished by expression of keratin-5, p63 and uroplakin (Figure 28B,C). These consist of a basal cell layer attached to a basement membrane in close proximity to capillary endothelial cells, an intermediate layer, and a superficial or apical layer that is in contact with urine and microorganisms and composed of a single layer of large 'umbrella cells' (423-426). These umbrella cells exhibit a distinctive plasma membrane that contains both 'hinge' and 'plaque' regions (Figure 29A,B). The umbrella cells (which are also termed facet or superficial cells) are the only cells that are interconnected by tight junctions (composed of multiple proteins such as the claudins). Another characteristic of the apical or umbrella cells is the expression of discoidal fusion vesicles or DFVs (Figure 29C). In response to bladder

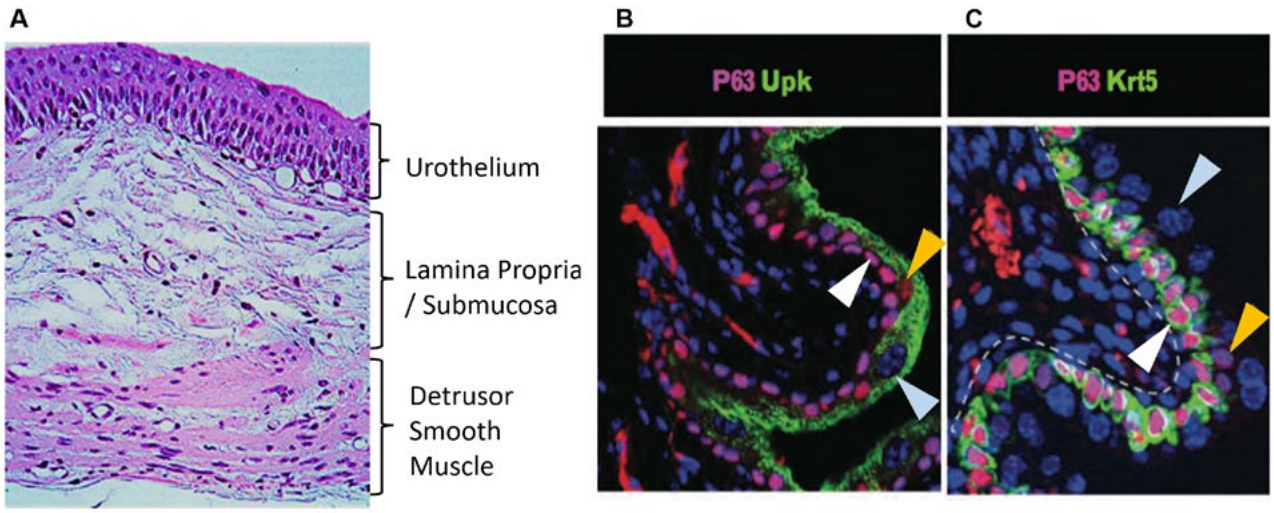

Figure 28. Structure of the bladder wall and urothelium. *A: Structure of the bladder wall. B,C. Three cell types of the urothelium distinguished by expression of p63 (purple), uroplakin (Upk, green, part B) and keratin-5 (Krt5, green part C)). Basal cells (white arrows) express keratin-5 and p63, but not uroplakin. Intermediate cells (orange arrows) express p63 and uroplakin, but not keratin-5. Superficial cells (light blue arrows) express uroplakin, but not p63 or keratin-5. Parts B,C [458], modified with permission.*

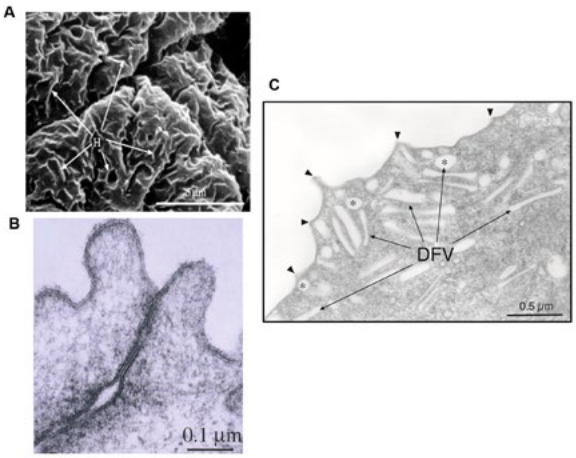

Figure 29. Ultrastructural features of the umbrella cell. *A: Scanning electron micrograph of apical surface of rabbit umbrella cell layer (hinges "H" marked with arrows, calibration bar 5 µm). B: high power view of a tight junctions. ([423,425], with permission). C: Transmission electron micrograph of the apical pole of a rat umbrella cell. Examples of discoidal/fusiform-shaped vesicles (DFV) are marked with arrows and hinges with arrowheads. Plaques in the intervening membrane between hinges. Apical cytoplasm contains disc-shaped (*) and fusiform-shaped vesicles. Multivesicular bodies (MVB; i.e., late endosomes) are indicated by arrows. ([426], with permission)*

filling, these DFVs fuse with the apical membrane releasing crystalline proteins termed uroplakins to the cell surface that assembles into hexagonal plaques (426-429). The attachment of *Escherichia coli* type I fimbriae to uroplakins also initiates the host-pathogen response, described more fully in later sections. It has been suggested that 'non-plaque' proteins that include receptors and ion channels, may be located to the hinge areas of these cells.

Uroplakins and other urothelial cellular differentiation markers, such as cytokeratin 20, are not expressed in the stratified epithelium of the urethra. There have been suggestions in early studies in some species, that umbrella cells and perhaps also the intermediate cells may have projections to the basement membrane (425). The ability of the bladder to maintain a highly effective barrier, despite large alterations in urine volume and increases in pressure during bladder filling and emptying, is dependent on several features of the umbrella cell layer. These features include specialised lipid molecules and tight-junction proteins (such as zona occludens-1, occludins, claudins) that reduce the movement of ions and solutes between cells (425,430) These proteins can adapt to mechanical stretching of the urothelium during filling and emptying. For example, the claudins are a family of integral membrane proteins (at least 24 members identified in mice and humans) and can be classified as either pore-forming (makes the epithelium leakier) or barrier-forming. The importance of claudin-based tight junctions *in vivo* has been studied in a number of tissues under various conditions. For

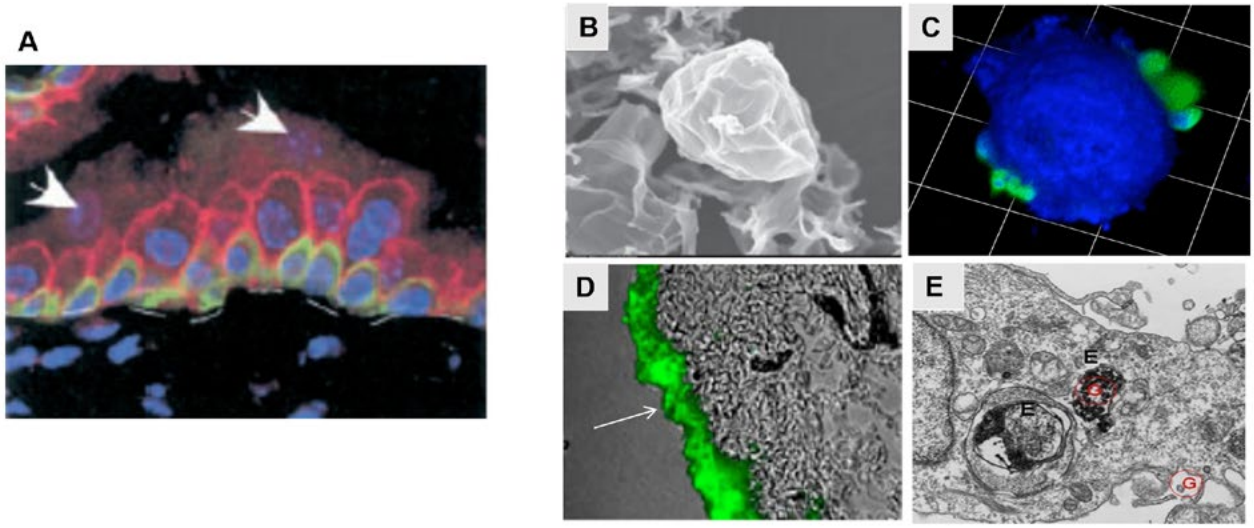

Figure 30: UPEC infection and liposomes. *A: UPEC infection leads to increased expression of the tight junction protein claudin-4 in intermediate cells. Levels of claudin-4 (red) are increased in intermediate cells 3.5 hr after UPEC infection. Cytokeratins 5/6 label basal cells (green). Nuclei are stained blue with bis-benzimide. Note: claudin-4 is absent in superficial cells, white arrows ([431], with permission). B: EM picture of liposome. C: liposomes (green) attached to primary cultured urothelial cell membrane. D: liposomes instilled in a rat bladder forming a coating (green) on urothelial surface. example, claudins (in particular claudin 4) may play a role in regulation of urothelial proliferation. There is evidence that attachment of uropathogenic *Escherichia coli* (UPEC) to urothelial superficial cells triggers the rapid induction of claudin-4 within the intermediate cells of the urothelium (Figure 30A) (431).

This increase in claudin-4 may explain how the urothelium is able to maintain the integrity of the urothelial barrier following infection and exfoliation of the apical urothelium. In another study, overexpression of the pore-forming claudin-2 in rat urothelium resulted in increased urothelial permeability that seemed to trigger inflammation and altered bladder function (432). It has not been established whether disruption of the urothelial barrier alone is sufficient to trigger inflammation and altered bladder reflexes or whether association with other factors (such as urine) may be needed to facilitate this response (433).

In addition, there is evidence in many types of epithelium (including uro-epithelium) that adhesion molecules such as members of the cadherin family play important roles in establishing and maintaining epithelial-cell contacts (434). Altered urothelial-cadherin expression has been reported in IC/BPS patient bladder urothelium.

The lipid composition of the apical membrane is unusual in composition and is rich in cholesterol, phosphatidylcholine, phosphatidylethanolamine and cerebroside (425). Recent studies suggest that liposomes, consisting of an aqueous core enclosed in one or more phospholipid bilayers, may help to restore urothelial-barrier function. Liposomes have typically been used to transport drug molecules in a variety of cells. Urothelial cells appear to take up liposomes via an endocytotic process, providing evidence for a possible mechanism by which liposomes act as a drug delivery system (435-437). In addition, empty liposomes have shown promise to repair and enhance the barrier function of a dysfunctional urothelium (Figure 30B-E)(438-440).

The apical surface of the urothelium is also covered with a sulphated polysaccharide glycosaminoglycan (GAG) or mucin layer that is thought to act as a nonspecific anti-adherence factor and as a defence mechanism against infection (441-443). In addition, during bladder filling the umbrella cells become flat and squamous and this shape change is accompanied by vesicular traffic (i.e. exocytosis/endocytosis), adding membrane to the apical surface thereby increasing overall urinary bladder surface area (426,444,445). This process of ongoing replacement of apical membrane by newly fused discoid vesicles also serves to maintain the urothelial barrier (446). There is evidence that this stretch-induced exocytosis is dependent on activation of epidermal growth factor receptor (EGFR) (447,448). These processes allow the bladder to accommodate increasing volumes of urine during filling without compromising the barrier function. There is some evidence that superficial urothelial cells exhibit a lower level of endocytotic activity, which may be a protective mechanism against internalisation of toxic substances excreted in the urine (449). Exocytosis/endocytosis (vesicular recycling) may also play an important role in modulating the release of a number of neurotransmitters/mediators as well as regulation of the function of many receptors and ion channels in urothelial cells (450,451).

2. REPAIR AND REGENERATION OF THE UROTHELIUM

Epithelial integrity is maintained through a complex process of migration and proliferation (to restore cell numbers) and differentiation (to restore function) (452). Basal cells normally exhibit a low (3-6 month) turnover rate, in fact the slowest turnover of any mammalian epithelial cell (444,453).

It has been suggested that neither urine-derived factors nor cyclic mechanical changes contribute to urothelial proliferation and differentiation. However differentiation of urothelial cells in culture can be stimulated by prostaglandin, which is abundant in the urine, (422,454) and accelerated proliferation and regeneration of the urothelium can occur in various bladder pathologies. For example, with acute injuries using agents (protamine sulphate; cyclophosphamide, chitosan) that damage the umbrella cell layer, it has been shown that the urothelium rapidly undergoes both functional and structural changes in order to restore the barrier in response to injury (449,455). Following disruption of the barrier, in the early stages of regeneration the superficial cells may appear smaller in size and

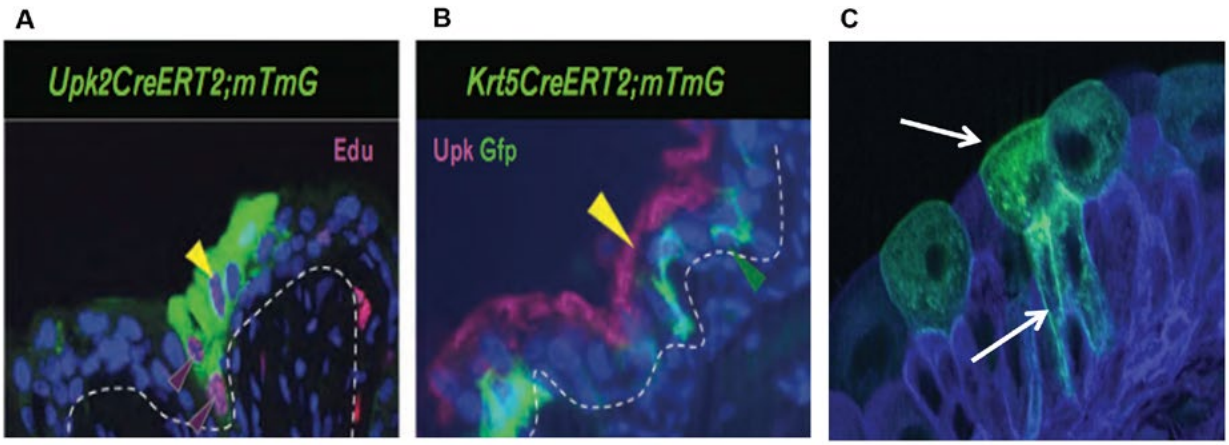

Figure 31. Intermediate cells as progenitors of superficial cells in adult urothelium. *A: Uroplakin-expressing cells labelled using a Upk2CreERT2;mtmg cell line. B: basal cells labelled using a Krt5CreERT2;mtmg cell line. Urothelial regeneration occurs after cyclophosphamide administration. Panel A shows intermediate cells are progenitors for superficial cells. Panel B shows basal cells proliferate but do not differentiate into intermediate or superficial cells. C: long, thin intermediate cells regenerate the outer protective layer - intermediate cells and progeny (white arrows) appear green ([458], with permission).*

often covered with microvilli (456). In some pathologies, deficiencies or defects in maturation or terminal differentiation of superficial umbrella cells have been reported, though the factors which may be involved are not yet known (457). Recent evidence has shown that following cyclophosphamide treatment of rodent bladders, there is a rapid desquamation, proliferation and regeneration of the urothelium. In this study, the intermediate cells (and not the basal cells) seem to be the adult progenitor cells for superficial cells, and are self-renewing (Figure 31)(458).

The processes underlying urothelial repair are complex; involving several structural elements, signalling pathways, trophic factors and the cellular environment. There is still incomplete understanding as to how the loss of umbrella cells is communicated to the underlying basal cell network and whether signalling pathways driving urothelial regeneration are similar for every type of injury. Furthermore, the interaction between these biochemical signals and mechanical forces in the bladder during the course of urothelial repair is not well understood. For example, the initiation of urothelial proliferation or differentiation of intermediate cells is thought to involve up-regulation of growth factors such as fibroblast growth factor and nerve growth factor (NGF) (459,460). In addition, members of the PPARγ and EGFR signalling pathways may contribute to urothelial 're-epithelialisation' in wound repair (454). PPARγ has been found to play an important role in a number of cellular functions including differentiation, maintenance and even regeneration of the urothelium (461). There is also evidence that Hedgehog/Wnt signalling acting across the basal urothelial cell-stromal cell boundary, contributes to increases in urothelial proliferation in response to injury (462). Retinoic acid (synthesised from underlying stroma) has been shown to be important for urothelial differentiation (463).

Though the urothelium maintains a tight barrier to ion and solute flux, a number of factors or stressors such as tissue pH, mechanical or chemical trauma, hormonal changes or bacterial infection and even changes in blood flow can modulate the barrier function of the urothelium(450,464). It has been shown that ischemia can augment release of inflammatory mediators such as reactive oxygen species or eicosanoids from urothelial and suburothelial tissues, altering bladder tone and contractility (465). Stress-mediated activation of the hypothalamic-pituitary-adrenal axis can result in increased production of corticotrophin releasing factor, which can regulate neuroendocrine and autonomic responses to stress. The net effect can include disruption of the epithelial barrier and increased prevalence of infection. In addition, altered levels of circulating oestrogens have been associated with changes to urothelial structure including epithelial shedding or mucosal atrophy (466,467). Other conditions such as bladder pain syndrome/interstitial cystitis (BPS/IC), senescence, diabetes or spinal cord injury are also associated with changes in the urothelial barrier(455,468). Studies utilising aged animals have demonstrated significant alterations to the bladder mucosa including areas of denudation(469,470).

3. OXIDATIVE STRESS, MITOCHONDRIAL DYSFUNCTION AND PURINE DYSREGULATION

Several bladder disorders, including those due to chronic psychological stress and the effects of age, can increase susceptibility to injury and apoptosis through pathways including oxidative stress (471). Oxidative stress, characterised in part by an increase in the level of proinflammatory mediators and reactive oxygen species or ROS, leads to disruption of various cellular components (472,473). Oxidative stress can be produced by bladder pathologies including ischemia or repeated ischemia/reperfusion during a micturition cycle (474,475). Indeed, the bladder mucosa exhibits a higher metabolic rate as compared to other regions in the bladder wall and the urothelium is highly vulnerable to any changes in blood flow. Both acute and chronic reduction in blood flow induce significant defects in the mucosal barrier, with disruption of urothelial tight junctions. Within the urethra and urinary bladder, age-related changes include a thinning of the epithelium and deceased vascularity. Findings from aged animals reveal that urothelial cells show a decreased antioxidant capacity with increased levels of markers for oxidative stress. This is associated with alterations in mitochondria and increased accumulation of an ageing pigment termed lipofuscin (Figure 32A) (476). In addition, ageing dramatically increases the volume of endolysosomes (organelles that degrade cellular debris), which may lead to accumulation of free radicals and decreased cel-

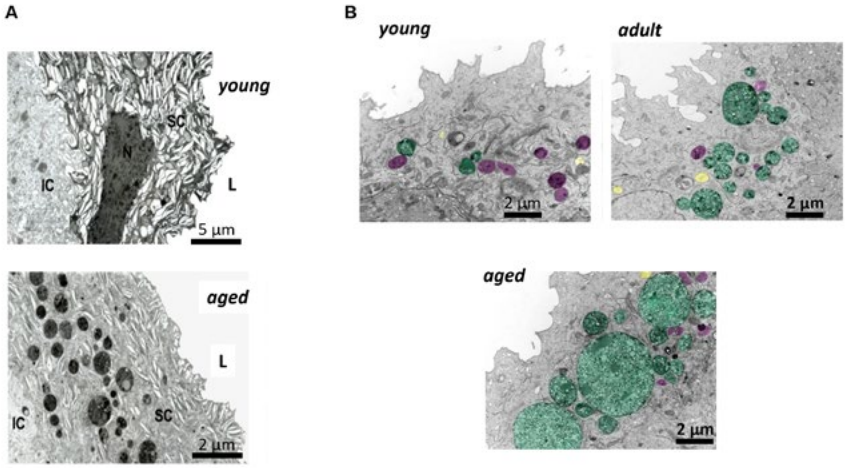

Figure 32. Structure of young and ageing mouse urothelium. *A: Ultrathin sections of a young mouse superficial cell (upper), with large amounts of fusiform vesicles in the cytoplasm but no lipofuscin granules, and of an aged mouse (lower) filled with vesicles and numerous osmiophilic lipofuscin granules. SC, superficial cell; IC, intermediate cell; L, bladder lumen; N, nucleus. ([476], with permission). B: The volume of endolysosomes increases in superficial cells with age from young, adult to aged mouse urothelium. Coloured structures show multivesicular bodies (MVBs, yellow), endolysosomes (green) and lysosomes (purple) ([477], with permission).*

lular functions (Figure 32B) (477). The decline in these various epithelial elements may lead to a decrease of both regenerative ability and also immunological defence mechanisms that are critical for maintaining epithelial integrity.

Mitochondria play a key role in cellular homeostasis, including generation of reactive oxygen species (ROS), apoptosis, and production of ATP via oxidative phosphorylation (478). Indeed, the study of bioenergetics and the influence of mitochondrial functions on cell signalling and disease is an emerging and exciting area of research. Mitochondrial dysfunction has been implicated in several disorders. These structures are highly sensitive to changes in their cellular environment and can be easily affected by a number of conditions. For example, chronic stress-associated activation of the sympathetic nervous system (using the water avoidance stress, or WAS model, in female rats) alters urothelial mitochondrial function, which may contribute to bladder dysfunction (Figure 33) (479). Studies have shown that mitochondrial abnormalities (such as increased ROS production) lead to changes in mucosal barrier function in several tissues, including the urinary bladder. Also, recent studies have shown some evidence demonstrating mitochondrial dysfunction and oxidative stress (elevated ROS) may play a role in urothelial barrier (and sensory) abnormalities observed in the urinary bladder with advanced age as well as in a number of conditions (480,481).

The purinergic nucleotide inosine is formed from the metabolism of adenosine and provides beneficial anti-inflammatory and protective effects to various target organ systems, including the LUT. Inosine and hypoxanthine can directly alter bladder function. Administration of exogenous inosine can exert protective effects on the urinary bladder following experimentally induced obstruction or spinal cord injury (482,483). The mechanism of action may involve actions on adenosine receptors and prevention of oxidative damage via scavenging of free radicals and peroxynitrite. This type of purine-sensitive mechanism is likely to improve motor and sensory functions, which is diminished in ageing.

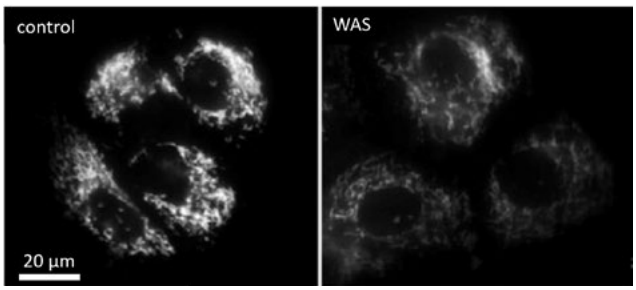

Figure 33. Urothelial cells isolated from rats exposed to water avoidance stress. *Examples of TMRM (tetramethylrhodamine) staining as a label for healthy (polarised) mitochondria from a control (left) and a WAS (right) rat. ([479], with permission).*

Increased oxidative damage by ROS is deleterious to cells and plays a key role in progression of a number of diseases. While there are several sources of free radicals (e.g. ROS), it is well established that the enzyme xanthine oxidase (XO) is able to generate a source of ROS due to metabolism of hypoxanthine to xanthine and then uric acid. Hypoxanthine (as well as XO) is able to cross easily the cell membrane (484) implying increased free radical production, which over time, may cause cellular and organ damage. Thus, though ROS can have physiological roles, sustained ROS levels (for example in age-related disorders) are likely to result in tissue injury due to oxidative damage and mitochondrial dysfunction - ultimately resulting in cellular loss/damage and excessive deposition of collagen fibres/loss of elasticity. Not surprisingly, treatments that inhibit oxidation of hypoxanthine suppress inflammatory cytokines and oxidative stress in a number of disorders. There is emerging evidence that changes in the levels of the enzyme purine nucleoside phosphorylase (PNPase) may reflect the extent of oxidative injury and cellular damage. Recent evidence has revealed that 8-aminoguanine (8-AG), an endogenous PNPase inhibitor, shows efficacy in reversing aging-associated functional, structural, me-

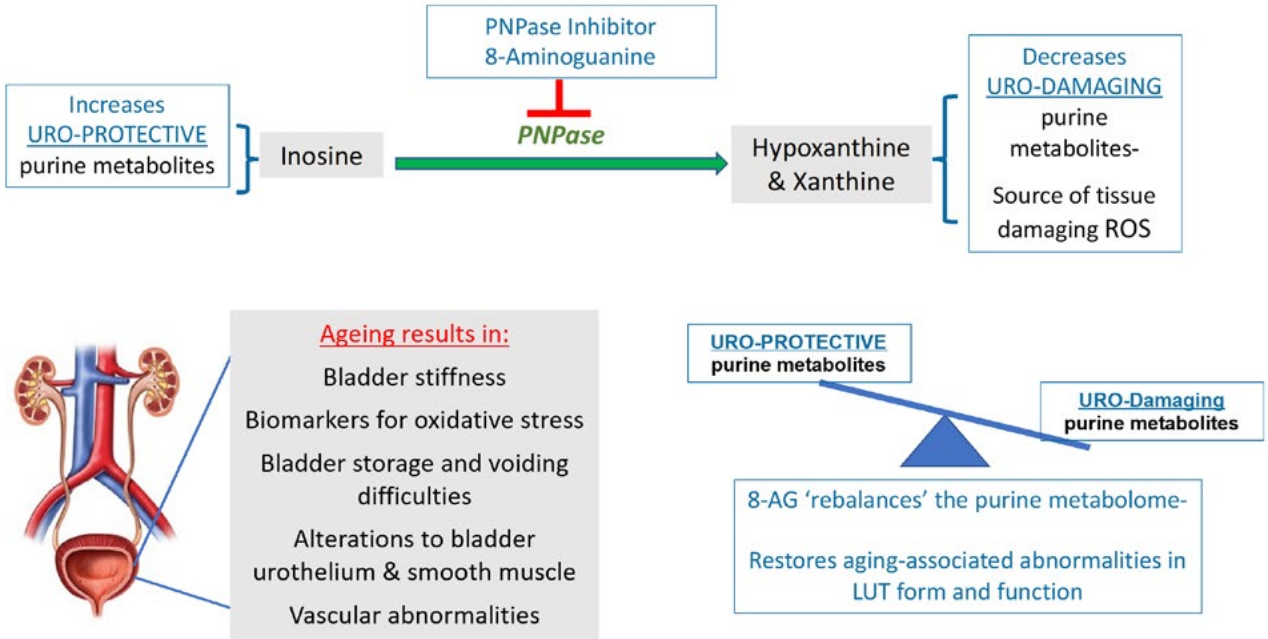

Figure 34. The purine nucleoside phosphorylase inhibitor, 8-aminoguanine (8-AG). *8-AG 'rebalances' the purine metabolome in the aged lower urinary tract; reversing ageing-related functional, structural, mechanical and biochemical urothelial/bladder abnormalities to that of a younger state ([485], with permission).*

chanical and biochemical urothelial/bladder abnormalities (485). The uro-protective effects of PNPase inhibitors in general, and 8-aminoguanine (8-AG) in particular, are likely due to simultaneous increases in tissue protective purines (inosine and guanosine) and decreases in tissue damaging levels of both hypoxanthine and xanthine (Figure 34).

4. ROLE OF THE UROTHELIUM IN IMMUNE AND INFLAMMATORY RESPONSES

There is new evidence that the human urinary tract contains a diverse microbiota that is likely to play an important role in bladder health and disease (486). Evidence in the GI tract supports a role for gut microbiota on intestinal barrier function that can be altered by psychological and physical stressors (487). With the urinary tract, the urothelium is the first line of defence against pathogens and irritative substances, with a number of mechanisms that limit inflammatory responses (488). Examples include uromodulin (or Tamm-Horsfall urinary glycoprotein), which prevents bacteria from interacting with the epithelial cell surface (489). Other factors such as β-defensin-1 are secreted from epithelial cells into the urine and restrict bacterial growth (490).

Both physiological and psychological stress can result in a failure of urothelial and suburothelial 'defensive' systems and thereby promote changes in both urothelial barrier and signalling function. For example, alterations in proteins including proteoglycans and bacterial defence molecules may lead to distinctive changes in urothelial structure and play a role in bacterial adherence (491). In this regard, urinary tract infections produced by uropathogenic *Escherichia coli* (UPEC) are initiated by bacterial adherence to uroplakin proteins on the apical surface of umbrella cells (464,492) UPEC express filamentous adhesive organelles (type-1 pili) that mediate bacterial attachment, invasion and apoptosis of the urothelial cells and urothelial differentiation (e.g. increased uroplakin III expression) may have a pivotal role in sensitising urothelial cells to UPEC-induced infections and possible cell death (493). Even acute contact (within hours) of the mucosal surface with bacteria may result in altered urothelial barrier function (494). UPEC can also internalise within umbrella cells forming intracellular colonies (biofilm-like pods) that has been implicated in generating chronic urinary tract infections. UPEC commandeer the endocytic/exocytic machinery of urothelial cells, residing inside fusiform vesicles (495). This permits bacteria to escape elimination during voiding and re-emerge into the urine during distension. When expelled into the urine during the storage phase, the urine may provide a nutrient-rich environment optimising bacterial survival. Infected urothelial cells also use their export machinery to reduce bacterial loads. For example, UPEC found in epithelial 'lysosomes' are sensed by transient receptor potential (TRP) mucolipin 3 (TRPML3) receptors. This is a cation channel expressed on lysosomes which leads to spontaneous exocytosis of the lysosome expelling the bacteria (Figure 35A) (496).

UPEC can trigger an inflammatory response within the urothelium with release of multiple mediators such as interleukins and cytokines (497). The result of this immune response is often structural damage to the urothelial barrier. Recent evidence has shown a role for hypoxia-inducible factor 1-alpha (HIF-1α) in modulating the innate immune cell function (498,499). Human urothelial cells treated with a HIF-1α stabilising agent exhibited less cell death when exposed to UPEC, further supporting a role for HIF-1α in defence against UPEC infections (500). State-of-the art imaging approaches in combination with mass spectrometry have revealed the presence of a chemokine-dependent crosstalk between the urothelium and macrophages during UPEC infection. Initiation of such crosstalk facilitates macrophage migration into the urothelium which in turn maintain the barrier function by reducing bacterial burden (501).

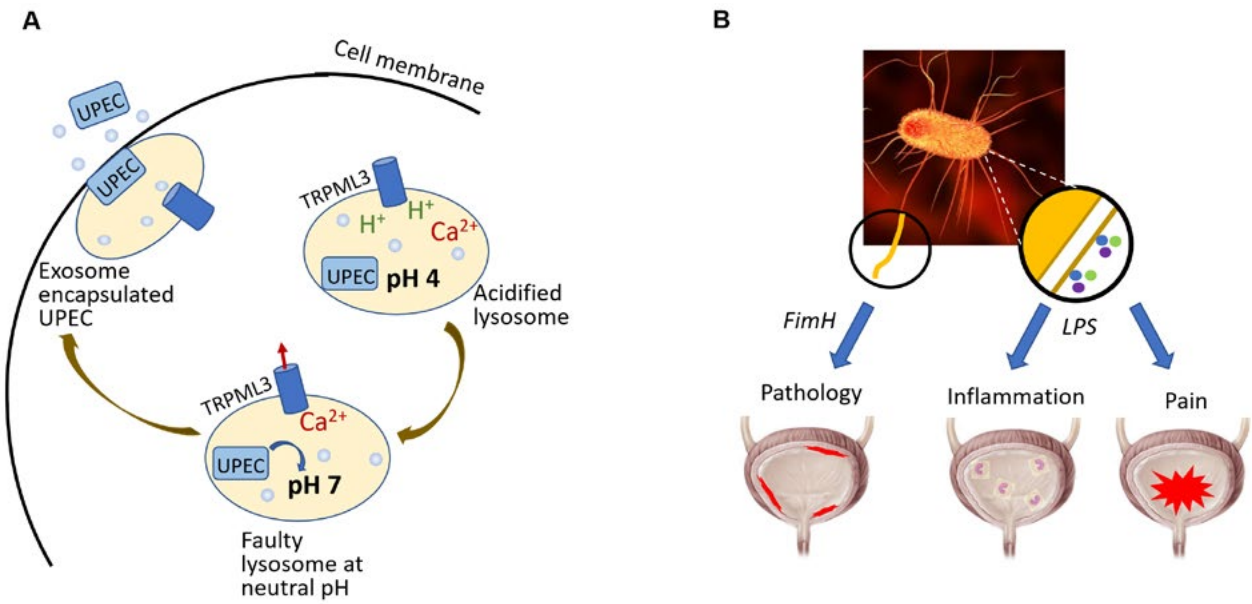

Figure 35. Lysosomal expulsion of UPEC and UPEC-induced pain. *A: After UPEC infection of urothelial cells, activation of the mucolipin TRP channel 3 (TRPML3) spontaneously initiates lysosomal exocytosis leading to an expulsion of exosome-encased bacteria. (modified from [496]). B: UPEC induces pain separable from other facets of UTI pathogenesis. FimH acts as a tethered toxin that mediates urothelial apoptosis and consequent bladder barrier dysfunction. LPS plays dual roles through its interactions with TLR4. In addition to triggering inflammation, LPS mediates pelvic-pain responses. (modified from [504]).*

There is also evidence for a role of endotoxin (lipopolysaccharide, LPS) on the bacterial cell wall in mediating pain associated with UPEC infections (502). This seems to function independent of urothelial damage, as erosion of the urothelial surface with protamine sulphate in mice failed to elicit bladder pain when instilled with UPEC. In addition, bacteria possess a wide range of pain phenotypes, largely dependent upon Toll-like receptors (Figure 35B) (503,504). Taken together, these findings support the view that UPEC-induced urothelial dysfunction is the transducer of the UTI pain signal.

Disruption of urothelial function can also be induced by more remote pathological conditions that influence neural or hormonal mechanisms. For example, spinal cord transection in rats leads to a rapid alteration in the urothelial barrier including ultrastructural changes and increased permeability (505). The changes are blocked by pre-treatment with a ganglionic blocking agent, suggesting an involvement of efferent autonomic pathways in the acute effects of spinal cord injury on bladder urothelium. Other types of urothelial-neural interactions are also likely, based on the recent reports that various stimuli induce urothelial cells to release chemical mediators that can in turn modulate the activity of afferent nerves (425,450). This has raised the possibility that the urothelium may have a role in sensory mechanisms in the urinary tract.

In summary, modification of the urothelium and/or loss of epithelial integrity in several pathological conditions can result in passage of toxic/irritating urinary constituents through the urothelium or release of neuroactive substances from the urothelium. This may lead to changes in the properties of sensory nerves and in turn sensory symptoms such as urinary frequency and urgency. Thus, chemical communication between the nervous system and the urothelial cells may play an important role in the generation of urinary bladder dysfunction.

5. EPITHELIAL HETEROGENEITY IN THE LOWER URINARY TRACT

Studies comparing a number of species have shown that the major part of the urinary tract is lined with a fully differentiated urothelium (422). Findings in cultured cells reveal a distinct difference in morphology of ureteral and bladder urothelial cells, supporting a difference in cell lineage. The present evidence suggests at least three lineages: 1) ureter/renal pelvis, 2) detrusor/trigone and 3) bladder neck/proximal urethra (506).

There seems to be no apparent difference between the urothelium of the trigone compared to the detrusor, in contrast to cells from the proximal urethra (422,507). In this region, there is a transition from urothelium to a stratified or columnar epithelium accompanied by a lack of urothelial-specific differentiation markers. In males, the proximal or prostatic urethra is lined by urothelium and distal to this is the membranous urethra where the urothelium is replaced by stratified columnal epithelium. In females, the transitional urothelium changes to stratified columnar epithelium. In addition, specialised chemosensory neuroendocrine cells are distributed within the urethral epithelia. These cells are often exposed to the lumen and may share similarities to GI enterochromaffin cells or chemosensory cells of the trachea or respiratory tract (often termed 'brush cells') (508), including expression of microvilli (Figures 36). These specialised urethral chemosensory cells are able to respond to potential noxious stimuli (using the classic taste transduction pathway) by releasing mediators such as acetylcholine (508,509). Similar to urothelial cells in the bladder wall, these urethral chemosensory cells are also in close proximity to sensory nerve fibres whereby intraurethral stimulation can lead to activation of underlying cells including bladder smooth muscle. In addition, there are also reports that have identified functional properties of sacral afferents that respond to changes in fluid flow through the urethra (510). While the

([509], with permission). B: Cholinergic eGFP-expressing epithelial cells are restricted to the urethra in the urinary tract. In other parts of the urinary system, cholinergic nerve fibres (arrows) were visualised, but not ChAT-eGFP-expressing epithelial cells. ([508], with permission).*

functional significance of these findings are not yet be fully appreciated, it is clear that such 'sentinel' type cells are able to recognise potentially harmful stimuli (including bacteria) in the urethral lumen and in turn alter bladder function.

6. ROLES FOR UROTHELIAL CELLS IN VISCERAL SENSATION

While urothelial cells are often viewed as bystanders in the process of visceral sensation, recent evidence has supported the view that these cells function as primary transducers of some physical and chemical stimuli and are able to communicate with underlying cells including bladder nerves, smooth muscle and inflammatory cells. (Figure 37)

6.1. Influence of the extracellular matrix.

The urothelium can respond to a wide variety of mechanical stresses during bladder filling and emptying by activating a number of possible transducer proteins. Possibilities of mechanical signals include bladder pressure, tension in the urothelium or bladder wall, torsion, geometrical tension, movement of visceral organs and even urine tonicity and pH (511). Alterations in the composition of urine are a type of stress, and the contents can vary in both their rate of delivery as well as the particular constituents. Additionally, dynamic reciprocal interactions of the urothelium with underlying extracellular matrix (ECM) not only aid in maintaining normal bladder structure but also play an important role in generating signalling responses. The urothelium is highly sensitive to the mechanics of the underlying ECM, thus understanding the complexity and relationship between mechanics and biological activities of cells throughout the bladder wall is important. In this regard, studies using multiphoton imaging have revealed differences in collagen fibre structure and recruitment throughout the bladder wall (Figure 38) (512,513). For example, collagen type III fibres display specific orientations depending on bladder volume. During bladder expansion, these collagen fibres straighten in the direction of the applied force and lie parallel to the urothelium and smooth muscle. This arrangement could permit maximal bladder storage without imposing stress on the bladder wall, thus assuring adequate bladder compliance (513). Moreover, ECM pathology impacts on the ability of the urothelium to sense changes in mechanical deformation occurring during a micturition cycle and release mediators, such as ATP, that influence sensation. ATP released by the urothelium and purinergic receptors on subepithelial sensory nerve terminals constitute a key part of a primary mechanical sensing system in the bladder. This type of epithelial-neural communication is a key component of Burnstock's 'tubes and sacs' hypothesis (514,515). It is likely that pathology-induced changes of fibre architecture could alter neural-epithelial interactions, including the response to mechanical strain, that can influence bladder compliance and sensation.

Additional lines of evidence suggest that urothelial cells participate in the detection of both physical and chemical stimuli. Bladder nerves (afferent and efferent) are localised in close proximity, and some within, the urothelium (516-519). In addition, urothelial cells express numerous receptors and ion channels similar to those found in both nociceptors and mechano-receptors. Finally, these cells secrete a number of transmitters or mediators capable of modulating, activating or inhibiting sensory neurons.

6.2. Urothelial-neuronal-smooth muscle signalling.

Recent studies have shown that both afferent and autonomic efferent nerves are located in close proximity to the urothelium. Peptidergic, P2X- and $TRPV_1$- immunoreactive nerve fibres presumed to arise from afferent neurons in the lumbosacral dorsal root ganglia are distributed throughout the urinary bladder musculature as well as in a plexus beneath and extending into the urothelium (450,518). In humans with neurogenic detrusor overactivity intravesical admin-

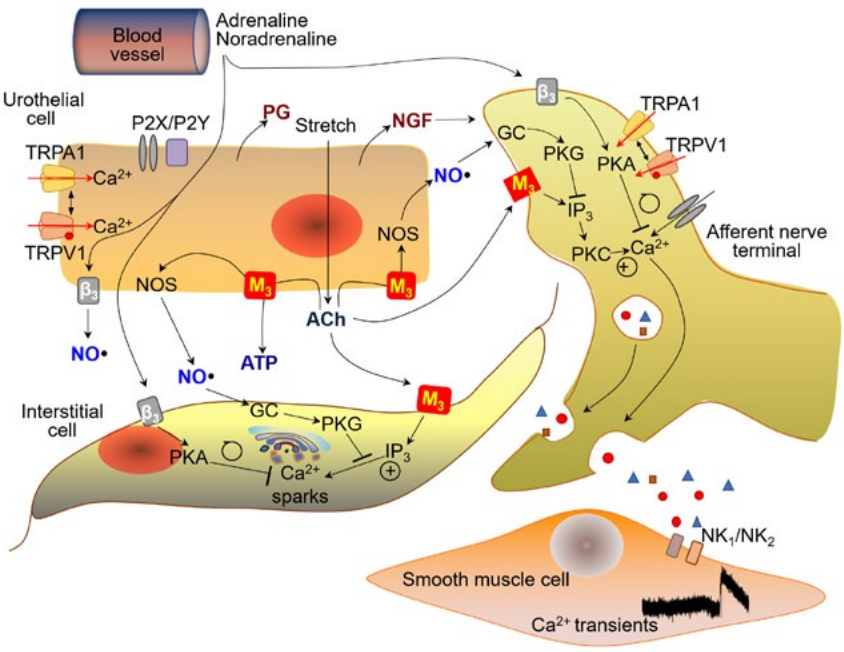

Figure 37. The sensory web. *Hypothetical model depicting possible interactions between bladder nerves, urothelial cells, smooth muscle, interstitial cells and blood vessels. Urothelial cells can also be targets for transmitters released from nerves or other cell types. Urothelial cells can be activated by either autocrine (i.e. auto-regulation) or paracrine (release from nearby nerves or other cells) mechanisms.*

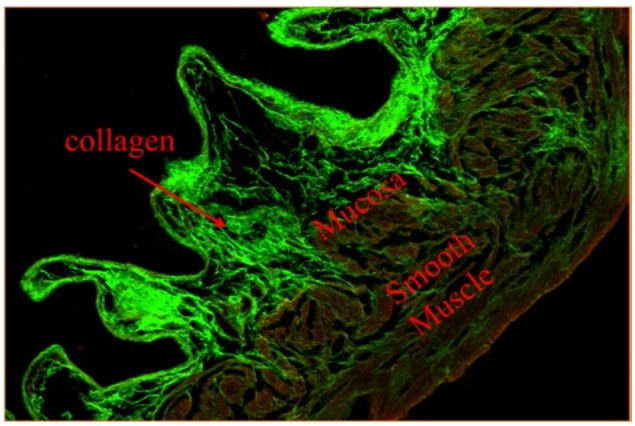

Figure 38. Collagen fibre orientation throughout the bladder wall. *([512], with permission).*

istration of resiniferatoxin, a C-fibre afferent neurotoxin, reduces the density of $TRPV_1$ and $P2X_3$ immunoreactive suburothelial nerves, indicating that these have sensory a sensory function (520,521). In addition, immunohistochemical studies have also revealed both adrenergic (tyrosine hydroxylase) positive as well as cholinergic (choline acetyltransferase, ChAT) positive nerves in close proximity to the urothelium (517).

A network of cells with morphologic characteristics similar to those of myofibroblasts or interstitial cells is also detected in the suburothelial space of the bladder in both humans and animals (522-525). These cells, extensively linked by gap junctions and have close contacts with nerves, can respond to neurotransmitters, such as ATP released from nerves or urothelial cells, suggesting that they could act as intermediaries in urothelial-nerve interactions (522,524,526). Thus, the anatomical substrate for bidirectional urothelial-neural communication exists within the urinary bladder.

As the urothelium functions as part of a 'sensory web', whereby these epithelial cells are likely to exert a local and direct influence on smooth muscle contractility. This type of modulation was initially reported as an inhibitory effect on bladder contractility in mucosal-denuded bladder strips (527). Studies by Hawthorn *et al.* suggested this effect was due to release of an unidentified 'urothelial-derived inhibitory factor' or UDIF (528). Subsequently, a series of urothelial-derived factors (such as ATP, acetylcholine, nitric oxide, prostaglandins) have been postulated to directly or indirectly modulate smooth muscle tone and contractility (529,530).

6.3. Involvement of the urothelium to 'sense' chemical and mechanical stimuli.

The involvement of urothelial function in sensory signalling is suggested by the finding that urothelial cells express various receptors that are linked to mechano- or nociceptive sensations. Examples of neuronal "sensor molecules" (receptors/ion channels) that have been identified in urothelium include receptors for purines ($P2X_{1-7}$ and $P2Y_{1,2,4}$), adenosine (A_1, A_{2a}, A_{2b} and A_3), noradrenaline (α and β), acetylcholine (muscarinic and nicotinic), protease-activated receptors (PARs), amiloride- and mechano-sensitive epithelial Na+ channels (ENaC), bradykinin (B1 and B2), neurotrophins (p75, trkA, EGF family ERbB1-3), corticotrophin releasing factor (CRF1 and CRF2), oestrogens ($ER\alpha$ and $ER\beta$), endothelins, PIEZO and various TRP channels ($TRPV_1$, $TRPV_2$, $TRPV_4$, $TRPM_8$ and $TRPA_1$) (84,531-542). The expression of these various receptors enable the urothelium to respond to a number of "sensory inputs" from a variety of sources. These inputs include increased stretch during bladder filling, soluble factors (many found in the urine) such as epidermal growth factor (EGF), or chemical mediators/peptides/transmitters such as substance P, calcitonin gene-related peptide (CGRP), corticotrophin releasing factor (CRF), acetylcholine, adenosine or noradrenaline released from nerves, inflammatory cells and even blood vessels (450,451,543,544).

Various stimuli can lead to secretion of numerous chemical substances such as neurotrophins, peptides, ATP, acetylcholine, prostaglandins, prostacyclin, nitric oxide (NO) and cytokines that are capable of modulating the activity of underlying smooth muscle (526,545) as well as nearby sensory neurons (450,451). For example, urothelial-specific overexpression of NGF results in increased bladder nerve 'sprouting' and increased voiding frequency (546,547). It has been shown that urothelial-derived NO can be released in response to mechanical as well as chemical stimulation and may either facilitate or inhibit the activity of bladder afferent nerves conveying bladder sensation (548). In this regard, activation of urothelial-receptors and release of inhibitory mediators may explain in part, the mechanism of action for therapies (e.g. β3-adrenergic receptor agonists) in treatment of bladder disorders such as OAB (549-551).

The mechanism underlying release of chemical mediators from the urothelium, including whether all sensory "inputs" stimulate membrane turnover (i.e., vesicular exocytosis) is not well understood. What little is known about the roles and dynamics of membrane-bound cytoplasmic vesicles in urothelial cell physiology is derived from measurements of membrane capacitance and microscopy of fixed tissues and cells (552). Alterations in membrane turnover can not only increase apical surface area (as described above) but also regulate the number and function of receptors and channels at the cell surface.

Epithelial cells in different organ systems may express similar receptor subtypes (553-555) Accordingly, epithelial cells could use multiple signalling pathways, whose intracellular mechanisms differ according to location and environmental stimuli. This would permit a greater flexibility for the cell to regulate function and respond to complex changes in their surrounding micro-environment. Whether urothelial-sensor molecules all feed into a diverse array of signalling pathways or share similarities with systems such as olfaction, whereby hundreds of receptors share identical transduction cascades (556), is yet to be uncovered.

Purinergic receptors. Since the first report of distension-evoked ATP release from the urothelium there is now abundant evidence supporting a role for urothelial-derived release of ATP in autocrine and paracrine signalling within the lower urinary tract (557). ATP is abundant in the cell cytoplasm and can be released extracellularly by several mechanisms including vesicular exocytosis, transporters such as a member of the ATP-binding cassette (ABC) transporter superfamily, or anion-selective channels such as the maxi-anion channel (84). ATP is released from both the apical and basolateral urothelial surfaces in response to bladder stretch and can act on $P2X_2$ and $P2X_3$ urothelial receptors to stimulate stretch-induced exocytosis (552). Furthermore, pannexin channels, which are expressed throughout the urothelium (Figure 39), may be involved in modulating voiding reflexes via urothelial release of ATP (538,558).

The expression of both P2X and P2Y receptors in nerve fibres and myofibroblasts in close proximity to the bladder lumen, and the sensitivity of these cells to ATP suggest that basolateral ATP release from the urothelium may also influence the function of myofibroblasts and bladder nerves (523,559). In addition, prolonged expo-

White line denotes boundary of umbrella cell layer, determined by cytokeratin staining, ([538], with permission). B: Activation of urothelial P2Y6 receptors (PSB 0474, P2Y6 receptor agonist; MRS 2578, P2Y6 receptor antagonist) can modulate urodynamic responses in the anesthetized rat. An increase of voiding frequency is postulated to be by increased ATP release from the urothelium through pannexin-1 hemichannels (modified from [558]).*

sure to a desensitising concentration of ABMA reduced the activity of mechano-sensitive pelvic nerve afferents in an *in vitro* model of rat urinary bladder (560). $P2X_2$ and $P2X_3$ receptors are expressed on unmyelinated afferent fibres innervating the bladder, and thus the hypothesis has been put forward that mechano-sensitivity, at least in those afferents in proximity to the urothelium, involve ATP release by stretch and activation of $P2X_2$ and $P2X_{2/3}$ receptors on afferents fibres (534,561). Mice lacking the $P2X_3$ receptor showed reduced inflammatory pain and marked urinary bladder hyporeflexia with reduced voiding frequency and increased voiding volume (562). This suggested that $P2X_3$ receptors are involved in mechano-sensory transduction underlying both inflammatory pain and hyperreflexia indicating a role in physiological voiding reflexes (562). Also, as $P2X_3$ null mice have a lower frequency of voiding contractions during bladder filling this suggests that P2X antagonists could play a role in treatment of OAB. The amiloride-sensitive apical Na^+ channel, ENaC, may be involved in mechano-transduction by controlling basolateral release of ATP (563,564). In addition, intercellular communication mediated by gap junctions in myofibroblasts could provide a mechanism for long-distance spread of signals from the urothelium to the detrusor muscle (526). Of interest, this type of nucleotide-mediated wave of cell-cell communication may also play a role in the response to injury (564). In the normal bladder, it may be hypothesised that a balance between the excitatory effects of ATP and inhibitory effects of nitric oxide (NO) release may determine micturition thresholds and frequency and that this balance may be disturbed in bladder disorders. For example, stimulation of muscarinic receptors localised near the luminal surface of the bladder affect voiding functions via mechanisms involving ATP and NO release from the urothelium that in turn altered the firing properties of afferent nerves (565). This supports the view that urothelial-afferent nerve interactions can influence reflex voiding functions. While evidence supports a role for ATP and purinergic receptors in modulating symptoms in several urological diseases, the mechanisms underlying activation of the micturition pathway at lower bladder volumes (during urgency) and mediators (amount; type) involved are not understood. In addition, the directionality of transmitter release, the mixture of receptor subtypes in the apical and basolateral domains and interactions between multiple transmitters is likely to affect the nature of the output in both health and disease.

TRPV1 channels.

The ability of capsaicin to evoke nitric oxide (NO) release from rat urothelium, first reported in 1998, provided, albeit indirect, demonstration that $TRPV_1$ channels are expressed in urothelial cells and that urothelial cells and afferent nerves, which also express these channels, share a number of common properties (566). This ion-channel protein is activated by capsaicin, as well as by moderate heat, H^+, nitro-fatty acids and lipid metabolites such as anandamide (an endogenous ligand of both cannabinoid and vanilloids receptors) (567,568). $TRPV_1$-positive nerves are in close contact with urothelial cells (569,570). Activation of urothelial cells with capsaicin or resiniferatoxin can increase intracellular Ca^{2+}, evoke transmitter (NO or ATP) release and elicit transient currents (518,571). Similar to that in sensory neurons, urothelial-response to vanilloids are enhanced by low pH, blocked by $TRPV_1$ antagonists and eliminated in $TRPV_1$ null mice (518). In afferent neurons, $TRPV_1$ is thought to integrate/amplify the response to various stimuli and to play an essential role in the development of inflammation-induced hyperalgesia. It seems likely that urothelial-$TRPV_1$ might participate in a similar manner, in the detection of irritant stimuli following bladder inflammation or infection.

Additional TRP channels.

Much less is known about the involvement of other TRPs in bladder function or disease. For example, the mouse urothelium expresses mRNA for an additional 19 TRP family members (572). $TRPV_4$, which is a nonselective cation channel activated by a number of stimuli including heat, shear stress, changes in osmolarity and lipid ligands, is expressed mainly within the epithelium of the urinary bladder (573). While a definitive role for $TRPV_4$ in bladder function has not been established, $TRPV_4$-null mice exhibit impaired voiding responses and, intravesical instillation of a $TRPV_4$ agonist in the rat triggers a novel voiding reflex that could regulate the late phase of micturition (519,574). Additional studies suggest activation of urothelial-$TRPV_4$ facilitates bladder reflexes via activation of mechano-sensitive, capsaicin-insensitive, C fibres (575). In addition, in the awake ewe, $TRPV_4$ may also be involved in a urethra-to-bladder reflex, proposed to facilitate bladder emptying (576). Another member of the TRP family, $TRPA_1$ (characterised as a thermoreceptor activated by noxious cold), is expressed in C-fibre afferents as well as urothelium and agonists to this channel induce bladder hyper-

reflexia (577). Of interest is the finding that hydrogen sulphide, which may be formed during infection/inflammation, is an activator of $TRPA_1$.

Acetylcholine and the urothelium.
The urothelium expresses the full complement of muscarinic receptors as well as enzymes necessary for the synthesis and release of acetylcholine (543,578). Furthermore, the urothelium releases acetylcholine following both chemical and mechanical stimulation (543). The mechanism underlying acetylcholine release from urothelium may be through organic cationic transporters (OCTs) rather than vesicular exocytosis, differing from that of bladder nerves (579). Once released, urothelial-derived acetylcholine is likely to exert effects via a number of sites including smooth muscle and nerves, as well as by urothelial associated-muscarinic or nicotinic receptors, the latter could contribute to feedback mechanisms modifying urothelial function (580). In addition, stimulation of urothelial-cholinergic receptors elicits release of mediators such as nitric oxide, prostaglandin as well as ATP, which could alter bladder sensation by stimulating nearby sensory afferent nerves (581-583).

Thus, targeting muscarinic receptors and/or urothelial synthesis or release mechanisms may play an important role in the treatment of several bladder disorders. By inhibiting SNARE-dependent exocytotic processes, botulinum toxin A (BTX-A) can prevent the release of transmitters from bladder nerves as well as translocation of various receptors and channels to the plasma membrane (584) Urothelial-derived acetylcholine may not be sensitive to BTX-A, however studies have shown that other transmitters (such as ATP) released by the urothelium can be blocked by this treatment in addition to normalising the expression of urothelial-receptors ($TRPV_1$; muscarinic) and trophic factors (585,586). These and other studies suggest that the urothelium may be a target for this treatment and that urothelial-released mediators may contribute to sensory urgency.

Cannabinoids.
The multi-centre CAMS (Cannabinoids in Multiple Sclerosis) study reported that the use of cannabis-based extracts significantly improved symptoms of urge incontinence and detrusor overactivity in patients with multiple sclerosis. This observation has provoked interest in the study of expression and function of cannabinoid receptors in the bladder. Endogenous cannabinoids can potentially interact with $TRPV_1$ but in addition can act on G-protein coupled cannabinoid receptors 1 and 2 (CB1, CB2). In the human bladder, both receptors could be identified in the urothelium and detrusor where CB1 receptors were more abundant than CB2 (587). In patients with bladder pain syndrome and idiopathic detrusor overactivity (IDO), a significant increase of nerve fibres expressing CB1 in the urothelium was observed, strongly suggesting a role for CB1 in overactive bladder (588). In contrast, Gratzke *et al.* (589) found CB2 receptors predominated in the urothelium, suburothelium and on sensory nerve fibres, In addition, that CB2 agonists inhibited nerve induced contractions of the bladder providing evidence that CB2 receptors are important in micturition.

Expression of CB1 receptors were also identified in the urothelium and on nerve fibres in the detrusor of mouse bladder (590). These receptors co-localised with $P2X_3$ receptors, suggesting an interaction between cannabinoid and purinergic systems. In addition, a synthetic cannabinoid active at both CB1 and CB2 receptor was shown to inhibit the evoked release of CGRP from afferent nerve terminals (591). Functional experiments also found a reduction in distension-evoked afferent firing in response to application of a CB1 agonist. In particular, high threshold afferents typically associated with noxious stimuli were directly affected. A recent study in the rat bladder by Aizawa *et al*. (592), used a peripherally restricted inhibitor (URB937) of the endocannabinoid-degrading enzyme fatty acid amide hydrolase (FAAH). Consequent upregulation of the peripheral endocannabinoid system reduced bladder overactivity and C-fibre hyperexcitability provoked by PGE2 and suggested an important role of the peripheral endocannabinoid system in bladder overactive conditions induced by afferent hypersensitivity. There is also evidence that the fatty acid amid anandamide, which activates both CB1 as well as $TRPV_1$ receptors on primary afferents, is upregulated in a model for inflammatory pain and induces bladder hyperreflexia (593). Taken together these studies suggest that CB receptors in the bladder may have a modulatory role in sensory afferent signalling; a greater understanding of which could lead to new therapeutic strategies for treatment of bladder disorders. Understanding the differential roles of CB1 and CB2 receptors may add a new dimension to our ability to target these pathways.

PIEZO channels.
Recent findings have revealed that a mechano-sensitive ion channel, PIEZO2, is involved in 'sensing' bladder filling (531). This channel is expressed in bladder urothelial (umbrella) cells in addition to nerves that innervate the urinary bladder. Further, PIEZO2-null mice exhibit a reduction in activation of bladder nerves to bladder stretch which in turn lengthens the interval between bladder contractions. PIEZO2-null mice also exhibit larger bladders, and this type of bladder wall re-modelling may suggest alterations of the extracellular matrix. During bladder filling, the matrix impacts on the ability of the urothelium to sense changes in mechanical deformation occurring during a micturition cycle and thus releases mediators that affect sensation. Findings in PIEZO2-null mice also has translational relevance, as humans lacking PIEZO2 exhibit a small number of voids per day though often suffer urinary urgency. The involvement of PIEZO2 in bladder mechano-sensation is important and also suggests a basis for the observation that urgency and frequency may be differentially regulated.

7. CLINICAL SIGNIFICANCE OF THE SENSORY WEB

Defects in urothelial sensor molecules and urothelial cell signalling are likely to contribute to the pathophysiology of bladder diseases. For example, a number of bladder conditions (BPS/IC, spinal cord injury (SCI), chemically-induced cystitis) are associated with augmented release of urothelial-derived ATP, which is likely to result in altered sensations or changes in bladder reflexes induced by excitation of purinergic receptors on nearby sensory fibres (536,594). ATP can also act in an autocrine manner that would act to facilitate its own release from urothelial cells. Augmented expression/release of urothelial-derived chemical mediators is likely to reduce the threshold for activation of nearby bladder afferents. Thus, the urothelium has the potential for amplifying signals, both within the urothelium and the bladder wall and contributing to a gain of function in sensory processing. Stressors that can impact on this 'gain of function' include alterations in levels of trophic factors as well as stress and steroid hormones. For example, altered levels of circulating oestrogens may play a role in urinary bladder dysfunction, including urgency and frequency (466,59) The resulting structural and functional abnormalities may lead to enhanced signalling between the urothelium and underlying cells.

Changes in epithelial signalling/barrier function are not unique to the urinary bladder. Activation of keratinocytes alone in mice expressing a light-activated channel can result in nociceptive re-

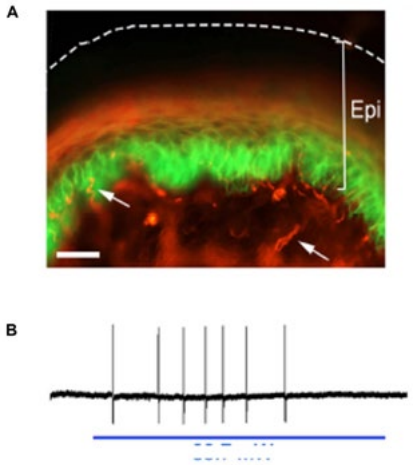

Figure 40. Blue light stimulates multiple types of afferents in KRT-ChR2 transgenic mice. *A: ChR2-YFP expression in glabrous skin of KRT-ChR2 mouse. ([596], with permission).*

sponses, demonstrating signalling between epithelial and neural tissues (Figure 40) (596). In addition, airways epithelia in asthmatic patients, as well as keratinocytes in certain types of skin diseases, also exhibit a number of similar abnormalities and compromised repair processes (553,597,598). This is particularly relevant given the high incidence of associated diseases that can include both visceral and somatic conditions, many of which exhibit a shared loss of epithelial barrier function. This altered urothelial permeability seen in many bladder disorders may actually be an advantage for drug delivery, as uptake of intravesical drugs is likely to be enhanced. Further, many of these systems do share a number of commonalities that include increased afferent activation of supraspinal centres in order to effectively coordinate efferent outflow as well as dependence on similar types of neurotransmitters (such as ATP) to mediate sensory responses. A recent example is the use of $P2X_3$ antagonists in the treatment of both respiratory and urological disorders (599). However, though major advances have increased our understanding of urothelial biology and potential impact on bladder physiology, there are still a number of unanswered questions that persist. These include mechanisms by which mediators are released, which mediators are most important for normal bladder function and the influence of pathology and co-morbidities on the urothelial 'sensory web'. Ideally, further knowledge of the unique properties of the urothelium could lead to the development of smart delivery systems (e.g., transporting drugs to intended sites and releasing drugs in response to specific signals) in addition to tissue engineering.

VI. THE CELL PHYSIOLOGY OF BLADDER WALL TISSUES

1. INTRODUCTION

For the majority of the 24-hour day/night cycle, the bladder is in a relaxed state, enabling the filling phase, accommodating increasing volumes of urine at low intravesical pressures until a convenient time is chosen to void. Voiding is achieved by forceful, coordinated contractions of detrusor smooth muscle with concomitant relaxation of the urethral sphincter and is completed in typically less than thirty seconds.

The relaxed state of the bladder during filling is anything but passive; multiple cellular players are active, sensing bladder volume, adjusting their length and surface area and relaying information locally to sensory afferents and neighbouring smooth muscle layers. Given the remarkable complexity of the bladder wall and the 'agility' of cells to respond to a constantly changing environment, it is not surprising that the cellular components have a rich array of physiological mechanisms and associated regulatory machinery.

This section will review our knowledge of the physiology of the smooth muscle tissues of the bladder wall, namely the *muscularis mucosae* contained within the *lamina propria*, and the detrusor. A helpful description of the term 'tissue' in this context has been given by Gabella who stated that '*the muscle is not just an assembly of cells but is a tissue, where interaction of all of its cells is of crucial significance'* (600). Focus will be given to the functional expression of ion channels and G-protein coupled receptors (GPCRs) and how these contribute to smooth muscle tissue physiology; consideration will also be given to putative modulatory non-muscle cells.

2. STRUCTURE OF THE BLADDER WALL

The multi-layered bladder wall is commonly considered to comprise the urothelium, *lamina propria* (potentially with a sub-urothelial layer), *muscularis mucosae* (in some species), detrusor, and serosa/adventitia (601) (Figure 41).

2.1. Urothelium.

The urothelial layer contains umbrella cells that luminally are in direct contact with the urine and basally, contact the underlying intermediate and basal cells. The base of the urothelium is adjacent to a basement membrane which delineates the *lamina propria* layer; moreover, the upper *lamina propria* is sometimes referred to as the sub-urothelium (602) and the deep *lamina propria* referred to as the submucosa. The urothelium is reviewed in Section V and briefly referred to here for context.

2.2. Lamina propria.

The *lamina propria* is a rich milieu of connective tissue, abundant collagen and is home to a variety of cells including mast cells, macrophages, afferent and efferent nerves and the bladder's microvasculature (603-605). Its main cellular residents - fibroblasts, interstitial cells (IC) and myofibroblasts have been the focus of morphological and physiological investigation in recent years; while there is not yet consensus on nomenclature, the evidence supports heterogeneity in terms of molecular phenotype and physiology.

The *lamina propria* provides the skeletal structure to the bladder, maintaining its overall ovoid shape across a dynamic range of volumes (605) that includes rapidly changing from full to empty following contraction of the surrounding detrusor smooth muscle during micturition. A demonstration of this important role and surprising strength of bladder *lamina propria* tissue is seen in *ex vivo* pressure-volume recordings of murine bladder where filling pressure curves were similar in intact and detrusor-free preparations (606-607).

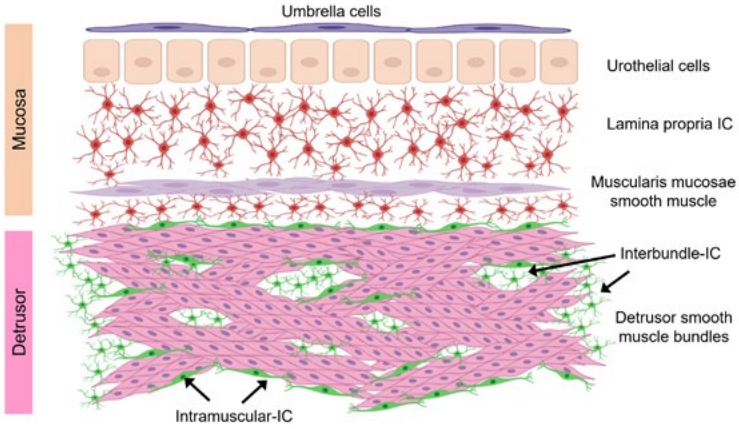

Figure 41. Schematic of major cell types in the bladder wall. *A simplified summary of the three major cell types in the bladder wall representing guinea-pig, pig or human bladder. The urothelium is shown comprising urothelial cells and the luminal-facing umbrella cells. Within the lamina propria is a network of interstitial cells (IC) and abundant collagen (not shown). Nerves and microvessels are abundant within the lamina propria and are not illustrated here. The relatively sparse smooth muscle component within the lamina propria, namely the muscularis mucosae is separated from the underlying bulk detrusor smooth muscle by IC and collagen (not shown). IC are associated with the detrusor smooth muscle bundles, either running in parallel with the bundles, intramuscular-IC, or a more stellate-shaped population, the interbundle-IC occupying the spaces between smooth muscle bundles. Graphic created in BioRender software.*

Histologically, the *lamina propria* shows specialisation from the base of the urothelium to the detrusor boundary. Transmission electron microscopy (TEM) studies of rat bladder demonstrate that the sub-urothelium or superficial/upper *lamina propria*, is rich in fibroblasts, afferent nerves, capillaries and associated pericytes and a loose arrangement of collagen. The deep *lamina propria*, abutting the detrusor layer has comparatively fewer fibroblasts and dense, woven, thick collagen fibrils (604). This structure explains the remarkable strength of the mucosa layer.

Within the *lamina propria* of several species, including human (608-614), pig (615) and guinea-pig (614,616,617) a further specialisation is found, specifically, a distinctive layer of smooth muscle, the *muscularis mucosae* (MM), that although less dense than detrusor tissue, has surprisingly robust contractile activity. Bladders of smaller laboratory mammals, namely rat and mouse, apparently do not contain MM tissue (614,618). In bladders containing an MM layer, a dense layer of connective tissue layer connects with the detrusor, regarded as the submucosa (604); this is notably absent in murine or rat bladder.

Cells in the *lamina propria* as described above, that are named fibroblasts, fibroblast-like cells, myofibroblasts, interstitial cells (IC), interstitial cells of Cajal (ICC), or ICC-like cells can be visualised in histological sections stained with traditional haematoxylin & eosin; moreover, immunolabelling studies with antibodies to e.g. smooth muscle α-actin, vimentin, PDGFRα (Figure 42) and other proteins, support the notion of diverse heterogeneous cells in this region (618-626). Species variability seems likely, given that some bladders have MM (see above) and others do not; similarly, intramural ganglia are absent from rat bladder but are present in guinea-pig (620,627) and pig bladder (628). Some TEM studies support the presence of cells with a fibroblast ultrastructure (605); others support cells with a myofibroblast-like ultrastructure (619,629-631), some have reservations about the presence of true myofibroblasts in healthy bladder (632,633) and some conclude that some combination of fibroblasts, myofibroblasts and IC that are ultrastructurally distinctive from each other are present (622,634). While a consensus has not yet been reached it is possible that the *lamina propria* contains cells which are ultrastructurally fibroblast-like and that there is heterogeneous expression of molecular markers and associated physiological phenotype.

The putative role(s) of such cells will be considered below in the context of their known physiological properties. Whether or not they make structural connections with each other, or with other players in the bladder wall is uncertain and understanding their role(s) will be enabled by knowing if they act individually or can communicate physiologically. A TEM study of rat bladder showed that while cells with a fibroblast ultrastructural profile were abundant and came into close proximity to each other (10-20 nm), there were no specialised junctions connecting adjacent cells (605). This contrasts with the findings of a TEM study of human, rat and mouse bladder which reported *adherens* junctions connecting *lamina propria* IC (624) and also contrasts with studies reporting gap junctions between *lamina propria* IC in human bladder (619).

2.3. Detrusor.

The detrusor is the main component of the bladder wall, comprising smooth muscle cells (SMC), nerves and IC. Detrusor smooth muscle has an idiosyncratic arrangement, with cells grouped in bundles that interlock and interweave with large spaces between the bundles in a full bladder that become smaller spaces when the bladder has emptied (601). This arrangement enables accommodation of varying volumes of urine, importantly at low intravesical pressures, a phenomenon described as compliance.

Communication between detrusor SMC within a bundle may be facilitated by the presence of gap junctions; evidence supporting their presence at the mRNA and protein level indicates low expression of connexins in normal bladder (635) compared with upregulation in obstructed rat bladder (636-638) and in cyclophosphamide-treated mice (639). TEM both supports (637,640,641) and fails to provide (600) ultrastructural evidence for gap junctions connecting SMC in the detrusor. *Adherens* junctions are reportedly common between detrusor SMC, with adjacent membranes around 30-50 nm apart (600). Interestingly, SMC are also structurally associated with each other via contacts from membrane digitations and also via fusion or adhesion of basal *laminae* forming a sealed region; areas of contact as close as 10 nm have been reported (600).

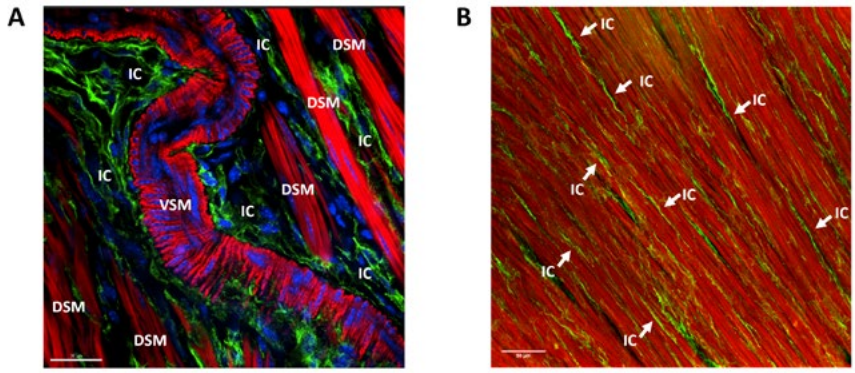

Figure 42. PDGFRα+-cells in murine bladder. *A: Fluorescence micrograph of C57Bl/6 murine bladder flat-mount stained with phalloidin (red) to show smooth muscle, anti-PDGFRα IC (red) and DAPI to counterstain nuclei (blue). Scalebar represents 30 μm. DSM – detrusor smooth muscle; VSM – vascular smooth muscle in arteriole; IC – interstitial cells. Detrusor innervation is dense and efferent nerves are abundant although afferent axons are also present (642). In the detrusor, axons contact SMC commonly through the surface of a varicosity, with a glial-free 'window' that is concave to the SMC cell membrane, forming an intercellular gap of around 40nm (600). There is a rich literature on bladder innervation, spanning several decades where efferent nerves bring about detrusor contraction via parasympathetic signalling mediated by acetylcholine and ATP (643). A notable variance is human detrusor where contraction is considered to be almost exclusively mediated by acetylcholine, with emergence of purinergic components in pathophysiology (644,645)

As was the case for *lamina propria*, there is a body of evidence supporting the presence of interstitial cells (IC) in the detrusor, also described as ICC, ICC-like cells, Cajal-like cells and fibroblast-like cells (613,620,623,624,626,646-658). The functional relevance of these cells, and indeed their nomenclature and biomarkers have been the focus of debate in the field. Here, their physiological properties in relation to ion channel and GPCR expression will be reviewed and their potential relationship to detrusor smooth muscle physiology will be explored. In this article they will be referred to as 'IC' and no disrespect is intended to published works that have used a different nomenclature.

3. LAMINA PROPRIA PHYSIOLOGY

In addition to the important structural role of the *lamina propria* in acting as a *de facto* skeleton for the organ, it is increasingly recognised as having physiological relevance (603), particularly during bladder filling. Under-recognition of the contribution of the *lamina propria* to bladder physiology may in part be due to the traditional research focus on detrusor contraction and associated pharmacology. A substantial proportion of studies utilising *in vitro* myography/tension recordings tended to be carried out on bladder strips that were either 'intact' or had the 'urothelium' removed. This descriptor was often somewhat of a misnomer, as removal of the entire mucosa (urothelium and *lamina propria*) was carried out. Nevertheless, it is apparent that the presence of the mucosa could modify contraction measurements from bladder tissue strips, whether evoked by exogenously applied agonists, in response to electrical field (EFS) of intramural nerves, or indeed spontaneous activity stimulation (659).

Several hypotheses have been examined in relation to the contribution of the mucosa to bladder contraction, and in particular, modulation of detrusor contraction by elements of the mucosa. Firstly, release of transmitter substances from the urothelium, including excitatory (acetylcholine and ATP) and inhibitory substances impact detrusor contraction (for reviews see (660,661). An as yet unidentified urothelial-derived inhibitory factor (UDIF) is proposed to be the cause of mucosal/urothelial inhibition of detrusor contraction (662-666) ; a number of candidate substances have been eliminated from the identification of this elusive UDIF and we await further work in this area. A second possibility is that *lamina propria* IC or myofibroblasts themselves contract and therefore the contractility measured in intact strips of bladder is the sum of IC and detrusor SMC contraction. There is some evidence to support such a scenario in bladder (667); moreover, myofibroblasts are known to have a contractile phenotype and contribute to wound closure (668,669). A third explanation is the contribution of the *muscularis mucosae* (MM) smooth muscle which is discussed below.

3.1. Muscularis mucosae.

The *lamina propria* of bladders of larger laboratory animals including guinea-pig (614,616,617,670,671), as well as pig (614,615) and human (608-612,614,653,670) have a MM layer comprising a discontinuous layer of smooth muscle cells, separated from the underlying detrusor by a submucosa of connective tissue. The physiological relevance of this tissue is intriguing, and recognition of its properties may help to explain some of the aspects of mucosal contribution to bladder contraction.

Receptor-mediated contraction/relaxation.

Accumulating evidence indicates that MM smooth muscle is physiologically different from detrusor smooth muscle even though, like the detrusor, MM smooth muscle also exhibits spontaneous contractions, Ca^{2+}-waves and flashes, and contracts in response to EFS and exogenously applied agonists. A study of contractile activity in MM and detrusor strips of porcine bladder, found that MM exhibited contractions in response to agonists, EFS or that were spontaneous. In contrast to the detrusor, in MM strips, inhibitors of muscarinic, adrenergic and purinergic receptors did not affect tetrodotoxin-sensitive EFS-contractions, nor did a nitric oxide synthase inhibitor (672). Functional evidence supporting expression

of muscarinic and purinergic receptors in porcine MM is seen in its ability to contract to carbachol and αβ-methylene ATP (672,673), thereby suggesting that neural release of acetylcholine, ATP or noradrenaline to MM does not occur during EFS. Conversely, another study found EFS-contractions to be inhibited by the muscarinic inhibitor, atropine (614) but also agreed that adrenergic inhibition had no effect. The situation is reportedly different in guinea-pig bladder where EFS-contractions in both MM and detrusor strips were sensitive to cholinergic and purinergic inhibitors (616) and were largely indistinguishable from each other in terms of pharmacological sensitivity.

Relaxation of MM occurs via nitrergic and adrenergic signalling although the mechanisms are not yet fully elucidated. Porcine MM inhibitory nitrergic innervation is seen in EFS-relaxations in preparations pre-contracted by the thromboxane A2 agonist, U46619, that were abolished by the nitric oxide synthase inhibitor, L-NNA. Interestingly, while a β-adrenoceptor agonist relaxed the tissue (614), similar to effects on detrusor (674), EFS-relaxations were insensitive to guanethidine (sympathetic nerve depletion) indicating that β-adrenoceptors are functionally expressed but neurally-released noradrenaline does not mediate MM relaxation. The study also showed that sympathetic nerves were not structurally associated with MM but with the mucosal vasculature, paralleling observations in the detrusor layer (614).

Spontaneous activity.
Spontaneous activity in the MM from porcine and guinea-pig preparations, as per detrusor smooth muscle, is considered 'myogenic' as it is unaffected by tetrodotoxin, muscarinic, purinergic or adrenergic inhibitors. This non-neuronal origin is further understood as not being generated by release of acetylcholine, ATP or noradrenaline from nearby non-neuronal cells (616,672) although as described below, the activity can be modulated by transmitters.

Interestingly, the force generated by a MM spontaneous contraction was found to be similar to that of a spontaneous contraction from a detrusor strip; this seems remarkable given that histologically, the smooth muscle content of detrusor strips is markedly greater than the loose arrangement of SMC in the MM (616). An explanation may be found in the observations that (a) detrusor strip maximal contraction to depolarisation with 60mM K^+ is reportedly 40-fold greater than MM strips and (b) the maximal depolarisation-evoked contraction in MM strips was not significantly larger than its preceding spontaneous contractions, suggesting that MM spontaneous contractions are generated by the majority of SMC present, whereas in detrusor strips, only a fraction of available SMC were active.

MM spontaneous contractions are modulated by chemical and mechanical signalling native to the bladder wall. Human and guinea-pig MM typically exhibited spontaneous contractions and further contracted in response to carbachol although the P2Y agonist UTP did not modify or evoke contractions (670). The amplitude of porcine bladder MM spontaneous contractions amplitude were also enhanced by carbachol (658); moreover the contractions were markedly larger in juvenile vs adult bladders. The rate of spontaneous activity of porcine mucosa was found to be increased during mechanical stretch; this phenomenon was sensitive to atropine and M3-preferring anti-muscarinic drugs (673).

These observations are consistent with substances released from the adjacent urothelium and a recent study examined the effect of the urothelium on MM contractility. Comparison of spontaneous contractions in MM that were either urothelium-intact or had the urothelium-removed, showed similar amplitude and frequency (615) suggesting that the urothelium was not the *origin* of activity and that under basal experimental conditions, did not release modulators that impacted spontaneous activity. Receptor-operated contractions e.g., evoked by angiotensin II, carbachol or U46619 (thromboxane A2 agonist) were smaller in MM/urothelium strips than in MM-alone leading the authors to speculate that these agonists may also have evoked release of a UDIF that then acted on MM smooth muscle. In another study, adrenergic agonists (α1) increased the rate of spontaneous contractions in MM and enhanced basal tension, whereas β-agonists slowed events and relaxed the preparations (674), giving further sites of action for β-agonists (675). Given the possibility that adrenergic nerves do not directly innervate the MM, the source of adrenergic agonists may be from nearby cells.

Ion channels.
There is a modest body of information on functional expression of ion channels in MM SMC to date. In guinea-pig MM strips, spontaneous contractions were unaffected by pharmacological blockade of BK or SK channels, in contrast to detrusor SM where these modulators significantly increase contraction force integral; moreover, BK current density in enzymatically-dispersed SMC from MM was around 20% that of detrusor SMC (616).

Activation of $TRPV_4$ channels in guinea-pig bladder MM by GSK-1016790A increased basal tension and prevented spontaneous contractions, effects that were sensitive to a $TRPV_4$ antagonist (676). In spite of BK blockers having no effect on MM spontaneous contractions (616), they were able to restore spontaneous activity in GSK-contracted MM preparations (676), this was not true when the SK blocker, apamin, was tested. Further, pre-treatment of MM to block BK channels and subsequent $TRPV_4$ activation with GSK evoked a sustained contraction but did not abolish spontaneous contractions, although there were notably smaller. A putative mechanism encompasses BK channels being largely closed at resting levels but due to being functionally coupled to $TRPV_4$, can be activated by $TRPV_4$-mediated Ca^{2+}-influx during a sustained contraction, resulting in suppression of spontaneous contractions (676).

Intracellular microelectrode recordings and tension recordings from guinea-pig MM has further elucidated the contribution of ion channels to MM physiology. Influx of Ca^{2+} via L-type, voltage-dependent Ca^{2+} channels are responsible for the upstroke of the action potential, depolarisation and subsequent contraction (616,671). On a mean resting membrane potential of -42.5mV, MM typically exhibit spontaneous action potentials with the majority of preparations having a bursting pattern of activity (671). In contrast, detrusor preparations typically exhibit individual action potentials, although bursting patterns are possible. In MM, bursts of spontaneous action potential were converted to individual action potentials by an SK channel opener (NS 309) with prolonged after-hyperpolarisations; moreover, the SK blocker apamin increased the number of action potentials during bursts. These observations may suggest that SK channels have low open probability at rest in MM; furthermore, the bursts may explain the larger unit force in MM compared with detrusor (671).

In microelectrode recordings, blockade of BK channels enhanced action potential amplitude and duration as well as unmasking a slow after-hyperpolarisation in MM preparations. In addition, in contrast to a previous study which used MM-urothelium preparations (616), BK modulators had the expected effects on spontaneous contractions of urothelium-denuded MM (671). Absence of the urothelium may have removed confounding factors such as the effect of BK modulators on urothelial cells, evoking release of urothelium-de-

rived contracting factors that might mask the effect of BK modulators on MM contractility.

Kv7 channels, reported to be functionally active in detrusor smooth muscle from a number of species (677-680) are expressed in guinea-pig bladder MM and had a small effect on the resting membrane potential (671); however, their role is modest compared with BK or SK channels.

3.2. Interstitial cells in the lamina propria. Ion channels and GPCRs.

IC in the *lamina propria* are widely reported in the literature, across many species, in studies based on histology, immunolabelling and TEM (see earlier section). A number of scenarios in which they contribute to bladder physiology have been proposed including participation in bladder sensation or mechano-transduction (603) and initiation of spontaneous activity (681). There are indications that their expression changes in various pathophysiological manifestations (613,681,682).

Patch-clamp studies of IC from guinea-pig bladder *lamina propria* demonstrated spontaneous transient inward currents that were Ca^{2+}-activated Cl^- currents (683). Similar conductances and intracellular Ca^{2+}-transients could be activated by reduced extracellular pH (684), purinergic agonists including ATP, UTP or ADP but not αβ-methylene-ATP, suggesting P2Y receptor activation; this was supported by immunodetection of $P2Y_6$ receptors (523). Such data suggest that *lamina propria* IC could respond to ATP and purines released from the urothelium (606,631,685,686) potentially transducing sensation information to afferent nerves and other cellular players.

Ex vivo tissue sheets or whole-mount preparations of bladder mucosa support physiological signalling within a *lamina propria* IC network, notwithstanding the lack of clarity in the literature whether the cells are structurally connected or coupled. A study of IC located at the suburothelium/upper *lamina propria* of rat pups found spontaneous Ca^{2+} transients across a network with varying levels of coupling. Evidence for $TRPC_4$ activity was found when an agonist increased the number of IC firing and their integration; a similar effect was found with ATP, suggesting that *lamina propria* IC can behave in network fashion, modulated by $TRPV_4$ channel activity and purinergic receptor stimulation (616). A similar scenario has been reported in guinea-pig bladder whole-mount mucosal preparations where IC-LP (identified morphologically) exhibited Ca^{2+}-transients that sometimes appeared to be transmitted to neighbouring IC, and could also occur individually (687). EFS evoked simultaneous signals Ca^{2+}-transients in neighbouring cells that were sensitive to atropine or suramin, indicating that the *lamina propria* IC may receive a functional innervation (687).

IC in the *lamina propria* may also respond to acetylcholine, either released from nerves (687) or perhaps released from the urothelium. Although muscarinic activation with carbachol neither evoked currents nor Ca^{2+}-transients in dispersed IC in one study (683), M3 receptors have been visualised on IC in morphological studies (688,689). Understanding the functional relevance of muscarinic signalling in *lamina propria* IC may be important in the context of the mechanism of action of anti-muscarinic drugs to treat bladder dysfunction, commonly regarded to act on detrusor SMC.

Increased IC numbers in the upper *lamina propria* or sub-urothelium in spinal cord injured rat bladders were considered to be the origin of Ca^{2+}-waves in the bladder wall that then propagated to the urothelium and detrusor (681). P2Y agonists ADP, UTP and UDP and selective $P2Y_6$ agonists enhanced spontaneous contractions and the conduction velocity of Ca^{2+}-waves or depolarisation throughout the mucosa. An interesting observation in this spinal cord injured study was that excitation (Ca^{2+} or electrical signalling) originated in the suburothelial space, that is rich in IC, and subsequently propagated to the detrusor and the urothelium. Opinions on the origin of spontaneous activity in the bladder include the *lamina propria*, the smooth muscle itself in the myogenic hypotheses of MM and detrusor tissues and contribution/modulation from other elements including the urothelium (659).

3.3. Summary.

The research community is using a relatively new lens on the bladder, specifically on the components of the *lamina propria* and integrating new evidence to understand its contribution to bladder physiology. Focus has largely been directed at understanding the role of the MM and IC during bladder filling or the storage phase. If the primary function of the *lamina propria* is indeed structural, its other functions are likely to be just as important.

In species where there is a MM layer, this discontinuous smooth muscle tissue is surprisingly active in terms of generation of spontaneous contractions and force production per unit area. The purpose of MM spontaneous activity is not known but has been suggested to include rearrangement of the mucosa, including the urothelium during bladder filling, when the rugae folds are ‘smoothed out’ in high volumes. Another suggestion is that it acts to prevent excessive stretching of the bladder microvasculature during filling and storage phases. If the origin of MM spontaneous activity is myogenic, its sensitivity to transmitters released from the urothelium (including acetylcholine, nitric oxide, ATP, other purines) indicates local regulation. The functional expression of a number of Ca^{2+}, K^+ and TRP channels, and undoubtedly others, provide the electrophysiological machinery to responsively tune up and tune down spontaneous action potentials and associated spontaneous contractions within a dynamic range.

Mucosal preparations from rat or murine bladder which lack a MM layer fail to display spontaneous contractions, or generate very small amplitude events, supporting the hypothesis that the MM is responsible for the generation of mucosal contractions (614). It has been suggested that in rat mucosa, the small amplitude spontaneous contractions could in fact have been generated by mucosal venues as the frequency of events are similar (614,690). In support of this, is the unexpected finding that noradrenaline increased the basal tone of rat mucosa preparations, a reasonable explanation may lie in the change of tone actually being generated by vascular contraction within the preparation. Yet, one might expect alternative mechanisms to structurally rearrange the mucosa during filling in species where a MM is not present. This role may be delivered by contractile myofibroblasts in mouse or rat bladder *lamina propria* and further research is needed.

The identity of contractile cells other than MM SMC or detrusor SMC remains unresolved. A species comparison of human, pig, guinea-pig, rat and mouse bladder failed to find cells immunopositive for αSMA apart from MM or detrusor SMC (614). Others have found αSMA-positive IC in the suburothelial region of human *lamina propria* but not the submucosa/deep *lamina propria* (634).

The question of whether MM and indeed *lamina propria* contraction contributes to whole bladder contraction either in non-voiding/spontaneous/autonomous contractions, better described as changes in intravesical pressure or in large voiding contraction, is interesting. *Ex vivo* pressure-volume recordings of intact murine

bladder demonstrate non-voiding contractions that are notably absent or non-detectable in preparations where the detrusor has been removed (606). Given that murine bladder does not have a MM, perhaps this is to be expected and any contraction of *lamina propria* fibroblasts or IC would be below threshold detection. Similar experiments on the bladders of larger animals e.g. guinea-pig will enable this question to be addressed.

In elucidation of the contribution of MM to whole bladder contraction, comparison of intact, detrusor and mucosa strips from porcine bladder demonstrated that (1) carbachol-evoked contractions in detrusor and mucosal strips were similar and (2) these were significantly larger than contractions generated in intact strips (667). Removal of smooth muscle bundles from mucosal strips by micro-dissection, confirmed by absence of smooth muscle immunostaining, did not prevent contraction of the mucosa by neurokinin A, suggesting that non-muscle players, likely suburothelial myofibroblasts or mucosal vessels were generating the contractions in these preparations. Returning to the intact vs detrusor or MM contractions, the smaller agonist-evoked contractions observed in intact preparations may argue in support of UDIF limiting contraction amplitude or force integral and may represent how the physiological integration of the tissues bring about optimal contraction that can be increased for voiding or diminished during filling.

4. DETRUSOR PHYSIOLOGY

Our knowledge of detrusor smooth muscle physiology and related pharmacology is extensive and evidenced by a rich body of evidence in the literature. The aim of this section is not to provide a comprehensive review (the reader is referred to published reviews for overview of ion channels and receptors in the detrusor (643,644,691-694) but to highlight our current understanding of the roles of key ion channel and GPCR players in detrusor smooth muscle physiology. IC in detrusor tissue will also be considered and their potential interactions with detrusor smooth muscle will be discussed.

4.1. BK channels.

Perhaps the most widely studied ion channel in detrusor smooth muscle is the large-conductance, Ca^{2+}-activated K^+ channel (BK) that is highly expressed on the plasma membrane of detrusor SMC (695). BK channels are activated by depolarisation and Ca^{2+}, generating hyperpolarisation of the membrane potential and relaxation of detrusor SMC as demonstrated in earlier patch-clamp experiments (696-699), microelectrode recordings of detrusor tissue (700) and *in vitro* recordings of tissue strips (701,702). As the bladder fills and the wall stretches, BK channel activation appears to be enhanced, supporting the hypothesis of a 'brake', limiting spontaneous contractions (703). Their functional importance in bladder physiology seems to lie in limiting depolarisation of detrusor SMC during bladder filling, preventing aberrant coordination of low-amplitude, normally uncoordinated spontaneous contractions (695).

In normal physiology, BK channel activity is impacted by and responsive to the local environment. An example is seen in modulation by circulating hormones; 17β-oestradiol enhanced BK currents in human detrusor SMC, translating to hyperpolarisation of the resting membrane potential, decreased spontaneous and EFS-mediated contractions (680,704). Similarly, testosterone enhanced BK currents in guinea-pig detrusor SMC and hyperpolarised the resting membrane potential thereby reducing excitability (705). BK channels are functionally coupled to other channels indicating the presence of other modulatory mechanisms. In guinea-pig detrusor SMC, Ca^{2+}-influx via $TRPV_4$ is thought to activate BK/$TRPV_4$ coupled channels that then bring about suppression of spontaneous contractions (676).

Muscarinic M3 receptors may also be functionally coupled to BK channels as carbachol evoked large transient outward currents in human and guinea-pig detrusor SMC, followed by abolition of spontaneous transient outward BK currents and associated transient hyperpolarisations, leading to overall depolarisation (706,707). Such a mechanism would act to release the 'BK brake' during EFS or during voiding when acetylcholine, released from parasympathetic nerves, evokes large-amplitude contractions via M3 receptor signalling. It is not known whether ATP or other purines similarly inhibit BK to enable depolarisation and detrusor SMC contraction.

Activation of β3 adrenoceptors causes relaxation of the bladder (708,709) and there is a compelling literature on the potential of β3-agonists to relieve urgency in overactive bladder syndrome (675,710). A number of mechanisms of action have been reported (710) including contribution from β3-adrenoceptors expressed on detrusor SMC that include inhibition of cholinergic-evoked Ca^{2+} oscillations (711), reduction of purinergic postjunctional contractions via inhibition of $P2X_1$-currents and activation of BK channels (712-715).

There is limited indication of BK channel expression in murine detrusor IC with a study of PDGFRα-IC from GFP mice reporting low expression of the BK αslo gene transcript (657). A patch-clamp study of outward currents in guinea-pig detrusor IC, identified on the basis of morphology and inability to contract, reported paxilline-sensitive BK currents (716). To date, BK expression in detrusor SMC has significant functional relevance and increasingly, the role of these channels in urothelial cells is being elucidated (717,718)

BK channels have long been considered as a promising therapeutic target for overactive bladder (OAB) (719,720) as BK openers cause hyperpolarisation and suppression of action potentials in detrusor SMC (705,721) whereas BK blockers increase contraction amplitude and frequency (722). In spite of this, BK openers have little effect on contractility of neurogenic bladder (723), explained by reduced expression of the BKα-subunit, encoded by KCNMA1 in neurogenic bladder (724,725), in the pBOO rabbit bladder model (726) and also in high-fat diet induced obesity in rats (727). Conversely, in pBOO rat detrusor, the BKα-subunit was not significantly affected whereas the β1 subunit was increased (728). In diabetes, reduced functional expression of KCNMA1 and changes to methylation of the gene was not corrected by insulin treatment, known as hyperglycaemic memory (729). An alternative approach to the use of BK channel openers that may be effective in neurogenic bladder or diabetes, may lie in gene therapy to restore expression of KCNMA1 in detrusor SMC via a non-viral, naked plasmid (725,730). This approach has been shown to be promising in pre-clinical obstructed rat bladder models (731) and early human trials although statistical significance of primary endpoints was not reached (730).

4.2. SK channels.

The presence of SK channels in detrusor tissue, presumed to be in the SMC has been reported over the last two decades. Pharmacological modulators such as the SK channel inhibitor apamin, enhances spontaneous contractions in detrusor strips (702,722,732,733) and mRNA/WB/immuno-fluorescence data supports SK expression in detrusor tissue at gene or protein level (734,735). Apamin-sensitive SK currents have been reported in murine and guinea-pig detrusor SMC (733,736) although the former authors noted relatively low current density of SK compared with BK.

Building on the hypothesis that BK currents in detrusor SMC act as a 'brake' mechanism to limit excitability and contraction during bladder filling, the detrusor IC may also act to limit detrusor SMC activity. Detrusor IC reportedly express a number of K^+ channels based on evidence from studies using patch-clamp electrophysiology, immunofluorescence and recordings of intracellular Ca^{2+}-signalling. To date, SK3 (626,657,737), BK (716,738) and Kv7 (738) have been explored in detrusor IC. Functional expression of K^+ channels might enable IC to generate hyperpolarisation and a potential mechanism is one of a 'damper' where instead of originating depolarisation and therefore spontaneous activity in detrusor SMC, hyperpolarisations from IC could transmit to neighbouring detrusor SMC and limit their excitability. As discussed above for BK channels, such a scenario would be physiologically beneficial during bladder filling to enable sufficient spontaneous contractions to maintain optimal bladder tone and 3D shape but provide a limiting mechanism to prevent coordination of contractions that might to bring about urgency or even incontinence (659,739).

Evidence supporting the existence of such a system within detrusor IC came from studies using a PDGFRα-GPF mouse and are based on SK channel expression in IC. Patch-clamp recordings of enzymatically-dispersed PDGFRα-expressing IC and detrusor SMC showed significant SK3-currents in the IC and comparatively currents in the SMC (657). Prior to this, apamin-sensitive SK channels were considered to be functionally active in detrusor SMC (see above), a reasonable conclusion given that SK blockade with apamin enhanced the amplitude of spontaneous contractions in tissue strips; moreover, studies of a transgenic SK3-overexpressing mouse bladder showed reduced frequency of spontaneous contractions in tissue strips (722,733,734). In another study, SK openers had been found to increase duration of after-hyperpolarisations in guinea-pig detrusor SMC followed by abolition of action potentials (721) (Figure 43).

Clarification of high SK expression in PDGFRα-detrusor IC through cell sorting and subsequent characterisation of selected gene expression provided compelling evidence of an SK3-hyperpolarising mechanism in the IC (657). These cells responded to ATP and a $P2Y_1$ agonist with large outward currents and hyperpolarisation; the sustained component of EFS-contraction was shown to be partly mediated by a $P2Y_1$-mechanism to limit tissue contraction (740). The cells also express $P2Y_2$, $P2Y_4$ and $P2Y_{14}$ at gene level; activation of apamin-sensitive currents and hyperpolarisation by the $P2Y_2$/$P2Y_4$ antagonist, UTP, supports a functional role for these P2Y receptors in detrusor IC physiology (741). Further support for a novel hyperpolarising SK3 mechanism in the detrusor PDGFRα-detrusor IC, was seen in patch-clamp experiments where Ca^{2+}-influx via $TRPV_4$ activated SK channels in detrusor IC, and the suppression of non-voiding contractions in *ex vivo* bladders during filling by an SK activator (737).

While an attractive hypothesis with accumulating evidence, support for some of the constitutive steps has not yet emerged, specifically communication of the SK3-hyperpolarisation from detrusor IC to detrusor SMC. In fact, another study concluded that such IC-SMC signal transduction does not occur in murine bladder as purinergic agonists increased Ca^{2+}-transients in the IC without concomitant suppression of Ca^{2+}-signalling in neighbouring detrusor SMC nor of spontaneous contractions (626). The findings also did not support a functional innervation of PDGFRα-detrusor IC in contrast to detrusor SMC, as the former did not respond to electrical field stimulation. The lack of proof for specialised junctions between IC and detrusor SMC (600) may also be consistent with the absence of functional coupling evidence. Another area of contradiction is

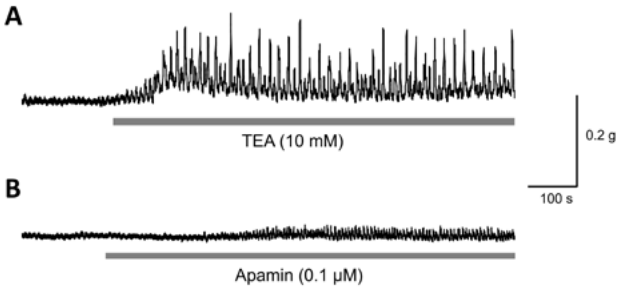

Figure 43. Effect of potassium channel inhibitors on mouse bladder spontaneous activity. *A: Sample trace of in vitro tension recording from mouse detrusor strip showing marked increase in spontaneous contraction amplitude with the non-selective-K+ channel blocker, tetraethylammonium chloride (TEA). B: Sample trace of in vitro tension recording from mouse full-thickness bladder strip showing the effect of the SK blocker, apamin which enhanced spontaneous contraction amplitude. Figures courtesy of McCloskey group, Queen's University Belfast.*

that P2Y1R stimulation was found to evoke transient contraction, but not subsequent inhibition of spontaneous contractions in murine detrusor. Furthermore, in PDGFRα-IC-GFP bladders, P2Y1 agonists, ADP or ATP all increased intracellular Ca^{2+}- in the IC but did not inhibit spontaneous Ca^{2+}-transients or spontaneous contractions in detrusor SMC leading the authors to conclude that the SK3-dependent hyperpolarisation in IC is unlikely to be transmitted to SMC to limit their activity. Undoubtedly, further research will build our knowledge of detrusor SMC-IC interactions and either establish or shift the existing paradigms.

Similar to the situation for BK channels, a number of studies have reported altered expression of SK channels in bladder in pathophysiology. In 2010 it was reported that the obstructed female rat detrusor (six weeks post-obstruction) had increased SK3 expression; moreover, apamin significantly enhanced spontaneous contractions, in excess of its effect on control bladders (728). Gene expression for SK1, SK2 and SK3 channels were reportedly downregulated in isolated SMC from obese rats along with reduced SK current density and a smaller hyperpolarisation in response to SK agonists compared with control rats (742); similar findings were reported in obstructed guinea-pig bladder (743). A recent paper reported reduced detrusor, PDGFRα-IC in spinal cord injured mouse bladder (744), consistent with a number of reports of reduced detrusor IC in spinal cord injured rat bladder (613,745). In the murine bladder study, decreased gene and protein expression of PDGFRα and SK3 was associated with enhanced non-voiding spontaneous contractions in *ex vivo* bladders (744). Taken together, the evidence supports altered SK3 expression across several rodent models of detrusor overactivity and strongly suggests that detrusor cells, likely IC are affected.

4.3. Voltage-dependent K^+ channels.

A number of voltage-dependent K^+ channels are functionally expressed in detrusor and their role remains an emerging area of research. A recent review (694) summarised findings supporting diversity of Kv channel expression including Kv1.2, Kv1.3, Kv1.5, Kv1.6, Kv2.1, Kv2.2, Kv3.2, Kv4.2, Kv4.3, Kv5.1, Kv6.1, Kv6.2, Kv6.3, Kv7.1-Kv7.5, Kv8.2, Kv9.1, Kv9.2, Kv9.3, Kv11.1. Kv channels have been characterised in patch-clamp experiments and contribute to action potential repolarisation and maintenance of the resting membrane potential. Perhaps the most promising of the Kv expressed in detrusor in terms of potential clinical relevance are

those of the Kv7 family. There are a number of drugs targeting these channels that have been used in clinical settings e.g. retigabine, a Kv7 channel opener that was trialled to treat epilepsy but had a number of adverse effects including urinary retention (746). Laboratory experiments support gene, protein and functional expression of Kv7 in detrusor across several species, reporting sensitivity of outward currents and membrane potential from dispersed detrusor SMC and IC to Kv7 pharmacological modulators (677,678,738,747). *In vitro* tension recordings and Ca^{2+}-imaging has shown contribution of Kv7 to spontaneous activity where Kv7 blockers or openers respectively enhanced or diminished spontaneous contractions and action potentials (678,721,748-751).

The evidence to date supports the need for further research in this area, particularly whether Kv7 expression is altered in pathophysiologies relating to detrusor overactivity. If their expression in these conditions is similar to normal bladder or even upregulated, then there may be opportunity for Kv7 openers to reduce excitability and diminish aberrant contractions. Should this be achieved without impacting neurogenic voiding contractions in view of a side effect of urinary retention with regitabine, this would be a promising area of enquiry. Lessons should be noted from the early potential of BK openers being useful to treat neurogenic bladder overactivity was not realised as BK channels were markedly under-expressed. There is therefore a present need to focus efforts on characterising Kv7 in overactive human bladder tissue.

4.4. CaV channels.

Early electrophysiological studies revealed the dependence of the upstroke of the detrusor SMC action potential on Ca^{2+} ions and demonstrated the presence of inward L-type Ca^{2+} currents (696,700,752). Contraction of detrusor smooth muscle is dihydropyridine-sensitive (722) and both L-type $Ca_V1.2$ and T-type $Ca_V3.1$ currents have been characterised in a number of animal models and human detrusor SMC (753-756). Our knowledge of the essential role of $Ca_V1.2$ channels in detrusor contraction contrasts with rather incomplete understanding of the importance of T-type $Ca_V3.1$-3.3 currents which may be upregulated in bladder dysfunction (756). This remains an area where research efforts should be focussed.

4.5. Other ion channels.

An emerging picture of the contribution of TRP channels shows that these are integrated with other ion channels and GPCRs in detrusor physiology. They are involved in mechano-sensory signalling and pain sensation and their roles in bladder afferent signalling and related filling disorders are discussed in section V. Several TRP channels are expressed on detrusor SMC and other cells in the bladder wall, including urothelium. In murine detrusor SMC, $TRPC_4$ channels mediate Ca^{2+} influx followed by Ca^{2+} release from IP_3-intracellular stores during muscarinic-evoked contractions; this is in addition to the well-known Ca^{2+} influx via L-type Ca_V channels during muscarinic receptor stimulation (757). In support of this role, carbachol-evoked contractions are smaller in detrusor of TRPC4 deficient mice and spontaneous contractions were also smaller (757).

Activation of $TRPA_1$ in rat bladder detrusor strips increased basal tone and EFS-contractions (758); this channel also activates afferent nerve signalling in rat bladder (759) consistent with immunofluorescence studies showing expression in urothelium, *lamina propria*, detrusor and around blood vessels suggesting multiple sites of action on bladder activity (760).

$TRPM_4$ in rat detrusor SMC are active in contraction regulation as channel inhibition reduced intracellular Ca^{2+} and diminished spontaneous and neurogenic contractions (761,762). In human detrusor, $TRPM_4$ expression is confirmed at gene and protein level; moreover, patch-clamp experiments revealed currents that were sensitive to a $TRPM_4$ inhibitor which also evoked hyperpolarisation (763). Importantly, $TRPM_4$ inhibitors reduce spontaneous activity, carbachol-generated contractions and EFS-induced contractions in human and murine detrusor (763,764). $TRPM_4$ is overexpressed in spinal cord injured murine detrusor SMC and this is associated with enhanced spontaneous activity in detrusor strips which was inhibited by a $TRPM_4$ blocker (765). The independently corroborated evidence of the functional expression of $TRPM_4$ across human and rodent bladders makes this a promising area of translational research; furthermore, $TRPM_4$ overexpression in detrusor overactivity suggests it could be a drug target. Further research will undoubtedly investigate whether $TRPM_4$ inhibition will dampen non-voiding contractions without impacting neurogenic, voiding contractions and potentially avoid urinary retention.

$TRPV_4$ channels regulate detrusor SMC and MM contraction via BK channel coupling, where Ca^{2+}-influx mediated by $TRPV_4$ causes a tonic contraction and also activates BK to inhibit spontaneous contractions in a so-called self-limiting mechanism (676). $TRPV_4$ is functionally expressed in mouse and rat detrusor, where an activator contacted the strips of normal and spinal cord injured rat bladder (766,767)

Ca^{2+}-activated Cl^- channels have prominent roles in some smooth muscles, generating spontaneous transient depolarisations and activated by Ca^{2+}-oscillations (365,768-770). Yet, despite the detrusor having spontaneous Ca^{2+}, electrical and mechanical activity, the limited available data highlighting the presence of Ca^{2+}-activated Cl^- channels is not yet fully supported by patch-clamp characterisation. A study of *ex vivo* whole rat bladder showed that the channel blocker niflumic acid, reduced frequency of spontaneous pressure changes (771). Gene expression of Ca^{2+}-activated Cl^- channels in normal rat bladder is enhanced in obstructed models and imaging methods indicated that channel modulators may change the membrane potential (772). In rat detrusor strips, niflumic acid inhibited spontaneous contractions and immunofluorescence showed expression of the channel protein (Ano1) in vimentin$^+$ IC rather than in detrusor SMC (773). Further information from patch clamp experiments from guinea-pig detrusor SMC revealed a Ca^{2+}-independent, voltage-dependent Cl^- channel that was sensitive to niflumic acid (774). Immunofluorescence studies in murine bladder showed expression Ano1 on IC (656) in contrast to a study of human, rat, guinea-pig and mouse bladder where the authors failed to find Ano1-positive IC (775).

4.6. HCN channels.

Hyperpolarisation-activated nucleotide-gated (HCN) channels are expressed in bladder and in recent years, have been studied in normal and dysfunctional bladder models. HCN1-HCN4 are expressed in rat and human bladder mucosa and detrusor (776-778). In human or mouse bladder detrusor strips, HCN inhibition enhanced baseline tone and increased the amplitude of superimposed, phasic contractions (779). In another study of human bladder, HCN inhibition increased resting tension and amplitude of phasic contractions; however, had no effect on EFS or carbachol contractions (780). In rat and human detrusor strips, activation of β3-adrenoceptors decreased baseline tension of rat bladder strips, an effect that was prevented by HCN inhibitors thus suggesting interaction of HCN channels and β3-adrenoceptors (778).

Evidence from patch-clamp recordings of detrusor IC showed typical HCN currents that were modulated by cAMP (781), in keeping

with the effect of β3-adrenoceptors above; interestingly HCN1-4 was reportedly lower in diabetic rat bladder and cAMP activation of the HCN current was reduced although the number of IC was not changed (781,782). In contrast, HCN1-4 expression was upregulated in obstructed rat bladder along with increased HCN current density in detrusor ICs, detrusor strips, furthermore, HCN inhibition reduced the spontaneous contractions suggesting upregulated HCN contributed to detrusor overactivity (783).

4.7. Receptor-mediated contractions.
Detrusor smooth muscle expresses muscarinic, purinergic, adrenergic and other GPCRs (643) that mediate contraction or relaxation. Muscarinic agonists e.g. acetylcholine or its stable analogue carbachol, elicit large-amplitude contractions (784); moreover, in non-human mammalian bladder, EFS-contractions are significantly inhibited, around 50%, by muscarinic receptor antagonists (785). In human bladder, EFS-contractions are almost exclusively mediated by acetylcholine and a purinergic-mediated component emerges in some pathophysiological conditions (644).

An important consideration at tissue physiology level is functional connectivity between receptors and ion channels to bring about or prevent contraction. Cooperation between M3 muscarinic receptors and BK channels in rat detrusor SMC was seen in large, transient BK currents that were evoked by carbachol followed by inhibition of spontaneous, transient BK currents and concomitant inhibition of spontaneous transient hyperpolarisations. Mechanistically, M3 activation evoked mobilisation of intracellular Ca^{2+} via PLC-PIP_2-IP_3 which initially activated BK, followed by depletion of intracellular Ca^{2+} and cessation of BK-mediated transient currents (706). Cooperation between M3 receptors and $TRPC_4$ channels was described above (757,786) is another example of the integration of M3 and ion channels in detrusor SMC physiology.

Similar interactions are reported for BK channels. Cholinergic and purinergic contractions in murine detrusor, are increased by BK pharmacological blockade, or in BK-knockout mice (deletion of mSlo1), indicating that BK channels normally act to reduce receptor-mediated detrusor contractions (787,788). BK channels also interact with β-adrenoceptors as shown in patch-clamp studies where isoproterenol or forskolin enhanced BK currents via cAMP/protein kinase A signalling (789). The bladder's inhibitor sympathetic innervation is of particular translational relevance as it causes relaxation. The success of β-adrenoceptor agonists, in particular the β3-adrenoceptor agonist, mirabegron, is positively impacting many patients with overactive bladder. The reader is directed to a number of recent reviews on this topic (675,790,791)

Detrusor IC also express purinergic and muscarinic receptors and will respond to extracellular acetylcholine or ATP. Detrusor IC from guinea-pig bladder respond to carbachol with Ca^{2+}-transients via release from intracellular stores and Ca^{2+}-influx (784); furthermore, in whole-mount tissue preparations, detrusor IC respond to EFS with Ca^{2+}-transients that are sensitive to tetrodotoxin (687). As noted above, $P2Y_1R$ activation by a selective agonist or ATP, evoked SK currents in murine detrusor PDGFRα-IC (740) showing multiple cellular targets and effects of purinergic agonists.

5. INTEGRATION OF PHYSIOLOGY IN TISSUES OF THE BLADDER WALL DURING FILLING AND EMPTYING

The integration of nerve and SMC activity in the bladder is paramount to its dual functions of filling and emptying. The spontaneous contractions, regarded as important for setting bladder tone, may also communicate fullness to afferent nerves and we need to be clear when describing activity from the intact bladder, MM, SMC or indeed muscle-free activity in the *lamina propria*. Experimental data from a seminal paper by Heppner et al, provided insights into how the cellular elements of the bladder might work together during filling. An experimental design incorporating simultaneous recordings of pressure, volume and afferent nerve activity in *ex vivo* mouse bladder illuminated the mechanism where spontaneous detrusor (absence of MM in this species) contraction (changes in pressure) evoked significant afferent nerve activity and the rising phase of a spontaneous contraction was correlated with action potential frequency (792). In this setup, BK or SK channel inhibition increased spontaneous contraction amplitude and subsequent afferent activity demonstrating the ability of BK and SK channels to 'tune up' afferent signalling during intravesical volume increases (792). The authors proposed an elegant model of activity during bladder filling based on these findings and proposed that the interstitial cells, known to highly express SK channels, may act as a 'gain regulator', transducing pressure to afferent nerves (Figure 44).

Further work is needed to understand how the tissues of the bladder and their cellular components work together during the main storage function of the bladder. Do BK channels in detrusor SM act as a primary brake mechanism, secondary to the IC SK-limiting pathway, and/or are both mechanisms regulated dynamically by modulators e.g. acetylcholine, ATP, purines etc? Another question is whether SK channels in detrusor IC can be activated therapeutically to dampen aberrant detrusor contraction without bringing about urinary retention? We are learning more about the MM in terms of physiological properties; however, it is not yet known whether it contributes to overactivity. If not, it would be better to develop detrusor-targeting therapies that spare the role of MM tissue e.g. in dynamically regulating the architecture of the mucosa and potentially preventing over-distension of blood vessels.

A final remaining question is the identity of the pressure/filling sensor, whether it sits within IC, SMC or both. A promising candidate lies with the mechano-sensitive ion channels, Piezo 1 and Piezo 2, channels which transduce mechanical stress into Ca^{2+} signals. There is emerging evidence of Piezo-1 and -2 expression in the bladder, including within urothelial cells, sensory neurons and IC (321,531,793,794). Mouse models and humans lacking functional Piezo 2 have bladder dysfunction and patients reported deficient sensation of bladder filling (531). Enhanced understanding how Piezo channels operate in urothelial cells, afferent nerves and other cells of the bladder wall in relation to all of the signalling processes that bring about contraction and relaxation will undoubtedly shed further light on this area.

VII. NOVEL APPROACHES TO STUDY THE PATHOPHYSIOLOGY OF LUT DYSFUNCTION

This chapter section will discuss the use of animal models and experimental approaches to investigate the pathophysiological mechanisms and therapeutic potentials for detrusor overactivity (DO).

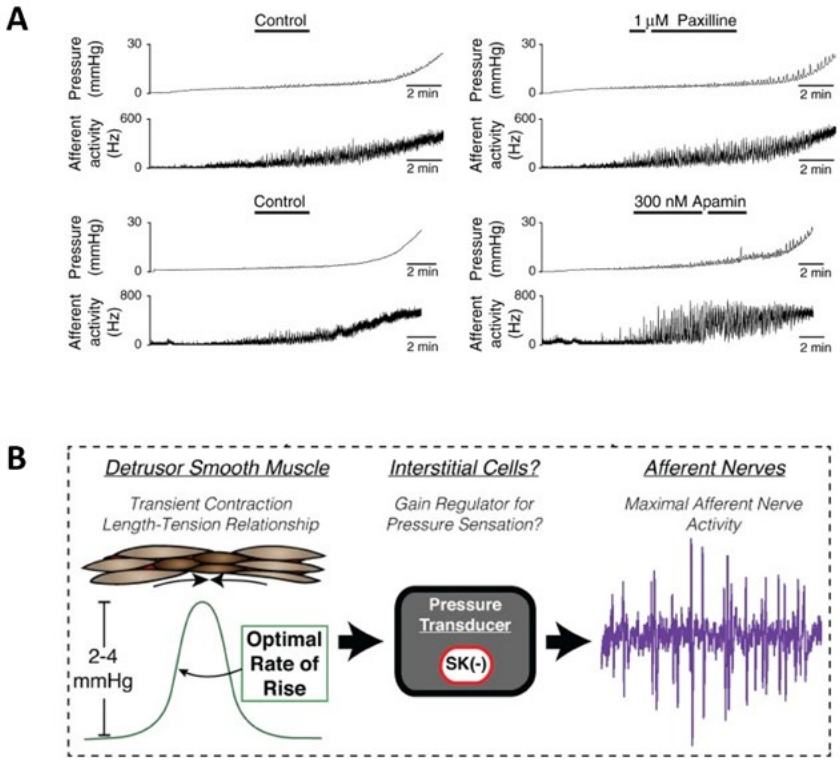

Figure 44. Integration of spontaneous (transient) contractions and afferent nerve activity during bladder filling. *A: Recordings of intravesical pressure and afferent nerve activity in ex vivo murine bladder, adapted from Heppner et al (792). During bladder filling, a low pressure is maintained and is followed by development of small non-voiding pressure changes (contractions) and a more rapid pressure rise at the end of the recording. The initial quiescent tracing of afferent nerve activity changes to substantial firing as the bladder fills. Inhibition of BK channels with paxilline enhanced the amplitude of pressure waves. Blockade of SK channels with apamin markedly enhanced afferent nerve firing with concomitant increase in spontaneous pressure changes. B: Proposed model by Heppner et al (792) showing a transient change in pressure/contraction with an optimal rate of rise which is a function of detrusor smooth muscle's length-tension relationship. The model proposes that transient contractions stimulate bursts of afferent nerve activity; SK+-interstitial cells may act as a gain regulator as their inhibition enhanced afferent firing and subsequent transient contractions. Figures modified from (792), with permission of Professor Mark Nelson.*

This may arise from neuropathic or idiopathic (NDO or IDO) causes and is associated with afferent sensitisation and increased bladder micromotions. The utility of these models and approaches will be demonstrated by using an example of the nitric oxide (NO)-soluble guanylate cyclase (sGC)-cyclic guanosine monophosphate (cGMP) signalling in LUT pathophysiology and modulation of the pathway for treatment of various bladder conditions. For example, the clinically relevant effects of phosphodiesterase type-5 (PDE5) inhibitors, *e.g.,* sildenafil, on LUT dysfunction may be investigated using mouse models of T_8-T_9 spinal cord transection (SCT) and acrolein- or irradiation-induced cystitis (Figure 45). Selective irradiation of the colon causes bladder NDO and thus may be used to investigate organ cross-innervation. Also discussed will be different approaches to study bladder outlet obstruction (BOO).

1. ANIMAL MODELS: NEUROGENIC DETRUSOR OVERACTIVITY.

1.1. Bladder/colon irradiated, acrolein-induced cystitis and SCT mouse models: pathological changes to bladder function.

Radiation cystitis is a chronic condition that in humans develops months to years following radiotherapy for pelvic malignancies. Acutely, radiation cystitis is associated with extensive inflammation and NDO symptoms that can resolve over time. However, a small proportion of patients will experience chronic inflammation resulting in fibrosis, poorly compliant bladders and potentially fatal haemorrhagic cystitis. The consequences of chronic radiation cystitis can be demonstrated in a mouse model by selective irradiation of the urinary bladder that has been temporally removed from the abdominal cavity without disruption to its vascular or nervous supplies (Figure 46A). In his way, the bladder can be selectively exposed to an otherwise lethal dose of irradiation (10 Gy, 1 Gy = 100 Rads) without compromising surrounding pelvic organs or affecting survival (*e.g.,* disruption of haematopoiesis) (795). This minimises injury to pelvic organs near to the bladder, mediated by cross-innervation

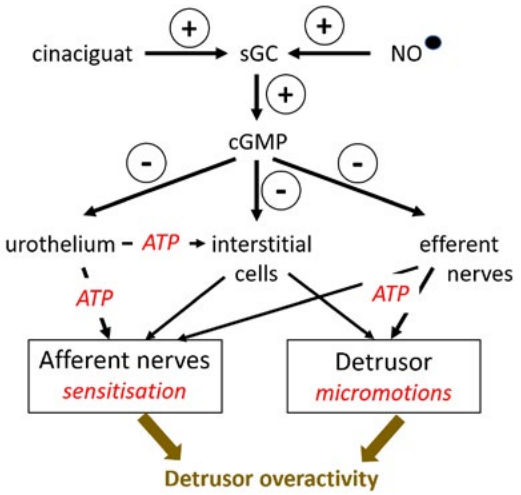

Figure 45. Flow diagram of soluble guanylate cyclase (sGC) activity to ameliorate the pathophysiology of detrusor overactivity. *Naturally-occurring pathways (mediated here by nitric oxide (NO)) and drugs (here cinaciguat) increase cGC activity and hence cGMP levels. This is turn modulates the release of agents, such as ATP, from several cell types that reduce aberrant activity of detrusor smooth muscle and afferent nerves that underly symptoms of detrusor overactivity (DO). IC: interstitial cells.*

of sensory projections. Such cross-sensitivity has been demonstrated with instillation of chemical irritants to the descending colon, with associated bladder overactivity (796). A similar effect can be achieved by selective irradiation of the externalised descending colon (Figure 46B).

Such irradiation models show indications of bladder overactivity with shortened voiding intervals and the presence of non-voiding contractions (Figure 46C). However, tension recordings of isolated bladders from the same animals are generally quiescent (Figure 46D) indicating that *in vivo* observations are neurogenic in origin. Chemically induced cystitis also mimics the effect of the radiation injury. The best described model is that induced by cyclophosphamide, a chemotherapy agent that generates acrolein as a urinary by-product. Acrolein is an alkylating agent that covalently modifies and activates transient receptor potential ankyrin-1 ($TRPA_1$) channels (797), abundant on bladder sensory projections and urothelial cells (760). Bladder acrolein instillation and $TRPA_1$ channel activation is associated with severe inflammation and nociceptive responses (798) that contribute to chronic pain conditions (799). Accordingly, chemical cystitis such as that caused by acrolein mainly enhances neurogenic activity of the bladder and is not associated with large amplitude, autonomous bladder micromotions that are observed with neurogenic injury (639) (Figure 46C,D).

Urine storage and voiding depends on coordination of the contractile activity of bladder/urethral smooth and striated muscle. During storage, the bladder is quiescent and urethral muscles are active to maintain continence; upon micturition, the bladder contracts and the urethra relaxes. Following spinal cord injury rostral to the lumbosacral spinal segments, voluntary control of micturition is lost, and the bladder becomes areflexic. However, after recovery from the initial spinal shock, reflex bladder activity emerges due to the formation of a spinal micturition reflex. Ultimately, the bladder becomes hyperreflexic (Figure 46C) as detrusor-sphincter dyssynergia develops, decreasing voiding efficiency and resulting in urinary retention (800). Accompanying overdistension, there is urothelial hyperplasia but decreased numbers of terminally differentiated umbrella cells (801), increasing the risk of urinary tract infections. Furthermore, chronic overdistention causes bladder wall hypertrophy, hyperplasia and greater gap junction connectivity of *lamina propria* ICs (526) that enhance detrusor micromotions, stimulate sensitised afferents (802) and promote DO (Figure 46D). Accordingly, this SCT model may be used to induce and study neurogenic and myogenic overactivity and radiation- and acrolein-induced cystitis models of neurogenic dysfunction. Thus, it is possible to address

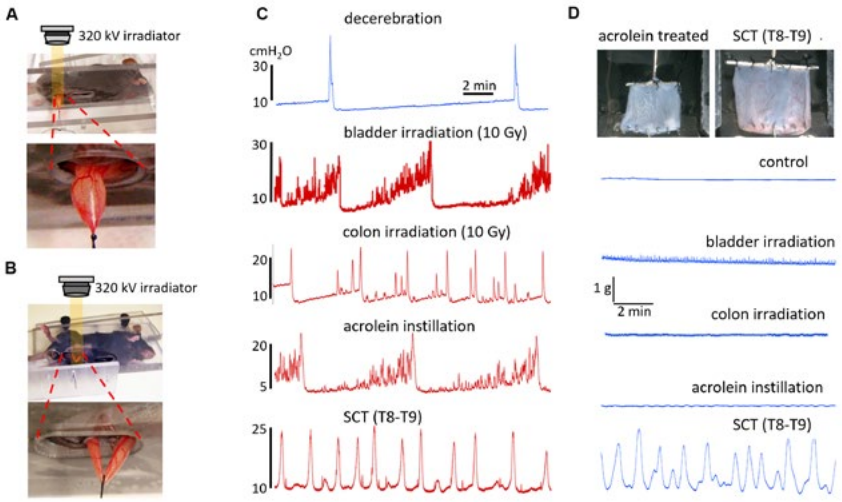

Figure 46. Mouse models of bladder overactivity and associated pathological features. *A: Externalisation procedure for selective bladder irradiation. B: Similar procedure for the descending colon to induce pelvic organ cross-sensitisation. C: Representative filling cystometrogram (CMG) traces from decerebrated normal adult, colon and bladder irradiated, acrolein-instilled and SCT mice. D: Corresponding isometric tension traces from isolated whole bladders of mice in C. Inset images show bladder sheets from acrolein-treated and SCT mice, where the latter is approximately double in size due to outlet obstruction-induced overdistention and hypertrophy. B: Fluorescence (excitation 675±25 nm) from the bladder, visualised under infrared light with a long wave pass (LWP, 695 nm) filter, for targeted irradiation. C: Image of urothelial cells from mt-keima mouse one day after irradiation. The mt-keima protein is conjugated to mitochondria, with green fluorescence at neutral pH (pH 7.0-7.5, white circle) and red fluorescence in acidic environments (red circle, e.g. within lysosomes). Figures courtesy of Drs AJ Kanai, Y Ikeda and IV Zabbarova.*

the mechanisms that induce the respective pathologies and study the therapeutic benefits of different agents.

1.2. Novel methods for selective bladder irradiation.
The externalised organ irradiation model, described above, is useful to isolate radiation effects to the LUT. However, the method does not fully mimic radiation therapy utilised clinically which does not involve surgery and is performed by targeted application with the potential to affect surrounding tissues. A novel method to selectively irradiate mouse urinary bladders *in situ* is by installation of an infrared dye, 680RD, reproducing the key features of radiation cystitis (Figure 47A,B).

1.3. The mt-keima mouse to evaluate mitochondrial function.
Oxidative stress is a key feature of radiation injury and there are a broad range of cellular pathways affected, with damage to mitochondria featuring predominately. Previous studies have relied heavily on cell-based assays with relatively few intact-tissue or *in vivo* studies. A model to monitor mitochondrial damage *in vivo* is the mt-keima transgenic mouse. These mice ubiquitously express a pH sensitive, dual excitation ratiometric fluorescent protein that localises selectively in mitochondria (803). When mitochondria are damaged, they are processed for lysosomal degradation (mitophagy) and in neutral cytosolic environments the mt-keima protein fluoresces more readily at shorter excitation wavelengths. In contrast, in the acidic environment of lysosomes, the emission predominates at longer excitation wavelengths. Thus, the model allows dynamic monitoring of mitochondrial degradation in cells, tissue and whole animals. Figure 47C shows a fluorescence image (1000x) of mitochondria from the mucosal surface of an irradiated bladder sheet from a mt-keima reporter mouse that tracks mitophagy, showing cells with increased mitochondria trafficking to lysosomes.

2. REPEATABLE MEASUREMENTS OF LUT FUNCTION IN AWAKE ANIMALS.

Physiological comparison of animal LUT function to that of humans is challenging. Most animal studies use anaesthesia, decerebration or restraints to obtain bladder pressure and external urethral sphincter electromyograms (EUS-EMG) recordings. Cortical influences are removed using anaesthesia or decerebration, restrain methods can add psychological stress which would more than likely influence voiding behaviour. Thus, methodologies that can minimise stress/pain and facilitate conscious voiding behaviour would have the highest likelihood of obtaining relevant physiological responses.

2.1. Telemetric measurements of bladder pressure, voided volume and frequency in freely mobile mice to evaluate BOO.
Telemetric recordings of physiological parameters (*e.g.,* vessel pressure, electrical impulses, temperature, movement) are possible through commercially available telemetry systems designed specifically for animal research. Initial studies demonstrated the feasibility in rats where bladder pressure and voided volumes could be simultaneously recorded (804). These recordings are also feasible in mice where smaller implantable telemeters (HD-X10, Data Science International) may be used to record simultaneously bladder pressures and voided volumes and frequencies in freely mobile mice. Animals with subcutaneous telemeters (30-day battery life; activated only during recordings) can be housed for up to 72 hrs in modified metabolic cages where food and water consumption can also be accurately measured. In this way, data can be recorded over periods as long as six months. The pressure line is sutured into the bladder wall to record intravesical pressure. Urine output is measured simultaneously by highly sensitive load cells in the floor of the metabolic cages and used to estimate voided volume and frequency. Void spots can be collected by filter paper on the load cell to record changes in voiding behaviour (void spot tests). Recordings from an adult male mouse (9-months, Figure 48A) show a rise of bladder pressure followed by a single bladder emptying event after a 2-second delay. By contrast, an aged mouse (24-months, Figure 48B) showed a large rise in bladder pressure, followed by a much longer delay and multiple voiding attempts as evident from much smaller voided volumes dispersed over multiple locations. Overall, this bladder outflow obstruction phenotype, characterised by raised bladder pressures and reduced voided volumes as seen in Figure 48B, is measured in ~75% of aged animals (unpublished data, Kanai lab). In the remainder, greater bladder pressures and reduced voided volume are also recorded, but to a lesser extent. This innovative *in vivo* approach allows the diagnosis of severe (high bladder pressure/low urine flow) bladder outlet obstruction in aged animals and a lack of obstruction (low bladder pressure/high urine flow) in mature adult animals. Thus, it is possible to monitor the actions of daily treatment with potential therapeutic agents in freely mobile mice and to adjust the dosing regimen for optimal benefit and minimisation of potential side-effects. For example, telemetry combined with urine output analysis can follow progressive improvement in voided volumes, urine flow rates and characteristics of micturition contractions from an aged mouse before, and after two weeks of daily treatment with cinaciguat (10 $mg.kg^{-1}.day^{-1}$ over 2-weeks), an activator of soluble guanylate cyclase (sGC) to increase intracellu-

lar cGMP levels (Figure 48C). This treatment normalised voided volume and flow rate as well as maximum voiding pressure and partially lowered micturition frequency. Thus, telemetric cystometric and voiding data in different age groups of mice can be used to test potential therapeutics to treat bladder outlet obstruction.

The recorded LUT variables, as described above, can be expanded to include electromyographic signals from the external urethral sphincter (EUS-EMG) through use of implantable telemeters with pressure sensors and electrical leads for biopotential recordings. As an example, Figure 49A,B shows bladder pressure, EUS-EMG, voided volume and void spot patterns recorded from normal and SCT mice implanted with HD-X11 telemetry units. The normal mouse shows a rise in bladder pressure and voiding corresponding to a decrease of EUS-EMG tonic activity. By contrast, an SCT mouse shows bladder pressure-transients without a decrease of EUS-EMG tonic activity, indicative of detrusor-sphincter dyssynergia. Accordingly, there were no void spots recorded on the load cells and the mouse showed signs of overflow incontinence. There are limitations to the use of telemetric recordings, including recording time constrained to battery life and inability for adjustment to probes following implantation. However, the advantages of achieving repeatable and near-physiological LUT recordings from awake unrestrained animals outweigh the limitations of such an approach.

2.2. Filling and non-filling cystometrograms and voided volumes in tethered mobile mice; the use of implantable access ports for long-term monitoring of bladder function.
Implantation of indwelling bladder catheters for pressure recordings is an established method for cystometrogram (CMG) recordings in awake rodents. In contrast to the telemetric methodology described earlier, catheter implant CMG recordings can only be performed once, as the catheter is placed subcutaneously on the animal and requires surgical externalisation after a recovery period. To achieve repeatable, filling and non-filling bladder pressure recordings, implantable vascular access ports (Instech, Inc) can be adapted for insertion of a pressure line into the bladder lumen and the access port placed on the back of the animal (Figure 49C). The access ports and check valve allow for measurements of bladder activity under continuous infusion (Figure 49D) or under physiological filling (Figure 49E) in freely mobile mice. Thus, multiple recordings can be performed over time in conjunction with metabolic cages with sensitive load cells to measure voided volumes. This technique facilitates repeatable recordings of both filling and ambient bladders pressure over a time course, allowing assessment of therapeutic agents and pathological processes. Theoretically, this methodology would also reduce the number of animals for CMG assessments as multiple evaluation time points can be derived from a single animal.

3. EX VIVO AND *IN SITU* BLADDER ASSESSMENTS

In the previous sections, the importance of assessing LUT function in awake, unrestrained animals was emphasised. *In vivo* assessments can be useful for characterising the pathophysiology or efficacy of treatment protocols but still need to be combined with information from *in vitro* or *in situ* methods to validate the modes/sites of action. The following sections will describe examples of *in situ*, tissue and cell-based recording techniques to assess various aspects of bladder function.

3.1. Stretch and micromotion-evoked bladder afferent firing: effect of cinaciguat on mouse bladders with irradiation-induced cystitis or following SCT.
A principal role for sensory dysfunction has been implicated in multiple LUT pathologies. This can be evaluated in animal models by direct measurement of sensory nerve activity in response to bladder stimulation using either *in vitro* (802) or *in vivo* (805) techniques. These methodologies allow afferent fibre subtypes to be categorised based on conduction velocity (Aδ- *vs* C-fibre) or their response to different stimuli (*e.g.* bladder distension, chemical irritants, tactile interventions). Single-unit *in vitro* bladder afferent recordings from irradiated mouse bladders (3- to 4-days post-irradia-

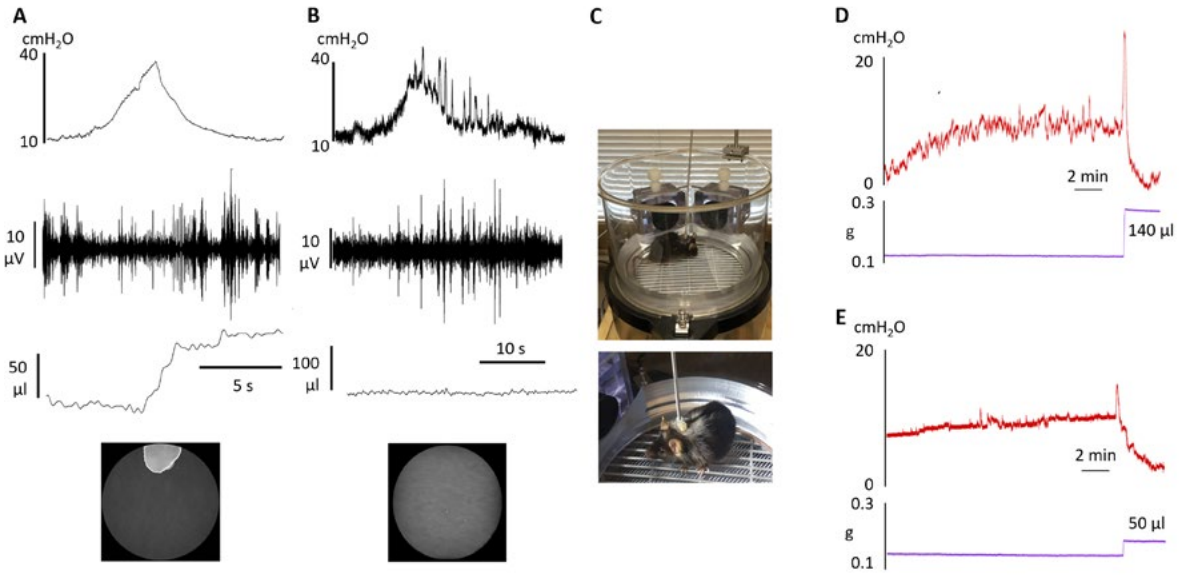

Figure 49. Assessment of LUT activity in awake mobile rodents. *A: Telemetric recordings from an adult male mouse of bladder pressure (upper) and EUS-EMG activity (lower). Also shown is voided volume and a corresponding spot test after three hours of activity. Note the phasic and more tonic EMG activity before and after voiding, respectively. B: Corresponding recordings from a mouse with spinal cord transection. Note the absence of voiding over the recording time. C: Metabolic cage with adult mouse. The mouse has an implanted bladder access port connected to a tethered catheter system for filling/non-filling mobile cystometry. D: Tethered filling cystometrogram (0.1 ml.min-1 at room temperature, upper) and voided volume (recorded by a sensitive (10μl detection) load cell, lower). The tether is magnetically attached to a check valve for easy attachment and detachment allowing multiple recordings. E: Natural fill cystometrogram with the same system as in D. tion, Figure 50B) exhibited spontaneous discharges not associated with changes in bladder tension, indicating increased sensitivity of afferent nerves in comparison to recordings from control preparations, Figure 50A: there was no indication of spontaneous detrusor contractions as a result of irradiation at the time when recordings were made. Cinaciguat decreased spontaneous and stretch-induced afferent firing as well as baseline tension *in vitro* demonstrating a direct action on afferent nerves (Figure 50B). Mechano-sensitive and spontaneous afferent firing rates were enhanced in SCT mouse bladders (Figure 50C). Furthermore, afferent firing in response to both stretch and micromotions observed in SCT mouse preparations were also dampened by cinaciguat (Figure 50C,D).

3.2. Optical mapping of SCT-induced bladder micromotions.
Detrusor micromotions are augmented in some bladder pathologies, specifically through enhanced gap junction coupling to coordinate greater activity of different contractile units in the bladder wall (526). Enhancement of autonomous bladder activity is most pronounced in models of bladder outflow obstruction such as physical outlet obstruction or due to spinal cord injury to produce DSD. Coordinated activity characteristic of SCT-induced micromotion can be evaluated using an optical mapping array system (Figure 51A,B**).** This system records fluorescent signals from a large surface area of tissues that are loaded with intracellular sensors that measure Ca^{2+} concentration changes or changes to membrane potential (E_m). Fluorescence sensors with comparable excitation wavelengths, but with different emission spectra may be used (*e.g.,* Rhod-2AM for Ca^{2+} and Di-4ANEPPS for E_m), allowing simultaneous recording of Ca^{2+} transients, E_m changes as well as isometric tension by attaching the preparation to a force transducer. In this example, when the bladder was relaxed, there were no recorded isometric micromotions. However, after an increase of baseline tension, large-amplitude, rhythmic micromotions developed. Cinaciguat reversibly inhibited micromotions (Figure 51C) and the clustering of Ca^{2+} transients (Figure 51D).

3.3. Optical mapping of isolated bladders to examine micromotion organisation.
Optical mapping of intracellular Ca^{2+} transients and E_m changes can be used, for example, to investigate the effect of cGMP signalling on bladder micromotions (Figure 52A-D). This technique may be used to show the organised nature of pathological bladder micromotions and uncover signalling mechanisms between the urothelium and underlying cells which could not otherwise be demonstrated (526,559,806-811). Thus, the system has been used to show propagation of Ca^{2+}/E_m activity in intact bladders, whole bladder sheets and across the different layers of the bladder wall (Figure 52A,B). The conduction velocity of activity propagation can be calculated from the magnitude of signal delays and may be represented as greyscale isochrone maps to visualise initiation sites (Figure 52C,D). An in-line laminar flow chamber (Figure 52E) holds three 12x12 mm plastic slides, each with primary cell cultures in free communication. The slides held urothelial, interstitial and detrusor smooth muscle cells to reproduce the structure of the bladder wall. Figure 52F,G shows schematics of the three adjacent and the traces above are actual recordings from the respective slides. Here, introduction of a superfusate of decreased osmolality generated Ca^{2+} transients in urothelial cells (UC) that spread to the interstitial cell layer and then to the detrusor smooth muscle layer. Figure 52F shows that removal of the slide holding interstitial cells abolished the spread of Ca^{2+} transients from the urothelial cell slide to that holding detrusor smooth muscle cells (Figure 52G). Figure 52H shows another phenomenon, namely that the interstitial cell layer can spontaneously generate intracellular Ca^{2+} transients. Ac-

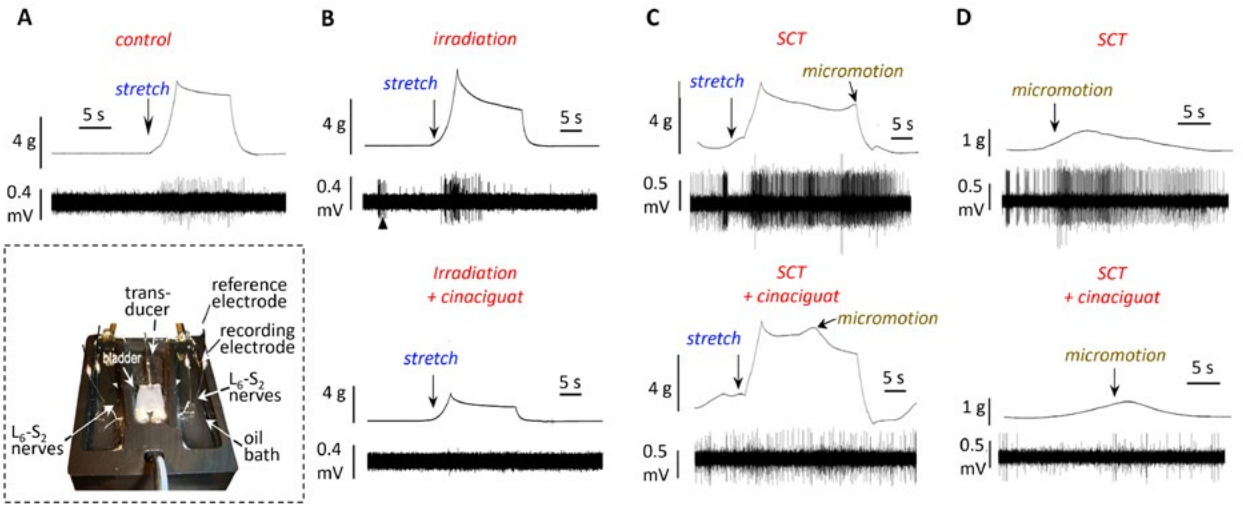

Figure 50. Recording of afferent activity from a bladder sheet with attached nerves. *A: Simultaneous recordings of isometric tension (upper trace) and single unit activity of lumbro-sacral spinal roots before, during and after a rapid stretch (1 mm, 100 µm.s-1, hold 20 s). An image of the recording chamber is shown below. B: Recordings from bladder irradiated three days previously, before (upper) and during (lower) superfusion with 1 µM cinaciguat. Note spontaneous activity before stretch (arrowhead, upper) and the increased compliance of the tissue and absence of nerve activity with cinaciguat (lower). C: Recordings from an SCT mouse preparation before and during exposure to cinaciguat. Note the small spontaneous contraction (micromotion) during the stretches. D: Recordings from an SCT mouse preparation showing larger micromotions, without stretch, before and during exposure to cinaciguat. Note that cinaciguat reduced both the micromotion and of afferent nerve activity. Figures courtesy of Drs AJ Kanai, Y Ikeda and IV Zabbarova.*

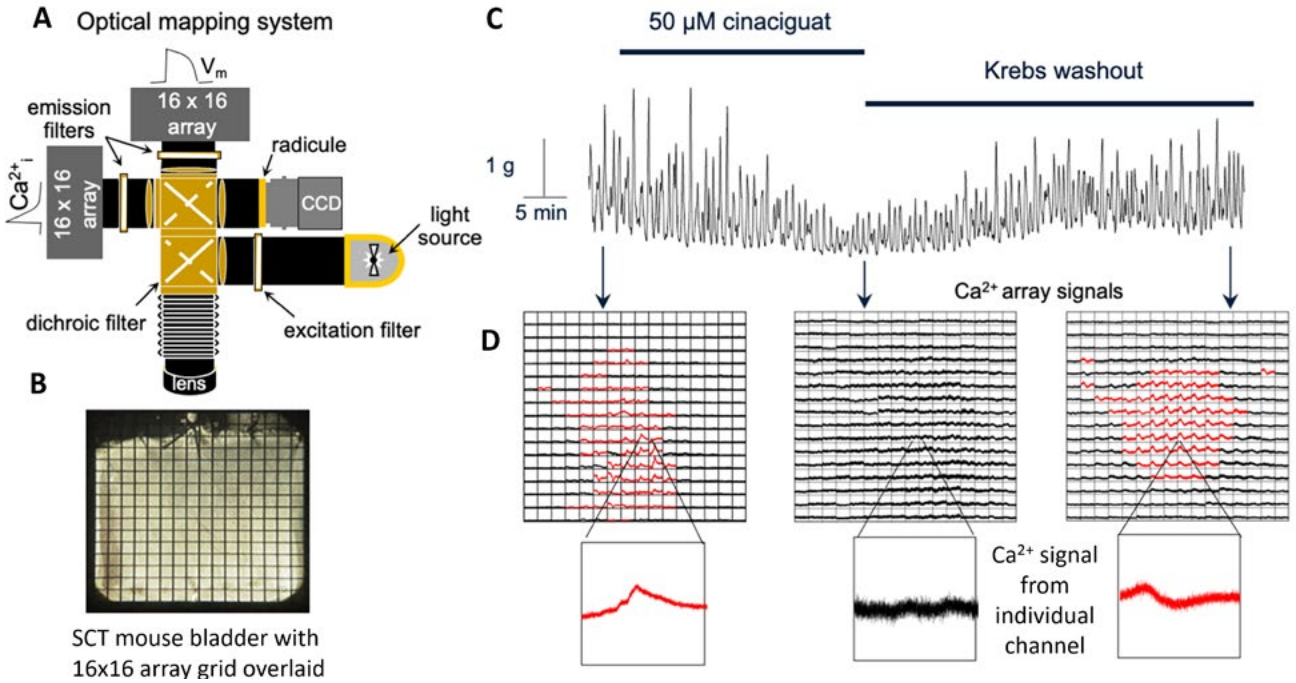

Figure 51. Simultaneous optical mapping and tension recording. *A: Schematic of the optical mapping system. cordingly, this experimental model is one that may be used to test the action of agents designed to inhibit spontaneous interstitial cell activity that may underlie spontaneous activity of the bladder wall.

3.4. The decerebrate arterially perfused rodent (DAPR) model. The normal function of the lower urinary tract is based on coordinated responses from the cortical and autonomic nervous systems. The DAPR model (812-816) allows for recording of multiple physiological parameters while maintaining the brainstem and spinal control centres that control lower urinary tract function (Figure 53A). Rodents are heparinised and anesthetised with isoflurane. After a midline laparotomy, the vascular supply to the stomach, spleen, and free intestine are ligated and removed. The animals are immersed in artificial cerebrospinal fluid (CSF) at 4°C and decerebrated, by aspiration, at the pre-collicular level. After a midline sternotomy, the preparation is then transferred to a recording chamber and placed supine. A double-lumen cannula is inserted into the ascending aorta *via* the left ventricle and held in place by a ligature. The preparation can be arterially perfused with carbogenated artificial CSF at 32°C at a rate gradually increasing from 1 to 3 ml.min^{-1}. A 30G needle is inserted into the bladder dome to measure intravesical pressure and enable bladder filling. The left bladder afferent input to the pelvic nerve is used for afferent fibre recordings. EMG activity of the EUS is recorded with a glass suction electrode. Important simultaneous measurements that can be obtained include bladder intra-luminal pressure, EUS-EMG, pelvic nerve afferent nerve activity and pudendal motor nerve activity, along with recordings from respiratory nerves, electrocardiograms (ECG) and blood pressure (Figure 53B). This model has been used to demonstrate the effect of systemic sildenafil on both sensory and sphincter activity in normal male mice (813) where sildenafil increased pelvic nerve afferent firing, increased EUS activity while increasing bladder compliance. These unique findings suggest that PDE5 inhibitors may be elicit therapeutic effects through afferent regulation of EUS activity.

VIII. NEW DRUG TARGETS: MOLECULAR APPROACHES TO INVESTIGATE LUT DYSFUNCTION

1. INTRODUCTION

The control of bladder function is far more complex than previously believed and as illustrated by the previous sections. Prominent roles have emerged for afferent pathways, as well as the urothelium and suburothelium that line the muscular tissues of the urinary tract. Together this advancing knowledge of mechano-sensory control has consequences for improved understanding of the pathophysiology of lower urinary tract dysfunction (LUTD). This section will build on this knowledge to summarise some advances in drug development to manage different manifestations of LUTD. A con-

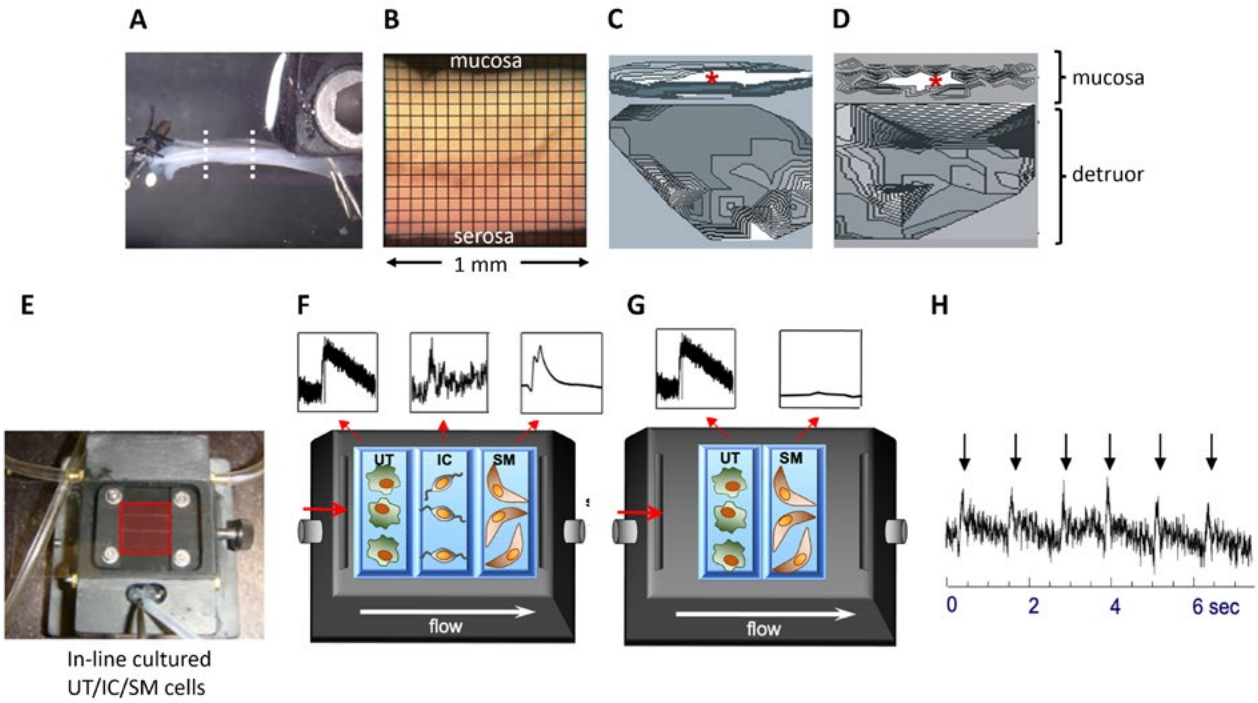

Figure 52. Optical mapping from bladder wall cross-sections and cultured primary cells. *A: Female adult rat bladder sheet shown in cross-section, stained with Rhod-2-AM for Ca2+ imaging. B: Photo image of the region denoted in A (white dotted lines) with 16x16 array grid overlay, mucosa and serosa surfaces labelled. Figure 54. Schematic of the different signal transduction systems.

sideration of how different signalling mechanisms influence other tissue of the body will be included not only to gain more insight into their functions but also highlight potential side effects that must be considered in the development of any novel agent.

According to the most recent classification, signal transduction mechanisms as potential targets have been subclassified into a number of different categories. These are: G-protein coupled receptors; ligand-gated ion channels; other ion channels; nuclear (hormone) receptors; kinases and catalytic receptors; transporters; enzymes. In turn, ligands for the above mechanisms maybe subclassified for convenience and may be listed as: approved drugs; synthetic organics; metabolites; natural products; endogenous peptides; other peptides; inorganics; antibodies and labelled ligands. The terminology and definitions used are derived from the most recent classification “The Concise Guide to Pharmacology, 2019/20” [817] (Figure 54).

This section of potential novel molecular targets for managing LUTD will focus on the most currently relevant G-protein coupled receptors; promising ligand-gated and other ion channels; and briefly consider the role of vesicular nucleotide transporters. A n equally brief introduction to the function of clock genes will be described that may give insight into the design of therapies for cyclical LUT disorders such as nocturia. Finally, a section is devoted to the control of fibrosis, a connective tissue disorder that has profound implications for lower urinary tract function during paediatric and adult levels of development.

2. G-PROTEIN-COUPLED RECEPTOR (GPCR)S

G-protein coupled receptors are subclassified into 74 subfamilies, including orphans, and here, the nine pertinent receptor subfamilies will be described

2.1. Orphan GPCRs.

The nociceptin/orphanin FQ peptide (N/OFQ)[818,819]] is involved in a wide range of physiological responses with effects in the central and peripheral nervous systems, the cardiovascular system, airways, the gastrointestinal tract, the urogenital tract and the immune system [820,821] The N/OFQ receptor (NOP; also known as ORL1, OP4 or LC132) is a deorphanised member of the GPCR superfamily and is currently classified as a non-opioid member of the opioid receptor family. Although NOP shares considerable structural and localisation features with classical opioid receptors, NOP activity is insensitive to the opioid receptor antagonist naloxone.

In the rat, NOP receptors located on capsaicin-sensitive bladder primary afferent fibres inhibit the volume-evoked micturition reflex [822,823]. There are no studies detailing NOP expression in human bladder tissue. However, based on animal data a series of elegant clinical studies have been performed using intravesical N/OFQ. In a pilot study of 14 patients, intravesical instillation of N/OFQ increased bladder capacity and the volume required to elicit detrusor overactivity (DO). However, one patient had previously received intravesical capsaicin treatment and the effects of N/OFQ were minimal, indicating a capsaicin-sensitive target [824]. In a placebo-controlled study, N/OFQ was compared with the structurally similar but inactive [desPhe1]N/OFQ (a major metabolite of N/OFQ, which does not bind to NOP) in 14 patients with DO due to spinal-cord damage. Intravesical administration of N/OFQ, but not [desPhe1]N/OFQ, increased bladder capacity and volume required to elicit DO [825]. In a further study of 18 patients with incontinence from neurogenic DO, the number of daily urine leakage episodes was reduced in the N/OFQ (but not the control) group. There were no major practical problems and the effects of a single instillation in the morning lasted the whole day [826].

Collectively, these studies broadly agree with studies in rats that NOP is probably expressed on capsaicin-sensitive primary affer-

ents and their activation inhibits the micturition reflex. However, primary research has only been done in normal rats, and with humans N/OFQ is only effective in spinally injured patients where there may be afferent fibre switching [827]. However, N/OFQ and N/OFQ mimetics have a potential role in the treatment of OAB.

2.2. Acetylcholine-muscarinic receptors.
Molecular cloning studies have revealed five distinct genes for muscarinic ACh receptors in rats and humans, with five corresponding receptor subtypes. Muscarinic receptors are coupled to G-proteins; M1, M3, M5 are facilitatory (Gq) and M2, M4 are inhibitory (Gi) [828]. The signal transduction systems of M1, M3, and M5 preferentially couple to phosphoinositide hydrolysis leading to mobilisation of intracellular Ca^{2+}, whereas activation of muscarinic M2 and M4 receptors inhibits adenylate cyclase activity. Detrusor smooth muscle expresses both M2 and M3 receptors [829] and activation of either subtype elicits contraction. Although M2 receptors predominate in receptor binding studies, the M3 receptor mediates contraction in normal detrusor.

Desensitisation of muscarinic receptors is one mechanism whereby detrusor smooth muscle becomes less sensitive to incoming stimuli. This is mediated by phosphorylation of muscarinic receptors by guanosine phosphate binding (G) protein-coupled receptor kinase (GRK)[830]; all m2, m3, and GRK2 mRNAs have been isolated. However, protein expression of GRK2 in normal detrusor is significantly higher than in tissue from obstructed bladders in patients with benign prostatic hyperplasia [831] and failure of this desensitising mechanism may contribute to DO in BPH patients.

Currently, the principal treatment for OAB is with anticholinergic drugs that initially were believed to act by reducing the action of acetylcholine on the detrusor as released by parasympathetic nerves. However, there is now considerable evidence to suggest that anticholinergic drugs also interact with sensory pathways. Stimulation of muscarinic receptor pathways depresses sensory transduction by a mechanism independent of changes to bladder tone [832]. The density and binding affinity profile of the muscarinic receptor population in human bladder mucosa, by radioligand binding assay, is similar to that of detrusor muscle. Moreover, the density of the M3 subtype in mucosa is similar to that in detrusor muscle, but lower than that in the parotid gland [833]. Finally, clinically effective muscarinic receptor antagonists bind to receptors on both the bladder mucosa and the detrusor. Thus, there is experimental support for the hypothesis that muscarinic receptors in the mucosa may represent an important site of action for these agents in OAB [834], but there is at present no compelling evidence in the clinical setting.

2.3. Adrenergic b-receptors.
There are three adrenergic β-receptor subtypes ($\beta1$,$\beta2$,$\beta3$) and relaxation of detrusor smooth muscle was regarded as mediated by $\beta2$-receptors [835]. The $\beta3$-receptor was considered to be related only to fat metabolism, but gene expression of the β3-adrenergic receptor in human detrusor and relaxation of isolated human detrusor preparations was reported [836-839]. Now, the role of adrenergic $\beta3$-receptors in determining the contractile state of detrusor is regarded as significant. Consequently, several β3-agonists (KUC-7483, YM-178, FK-175) were developed in Japan and YM-178 (mirabegron) has been launched to manage OAB in in Japan, USA and European Countries. Vibegron, another β3-agonist, is now also used to treat OAB.

The $\beta3$-receptor is Gs protein-coupled, and its activation increases intracellular cAMP and this is believed to be the key pathway that elicits detrusor relaxation. Downstream effectors activated by cAMP-dependent mechanism(s) include membrane K^+ channels, such as BK channels, and (de)phosphorylation pathways that directly regulate the Ca^{2+}-sensitivity of the contractile proteins. However, there may also be cAMP-independent signalling pathways, as evidenced in airway smooth muscle where activation of BK channels, independent of cAMP elevation, causes relaxation [840].

The $\beta3$-receptor is an attractive target for drug discovery, but selectivity is important, as activation of $\beta1$- or $\beta2$-ARs will cause undesirable side-effects. The $\beta3$-receptor agonist GW427353 evokes bladder relaxation and facilitates bladder storage mechanisms in the dog [841] and another agonist, CL-316243, increases urine storage in spontaneously hypertensive rats [842]. In addition to direct detrusor relaxant effects, $\beta3$-receptor agonists have been reported to inhibit cholinergic neurotransmission through adenosine release and prejunctional A1 receptor stimulation in the human and rat bladder [843] and also reduce postjunctional purinergic receptor-mediated contractions of mouse detrusor [844].

A further potential site of action is the urothelium and $\beta3$-receptor agonists mediate reduction of pig detrusor contractions via the urothelium (mucosa) [845]. The isolation of $\beta3$-receptor mRNA from the urothelium as well as detrusor muscle suggest multiple sites of action in the lower urinary tract [846]. In addition, β-receptor agonists, including $\beta3$-agonists, promote expression of matrix metalloproteinases (MMPs) in human urothelial cells, which may have a pivotal part in structural remodelling and fibrosis, as may occur under pathological increases of hydrostatic pressure [847]. Because MMP expression is regulated by the PKA/CREB pathway, this may also be an attractive target for $\beta3$-receptor agonists in OAB patients.

2.4. Cannabinoid receptors.
Cannabinoids, the active components of *Cannabis sativa linnaeus* (marijuana) and their derivatives, are drawing renewed attention because of their diverse pharmacological activities such as cell growth inhibition, anti-inflammatory effects, and tumour regression [848-850]. The cannabinoid receptor has two subtypes, CB1 and CB2, both of which are GPCRs [851] and are activated by endogenous ligands such as N-arachidonoyl-ethanolamine (anandamide), N-homo-γ-linolenoyl-ethanolamine, N-docosatetra-7,10,13,16-enoylethanolamine and 2-arachidonoylglycerol [852].

CB1 is expressed in urinary bladder hypersensitivity and overactivity disorders and correlates with symptom changes in human and animals. In rats with bladder outlet obstruction, immuno-fluorescence labelling and protein expression of CB1 and CB2 receptors were increased, and receptor agonists improved contraction interval and contraction pressure [853]. Also, CB2 agonists selectively inhibit the mechano-sensitivity of capsaicin-sensitive mucosal bladder afferents, but not muscular-mucosal afferents. This indicates endocannabinoids may modulate bladder function though sensory pathways in pathological states [854].

CB1-immunoreative suburothelium nerve fibres were significantly increased in the suburothelium of tissue from painful bladder syndrome (PBS) and idiopathic DO (IDO) patients, and also in the detrusor layer from IDO patients. Suburothelial nerve fibre density correlated significantly with pain scores in PBS and urgency scores in IDO patients [588]. A *Cannabis sativa* extract enriched in cannabidiol (CBD) botanic drug substance (BDS) and pure CBD reduced cholinergic-mediated contractility. If confirmed *in vivo*, such results could provide a pharmacological basis to explain, at least in part, the efficacy of Cannabis medicines in reducing incontinence episodes in patients with multiple sclerosis [855].

Amplification of endocannabinoid activity by fatty acid amide hydrolase (FAAH) inhibitors may be an attractive drug target in specific pathways involved in LUTS [856]. FAAH degrades endocannabinoids and is expressed in human, rat, and mouse bladder mucosa. The FAAH inhibitor oleoyl ethyl amide (OEtA) altered urodynamic parameters that reflect sensory functions of micturition in rats, suggesting a role for the endocannabinoid system in bladder mechano-afferent functions of rats [857]. FAAH inhibition in the sacral spinal cord by OEtA also modulated urodynamic activity of normal and obstructed rat bladders, which also suggests involvement of a spinal endo-cannabinoid system in micturition control [858,859].

The endocannabinoid system may also be involved in physiological control of micturition through regulation of afferent signals [592]. CP55,940 is a synthetic analogue of tetrahydrocannabidiol, a psychoactive ingredient of the Cannabis plant. It decreases normal rat bladder activity and urinary frequency induced by nociceptive stimuli, probably by suppression of bladder afferent activity and are abolished by both CB1 and CB2 antagonists. However, the role of the two CB subtypes in micturition is yet to be established [860]. The endocannabinoid system is a potential drug target for pharmacological management of LUTS, with a more favourable adverse event profile than antimuscarinic agents [861].

2.5. $GABA_B$ receptors.

Functional $GABA_B$ receptors are formed from the heterodimerisation of two similar subunits: $GABA_{B1}$ and $GABA_{B2}$. Stimulation of spinal GABAergic mechanisms by intrathecal application of $GABA_A$ and $GABA_B$ receptor agonists could be effective for the treatment of neuropathic DO as determined in spinal cord injured rats [862]. ADX71441, a novel positive allosteric modulator of the $GABA_B$ receptor, also has a potential to modulate bladder nociception through supra-spinal sites from rat studies but did not affect normal bladder contractions and micturition [863].

DO may also be controlled by modulating afferent input from the bladder as well as the excitability of the sacral reflex centre. This suggests a novel method to treat OAB patients with oral gabapentin, as it reduced urinary frequency in a lipopolysaccharide-induced chronic cystitis model [864]. This was corroborated in a clinical trial where gabapentin improved OAB symptoms with an acceptable safety profile, [865].

2.6. Glutamate metabotropic receptors.

Glutamate receptors consist of two major classes, ionotropic receptors that form ligand-gated cation channels and metabotropic receptors (mGluRs) that are a family of GPCRs. The former includes NMDA, AMPA and kainite receptors which have essential roles in the control of micturition reflexes [866,867]. mGluRs have eight subtypes (mGluR1 - mGluR8) and are placed into three subgroups (groups I-III) based on sequence homology, transduction mechanism and agonist pharmacology. Less is yet known about their functional roles in the LUT.

Wild-type and mGluR1 knockout mice were used for *in vivo* cystometry with a selective mGluR5 antagonist 6-methyl-2-(phenylethynyl) pyridine. Loss of function of both receptors increased bladder capacity and reduced afferent signal transmission from the bladder [868]. Thus, blockade of both mGluR1 and mGluR5, could have a beneficial effect to manage storage dysfunctions including OAB and urgency urinary incontinence. Similar data suggests glutamic acid has a transmitter function in somato-bladder reflex mechanisms and raises the potential for mGluR5 as a target for LUTD [869]

2.7. Prostanoid receptors.

Prostanoid actions are mediated by specific membrane receptors: DP, EP, FP, IP and TP that respond to PGD_2, PGE_2, PGF_2, PGI_2 and thromboxane, respectively. EP itself is subdivided into EP1, EP2, EP3 and EP4 receptors [870].

EP1 receptor-knockout mice have normal cystometry but do not react to intravesical PGE2 instillation which causes bladder overactivity in wild-type controls. Obstruction of EP1 receptor-knockout mice still increases bladder weight but prevents the increase of non-voiding contractions seen in the wild-type controls [871]. PGE_2 enhances the micturition reflex through C-fibre afferents via EP1, so that selective antagonists may improve bladder storage function [872]. However, the EP1 receptor antagonist ONO-8359 had no significant effect on patients with non-neurogenic OAB [9][72]. A recent study showed that the main contractile effects of PGE_2 on both mucosa and detrusor contractions is mediated by the FP receptor. Thus, there is significant interaction between different prostanoids and their receptors [873].

For EP2 receptors, there is little information on their role in the normal micturition cycle, even though receptor expression has been demonstrated on the urethra and bladder of animals [874]. EP3 receptor knockout mice show an enhanced bladder capacity and implicates their contribution to bladder overactivity when PGE_2 production is enhanced [875]. The EP4 receptor antagonist AH23848 reduces cyclophosphamide-induced OAB in rats [876].

Contrary to antagonists, potent agonists for EP2 and EP3 have been developed as potential treatments for detrusor underactivity, e.g. from diabetes [877]. A highly potent and selective agonist for EP2 and EP3 receptors, ONO-8055, contracted bladder strips and relaxed urethral strips, and decreased post-void residual urine. Thus, the beneficial effects may be a dual action on bladder and outflow tract [877,878]. Finally, the EP4 agonist ONO-AE1-32p reduces detrusor muscle contraction and afferent activity [879].

2.8. Tachykinin receptors.

Tachykinin receptors are activated by the endogenous peptides substance P (SP), neurokinin A (NKA), neurokinin B (NKB), neuropeptide K and neuropeptide G. NKA and NKB are mammalian members of the tachykinin family, which includes peptides of mammalian and non-mammalian origin containing the consensus sequence, Phe-x-Gly-Leu-Met. Several neurokinin-1 receptor antagonists or SP-reducing agents has been tested for efficacy in reducing OAB, including aprepitant, cizolirtine citrate and netupitant [880-882] and have provided clinical evidence that modulation of tachykinin pathways could be an effective way to treat OAB.

2.9. Taste receptors.

Expression of a functional sweet taste receptor has been reported in numerous extragustatory tissues [883]. Artificial sweeteners may activate sweet taste receptors in the bladder, resulting in OAB symptoms. $T1R_{2/3}$ sweet taste receptors are expressed in human and rat bladder urothelium and their activation by artificial sweeteners may result in augmented bladder contractions [884].

The family of bitter taste receptors (TAS_2Rs) also perform non-gustatory functions outside the mouth and mRNA expression of various TAS_2R subtypes has been shown in both human and mouse detrusor smooth muscle. Chloroquine, a TAS_2R agonist, relaxed carbachol- and KCl-induced contractions of human detrusor smooth muscle strips in a concentration-dependent manner and treatment significantly suppressed OAB symptoms of mice with partial BOO [885].

3. ION-CHANNELS

Ion channels are pore-forming proteins that allow the flow of ions across cell or organelle membranes. Many ion channels (e.g. most Na^+, K^+, Ca^{2+}, TRP channels, and some Cl^- channels) are voltage-gated and others (e.g. certain K^+ and Cl^- channels, ryanodine receptors and IP_3 receptors) are relatively voltage-insensitive and are gated by extracellular or intracellular mediators. Ligand-gated ion channels are integral membrane proteins that contain a pore which allows the regulated flow of selected ions across the plasma membrane. Ion flux is passive and driven by the electrochemical gradient for permeant ions. The channels are opened, or gated, by the binding of a neurotransmitter to an orthosteric site to trigger a conformational change that results in the conducting state. Ion channels represent the second largest target for existing drugs after G protein-coupled receptors. However, the advent of novel, faster screening techniques for compounds acting on ion channels suggests that these proteins represent promising targets for the development of additional, novel therapeutic agents. This section will summarise selected channel targets.

3.1. P2X receptors.

Purinergic receptors form two main classes, P1 and P2, and P2 receptors are further divided into ionotropic P2X and metabotropic P2Y receptors. Their role in normal and pathological lower urinary tract function has been described extensively [886]. ATP is released from parasympathetic post-ganglionic fibres where it can activate $P2X_1$ receptors and contribute to contractile activation. In the normal human bladder, the purinergic component of parasympathetic contractile generation is very small, but in pathological conditions, such as interstitial cystitis, obstructed and neuropathic bladder, or in the paediatric bladder (see later) the purinergic component is substantial. ATP is also released from the urothelium of the bladder and ureter under conditions of physical or chemical stresses to act on $P2X_3$ and $P2X_{2/3}$ receptors on suburothelial sensory nerves to initiate the voiding reflex, via low threshold fibres, and nociception, via high threshold fibres, as discussed previously. Purinergic therapeutic strategies are being explored to bring benefit and relief to many patients with urinary tract disorders [886].

Functional P2X receptors exist as polymeric transmitter-gated channels; the native receptors may occur as either homopolymers (e.g. $P2X_1$ in smooth muscle) or heteropolymers (e.g. $P2X_{2/3}$ in the sensory nerve terminals and the nodose ganglion and $P2X_{1/5}$ in cortical astrocytes). $P2X_2$, $P2X_4$ and $P2X_7$ receptors also form functional homopolymers which, in turn, activate pores permeable to low molecular weight solutes. The hemi-channel pannexin-1 has been implicated in the pore formation induced by $P2X_7$, but not $P2X_2$ receptor activation [852].

Several $P2X_3$/$P2X_{2/3}$ receptor antagonists have been developed in the light of this mapping of P2X receptors in the urinary tract. AF-792 ([5-(5-ethynyl-2-isopropyl-4-methoxy-phenoxy)-pyrimidine-2,4-diamine]) is a novel selective $P2X_3$/$P2X_{2/3}$ antagonist which significantly inhibited micturition reflex activity. Afferent signals originating from the bladder are regulated by spinal $P2X_3$/$P2X_{2/3}$ receptors and establish directly an endogenous central presynaptic purinergic mechanism to regulate visceral sensory transmission. Thus, $P2X_3$/$P2X_{2/3}$ receptors are promising agents to treat not only urological dysfunction, such as overactive bladder but also sensory disorders, including chronic pain states [887]. After bladder outlet obstruction in rats, $P2X_3$ receptor expression, as well as of M2 and M3 receptors, is increased along with bladder overactivity, consistent with changes in urothelium purinergic, and muscarinic, receptor expression having a role in mediating bladder afferent sensory responses [888]. Furthermore, the $P2X_3$/$P2X_{2/3}$ receptor antagonist A-317491 improves signs of cyclophosphamide-induced cystitis in the rat [889].

3.2. Acid-sensing (H^+-gated) ion channels (ASICs).

Acid-sensing ion channels (ASICs) are members of a Na^+ channel superfamily that includes the epithelial Na^+ channel (ENaC), the FMRF-amide activated channel (FaNaC) of invertebrates, the degenerins (DEG) of *Caenorhabitis elegans*, channels in *Drosophila melanogaster* and 'orphan' channels. ASIC subunits contain two transmembrane domains and assemble as homo- or hetero-trimers to form H^+-gated, voltage-insensitive, Na^+ permeable channels.

A number of subtypes have been reported: ASIC1 is the dominant subunit expressed in urothelium, whereas both ASIC1 and ASIC2 are expressed in detrusor smooth muscle. ASIC3 expression is less abundant but is localised to the suburothelial region. In the mucosa overall, the ASIC1 gene is more highly expressed in male mice, whereas ASIC2 expression in detrusor is greater in females.

For comparison $TRPA_1$ and $TRPM_8$ expression are not different between sexes. Thus, the sex difference in the bladder responses to acidic irritation may in part be attributed to variation of ASIC subtype expression [890].

H^+ (acting via both ASIC and $TRPV_1$ channels) and capsaicin (via $TRPV_1$ channels) both induce ATP release from the rat bladder mucosa, that is principally of urothelial origin and mediated by a rise of the intracellular [Ca^{2+}]. This highlights the role of H^+ (or as H_3O^+) as a signalling moiety, and the potential involvement of ASIC channels, to modulate bladder function [571,891]. This ASIC system may be upregulated by bladder inflammation. Cyclophosphamide treatment increases expression of two ASIC subtypes (ASIC2a and ASIC3), although ASIC1 expression is unaltered [892], and may contribute to increased pain and hyperalgesia in patients with bladder pain syndrome [893].

Systemic administration of A-317567, a potent, non-amiloride ASIC blocker, increased inter-contraction interval during instillation of both saline and acetic acid in decerebrated, un-anaesthetised female mice. However, intravesical perfusion of A-317567 (100 μM) had no effect on bladder activity under the same conditions. Thus, blockade of ASIC signal transduction may increase bladder capacity under normal conditions and when intravesical pH is decreased, but possibly through effects distant from the bladder itself, such as via dorsal root ganglia [894].

3.3. Epithelial sodium channels (ENaC).

ENaCs have a role in Na^+ reabsorption by epithelium lining the distal part of the kidney tubule and fulfil similar functional roles in some other tissues such as the alveolar epithelium and the distal colon. This reabsorption of Na^+ is regulated by aldosterone, vasopressin (ADH) and glucocorticoids, and is one of the essential mechanisms in the regulation of sodium balance, blood volume and blood pressure. The degenerin epithelial Na^+ channel (ENaC) family has been proposed as mechano-sensitive transducers in several species [895,896]. In rabbit bladder, ENaCs alter their Na^+ transporter properties after changes to transmural hydrostatic pressure [896]. This is mirrored in rat renal pelvic epithelium where ENaC participate in the activation of afferent renal mechano-sensitive neurons by increased renal pelvic pressure [897].

The significance of ENaC in mediating normal and pathological sensory function is implied by several human and animal studies. ENaC mRNA and protein expression in human bladder urothelium correlates significantly with storage symptom scores [898] and

ENaC (γ-subunit) expression is increased in urothelium from patients with neuropathic DO [899]. With rats, intravesical infusion with 1mM amiloride (an ENaC inhibitor) significantly reduced the frequency of reflex voiding during bladder filling and increased bladder capacity, but without effect on the amplitude of micturition pressure. These findings were mirrored by a suppression of stretch-induced ATP release in mucosa-intact isolated preparations [900].

3.4. Potassium (K^+) channels.

Potassium channels are fundamental regulators of cell excitability and control the cell membrane potential, action potential frequency and waveform as well as secretion of hormones and neurotransmitters. Their activity may be regulated by transmembrane potential difference, [Ca^{2+}] or neurotransmitters. They consist of a primary pore-forming α-subunit, often associated with auxiliary regulatory subunits.

The 2TM (two transmembrane) and 6TM families of K^+ channels. This domain family of K^+ channels, also known as the inward-rectifier K^+ channel family includes the strong inward-rectifier K^+ channels (KIR2.x), G-protein-activated inward-rectifier K^+ channels (KIR3.x) and the ATP-sensitive K^+ channels (KIR6.x, which combine with sulphonylurea receptors). The pore-forming α-subunits form tetramers and heteromeric channels may be formed within subfamilies (e.g. KIR3.2 with KIR3.3). The 6TM family of K^+ channels comprises: voltage-gated K_V subfamilies; the KCNQ subfamily; the EAG subfamily (including HERG channels); the Ca^{2+}-activated, large conductance Slo subfamily (BK_{Ca} channels; actually with 7TM); and the Ca^{2+}-activated SK subfamily. Similar to the 2TM family, pore-forming α-subunits form tetramers and heteromeric channels may be formed within subfamilies (e.g. K_V1.1 with K_V1.2; KCNQ2 with KCNQ3). Considerable attention has been directed to modulation of BK_{Ca} channel activity, as outlined below and as highlighted also in section 6.

BK_{Ca} and SK_{Ca} channels play an important role in controlling membrane potential, cellular excitability and contractile function of urinary bladder smooth muscle [733,734,901,902]. Ca^{2+} entry through voltage-dependent Ca^{2+} channels activates both BK_{Ca} and SK_{Ca} channels, but Ca^{2+} release through ryanodine receptors also activates BK_{Ca} channels. Because phasic contractions depend on Ca^{2+} entry into the detrusor myocyte, BK_{Ca} and SK_{Ca} channels represent attractive pharmacological targets to modulate contractile function in OAB [691,719]. The importance of the BK_{Ca} channel as a potential target was demonstrated when local hSlo cDNA (i.e. BK_{Ca} channel) injection ameliorated detrusor overactivity in a rat model of partial urinary outlet obstruction [731]. It was suggested that expression of hSlo in the bladder functionally antagonised the increased contractile function normally observed in obstructed animals and thereby improved detrusor overactivity and form the basis of a gene therapy for urinary incontinence. This is consistent with increased frequency in Slo(-/-) mice and provides further evidence that BK channel dysfunction can lead to OAB [903].

Several BK_{Ca} channel modulators have been tested on bladder function. NS-8 increases Ca^{2+}-sensitive K^+-channel opening activity in rats and during bladder filling decreased pelvic nerve afferent discharge rate [904]. Kurarinone, a flavanone from *Sophora flavescens*, is a strong potentiator of BK_{Ca} channel activity, identified from screening a library of natural compounds, and relaxes detrusor muscle [905]. Finally, 4-(4-(4-chlorophenyl)-3-(trifluoromethyl) isoxazol-5-yl)benzene-1,3-diol (CTIBD), is another potent BK_{Ca} channel activator, on rat detrusor where a significant relaxation was measured [906]. By contrast, a non-peptidergic BK_{Ca} channel blocker, A-272651, enhanced field stimulated contractions in pig detrusor and spontaneous contractions in guinea-pig detrusor, as well as increasing the excitability of capsaicin-sensitive DRG neurons [907]. Overall, up- or down-regulation of BK_{Ca} channel activity have predictable effects on detrusor function. The translation of this research to human trials is awaited however, the safety and tolerability of escalating doses of hMaxi-K, a gene transfer product of human BK_{Ca}, were confirmed in a small patient cohort with moderate to severe erectile dysfunction [908].

Indirect modulation of BK_{Ca} channel activity is another feasible approach to achieve detrusor relaxation. Relaxation of pig and human bladder neck smooth muscle is greater with rolipram, a phosphodiesterase type 4 inhibitor that will increase cAMP activity, than by phospho-diesterase type 5 inhibitors, that will increase cGMP activity. This enhanced activity by rolipram was explained in part by PKA-dependent activation of BK_{Ca} [909].

3.5. Transient receptor potential (TRP) cation channels.

The TRP superfamily of cation channels, whose founder member is the *Drosophila* Trp channel, is divided in mammals into six families; TRPC, TRPM, TRPV, TRPA, TRPP and TRPML based on amino acid homologies. TRP subunits contain six putative transmembrane domains and assemble as homo- or hetero-tetramers to form cation selective channels with varied permeation properties (Figure 55). The TRPC ('Canonical') and TRPM ('Melastatin') subfamilies consist of seven and eight different channels, respectively (*i.e.*, $TRPC_1$-$TRPC_7$ and $TRPM_1$-$TRPM_8$). The TRPV ('Vanilloid') subfamily comprises six members ($TRPV_1$-$TRPV_6$) whereas the TRPA (Ankyrin) subfamily has only one mammalian member ($TRPA_1$). The involvement of TRP channels in disease is reviewed in [910,911]. Several TRP channels have mechano- or thermo-sensitive properties and are potential molecular targets for treatments of LUTD. However, knowledge of the mechanisms by which TRP channel function is still limited and in consequence few medical treatments have emerged based on targeting these channels. Several that were considered useful but not used for various reasons, however, may still be used to probe channel function so that more useful agents may be developed. Four TRP channels will be considered below; $TRPV_1$, $TRPV_4$, $TRPA_1$ and $TRPM_8$.

$TRPV_1$. $TRPV_1$ is an ion channel activated by capsaicin, heat, H^+ and endogenous ligands such as anandamide and receptor expression are prominent in sensory fibres and urothelial cells. Nociception was the first role attributed to $TRPV_1$ in the urinary tract. However, $TRPV_1$ also regulates the frequency of bladder contractions, either through direct excitation of sensory fibres or through urothelial-sensory fibre cross-talk involving the release of neuromodulators from epithelial cells. Capsaicin and resiniferatoxin (RTX) are agonists for $TRPV_1$ and their desensitisation of the receptor was investigated for therapeutic purposes for painful bladder syndrome and OAB of neurogenic and non-neurogenic origin. However, non-toxic, potent $TRPV_1$ antagonists are available [912] and may be used to ameliorate chronic pain, whereas $TRPV_1$ agonists that induce desensitisation may be used to treat diseases in which channel overexpression occurs [911]. A splice variant of $TRPV_1$, $TRPV_{1b}$, in which 60 amino acids are deleted in the intracellular N-terminal region, forms capsaicin-insensitive and stretch-inhibited cation channels [913]. This channel is activated by hypertonic cell shrinkage and mediates osmo-sensitivity in the supraoptic nucleus [914]. Such $TRPV_1$ variants might explain partly why a mechano-sensory function for $TRPV_1$ has been suggested in the bladder.

Patients with neurogenic detrusor overactivity (NDO) have increased immunoreactivity of $TRPV_1$ in the suburothelium and the basal layers of the urothelium compared to control patients. This

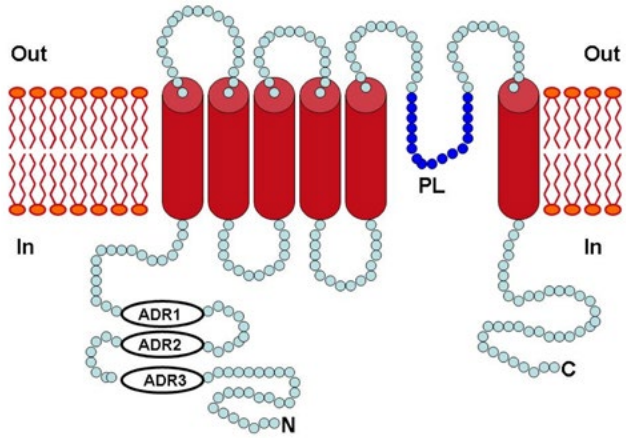

Figure 55. Molecular structure of TRP channels. *Most TRP channels are composed of six membrane-spanning helices with intracellular N- and C-termini. Ankyrin-repeat domains (ADRs), as the sensor, are in the C-termini. Mammalian TRP channels are activated by a wide variety of stimuli: e.g. osmotic pressure, volume, stretch, vibration, and regulated by post-transcriptional mechanisms like phosphorylation, G-protein receptor coupling, ligand-gating, and ubiquitination. Receptors are found in almost all cell types and largely localised in the cell membrane, modulating ion entry. PL, pore-forming loop; ADR, ankyrin-repeat domain.*

was reduced in patients who clinically responded to intravesical resiniferatoxin instillations to suggest a role for $TRPV_1$ in the pathophysiology of NDO [521]. The effects of GRC-6211, an orally active $TRPV_1$ antagonist, on the function and noxious input of normal and inflamed bladders has been evaluated in the rat and reduces bladder hyperactivity and noxious sensations induced by cystitis [915]. XEN-D0501, another $TRPV_1$ antagonist, has also been evaluated for use to manage OAB symptoms [916]. The effects of botulinum toxin A (BoNT/A) BoNT/A on the expression of nerve growth factor (NGF) and $TRPV_1$ in the urothelium and detrusor muscle of rats with detrusor overactivity due to partial bladder outlet obstruction have been investigated. Although BoNT/A reduced NGF expression, $TRPV_1$ expression, particularly in the urothelium, was not changed [917].

$TRPV_4$. $TRPV_4$ was originally postulated to act as a mechano- or osmo-sensor [918]. Studies with $TRPV_4$ knock-out mice revealed involvement in sensing mechanical pressure, osmolality and warmth *in vivo* [919,920]. $TRPV_4$ is abundantly expressed in rodent bladder epithelium and knockout mice manifest an incontinence phenotype with a spontaneous voiding pattern, a lower frequency of voiding contractions and increased bladder volume [519,574]. $TRPV_4$ agonists promote Ca^{2+} influx and enhance ATP release in cultured rat urothelial cells [519]. These studies indicate that $TRPV_4$ receptors sense distension of the urothelium.

Development of cystitis-induced bladder dysfunction is strongly impaired in $TRPV_4$ knock-out mice HC-067047, a previously uncharacterised, potent, and selective $TRPV_4$ antagonist increases functional bladder capacity and reduces micturition frequency in wild-type mice and rats with cystitis. However, it had no effect on bladder function in knock-out animals and indicate that $TRPV_4$ antagonists provide a potential treatment for such bladder dysfunction [921]. $TRPV_4$ expression may be regulated by NGF in LUT tissues. In transgenic mice with chronic urothelial overexpression of nerve growth factor HC-067047 increased inter-contraction interval (ICI) and void volume and decreased non-voiding contractions (NVCs) with reduced pelvic sensitivity and luminal ATP release [922,923]. $TRPV_4$ agonists may also have a role in detrusor underactivity. In rat models intravesical GSK1016790A, significantly decreased ICI, bladder capacity, voided volume, and post-void residual volume without increasing non-voiding contractions [924,925]. Finally, $TRPV_4$ receptors may also have functional roles in the sensory limb of the micturition reflex. An animal model of stress in rats showed increased urothelial $TRPV_4$ expression and $TRPV_4$ blockade ameliorated lower urinary tract dysfunction associated with this model [926].

It should be noted that $TRPV_4$ and $TRPV_1$ are present in different bladder afferent populations and the synergistic activity of antagonists for these receptors in very low doses may offer the opportunity to treat LUTS while minimising the potential side-effects of each drug [927,928]. Evaluation of $TRPV_4$ antagonists in larger trials across several indications is warranted given the availability of high-quality candidates and the promise of therapeutic benefit based on pre-clinical evidence [929].

$TRPA_1$. $TRPA_1$ is the only mammalian member of the Ankyrin TRP subfamily and is a potential mechano-sensor and nociceptor, responding to allyl isothiocyanate (in mustard oil), allicin (in garlic) and cinnamaldehyde (in cinnamon), as well as low temperature [797,919]. $TRPA_1$ is localised in the urothelial cells of the bladder and the prostate gland, as well as sensory C-fibres beneath the urothelium [930].

$TRPA_1$ receptors are proposed to play a role in the sensory responses and urinary frequency to inflammatory conditions, and up-regulation of c-fos mRNA in the spinal cord with such mediators is not observed in $TRPA_1$ knock-out mice [931,932]. Blockade of $TRPA_1$ receptors alleviates cyclophosphamide-induced bladder hyperalgesia [799]. In this context, the role of hydrogen sulphide (H_2S) as a $TRPA_1$ activator may be an intermediate in inflammatory bladder disorders [760]. Blockade of $TRPA_1$ receptors by antagonists, such as HC-030031 and A-967079, in a similar rat model of cystitis decreased afferent nerve activity and attenuated consequent detrusor overactivity induced by inflammation [933]. In addition, $TRPA_1$ activation induces bladder contractions, mediated by sensory afferent stimulation and release of neuropeptides and prostanoids. $TRPA_1$ activation is also proposed to contribute to LUT dysfunction in bladder outflow obstruction and spinal cord injury [563,934].

$TRPM_8$. $TRPM_8$ is also mechano-sensitive and cold-sensitive: and a bladder cooling reflex can be elicited by treatment with the $TRPM_8$ agonist, menthol. This reflex is sensitive to ganglion blockade or capsaicin-sensitive C-fibre deafferentation [935]. The $TRPM_8$ channel blocker, N-(3-aminopropyl)-2-[192]-N- (2-thienylmethyl) benzamide hydrochloride salt (AMTB), acts on bladder afferent pathways to attenuate the micturition reflex and nociceptive reflex responses in rats [936]. In addition, KPR-5714 (N-[(R)-3,3-difluoro-4-hydroxy-1-(2H-1,2,3-triazol-2-yl) butan-2-yl]-3-fluoro-2-[5-(4-fluorophenyl)-1H-pyrazol-3-yl] benzamide), a novel and selective $TRPM_8$ antagonist, has been shown to improve urinary frequency with inhibition mechano-sensitive C-fibres of bladder afferents after intravesical instillation of acetic acid [937].

Brief cold stimuli applied to the skin can evoke a sudden desire to urinate, which can be highly bothersome in patients with overactive bladder, but there is no clear explanation for such acute cold-induced urinary urgency. Cold and menthol stimuli to the skin generate bladder nerve responses conducted through dichotomising axons, which are significantly decreased in the presence of the

$TRPM_8$ blocker BCTC. $TRPM_8$-expressing sensory neurons with dichotomising axons projecting to the skin and bladder may therefore be responsible for the urinary urgency evoked by cold sensation [938]. The $TRPM_8$-selective antagonist DFL23448 [5-(2-ethyl-2H-tetrazol-5-yl)-2-(3-fluorophenyl)-1,3-thiazol-4-ol] has been shown to reduce cold-induced bladder overactivity. induced was tested and evaluated in cold-induced behavioural tests and tests on bladder function and experimental bladder overactivity *in vivo* in rats. According to the results, a role for bladder $TRPM_8$-mediated signals is present in experimental bladder overactivity [939].

3.6. Piezo channels.

Piezo1 and its close homologue Piezo2 are mechano-sensitive ion channels that in humans are encoded by the gene PIEZO1 and are predicted to have 24-36 transmembrane domains [940,941]. Piezo1 is expressed in the kidney, ureter, bladder, and urethra as well as organs in close proximity, including the prostate, seminal vesicles and ducts, ejaculatory ducts and the vagina [321]. Unlike Piezo2 which is highly expressed in sensory dorsal root ganglia, piezo1 is not expressed in sensory neurons [941].

Mouse urothelial cells exhibited a Piezo1-dependent increase of cytosolic Ca^{2+} concentration in response to mechanical stretch stimuli, leading to ATP release but Piezo1 and $TRPV_4$ respond to different intensities of mechanical stimulus. GsMTx4, an inhibitor of stretch-activated channels, attenuated Ca^{2+} into urothelial cells and decreased ATP release upon stretch stimulation. Hence, Piezo1 senses extension of the urothelium, leading to ATP release, and inhibition of Piezo1 might provide a potential target for treatment of bladder dysfunction [942,943] (Figure 56).

4. TRANSPORTERS

Membrane transporters carry solutes across cell membranes, which would otherwise be impermeable to them. The energy required for active transport processes is obtained from ATP turnover or by exploiting ion gradients. ATP-driven transporters can be divided into three major classes: P-type ATPases; F-type or V-type ATPases; and ATP-binding cassette transporters. P-type ATPases, are multimeric proteins, which transport (primarily) inorganic cations. F-type or V-type ATPases, are proton-coupled motors, which can function either as transporters or as motors. ATP-binding cassette transporters are importantly involved in drug disposition as well as transporting endogenous solutes.

The second largest family of membrane proteins in the human genome, after the G protein-coupled receptors, is the SLC solute carrier superfamily which transport a great variety of solutes, from simple inorganic ions to amino acids and sugars to more complex organic molecules like haem. SLC transporters include secondary active transporters that function as antiporters (counter-transporters) or symports (co-transporters). A third, relatively small group are equilibrative transporters, that allow solutes to travel across membranes down their concentration gradients. A more complex family of transporters, the SLC27 fatty acid transporters also ex-

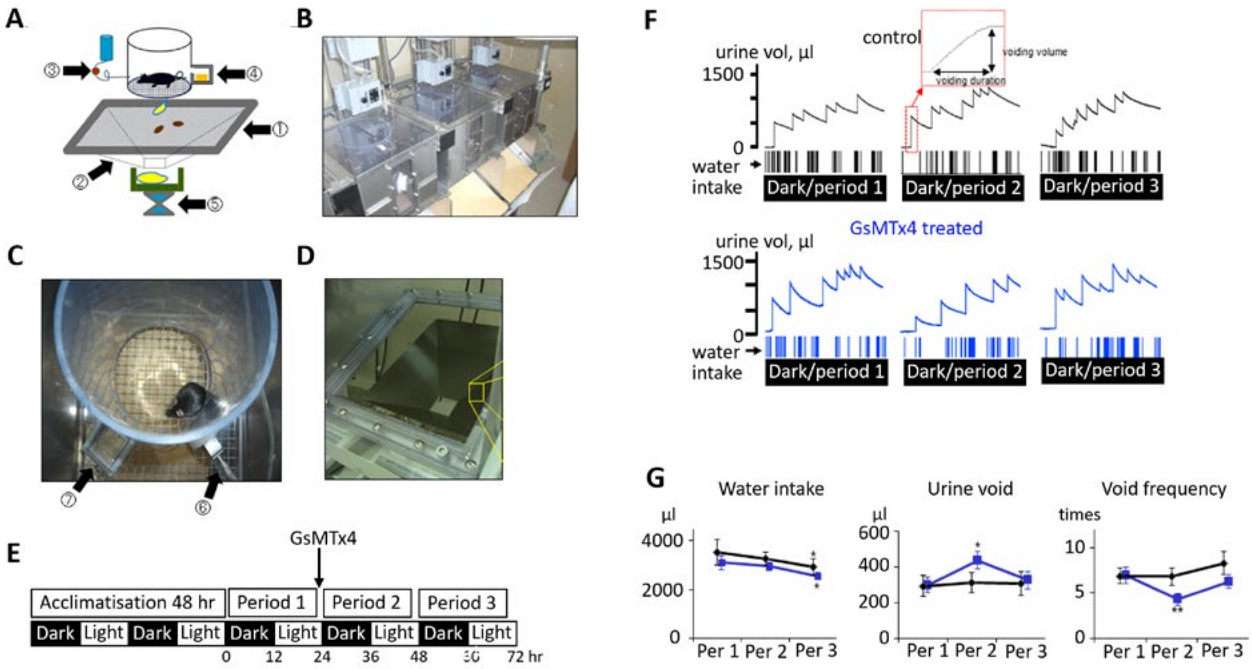

Figure 56. Metabolic cage system for micturition behaviour in mice, effect of GsMTx4. *A: Metabolic cage schema for collection of voided urine in a sound-proof wind-break room at 25°C. The mesh (patent licence no. 2009-187420, Mitsubishi Kumamoto Japan) that forms the floor allows passage of urine, weighed below, but catches faeces and food. Mice are provided with free access to food and water and housed with a 12/12 h dark/light period. Water intake is measured by a sensor. After two days acclimatisation, voiding frequency and voided urine are recorded continuously for 72 hours. The following are recorded: water intake (µl/12 h in dark period); urine volume (µl/12 h in dark period); voiding frequency (times/12 h In dark period). B: photograph of three cage systems. C: Top view of one cage showing he mesh floor. D: urine collection unit under the floor. E: Schematic of acclimatisation and collection periods. press enzymatic function. Many transporters also express electrogenic properties of ion channels [944].

The vesicular nucleotide transporter (VNUT), SLC17A9, is the most recent member of the SLC17 family to have an assigned function. Uptake of ATP is independent of pH, but dependent on Cl^- and membrane potential and endogenous substrates ATP, GDP and GTP. VNUT is inhibited by DIDS and Evans blue dye [945]. VNUT is abundantly expressed in the bladder urothelium and releases ATP by exocytosis. During the initial stages of bladder filling ATP is released by vesicular exocytosis and VNUT-deficient mice showed reduced bladder compliance and urinary frequency. From this, it has been concluded that VNUT-dependent ATP exocytosis is involved in urine storage that promote the relaxation of the bladder during this phase of bladder filling (Figure 57) [946].

5. CLOCK GENES

Clock genes exist in most cells and organs, and their products regulate oscillations in the sleep-awake rhythm and gene expression rhythms of various metabolic enzymes, channels, and receptors. Of more than 10 types of clock genes that have been identified, Per, Cry, Bmal, and Clock play the most important role in regulation of circadian rhythm. Exact circadian rhythms are driven by the formation of a large number of complex feedback loops under the control of the master clock in the suprachiasmatic nucleus (SCN) (Figure 58) [947].

The pathophysiological conditions of nocturia and nocturnal polyuria are multifactorial and complex, and their aetiologies remain unclear in many patients, but LUT functions are regulated by clock genes [948,949]. Moreover, melatonin secretion, which has a circadian rhythm that is regulated by clock genes in the SCN and affects circadian rhythms in peripheral tissues by controlling hormonal activities influences the onset of nocturia in patients [950]. A novel hypothesis has been proposed regarding the relationship between abnormalities in clock genes and LUT function.

The voiding behaviour of Clock-mutant (ClockΔ19/Δ19) mice over 24 hours has been measured to investigate the effect of clock genes on LUT function. Although no significant differences were observed in behaviour patterns between ClockΔ19/Δ19 and wild-type mice, ClockΔ19/Δ19 mice showed the phenotype of nocturia and nocturnal polyuria [951]. In primary cultured urothelial cells

from ClockΔ19/Δ19 mice expression of clock genes, mechano-sensors such as Piezo1 and ATP release mediators such as VNUT and connexins showed desynchronised circadian rhythms, with ATP release remained high in both the sleep and awake phases and providing a cellular basis for nocturia [952-954].

6. FIBROSIS AND THE URINARY TRACT: A TARGET FOR DRUG DEVELOPMENT

Fibrosis is a thickening of tissue associated with an excessive deposition of connective tissue, as part of a natural healing process or of a pathological development. Connective tissue itself, one of the four basic tissue types, is of mesodermal origin, has a supportive role for other tissue types and has three principal components: protein fibres of collagen and elastin; cells (including fibroblasts, macrophages, leucocytes and mast cells); both embedded in a ground substance of glycosaminoglycans and proteoglycans. Considerable variation and specialisation of connective tissue occurs throughout the body (e.g., to bone, cartilage, adipose tissue and blood) but this basic description is applicable to connective tissue in the urinary tract. The relative ratios of the principal components can vary, even in different manifestations of urinary tract tissues, that have a bearing on its supportive functions. Different proportions of protein fibres and ground substance will determine the biomechanical properties of connective tissue, as collagen and elastin offer a considerable stiffness compared to ground substance. Of relevance also is that of mesenchyme, a form of connective tissue in the developing embryo that contains cells capable of differentiating into other cells of matured connective tissue.

6.1. Fibrosis: cellular pathways and biomechanical consequences.

Tissue damage from chemical or mechanical injury, or an autoimmune reaction results in a shorter-term wound-healing phase that may lead to a fibrotic, chronic inflammatory phase (955). Important in the process is the recruitment of collagen-producing myofibroblasts from local fibroblasts, epithelial cells by a process of epithelial-mesenchymal transition, or even from a similar endothelial cell transition (956-958). If accumulation of extracellular collagen is eventually reversed then a wound-healing process can be achieved, but if dysregulated and allowed to accumulate fibrosis will ensue. Crucial to this is a balance or otherwise between activities

of matrix metalloproteinases (MMPs), that will degrade collagen, and various tissue inhibitors of MMPs (TIMPs) (959,960). Initiation of fibrosis is mediated by a number of soluble factors released by immune cells, such as macrophages. The best characterised is of transforming growth factor-β (TGF-β) through activation of an intracellular SMAD transcription factor pathway (961), although other mediators such as connective tissue growth factor (CTGF) and platelet-derived growth factor (PDGF) and interleukins such as IL-10 are also important (962-964). Associated pathways that may regulate the above include *wnt*-like signal transduction, also important in regulating tissue proliferation and development, to prevent degradation of the transcription factor β-catenin that in turn acts in a similar way to TGF-β/ SMAD pathways (965,966). Of relevance, inhibition of these pathways offers routes for antifibrosis strategies. An example is to increase intracellular cGMP concentrations, as this cyclic nucleotide will inhibit both Smad-dependent and -independent fibrotic pathways (967).

Fibrosis can influence the passive mechanical and active contractile properties of muscular tissues in several ways.

i. Passive mechanical stiffness will be altered dependent on the relative amounts of collagen/elastin or ground substance deposited, as the former is stiffer than contractile muscle and the latter less stiff. Note: an increase of mechanical stiffness is equivalent to a decrease of tissue compliance or distensibility.
ii. Replacement of muscular tissue by connective tissue will reduce overall muscle tissue contractility, simply by reducing the number of contractile units in a given volume of tissue. Reduction of tissue integrity may also permit less alignment of individual muscle fibres further reducing muscle force in a particular vector.
iii. Some of the cytokines released by inflammatory or other cells in a tissue mass undergoing fibrosis may have direct effects on muscle contractility. For example, histamine generates transient increases of detrusor contractile tone, through an HI-receptor action (968) and IL-6 enhances contractile responses to muscarinic agonists (969).

With respect to biomechanical integrity, collagen is deposited as two major subtypes, as collagen type-I and collagen type-III, the former increasing in proportion in hypertrophied bladders induced by say spinal cord injury (970). Measurement of tissue stiffness or elasticity modulus (inverse compliance) is measured as the slope of a linear stress(tension)/ strain(stretch) relationship with units of Pascals (Pa, or usefully MPa – 10^6 Pa). The elasticity of different isolated collagen subtypes has probably less meaning that how variation of type-I/type-III proportions has on mixed gels as the overall elastic properties of will depend on the relative orientation of different fibrils and their absolute size. However, for reference pure type-I fibrils, about 325 nm diameter, have an elasticity modulus of 100-360 MPa (971). Mixed gels of type-I and type-III collagen showed that maximum elasticity occurred with a type-1/ type-III ratio of 80% declining by more than 50% as the ratio either increased to 100% type-1 or decreased to 20% (972). Another confounding aspect is that stress-strain relationships for biological tissues with significant extracellular matrix are generally not linear but increasingly exponential with greater strains (513), reflecting additional re-orientation of collagen fibrils and other tissue components. Thus, most useful is to gauge how elasticity alters as tissue composition varies within a complex structure. This has not been as comprehensively investigated in urinary tract tissue as it has in blood vessels where for example in the ferret aorta elasticity is greatest (35 MPa) in the outer adventitia, rich in extracellular matrix, through to the innermost intima (8 MPa) (973). Thus, whilst there is still considerable required research with urinary tract tissue, it may be concluded that increased collagen-rich extracellular matrix deposition increases tissue stiffness (decreases distensibility) and variation of collagen subtype will alter this relationship. In the case where excess extracellular matrix deposition occurs with a greater proportion of ground substance it may be expected that a more floppy, less elastic tissue will result, as observed in models of excessive deposition (613,974).

6.2. Fibrosis: the adult and pediatric urinary tract.

Fibrosis is a feature of normal ageing in the human and animal bladders (975-977). The former study found fibrosis in both male and female subjects and concluded that it occurred independently of outflow tract obstruction, as may occur with benign prostate enlargement in men. However, fibrosis is also associated with a number of pathologies. With spinal cord injury in human and animal models, bladder tissue re-modelling is associated with fibrosis (978-980) and additionally associated with up-regulation of TGF-β1 levels (981). Equally, fibrosis is a consequence of the hypertrophied bladder following partial outflow obstruction, also with an increase of TGF-β1 and connective tissue growth factor (982-985). MicroRNAs, non-coding single-strands of RNA, have been proposed to regulate not only the hyperplastic and hypertrophic growth of the bladder, but also the increased deposition of extracellular matrix. This offers a potential range of targets not only to understand more about the process of bladder growth and remodelling, but also to control and even reverse these processes (986).

Fibrosis also occurs in bladders subjected to chronic ischaemia, the magnitude of which is related to the extent by which blood flow is reduced but sufficient to decrease filling compliance (987,988). A role for hypoxia inducible factors (HIFs) has been implicated, not only in metabolic adaptation to a more anaerobic metabolism, but to a more fibrotic phenotype (989). For example, fibrosis induced by bladder obstruction of young male mice was accompanied by up-regulation of genes associated with fibrosis and increased epithelial-mesenchymal transition the extent of which could be regulated by controlling HIF activity (990,991).

Fibrosis may also be induced by iatrogenic means. For example, radiation therapy that can significantly impact on bladder contractile function (992,993), most likely as a result of inflammation generated by the treatment and may be ameliorated by basic fibroblast growth factor (994). However, genetic predisposition may influence the extent of radiation-induced damage and dysfunction as shown by comparing data from different strains of mice (995).

Fibrosis is also a feature of the foetal and paediatric bladder. The proportion of smooth muscle compared to connective tissue increases with age in both the human and animal bladders (996,997). However, the extent of fibrosis is much greater in the bladder wall of children with a range of congenital anomalies including: exstrophy-epispadias complex, bladder obstruction in boys with posterior urethral valves (PUV); and neuropathic bladders through spinal cord defects (998-1000). This increase of connective was generally associated with increased passive stiffness of isolated tissue and would translate to reduced filling bladder compliance. This increased connective tissue content showed a significant association with reduced contractile ability of isolated detrusor preparations, whether evaluated with agonist- or nerve-mediated contractions, and a trend that is continued with adult human preparations (Figure 59). Parallel experiments with isolated smooth muscle cells showed no evidence of intracellular Ca^{2+} metabolism when exposed to contractile agonists (998). The figure also shows that tissue from one congenital, cloacal anomaly, showed contractile function and connective tissue content comparable with tissue from children with functionally normal bladders. These data were mirrored in experi-

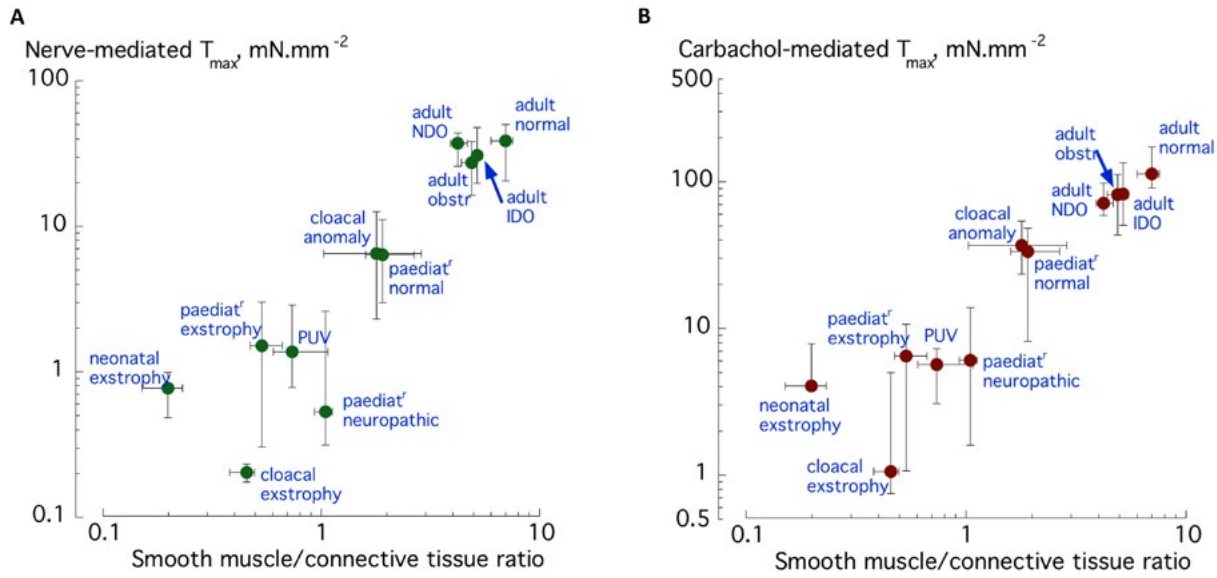

Figure 59. The relationship between human detrusor contractile performance and smooth muscle content. *A: In vitro maximum nerve-mediated contraction magnitude as a function of the smooth muscle/connective tissue ratio, note the logarithmic axes to express the wide range of both variables. B: A similar relationship for maximum carbachol contractions as a function of the smooth muscle/ connective tissue ratio. The close relationships indicate the predominant dependence of contraction magnitude as a function of smooth muscle content in tissue from a wide range of age and pathological conditions. Key: IDO, NDO; idiopathic and neurogenic detrusor overactivity in adult preparations. 'obstr'; obstructed bladder. 'paediatr' paediatric patients. 'neonatal exstrophy; samples obtained at first-stage repair. 'paediatr exstrophy; samples obtained at second-stage repair. PUV; posterior urethral valves. Data, unpublished and from (977,998-1000).*

ments with foetal sheep that were obstructed in the second trimester, as an experimental model for PUV (974,1001-1003). Further experiments showed that the duration of obstruction required to produce a phenotype of reduced contractility and fibrosis was only a few days (1004,1005) and raised the question of the desirability of *in utero* bladder decompression to prevent more severe bladder damage at birth. Overall, the data with human tissue specimens shows that reduction of smooth muscle mass, and consequent increase of connective tissue content, is the most important factor that determines detrusor contractile function. Reversal or reduction of connective tissue content is therefore a primary goal to restore near normal bladder contractile function in children with several important congenital anomalies of the lower urinary tract.

6.3. Strategies for reversal of fibrosis in the bladder wall.
A number of paradigms have been examined that may reduce the extent of fibrosis, whether by: inhibiting the intracellular pathways that regulate transcription of genes that regulate extracellular matrix generation; reduce epithelial-mesenchymal transition; or increase breakdown of extracellular matrix components. It is important to emphasise that approaches that may be successful in some fibrosis pathologies may not be successful in others. For example, fibrosis associated with paediatric congenital anomalies such as exstrophy, posterior urethral valves (PUV) or spinal cord defects can show variations in expression of proteins associated with cell cycle regulation (e.g. cyclin-D1), cell proliferation (c-Myc) or collagen degradation (MMP-7). Thus, whilst cMyc expression is reduced in all three conditions (compared to tissue from normally functioning bladders), cyclin-D1 expression is increased only in PUV bladders and MMP-7 expression whilst decreased in exstrophy bladders, in increased in PUV tissue and unaltered in neuropathic bladders (998-1000). This just highlights the complexity of regulatory pathways associated with one pathological feature (fibrosis) and their potential variability in different conditions.

Perhaps the most-studied fibrosis pathway is the TGF-β pathway whereby these ligands, released from cells under a number of chemical and mechanical stresses, bind to TGF-β receptor type-2 (TGFBR2). This initiates phosphorylation of intracellular SMAD proteins (SMAD2 and SMAD3) which in turn form a complex with SMAD4 to regulate transcription of genes including those involved in expression of extracellular matrix proteins and differentiation of collagen-producing myofibroblasts (1006). Manipulation of this pathway is a target for anti-fibrotic approaches. For example, original work has shown the effectiveness of cAMP analogues, prostaglandin (PGE2) and prostacyclin (PGI2) in reducing fibrosis (1007-1009) and interferon-γ (1010,1011) and PPAR-γ (1012) are effective in a number of tissues.

More recently agents that increase cGMP levels have been shown to exert antifibrotic action, potentially through the ability of cGMP-dependent protein kinase G to inhibit the TGFBR2:SMAD pathway by sequestration of SMAD3 (1013,1014). This may underlie the action of the endogenous antifibrotic hormone relaxin, a peptide hormone that is part of the insulin superfamily. The best characterised form, relaxin-2 binds to its receptor (RXFP1) to enhance NO-dependent generation of cGMP, through activation of soluble guanylate cyclase, and PKG activation (1015). Final actions are likely to be manifold but epithelial-mesenchymal transition and MMP expression are down-regulated and TIMP expression increased. Relaxin is effective in the bladder to reduce fibrosis after X-ray irradiation and reverses the overactive phenotype induced by this insult (992) and mirrors its success as an antifibrotic agent in pulmonary and renal fibrosis (1016,1017). The expense in manufacturing relaxin may limit it potential usefulness and so other means to increase

cGMP levels in LUT tissues should be sought. One possibility is the use of phosphodiesterase type-5 inhibitors (PDE5I) such as sildenafil and tadalafil. Sildenafil is effective in mice to prevent detrusor hypertrophy, collagen deposition and bladder overactivity that occurs after outflow tract obstruction, without affecting voiding function (1018). Tadalafil alone, or in combination with a PDE4I (roflimilast; to enhance cAMP levels), also reduced fibrosis and an overactive bladder phenotype in obstructed and ageing animal models (1019,1020).

Research to reduce fibrosis in lower urinary tract tissues lags equivalent work with other tissues, in particular with fibrosis in lungs, liver, heart and skin. But general principles gained from these tissues may be applied to LUT fibrosis, with the above caveat that information may not be wholly translated.

COMMITTEE 3

PATHOPHYSIOLOGY OF URINARY INCONTINENCE, PELVIC ORGAN PROLAPSE AND FAECAL INCONTINENCE

Co-Chairs
Finazzi Agrò, Enrico (Italy)
Salvatore, Stefano (Italy)

Members
Braga, Andrea (switzerland)
DeLancey, John (United States)
Fernando, Ruwan (United Kingdom)
Iacovelli, Valerio (Italy)
Laterza, Rosa (Austria)
Lowry, Ann (United States)
Serati, Maurizio (Italy)
Sievert, Karl-Dietrich (Germany)

Aknowledgements
The Authors thanks Dr. Michael Virgilio Ambrosi-Grappelli, Dr. Luca Orecchia, Dr. Eleonora Rosato and Dr.Alessandro Ruffolo, for their contribution in the revision of the Chapter.

COMMITTEE 3

PATHOPHYSIOLOGY OF URINARY INCONTINENCE, PELVIC ORGAN PROLAPSE AND FAECAL INCONTINENCE

LIST OF ABBREVIATIONS 251

I. PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE IN MEN 252
1. Introduction 252
2. CONTINENCE MECHANISM IN THE MALE 252
2.1. Supporting Structures Of The Membranous Urethra [29] 253
3. INCONTINENCE ASSOCIATED WITH BPH AND ITS TREATMENT 254
3.1. Sphincter dysfunction (Injury) 255
3.2. Bladder Dysfunction (Persistent or new onset) 255
3.3. Different Techniques 255
4. INCONTINENCE ASSOCIATED WITH RADICAL PROSTATECTOMY 256
4.1. Incidence 256
4.2. Recovery Of Continence After Radical Prostatectomy 256
4.3. Risk Factors 257
4.4. Etiology nd Pathophysiology of Post Radical Prostatectomy Incontinence: Sphincter Vs. Bladder Dysfunction 258
5. INCONTINENCE RELATED TO RADIATION THERAPY FOR PROSTATE CANCER 259
6. CONCLUSIONS 260
REFERENCES 260

II. PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE, FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE IN WOMEN 268
1. Anatomy and physiology of the female urogenital diaphragm 268
1.1. The Female Urethral Sphincter and Perineal Membrane 268
2. Effect of Childbirth, Vaginal Prolapse and Urethral Position on Urinary Continence 270
2.1. Introduction 270
2.2. Role of childbirth, vaginal prolapse and urethral position 271
3. ROLE OF CONNECTIVE TISSUE 276

I. PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE IN MEN

1. INTRODUCTION

Urinary incontinence (UI) in men is defined as an involuntary loss of urine experienced during the bladder storage phase [1]. UI is subdivided into three major groups [1-3]:

- Urgency urinary incontinence (UUI) defined as complaint of involuntary loss of urine associated with urgency,
- Stress urinary incontinence (SUI) defined as complaint of involuntary loss of urine on effort or physical exertion such as sporting activities, or on sneezing or coughing.
- Mixed urinary incontinence (MUI) is defined as the complaint of both stress and urgency urinary incontinence, that is, involuntary loss of urine associated with urgency as well as with effort or physical exertion.

Adult LUTD are classified as neurogenic (ANLUTD) only in the presence of a relevant neurological disease [5]. Changes in bladder ultrastructure and function can occur as a result of neurological diseases or associated with ageing [4]. Several changes may be related to benign and/or malignant diseases of the prostate and their treatment. [5,6]. Also, sphincter insufficiency resulting in SUI does not generally occur as a result of male ageing, but rather secondary to surgery or irradiation of the prostate leading to neurological injury [7].

Extra-urethral incontinence in men, defined as urine leakage through channels other than the urethral meatus [1] is only known as a result of a fistula. Fistulae in men are most often iatrogenic (surgery, radiotherapy, cryotherapy, HIFU (High-intensity focused ultrasound)) or inflammatory (diverticulitis) [1-3].

This section focuses on the pathophysiology of stress incontinence in men.

2. CONTINENCE MECHANISM IN THE MALE

According to Latini *et al.* [8], the continence mechanism in the male is related to three anatomical properties of the urethra: the bladder neck, the prostatic urethra and the membranous urethra.

The smooth muscle of the bladder neck is histologically, histochemically and pharmacologically distinct from the vesical detrusor muscle. In the male, the bladder neck is completely surrounded by a circular collar of smooth muscle which extends distally to surround the prostatic portion of the urethra. Because of the location and orientation of its constituent fibres, the term preprostatic sphincter is suitable for this particular component of urinary tract smooth muscle. This is a genital sphincter mechanism with an autonomic parasympathetic and sympathetic fibres from the inferior hypogastric plexus. Distally, this muscle merges with and becomes indistinguishable from the musculature in the stroma and capsule of the prostate gland.

The prostatic urethra extends from the proximal edge of the membranous urethra or the proximal verumontanum to the distal bladder neck. It is surrounded by the prostate. The prostatic urethra is c.3-4 cm in length and tunnels through the substance of the prostate closer to the anterior than the posterior surface of the gland. It is continuous above with the preprostatic part and emerges from the prostate slightly anterior to its apex (the most inferior point of the prostate). An elevation, the verumontanum (colliculus seminalis), at about the middle of the length of the urethral crest, contains the slit-like orifice of the prostatic utricle. On both sides of, or just within, this orifice are the two small openings of the ejaculatory ducts. Its walls are composed of fibrous tissue, muscular fibres and mucous membrane; the latter is pitted by the openings of numerous small glands. The lowermost part of the prostatic urethra is fixed by the puboprostatic ligaments and is therefore immobile.

The membranous urethra extends from the proximal bulbar urethra to the distal verumontanum. It is surrounded by the voluntary external sphincter mechanism, both the smooth muscle external sphincter and the striated/rhabdosphincter. The membranous urethra is unattached to any fixed structure and is the only segment of the male urethra not surrounded by any other structure. It descends with a slight ventral concavity from the prostate to the bulb of the penis, passing through the perineal membrane, c.2.5 cm posteroinferior to the pubic symphysis. The wall of the membranous urethra consists of a muscle coat, separated from the epithelial lining by a narrow layer of fibroelastic connective tissue. The muscle coat consists of a relatively thin layer of bundles of smooth muscle, which are continuous proximally with those of the prostatic urethra, and a prominent outer layer of circularly orientated striated muscle fibres, which form the external urethral sphincter (EUS), as it is commonly known. The bladder neck is sometimes called the internal urethral sphincter (IUS) mechanism, to distinguish it from the distal sphincter mechanism. This latter term has con-

siderable value because it recognises that the sphincter-active membranous urethra consists of several components, namely, urethral smooth muscle (lissosphincter); urethral striated muscle (rhabdosphincter), which is the most important component; and the periurethral part of levator ani, which is important to resist surges of intra-abdominal pressure (e.g. on coughing or exercise). The EUS represents the point of highest intraurethral pressure in the normal, contracted state. The intrinsic striated muscle component is devoid of muscle spindles. The striated muscle fibres themselves are unusually small in cross-section (15-20 µm diameter), and are physiologically of the slow twitch type, unlike the pelvic floor musculature, which is a heterogeneous mixture of slow and fast twitch fibres of larger diameter.

At the boundary between the IUS and EUS, the striated and smooth muscle fibres intertwine to some extent. The EUS extends from the prostatic urethra below the verumontanum through the membranous urethra. Hence, EUS includes the rhabdosphincter (intrinsic skeletal and smooth muscle) and extrinsic paraurethral skeletal muscle. At the prostate level, the superior part of the striated EUS is largely confined to the anterior side of the urethra and prostate. Inferior to the prostate, the EUS is horseshoe-shaped (although named as the rhabdosphincter, omega shaped) with the opening on the dorsal side. The dorsal muscle fibres of the left and right sides approach the midline and sometimes cross the prostate [14-16].

The rhabdosphincter has longitudinal smooth muscle and slowtwitch (type I) skeletal muscle fibres. The lissosphincter forms a complete cylinder of circular muscle fibres around the urethra can maintain resting tone and preserve continence [14,17-19] (Figure 1). The rhabdosphincter is invested in a facial framework and supported below by a musculofascial plate that fuses with the midline raphe, which is also a point of origin for the rectourethralis muscle [20]. Superiorly, the fascial investments of the rhabdosphincter fuse with the puboprostatic ligaments [21]. This dorsal and ventral support probably contributes to the competence of the sphincter. The striated fibres of the extrinsic paraurethral muscle (levator ani complex), on the other hand, are of the fast-twitch (type II) variety [17]. During sudden increases in abdominal pressure, these fibres can contract rapidly and forcefully to provide continence.

It is known that during radical prostatectomy the smooth muscle fibres of the bladder neck (IUS) are resected, which interrupted innervation. Furthermore, it is worth noting that impaired detrusor contractile function seems to be frequently associated with intrinsic sphincter deficiency. With the increasing knowledge of the periprostatic nerves and the improvement of the preservation of the bladder neck the functional outcome improved even further [22].

The EUS is innervated by the autonomic (via the pelvic nerve) and somatic (by the pudendal nerve) nervous systems. Nerve fibres are seen proximally in a dorsolateral position (5 to 7 o'clock), while more distally, they are located primarily laterally [20, 23]. The rhabdosphincter may also receive somatic innervation. Hollabaugh *et al.* described the so-called "putative continence nerves" as branches of the pelvic nerve travelling under the endopelvic fascia picking up intrapelvic branches of the pudendal nerve, given off before it enters the pudendal canal, which was further verified by Castello *et al*. [23,24].

It has also been proposed that somatic innervation is primarily sensory in origin, facilitating reflex contraction of the sphincter complex to maintain the continence [25].

A histological and immuno-histochemical study with 3-D reconstruction in the male fetus has confirmed mixed autonomic and somatic innervation (Figure 2) [14]. Unmyelinated (autonomic) nerve fibres destined for smooth muscle fibres run alongside of the myelinated (somatic) fibres. The majority of the unmyelinated fibres approach the smooth muscle layers at 5 and 7 o'clock while the majority of myelinated fibres penetrate the striated sphincter at 3 and 9 o'clock.

Tuygun *et al* have found a much higher incidence of periurethral (or perisphincter) fibrosis in incontinent vs. continent men after prostatectomy [26-28]. This might lead to the importance of the corpus spongiosum, which surrounds the bulbar urethra and supports with its blood filling in addition to its sphincteric function.

2.1. Supporting Structures Of The Membranous Urethra [29]

The supporting structures of the male urethra can be divided into the anterior and posterior support structures and the pelvic floor. The anterior urethral support structures contain the pubourethral ligaments, comprising the pubovesical ligament (PVL), the puboprostatic ligament (PLL), and the tendinous arch of the pelvic fascia. These ligaments stabilize the position of the bladder neck as well as the external sphincter complex and help to secure the membranous urethra to the pubic bone [30].

The posterior support consists of the perineal body (central perineal tendon), Denonvillier's fascia, the rectourethralis muscle, and the levator ani complex [31,32]. The third support structure is the pelvic floor, composed of the levator ani muscle and the surrounding fascia [33]. The pelvic floor is not directly connected to the urethra [33] but plays a role in continence by providing an additional occlusive force on the urethra via increased intraabdominal pressure [34].

It is postulated that the overall role of the support structures is to provide all-round stability and suspensory support for the urethral sphincter complex [35]. Normally the omega-shaped urethral rhabdosphincter has its anchoring points dorsally at the so-called conjoined fibrous tissue [36]. This conjoined fibrous tissue acts like a fulcrum for the anterior forces exerted by the rhabdosphincter. It compresses the urethra in an anteroposterior direction.

In summary, continence depends on the integrity of the IUS and/or EUS, on its support structures and on neural innervation and probably on the prostate. The IUS could be damaged during radical prostatectomy and continence seems to be maintained by the EUS mechanism. Thus, preservation of the IUS is important. The smooth muscle and slow twitch striated muscle of the rhabdosphincter (EUS) are probably majorly responsible for the sphincter continence; however, striated muscle contractions of the periurethral and paraurethral muscles are likely assist. Damage to the innervation (parasympathetic and somatic) of the smooth and striated muscle may indirectly contribute to post-prostatectomy incontinence. In addition, compromise of the sphincter support mechanism or post-operative changes such as fibrosis can compromise the sphincter function (Figure 1, Figure 2).

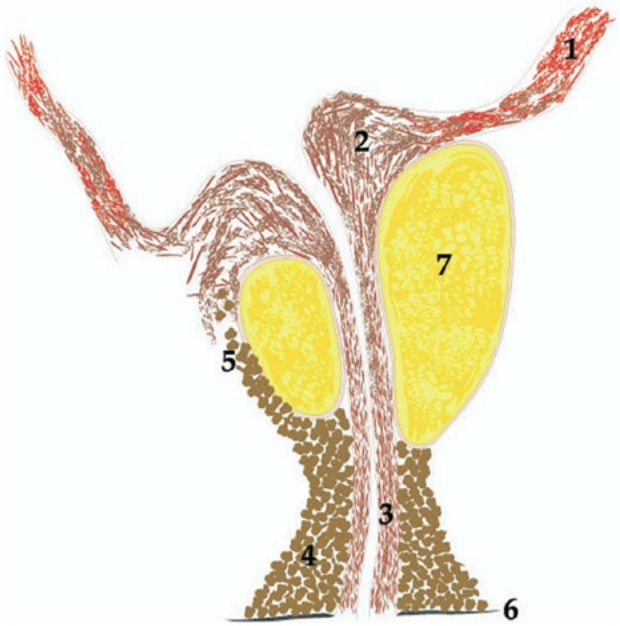

Figure 1: Revised concept of male urethral sphincter complex. 1, bladder musculature. 2, proximal part of lissosphincter internal sphincter. 3, distal part of lissosphincter smooth circular muscle layer of urethra. 4, rhabdosphincter. 5, prostatic part of rhabdosphincter. 6, perineal membrane. 7, prostate. The urethral sphincter complex extends in the form of a cylinder around the urethra from the vesical orifice to the distal end of the membranous urethra. While the outer component of skeletal muscle (rhabdosphincter) is most marked and thickest around the membranous urethra, and becomes gradually less distinct toward the bladder, in contrast, the inner component of smooth muscle (lissosphincter) has its main part at the vesical orifice and is thinner in its further course in the urethra. Also, whereas the lissosphincter forms a complete cylinder of circular muscle fibers around the urethra, the rhabdosphincter does not.

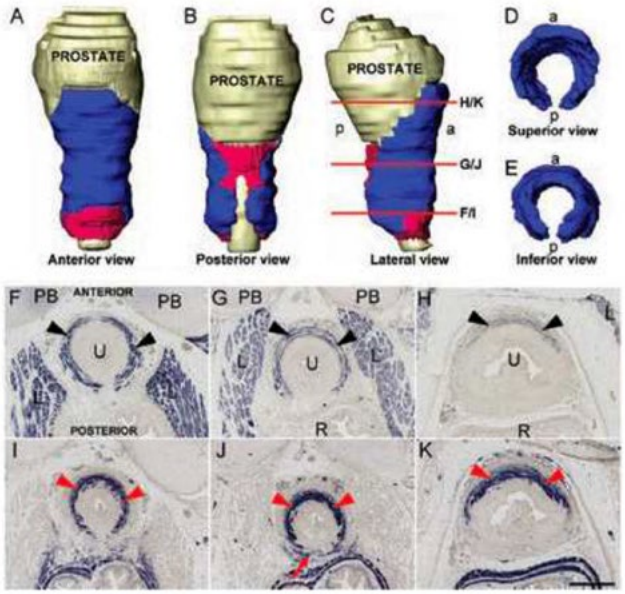

Figure 2: The external urethral sphincter (EUS) and internal urethral sphincter (IUS) in a male fetus (12 wk of gestation). Three- dimensional reconstruction in (A) anterior view, (B) posterior view, (C) right-lateral view, (D) superior view, and (E) inferior view. The EUS is shown in blue, and the IUS is shown in pink. The urethra and prostate are shown in light grey. Anterior and posterior directions are represented by the letters "a" and "p." Immunohistochemically stained sections: Sections from inferior (F) to superior (H) stained immunohistochemically for striated muscle, showing the EUS (black arrowheads). Panels (I) through (K) are from same level as sections (F) through (H), stained immunohistochemically for smooth muscle, showing the IUS (red arrowheads). Note the smooth muscle tissue at the dorsal side of the urethra, where the striated muscle of the external sphincter is lacking; see red arrow in (J). Red lines in (C) illustrate the level of the sections as seen in (F) through (H). L = levator ani muscle; PB = pubic bone; R = rectum; U = urethra; bar = 0.5 mm. From Wallner et al, Eur Urol 55(4):932-944, 2009 [14]

3. INCONTINENCE ASSOCIATED WITH BPH AND ITS TREATMENT

Benign prostatic hyperplasia (BPH) and benign prostatic obstruction (BPO) and their treatments have been widely associated with incontinence in men. Detrusor Overactivity (DO), impaired compliance and UUI are prevalent in men with BPO.

In adult males the prevalence of OAB ranges from 10% to 26% [37]. It increases with age and often is associated with other LUTS [37]. In men undergoing urodynamic investigation (UDI), DO is present in 40-80% of patients with obstruction [38-40]. In addition, impaired compliance, another potential cause of incontinence, has been shown to have a high correlation with outlet obstruction in men [41,42]. Thus, even before treatment of BPH and BPO there is a notable incidence of bladder dysfunction and incontinence.

Incontinence after the treatment of BPH may be related to 1. sphincter dysfunction (injury), 2. persistent bladder dysfunction or, 3. new onset bladder dysfunction. In 2015, Parker *et al.* reported an incidence of early incontinence of 30–40% and attributed this to UUI related to what was then termed detrusor instability. The authors reported an incidence of 0.5% for late incontinence, which was likely related to external sphincter damage, manifesting as SUI. [43]

In 2007, Han *et al* identified a cohort of men with BPH. From a total of over 12 million men, 411,658 men with BPH (3.3%) were identified. Most of these men (87.5%) did not have prior BPH surgery, but in those who did have surgery, 12.5% were diagnosed with incontinence [44]. The rates were almost identical whether the procedure was transurethral resection or incision, laser, transurethral needle ablation or transurethral microwave therapy [45].

Most studies evaluating post TURP and open prostatectomy incontinence from the past have found a significant incidence of sphincter and bladder dysfunction. The incidence of sphincter dysfunction ranges from 20-92% and bladder dysfunction from 56-97% [46-51].

3.1. Sphincter dysfunction (Injury)

According to Koraitim [19], urine is normally held at the level of the vesical orifice, which is a smooth muscle function. Also, after transurethral prostatectomy (TURP) urine is held at the lower limit of the prostatic cavity, where the lissosphincter is intact, and proximal to the membranous urethra, where the main part of the rhabdosphincter is located. Post-TUR incontinence may result from resecting a few mm in depth distal to the verumontanum, which obviously injures the lissosphincter but leaves the more distal rhabdosphincter intact. The presence of the whole length of the lissosphincter is not essential to maintain continence. However, a minimal length of lissosphincter is crucial below which incontinence is inevitable [19,52].

Causes of sphincter damage related to transurethral or open prostatectomy include direct damage due to poor surgical performance, electrocautery or thermal injury to the sphincter [53].

As mentioned above, incidence of sphincter dysfunction variesfrom 20-92%. The relatively high incidence of sphincter dysfunction may seem surprising as the incidence of DO before treatment is high and it persists in 18- 59% after surgery [38-42]. Therefore, one might expect that many patients would have persistent DO and UUI. However, in large series, sphincter dysfunction appears to be the main cause of incontinence. The high incidence of sphincter dysfunction is likely to represent a selection bias given that many patients are referred to tertiary centers for treatment of stress incontinence. Indeed, Nitti *et al.,* evaluating patients with voiding dysfunction after TURP, found that of those who had incontinence 75% had bladder dysfunction, while only 20% had sphincter dysfunction (the cause of incontinence could not be identified in 5%) [54].

3.2. Bladder Dysfunction (Persistent or new onset)

Turner-Warwick *et al*. first directed attention to the relationship of BOO, the symptoms of frequency, urgency and UUI and the correlation of these symptoms with DO seen on cystometry [55]. They noted that in 75% of men, symptoms were relieved by de-obstruction.

Several contemporary explanations for the cause of persistent overactivity after obstruction endure. These include denervation super-sensitivity of the bladder muscle [56,57], alterations in collagen composition of the obstructed bladder [58], emergence of altered and increased sensory reflexes mediating the micturition reflex [59,60] and physical changes in detrusor myocytes affecting electrical transmission [61] or even the the remaining influence of CRP as investigated by Kupelian *et al* [62]. In addition, the bladder itself,and particularly the trigone may be inadvertently resected during surgery, causing bladder dysfunction or even without prior surgical treatment.

3.3. Different Techniques

Monopolar TURP (M-TURP) has been considered as “gold standard” for the treatment of BPH in the past decades, although it is associated with complications such as transurethral resection syndrome (TURS) and blood loss [63]. Until theearly 2000s, M-TURP and open prostatectomy accounted for the majority of surgical procedures to treat BPO. In 1989, the American Urological Association published two major series on M-TURP and its complications [64,65]. Rates of post-TURP incontinence requiring a pad or collection device were 0.4% in the first and 3.3% in the second study. The AUA Cooperative study also reported mild stress incontinence in 1.2% [65]. In 1994, the Agency for Health Care Policy and Research reviewed the role of M-TURP vs open prostatectomy to analyze treatment outcomes. The panel ranked total incontinence of urine as the fourth most important outcome influencing a treatment decision. After M-TURP, 2.1% of patients experienced stress incontinence, 1.9 % had urgency incontinence, and 1.0% reported total incontinence. For open prostatectomy stress incontinence occurred in 1.9%, urgency incontinence in 0.5% and total incontinence in 0.5% of patients [66].

With the progress of surgical techniques and development of instruments, many transurethral procedures have been invented to overcome the faults of M-TURP. These alternative transurethral procedures include bipolar plasmakinetic, electrovaporization, and various lasers [67]. The modalities of prostate tissue ablation include enucleation, resection, and vaporisation [68].

All available surgical treatments are currently widely used, and each surgical procedure has its own advantages or disadvantages. However, the efficacy and safety of different transurethral procedures for the treatment of BPH are still undefined. Hundreds of randomized controlled trials have compared different types of transurethral procedures. However, most have only compared 2 or 3 types of procedures. The comparative efficacy and safety of different surgical procedures are therefore difficult to estimate [69].

Studies that have evaluated holmium laser resection (HoLRP) and potassium titanyl phosphate (KTP) laser vaporisation of the prostate have shown a similar incidence of incontinence. Two randomized controlled trials of HoLRP versus TURP have shown rates of stress incontinence to be very similar. Westenberg *et al* showed the incidence of stress incontinence with or without urgency incontinence to be 7% for HoLRP versus 6.7% for TURP at a minimum of 4 years follow-up [70]. Kuntz and colleagues found just 1% stress incontinence in each group at 12 months [71]. They also showed a similar rate of resolution of preoperative urgency incontinence for both groups (81% versus 85%). Two other prospective non-randomised trials of HoLEP found 0.6% -2.5% incidence of stress [72]. Two randomised controlled trials of KTP (green light) laser versus TURP reported 0% and 1% stress incontinence in each group respectively [73,74] while a third randomised trial did not mention incontinence [75]. A recent study comparing green light with TURP showed a comparable 24-month outcome and safety profile [76]. Retrospective studies on green light showed a 2- 3.3% incidence of stress incontinence [77,78]. Te *et al.* [79] reported 1-year results of Green Light in the first US multicentre prospective trial. At 12 months 2 of 139 men had persistent new onset UUI And reported no stress incontinence. Others report no superiority outcome for any standard approaches except for hospitalisation time [80].

Recently Sun *et al.* reviewed 88 random controlled trials utilisong fifteen procedures in a network meta-analysis. Procedures included were: DiLEP=diode laser enucleation of prostate, HoLEP=holmium laser enucleation of prostate, HoLRP=holmium laser resection of prostate, ILC= intrestitial laser coagulation, M-TURP=monopolar transurethral resection of prostate, PKEP=plasmakinetic enucleation of prostate, PKRP=plasmakinetic resection of prostate, PVP=photoselective vaporization of prostate, TmLRP=thulium laser resection of prostate, TmLEP=thulium laser enucleation of prostate, TURis=bipolar transurethral resection in saline, TUVP= transurethral electrovaporization of prostate. Stress urinary incontinence frequently occurred in KTP/Nd:YAG laser.HoLEP was the best choice to

reduce the incidence of stress urinary incontinence and retrograde ejaculation even though it demonstrated a potential damage of prostate capsule because of its pulse work mode and requirement of tissue morcellation [81-92]. In general, thulium laser, diode laser, and holmium laser showed equally high efficacy and safety [69].

In 2019, Huang *et al* reviewed 109 trials with a total of 13 676 participants. SUI was reported in 83 trials. The authors saw no significant difference between the new methods and M-TURP for this complication. However, the risk of short-term transient incontinence was higher in enucleation than in resection methods [93].

Recently, new minimally invasive treatment options entered the market. Besides theprostatic urethral lift (Urolift®) none has been compared to TURP. Although the rate of postoperative incontinence did not differ significant after one year (Urolift 85% vs. TURP 75%, p=0.4 patients recovered significantly faster from the minimally invasive procedure [94]. Results of a crossover study (LIFT®) with a two-year follow-up were similar [95]. In the initial published data, Roehrborn reported that UI after Urolift was moderate to mild [96].

In 2015, Aquablation (water ablation) was described as a novel minimally invasive therapy combining image guidance and robotics. In the preliminary study, no cases of urinary incontinence were reported [97]. The same authors reported results at 12 months and confirmed the absence of SUI cases [98]. In 2019, Bhojani *et al* reported a 2% *de novo* incontinence rate at 12 months in patients with large (80-150 cc) prostates [99].

In addition to surgical treatment, males with urinary tract infections had higher adjusted rates of UI with a pooled odds ratio of 3.5 (95% CI: 2.3 -5.2) [100-104].

Acute genitourinary toxicity, enuresis, incomplete urination (residual), and other urological conditions were associated with higher adjusted odds of UI in all studies that examined the relationship [100,105-107].

4. INCONTINENCE ASSOCIATED WITH RADICAL PROSTATECTOMY

4.1. Incidence

The incidence of incontinence after radical prostatectomy, commonly referred to as postprostatectomy incontinence (PPI), has been a source of controversy over the past several decades as reported rates have varied greatly depending on the definition and method of data collection. While multiple factors are associated with the development of PPI, surgical modifications also play a role. The incidence has probably declined over the past two decades, owing to advances in surgical technique and to earlier recognition of lower stage disease in younger patients, however the prevalence of PPI has risen [108].

About 30 years ago, Foote *et al* tabulated data from series published between 1977 and 1990 and reported incontinence rates ranging from 2.5% to 87% after retropubic radical prostatectomy [109]. In general, older single-institution studies utilizing physician assessments to determine incontinence rates reported relatively low rates (5-8%) [110-114]. Another study with a follow-up of up to 5 years reported frequent leakage in 14% or no urinary control men 60 months after diagnosis [115]. A variety of definitions of incontinence were used, making comparison of data difficult. Since then, validated patient questionnaires have helped to standardize definitions of incontinence, allow easier comparison between institutions, and assess of the impact of incontinence on quality of life. This eliminates physician bias, perhaps improving accuracy [116-118]. As expected, these studies show the incidence of incontinence to be significantly higher, 13-65%, depending upon the definition.

There appear to be differences in physician vs. patient reported outcomes and centres of excellence versus community surgeons' outcomes [119]. When trying to interpret all the data, it is clear that the varying definitions of incontinence make comparisons impossible. Even using the definition of pad free, totally continent has its limitations. As in earlier open and laparoscopic prostatectomy series, robotic series tend to be single institution studies with physician reported outcomes and continence status based on no or 0-1 pads. In the meantime, more robust data, comparing open vs. RARP demonstrate that RARP is more likely to result in continence post-operatively [120,121]. Others report this for the early post-operative phase but this seems to equalise after one year [122].

In a systematic review of more than 8000 men who underwent RARP, laparoscopic prostatectomy, or retropubic prostatectomy, Ficarra *et al*. found that for a ''no pad'' definition of UI, rates ranged from 4% to 31%, with a mean of 16%. Considering a "no pad" or "safety pad" definition, the incidence ranged from 8% to 11%, with a mean of 9%. Few comparative studies have evaluated the impact of different surgical techniques on urinary continence recovery after RARP. Posterior musculofascial reconstruction with or without anterior reconstruction was associated with a small advantage in urinary continence recovery 1 month after RARP. Only complete reconstruction was associated with a significant advantage in urinary continence 3 mnthso after RARP (odds ratio [OR]: 0.76; p = 0.04) [121]. Age, body mass index (BMI), comorbidity index, pre-existing lower urinary tract symptoms (LUTS), and prostate volume were preoperative predictors of UI after RARP. The authors concluded that the prevalence of UI after RARP is influenced by preoperative patient characteristics, surgeon experience, surgical technique, and methods used to collect and report data. The techniques purported to provide better functional results were nerve-sparing procedures, bladder neck preservation, preservation of anterior urethral ligaments, and proper urethrovesical reconstruction. RARP appeared to have better continence rates compared to open prostatectomy, whereas bladder neck preservation resulted in better continence rates compared to bladder neck reconstruction.

4.2. Recovery Of Continence After Radical Prostatectomy

While the majority of patients experience incontinence immediately following RRP, in most this is transient with a gradual improvement over time. It is important to consider that there is also a group of incontinent men who might not consider themselves as incontinent [123]. Most studies report progressive return of continence up to one year after surgery and, in general, intervention for incontinence is usually delayed until one year after surgery unless absolutely no improvement is seen. Thus, most prostatectomy series report continence rates at 1 year. Lepor and Kaci [124] showed that, based on objective and subjective measures, continence may continue to improve up to 24

months. They showed modest improvements in bother (UCLA RAND questionnaire), pad usage and rates of total control between 12 and 24 months. Pad weights were not determined so it is possible that some “improvements” could have been related to a change of patient tolerance and expectations over time. Smither *et al*. objectively assessed the natural history of post radical prostatectomy incontinence using a standardised I hour pad test [125]. This study showed a rapid improvement in urinary control during the first 18 weeks post-RRP with a flattening of the recovery curve beyond that point. Minimal incontinence, defined as < 1 g on a 1-hour pad test was as demonstrated in 3,37,66, 85, 87 and 91% of patients at 2, 6, 18, 30, 42, and 54 weeks. They concluded that the 18-week marker appears to be the time point atwhich the majority of patients achieve urinary control, although a small percentage will have continued objective improvement. This estimation is shaired by Sacco *et al.* reporting progressive improvement of continence until two years after RRP, but some patients may become continent even later [126] whereas others report that maximum continence was reached after three months [123].

4.3. Risk Factors

4.3.1. Age

An increased risk of PPI in older men is supported in theory by anatomical observations [108]. With advancing age, there is evidence of atrophy [20] and neural degeneration of the rhabdosphincter [127]. Several studies have shown advancing age to be a risk factor for postoperative incontinence [110,111, 114, 128-130]. Steiner *et al.* [113] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. Catalona *et al.* [110] reported that recovery of urinary continence occurred in 92% (1,223 of 1,325 men) and was associated with younger age (p<0.0001) which might be related to surgical approach (nerve sparing), perhaps performed more often in the younger than in the older patient, although they ultimately reached a similar outcome [131]. Khoder *et al*. noted that a nerve sparing procedure makes sense for older adults (>70y of age); this is of particular importance giventhat this patient group increased significantly over the recent years [132]. In a study that included 308 patients who underwent RARP, Novara *et al.* [133] found that patients who recovered their continence 1 yr after surgery were significantly younger than patients in the incontinent group. Karakiewicz *et al.* [134] reported that age was predictive of urinary functional outcomes among 2415 patients after RP. In an analysis of 2849 patients, Matsushita *et al* [135] confirmed that greater age was an independent predictor of worse continence outcomes at 6 and 12 months after prostatectomy. Conversely, univariate and multivariate analyses of data for 111 patients by Kadono *et al* [136] found no effect of age in continence recovery.

4.3.2. Body Mass Index [108]

A recent metanalysis performed by Wei *et al.* explored 6 trials with 2890 participants. The authors indicated that obesity (BMI ≥ 30) may increase the UI risk at 12 and 24 months after laparoscopic and RARP [137]. Previously, Wiltz *et al.* found that, among 945 patients who underwent RARP, urinary continence outcomes were significantly poorerfor patients with BMI >30 kg/m^2 at 1 and 2-yr follow-up [138]. Conversely, univariate and multivariate analyses of data from 111 patients by Kadono *et al*. revealed that BMI did not predict the post-RP continence outcome [136]. Hsu *et al.* observed no statistically significant relation between body weight and postoperative continence [139]. In one of the larger series evaluating preoperative predictors of urinary continence, Matsushita *et al*. reported that among 2849 patients who underwent prostatectomy, higher BMI was an independent predictor of worse continence outcomes at 6and 12-month follow-up [135].

4.3.3. Prostate size and Membranous Urethral Length (MUL) [108]

Urethral length preservation during RP improves continence outcomes [140]. Cambio *et al.* reported that in patients with a large prostate, RP is theoretically associated with excision of relatively longer parts of the urethra, which might impair continence outcomes in such patients [141]. Hsu *et al.* also assumed that PPI may be explained by pre-existing LUTS among men with a large prostate [139]. In a retrospective analysis of data from 355 patients who underwent extraperitoneal RARP, *Boczko et al.* explored the role of prostate size and found that the 6-months post-RP continence rate was significantly lower for men with prostate size >75 cm^3 than for men with a prostate <75 cm^3 [142]. Konety *et al.* from a group of 2097 patients reported that men with prostate size >50 cm^3 had lower rates of continence at 6 and 12 months after RP. Continence rates equalized across all prostate size categories at 24-mo follow-up [143].

Conversely, univariate and multivariate analyses by Kadono *et al.* [136] using data from 111 patients found that prostate size did not predict post-RP continence outcome. This data aligned with an evaluation of 3067 men performed by Pettus *et al*. who found that prostate size did not appear to have any effect on functional outcomes, includingUI , at 12 months after prostatectomy [144].

Nguyen *et al*. observed that preoperative urethral sphincter length (measured from the prostatic apex to the penile bulb) was approximately 14 mm. Continence recovery at 1 yr was 89% among patients with length >12 mm postoperatively, compared to 77% for patients with length <12 mm. This group also observed that urethral sphincter length was significantly associated with quicker postoperative recovery of continence. Longer preoperative and postoperative length was also associated with higher continence rates [145]. Indeed, Paparel *et al.* noted that preoperative and postoperative mid urethral length (MUL) and the MUL loss ratio were related to recovery time and the degree of urinary continence [146]. Matsushita *et al.* evaluated 2849 men and confirmed that longer MUL was strongly associated with improved continence rates at 6 and 12 months after prostatectomy [135].However, Borin *et al* did not find any difference in continence rates or in the time to achieve continence when dissecting more heavily at the apical borders to achieve less positive surgical margins. The continence rates were similar when the dissection was performed 1 cm below, 0 cm or 1 cm above the urogenital diaphragm. No correlation between continence rates and preoperative or intraoperative urethral stump length was observed [147].

4.3.4. Stage Of Disease

Most large series have found no correlation between the stage of disease and incontinence rates, whereas Loeb reported the importance of aiming to maintain continence in youngers patient in the high-risk group [148]. However, in certain cases, the stage of disease may influence the surgical technique (i.e. nerve sparing), but the effect appears to be related to surgical technique rather than disease stage [111].

4.3.5. Pre-Existing LUTS And TURP before RP [108]

Rodriguez *at al.* investigated the role of pre-existing LUTS in a cohort of 106 patients. They reported that 74 of 106 patients reporting occasional leakage after RP had significantly more noticeable LUTS compared to the 32 patients who were completely dry before surgery [149]. Multivariate analysis by Wei *et al.*, using data from 482 RP patients revealed that pre-RP baseline continence was a significant predictor of post-RP continence [150].

Pompe *et al.* analyzed a group of 470 patients who underwent TURP before RP. TURP patients exhibited a higher risk for urinary incontinence at the third post operative month (OR:1.47; 95% confidence interval [CI]1.01−2.12, P=0.04) and after the first year (OR: 2.06; 95% CI1.23−3.42, P=0.006) [151]. Conversely, in a controlled trial involving 124 patients, Palisaar *et al*. reported no significant difference in PPI rate between patients with and without TURP before RP [152].

4.3.6. Salvage RP Following Radiation Therapy (RT)

Patients who have undergone prior radiation for prostate cancer are at high risk of developing incontinence after RP with the possible need of postoperative RT [148]. In the past, some authors reported rates of incontinence after salvage prostatectomy ranging from 57-64% [153, 154]. In 2006, Sanderson and colleagues reported that 45% of men underwent artificial urinary sphincter placement after salvage prostatectomy and another 31% without an artificial sphincter had incontinence greater than occasional dribbling [155].

In a more recent systematic review, Chade *et al.* reported continence rates — defined as using no pads — ranging from 21% to 90% for open surgery, from 67% to 78% for laparoscopic surgery, and from 33% to 80% for robotic surgery [156].

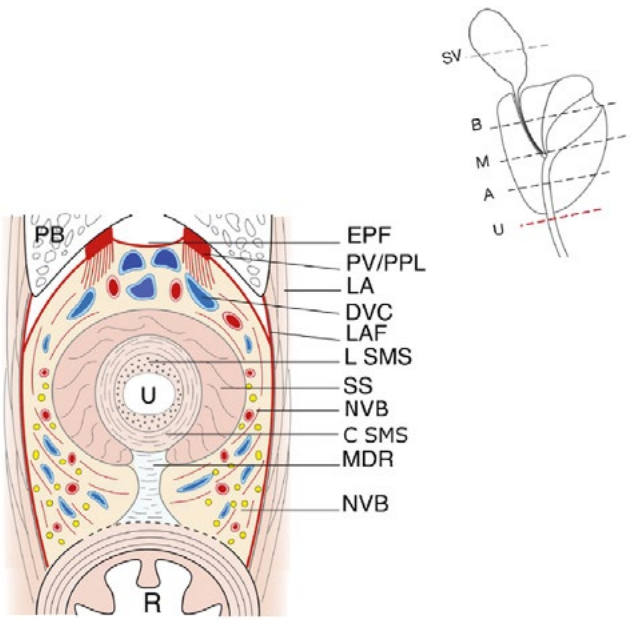

Figure 3: Axial section of the sphincteric urethra.
A = apex; B = bladder; C SMS = circular smooth muscle sphincter; DVC = dorsal vascular complex; EPF = endoplevic fascia; LA = levator ani muscle; LAF = levator ani fascia; L SMS = longitudinal smooth muscle sphincter; M = midprostate; MDR = median dorsal raphe; NVB = neurovascular bundle; PB = pubic bone; PV/PPL = pubovesical/puboprostatic ligament; R = rectum; SS = striated sphincter; SV = seminal vesicle; U = urethra.

A Critical Analysis of the Current Knowledge of Surgical Anatomy of the Prostate Related to Optimisation of Cancer Control and Preservation of Continence and Erection in Candidates for Radical Prostatectomy: An Update. Eur Urol 2016.

4.4. Etiology nd Pathophysiology of Post Radical Prostatectomy Incontinence: Sphincter Vs. Bladder Dysfunction

There is extensive literature on urodynamic investigation of post prostatectomy incontinence. While it is well established that both bladder and sphincter dysfunction may be present after RP, most studies agree that sphincter dysfunction (stress incontinence) is the main cause.

As described by Walz *et al*., the trigone may play a role in the maintenance of continence given that is formed by fibres of the vesical sphincter, which is an elliptic structure formed by circular smooth muscle fibres arranged circumferentially around the urethral opening. This muscular structure is part of the vesical sphincter that assures continuous urinary continence as well as bladder neck closure. Inferiorly, circular fibres of this muscle surround the proximal prostatic urethra down to the colliculus seminalis. This part of the sphincter is modified by and interspersed with the development of BPH, and the intravesical part may be displaced upwardsinto the bladder lumen [157]. The so-called bladder neck–sparing technique is performed in this anatomical area with the aim of improving postoperative continence. To date, the effect of bladder neck sparing on urinary continence, is unclear and no clear conclusion for or against the technique can be drawn [121,157-160]. Multiple studies have shown this to be a contributing factor [161-163]. However, Marien and Lepor showed that sparing of the bladder neck has no effect on continence rates [164].

Some have suggested that denervation of the urethra or the bladder may occur during radical prostatectomy. John *et al.* [165] studied trigonal innervation by biochemical markers and found that urinary incontinence was associated with decreased trigonal innervation, a high sensory threshold and low maximal urethral closure pressure which was evaluated differently by the same author in different reports [166].

Heesakkers *et al.* reported that there is some evidence that neurovascular bundles (NVBs) may play a role in PPI [108]. There is debate about the role and extent of the contribution of the NVB in the innervation of the external urethral rhabdosphincter [167,168]. Moreover, Strasser and Bartsch [169] found that the NVB directly innervates the membranous urethra leading to the thought that damage to the NVB does affect the continence mechanism and preservation does lead to at least earlier recovery of continence after RP. This has been shown by many good quality studies [126, 161, 170-174]. However, it has also been questioned by others who saw no difference in continence rates between nerve-sparing and non–nerve-sparing techniques [164].

Supporting structures of the membranous urethra may also play a role. Several studies have shown that preservation of the puboprostatic ligament and pubo-vesical ligament to allow proper sphincter functioning improves PPI [175-178]. Reconstruction of the posterior musculofascial plate of Denonvilliers or the

posterior fibrous raphe, a technique also known as the Rocco stitch, seems to improve PPI, as shown by multiple studies [175,179,180], although some surgeons did not note a similar improvement in continence after RP [181]. Total pelvic reconstruction with fixation and anchoring of the sphincteric complex and the bladder urethra anastomosis anteriorly and posteriorly has several biomechanical advantages and also seems to result in earlier return to continence [175].

Bladder dysfunction has been explored as a cause of PPI. Ficazzola and Nitti found that although 46% of patients reported bladder dysfunction, incontinence on UDS was demonstrated in only 27% in the context of an overwhelming majority of sphincter dysfunction [182]. Groutz and colleagues found a 33% incidence of bladder dysfunction but found that thiswas the main cause of incontinence in only 7.25% [183]. Some authors argue that in some patients with severe intrinsic sphincter deficiency, bladder dysfunction may occur as a result of filling the bladder to volumes to whichit is unaccustomed to holding [182].

Giannantoni *et al.* reported that after RRP a high proportion of patients (70.3%) were affected by DO. About half of these patients complained of overactive bladder (OAB) symptoms, in whom DO was observed in 61.2% before surgery. This suggested that DO may be attributed to surgical damage in a small percentage of patients [184]. At the 36-month follow-up, the dysfunction persisted in 56.3% of 32 men, and about 40% of these presented with OAB symptoms. At the three-year follow-up, the dysfunction persisted in 25% of cases [184]. Recently, Matsukawa *et al.* reported that *de novo* OAB was observed in 37.8% (87/230) of patients and that post-operative continence was significantly more likely in the OAB-free group (79.7%) than in the *de novo* OAB group (8.0%) [185].

Filling to capacity during cystometry may induce DO or give the impression of compliance. Thus, bladder dysfunction could be interpreted as an artefact, but could also demonstrate a partial decentralization of the bladder combined with somatic denervation, as a result of bladder mobilization during prostatectomy [182]. The branches of the pudendal nerves innervating the pelvic floor muscles and the striated urethral sphincter split before reaching the urogenital diaphragm. In addition, bladder dysfunction may stem from obstructive uropathology present before prostatectomy. For the placement of an artificial sphincter, the 2015 consensus conference suggested waiting at least 6 months following prostatectomy \ [186]. Recently a network metanalysis failed to reach consensus regarding the definition of severity of incontinence and found no statistically differences in continence rates when AUS versus adjustable sling were compared, with an RR of 0.78 (95% CI: 0.09-6.56) [187]. Machioka *et al*. recently suggested the use of the International Consultation on Incontinence Questionnaire-Short Form (ICIQ-SF) and 24-h pad weight test to compare UI status pre- and post-RP [188].

Post prostatectomy bladder dysfunction may have been present preoperatively, for example due to pre-existing outflow obstruction, may be caused by the operation itself, or may be due to age related changes in bladder function. Indeed, Juszczak *et al.* suggested that bladder hypertrophy could be identified as a predictor of OAB and/or UUI in the general population, as well as in patients after radical prostatectomy [189] and argued that preoperative OAB patients are at a higher risk of developing more severe UI after RP [190]. There are currently no data on how preoperative management or surgical technique may prevent post-prostatectomy OAB [191]. However, Yamada *et al.* reported that baseline OAB seemed to represent an independent negative predictor for recovery of continence within 12 months after RALP (p = 0.019) [192].

5. INCONTINENCE RELATED TO RADIATION THERAPY FOR PROSTATE CANCER

Radiation therapy, whether external beam or brachytherapy, can be a cause of voiding dysfunction and incontinence [7, 193]. Sometimes this is a direct effect of the radiation or it can be related to the treatment of other sequelae such as urinary retention. The initial response is primarily oedema and then gradual degeneration, fibrosis and disorganization of the bladder musculature. While radiation is primarily delivered to the prostate, portions of the bladder may also be affected [7]. Perivascular fibrosis of blood vessels may then cause vascular occlusion followed by ischaemia of the bladder wall, which can then progress to fibrosis within 6 to 12 months [194].

Symptom-specific associations to dose distribution have been demonstrated for urinary symptoms [195]. Global symptoms, like increased urinary frequency, are likely associated with the dose distribution across the whole bladder (i.e. mean dose) while associations with dysuria, haematuria and incontinence were shown to be more localized, dependent on the area of the bladder receiving a high dose [193,196].

A recent prospective study by Mylona *et al.* analyzed 272 patients with prostate cancer treated with intensity-modulated radiation therapy/image-guided radiation therapy. The authors observed that a local dose-effect relationship was found in the bladder and the urethra. Symptom-related subregions were identified for 5 symptoms: acute incontinence in the urethra, acute retention in the bladder trigone, late retention and dysuria in the posterior part of the bladder, and late haematuria in the superior part of the bladder, with significant dose differences between patients with and without toxicity, ranging from 1.2 to 9.3 Gy. This led to the conclusion that the dose delivered to the urethra and the posterior and superior parts of the bladder was predictive of acute incontinence and retention and of late retention, dysuria, and haematuria [197].

The rate of severe late incontinence ranges between 1 and 5% at 3–5 years after RT end, although higher incidences were reported with ultra-high doses and in the post-operative setting [198,199]. Moreover, Corazzini *et al.* reported that the risk of late patient-reported urinary incontinence markedly increased for 2Gy equivalent dose (EQD2) > 80 Gy. Previous abdominal/pelvic surgery and previous TURP were significantly predictive of late patient-reported urinary incontinence [200].

Choo *et al.* found that urodynamic bladder capacity decreased by an average of 54 ml, 18 months after radiation therapy [201]. Blaivas *et al.* evaluated 47 men with symptomatic LUTS after brachytherapy and found that 71% were incontinent and 85% had detrusor overactivity [202]. Similarly, radiation can cause damage to the distal urinary sphincter, which can result in incontinence.

Urinary retention and increased obstructive LUTS are other common problems particularly following brachytherapy. The

incidence of retention reportedly ranges from 2% to 30% after brachytherapy [203-205]. Most patients with retention will have resolution within weeks while others may require surgical procedures. Flam *et al*. reported that 19 of 600 (3.1%) patients receiving brachytherapy required TURP [206]. Kollmeier and colleagues reported a similar rate of 2% in 2050 men [207]. Incontinence following TURP after brachytherapy has been reported in 0-70% and is often severe [206-208]. External beam radiation is also a risk factor; Green *et al*. reported a 33% incidence of incontinence following TURP in patients post-irradiation for prostate cancer [209]. Some authors have emphasized that incontinence can be minimised by performing a limited resection [210] or by performing TURP within 2 years of brachytherapy [207]. However, others suggest that delaying TURP until 5 years after radiation can actually reduce the risk of incontinence [210].

6. CONCLUSIONS

Incontinence in the male can be broadly divided into causes related to bladder and/or sphincter dysfunction. The pathophysiology of incontinence is fairly well described; however, advances in science and anatomy will undoubtedly provide better understanding in the future. Although the causes of sphincter insufficiency are known (i.e. damage to muscle, nerve and/or supporting structures), sometimes clinicians are not able to accurately assess the exact cause. Therefore, much of our understanding of post treatment incontinence "pathophysiology" is derived from reports of incontinence (incidence/prevalence) after surgery or radiation. Following the AUA/SUFU guidelines, the time of incontinence after any procedures may vary; although non-surgical options, such as pelvic floor muscle exercises (PFME), can hasten continence recovery, patients who remain incontinent at one-year post-procedure, or have severe incontinence at six months, may elect to undergo surgical treatment [211].

In addition, the incidence of incontinence related to interventions for prostatic disease is still difficult to determine. Two future directions are important: a better standardization of pre and after treatment incontinence evaluation and a more accurate reporting data. New technologies for the treatment of BPH have been largely described and will provide additional evidence in the future.

Data regarding the incidence of post-radical prostatectomy incontinence is increasing due to the use of metanalysis.

II. PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE, FAECAL INCONTINENCE AND PELVIC ORGAN PROLAPSE IN WOMEN

1. ANATOMY AND PHYSIOLOGY OF THE FEMALE UROGENITAL DIAPHRAGM

The factors necessary for the urethra to remain closed at rest and during increased abdominal pressure have been well characterized, but their functional inter-relationships are still not fully understood. These factors include: 1) a healthy, functioning striated sphincter controlled by pudendal innervation, 2) well vascularised urethral mucosa and sub- mucosa, 3) a properly aligned and functioning intrinsic urethral smooth muscle, and 4) intact urethro-vaginal support.

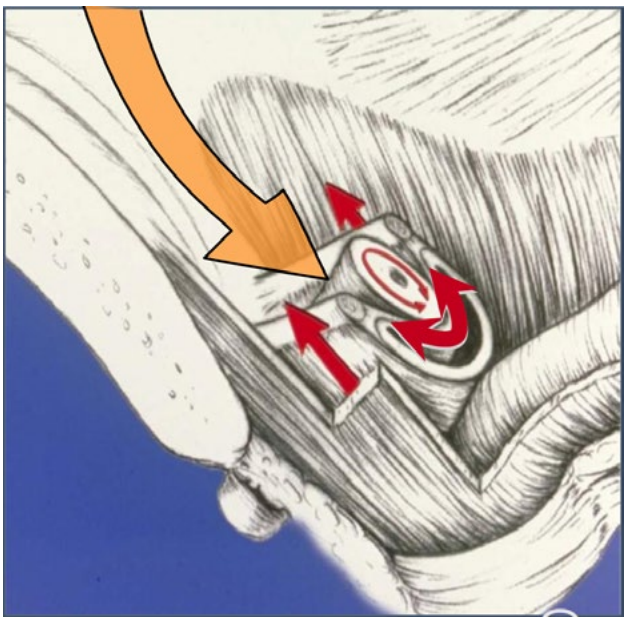

Figure 1: Schematic view of the continence mechanism seen from the right side after removal of near-side structures. The upward red arrows indicate the effect of levator ani muscles; the upward curving arrow, the fascial layer under the urethra; and the circular arrow, the spincter's action. The orange downward arrow, the effect of abdominal pressure on the system. © DeLancey

There are many historical theories proposed to explain stress incontinence. More recently, scientific studies have been conducted comparing objective measurements between stress incontinent and continent women that provide data against which these theories can be tested. Current data indicate that a combination of a weak urethral sphincter and disruption in the supportive mechanism of the bladder and urethra are both involved. [1; 2] and weakening of the muscular structures of the pelvic floor, bladder neck and urethral sphincters [3] can cause SUI. A view of the aspects involved in continence is seen in Figure X. Unfortunately, considering the complex interactions among tissue morphology, mechanical properties, perfusion, innervation and motor control, several factors may contribute to the pathophysiology of SUI, yet the evidence for some of these factorsis lacking, and their relative importance is largely unknown [1].

"The Integral Theory" (IT) [4] stated that stress urinary incontinence is mainly caused by connective tissue laxity in the vagina or its supporting ligaments. However, the "Urethral Hanging Theory" (UHT), hasquestioned the rationale of the IT. This theory states that is proximal urethral funneling also contributes to SUI and failure of sling procedures, [5]. IT and UHT both emphasize Pubo-urethral ligaments (PUL) as important structures, but are principally different [6]. IT postulates that the pathophysiology of SUI is multifactorial and that no single method can be expected to cure all patients. UHT postulates that the pathophysiology of SUI is unifactorial and that the cure is to "stop urethral hanging." Preventin the urethra from descending downward. Another recent theory suggests that continence is a result of defects in passive as well as active urethral closure mechanisms. The smooth muscles of the urethra, the vascular bed, and the oestrogen influenced urethral mucosa, combined with striated muscle tone, contribute to the intra-urethral pressure. A passive transmission of force to the urethra exists only in the abdominal proximal third of the urethra. In the distal two thirds of the urethra an active closure mechanism is present, dependent on sufficient urethral support in the proper anatomical position. This active closure mechanism is generated by reflex contraction of striated muscles of the urethra and the pelvic floor, milliseconds before abdominal pressure increases. [7].

1.1. The Female Urethral Sphincter and Perineal Membrane

Because failure of the urethral sphincter is a key factor in causing stress incontinence, an understanding of its structure and function is necessary. Detailed descriptions of the striated urogenital sphincter muscle have been made by Max Brodel working with Howard Kelly [8], Oelrich [9] and further expanded by DeLancey [10]. These reports have provided clear descriptions of the urethral rhabdosphincter. The location of the sphincter elements can be understood by dividing the urethral lumen into 5 equal segments. The first 20% is surrounded by the bladder muscle and detrusor loop, the next 40% surrounded by a sleeve of striated muscle that forms the sphincteric portion of the striated sphincter. Next, from 60 to 80% two arch shaped bands of muscle diverge from the wall of the urethra to surround the vagina (urethrovaginal sphincter) and perineal membrane (compressor urethrae). Manometric and electrophysiological recordings from the mid urethra have shown that it generates the highest level of resting pressure and electromyographic activity. This portion of the urethra is an intra-pelvic structure located immediately posterior to the pubic bone. In the past, much has been made of the loss of this intra-pelvic position in stress incontinence. It had been suggested that when the urethra descends away from its intra-abdominal position, intra-abdominal forces no longer constrict it during straining. This concept has survived and been modified into the "hammock hypothesis" [11] which suggests that the anterior vaginal wallprovides a backboard against which increasing intra-abdominal forces compress the urethra. The anterior vaginal wall is stabilized by its lateral attachments to the arcus tendineus fascia pelvis and levator ani muscle. Data supporting this hypothesis are drawn from urethral pressure transmission studies showing that continent patients experience an increase in intra-urethral pressures during coughing. This pressure increase is reduced in stress incontinence and may be restored following successful surgical

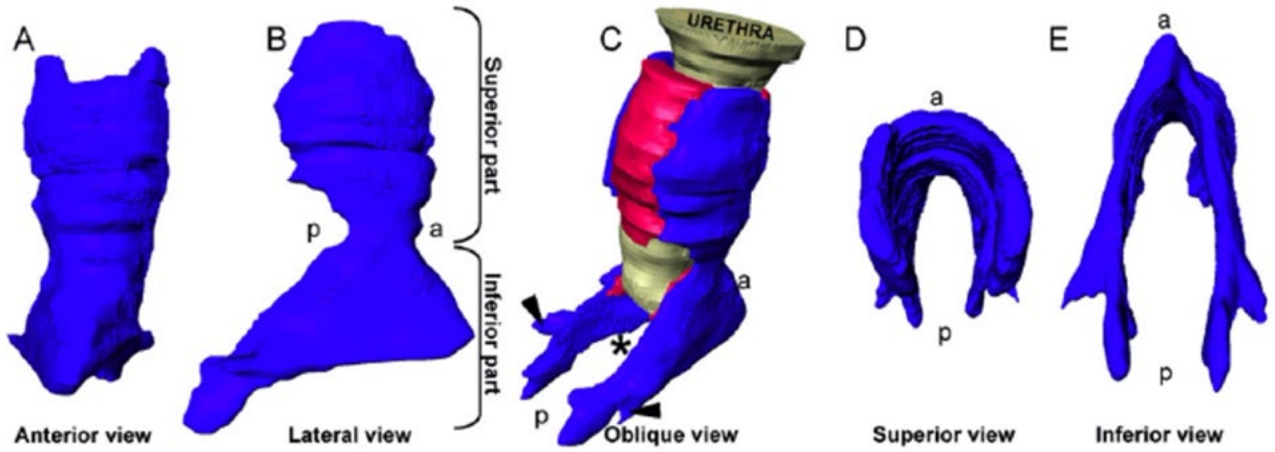

Figure 2: EUS in 18 weeks female foetus: A anterior view, B lateral view, C oblique view, D superior view, E inferior view - From Wallner et al., Eur Urol 2009 [222].

interventions designed to stabilize or elevate the sub-urethral vaginal wall [12-21].

The urethra is supported by the anterior vaginal wall. The superior vaginal sulcus, most clearly found in nullipara, exists at this junction of the lower and middle third of the vaginal wall. This point represents the two lateral insertion points of the vaginal "hammock ". Portions of the pubococcygeus muscle attach to these to sulci within the pelvis and can produce elevation during voluntary contraction.

Immediately anterior to the proximal urethra are found the reflections of the endopelvic fascia. The most prominent of these, the attachments of the arcus tendineus fascia pelvis (sometimes referred to clinically as "pubo-urethral ligaments", are sufficiently condensed to form distinct and recognizable ligaments on either side of the pubis where they attach to the pubic bone about 1 cm from the midline and 1 cm above the bottom of the pubis. These structures are continuous with a complex of tissues including the perineal membrane and levator ani. The arcus tendineus fascia pelvis, which can be seen at the time of retropubic surgery, are the more familiar of these. These are strong fascial condensations which most likely maintain their characteristics throughout life. Previous investigators have suggested that elongation of these structures may be responsible for the loss of urethral support seen in stress incontinence, yet objective evidence for this is lacking.

Different authors have described the striated urogenital sphincter (SUS) that has also been called the external urethral sphincter (EUS) by some authors, both in fetuses [22, 23] and adults [24] as a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina.

The Levator Ani Muscle (LAM) is involved in urethral support. Wallner *et al.* [25] investigated the topographical relationship between the SUS and the LAM (Figure 8.9), showing that in female fetuses, but not in male, the inferior part of the EUS is firmly attached to the LAM by a tendinous connection. This determines an anterior bending of the midurethral zone when a simultaneous contraction of the LAM and EUS occurs, closing the urethral lumen and maintaining continence. The functional

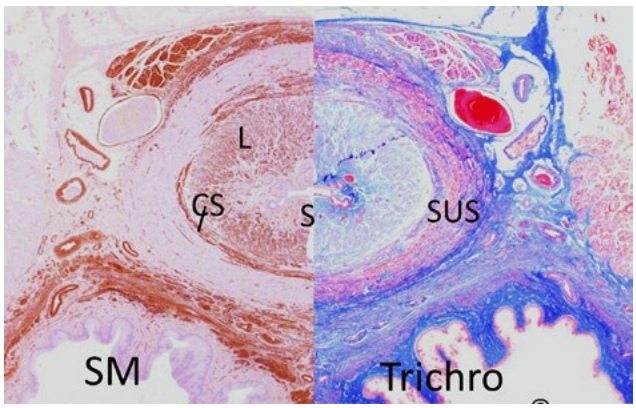

Figure 3: Axial midurethral actin immunoperoxidase histological section for smooth muscle (SMA) (a) and mirrored Mallory trichrome histological section (b) from the same specimen. A few small spots are identified in the submucosa (SM). The longitudinal (LMU) and circular (CMU) smooth muscle of the urethra, the pubovesical muscle (PVeM), and the smooth muscle layer of the anterior vaginal wall (AV) are easily identified on the actin-stained immunoperoxidase preparation, whereas the striated urogenital sphincter muscle (SUS) does not stain with actin. Abbreviations: ATFP, arcus tendineus fasciae pelvis; LA, levator ani muscles.

integrity of this connection between the EUS and the LAM is therefore crucial to avoid urinary incontinence.

The striated external urethral sphincter (EUS), both in fetuses and adults, has a superior horseshoe structure covering the urethra and an inferior one surrounding the anterolateral aspect of the urethra and the lateral part of the vagina.

Moreover, while the lower one-third of the vagina is orientated more vertically in nullipara, the upper two-thirds of the vagina deviate horizontally ~~[Iuo 2016].~~ This orientation is dueto the posterior attachments of the cervix by the cardinal and utero-sacral ligaments and to the anterior position of the levator hiatus.

Modifications of the genital hiatus determining an increase in the genitohiatal distance can be associated with urodynamic

stress incontinence. In a retrospective study of 396 women with urodynamic stress incontinence [26], pelvic floor ultrasound revealed a small but statistically significant negative association of the genitohiatal distance to urodynamic functional urethral parameters such as the functional profile length, the maximum urethral closure pressure and a low Valsalva leak-point pressure ($r = -0.148$, $P = 0.018$ and $r = -0.227$, $P = 0.009$, $r = -0.199$, $P = 0.02$ respectively) that would explain about 5% of the observed variation.

2. EFFECT OF CHILDBIRTH, VAGINAL PROLAPSE AND URETHRAL POSITION ON URINARY CONTINENCE

2.1. Introduction

Labour and delivery alter vaginal and pelvic anatomy and innervation in several ways as has been discussed in other sections of this chapter. Each of these may contribute to the eventual development of urinary incontinence:Direct crushing or traction on the pudendal nerve has previously been suggested as a primary cause of sphincter incompetence in stress incontinence. The pudendal nerve, which projects from Onuf's nucleus and traverses Alcock's canal before entering the ischiorectal fossa and innervating the EUS, can be injured during vaginal delivery, particularly in the area between the sacrospinous and sacrotuberous ligaments. Two different mechanisms of pudendal nerve damage during delivery have been described: 1) nerve compression and stretching which may cause an elongation of the 13% of its motor branch innervating the EUS [27]; 2) reduced at8% stretch and complete ischaemia at 15% stretch of the nerve in a tibial nerve rat model [28]. Thus, pudendal nerve ischaemia could occur during vaginal delivery as a result of both stretch and compression [29]. However, evidence of denervation associated with childbirth has been extensively evaluated in the literature, yet longitudinal studies [30] fail to correlate such changes to urinary incontinence symptoms later in life, leaving their role in the childbirth-related stress incontinence somewhat unclear.

Birth damage to the innervation of the pelvic floor might also be an important factor in the aetiology of SUI. Neuropeptides, which are considered a marker of nerve damage, are well-represented in the innervation of the human female reproductive tract. Neurons that contain vasoactive intestinal polypeptide (VIP) are abundant in the vagina, where they innervate blood vessels and smooth muscle in the vaginal wall and form a plexus beneath the epithelial layer. Previous studies have shown that VIP levels were significantly decreased in the anterior vaginal wall in premenopausal and postmenopausal SUI patients. Also, neuronal Nitric oxide (nNO), an anorganic free-radical gas that stimulates soluble guanylyl cyclase activity and creates smooth muscle relaxation, decreased significantly in the anterior vaginal epithelium of the patients with SUI [31]. Although visible damage to the levator ani is more common in stress incontinent women soon after birth [32], they are not more common in women presenting for treatment of SUI later in life [33]

Some authors have suggested that cardinal and utero-sacral ligaments may be stretched or torn, resulting in anterior displacement of the uterus during straining or under the influence of gravity. Lepage *et al.*, [34] using a computerized pelvic model of the pregnant woman at term during a simulated delivery, showed that utero-sacral ligaments undergo a displacement depending on the size of fetal head. When a fetal head at the 50th percentile for the term goes through the pelvic system, uterosacral ligaments undergo a deformation of around 30%. Another computerized analysis [35] revealed an increase in the length of utero-sacral ligaments during the pregnancy. Shortening occurs during the postpartum period but the ligaments do not return to their initial length. These results confirmed that lesions of utero-sacral ligaments, which are the major pelvic sustaining structures, may be a potential cause of pelvic floor disorders. These observations require validation in clinical testing to see whether these simulations correspond to what is seen during human birth.

The vagina itself may be torn away from its intrapelvic attachments with subsequent loss of the superior vaginal sulcus. There may be direct attenuation of the vaginal wall itself, manifested by loss of vaginal rugae and a thin appearance. Cullen-Richardson has suggested four distinct kinds of vaginal injuries: paravaginal, central, distal, and cervical, the first two being the most commonly seen in women with stress incontinence. These defects have been identified by sonographic examination [36]. Finally, detachment of the pubococcygeal (sometimes called pubovisceral) portion of the levator ani muscle occurs during birth and results in a longer and wider levator hiatus and reduced force of contraction [37, 38]. This is not due to nerve injury or muscle compression as sometimes suggested. Here, the perineum is displaced anteriorly and posteriorly under stress and temporarily fails to support the pelvic organs. These changes in the levator hiatus with or without associated relaxation of cervical support result in chronic anterior displacement of pelvic organs with a loss of both active and passive organ support during rest and especially during straining. In the patient with stress urinary incontinence these changes typically give rise to a rotational descent of the proximal urethra away from its retropubic position.

A direct comparison of 80 primiparous women with de novo stress incontinence that persisted 9 months after vaginal birth to 80 women who did not develop incontinence and 80 nulliparous women of the same age allows urethral function and support to be evaluated [32]. Urethral closure pressure was 25% lower in primiparous incontinent women compared to continent women, who were similar to nulliparous women. Vesical neck movement measured during cough with ultrasonography was 5 mm more in stress incontinent women than the other two groups. In logistic regression, urethral closure pressure explained 25% of incontinence while support explained 16%. Levator injuries were twice as common in the incontinent group. Studies on passive and active material parameters of the pubovisceralis muscle using an inverse numerical method, showed as incontinent women have a lower passive parameters as consequence of softer muscles. This may be explained by a significant reduction of type III collagen, due to increased degradation of nascent collagen rather than decreased production. Thus, incontinent women have decreased active force and stiffness that can be associated with muscular weakness. Furthermore, also showed that incontinent women have an increased number of fibres, but these are significantly narrower than that of the asymptomatic women [39].

Mechanical injury of the pelvic floor (such as childbirth) may disrupt the supportive tissues and connections via the remodeling of Extra Cellular Matrix (ECM). Then, the urethra will lose the hammock-like support and result in SUI. The metabolism of

ECM shows an increase of matrix synthesis in response to suitable mechanical strain, while excessive force would reduce the production of ECM, which may be one of the main pathological mechanisms underlying childbirth trauma-induced SUI.

Tang *et al.* suggest that mechanical strain induced ECM remodeling of L929 fibroblasts might be associated with Nrf2/ARE signaling suppression mediating TGF-β1/Smad3 signaling inhibition, which might be the pathomechanism of mechanical trauma-induced SUI. This might reflect a new molecular target for SUI research. [40]

Perineal sonographic studies of urethrovesical angle found differences in women with stress incontinence compared to women with other urologic disorders have found excellent correlation between the angle and degree of incontinence, supporting these original observations [41].

Although we have considerable knowledge about anatomical defects in most patients with urodynamic stress incontinence (USI), less is understood about the effect of these defects and the vaginal position itself, on urethral closure. Early experience with operations for stress incontinence showed that not all women with stress urinary incontinence had vaginal prolapse, that correction of vaginal relaxation did not always correct stress incontinence, and that women who developed recurrent stress incontinence symptoms after apparently successful surgery did not necessarily show a recurrence of their prolapse [42].

In animal models, the effect of anatomical defects in the urethral mechanism induced by vaginal delivery has been investigated. A rat model of birth trauma has been simulated inducing vaginal distension by balloon catheter inflation [43]. Sneeze induced stress urinary incontinence was caused by decreased active closure mechanisms at the mid urethra without affecting the passive transmission of abdominal pressure in the proximal urethra. The greater involvement of the urethral mechanism in the occurrence of post-partum stress incontinence was confirmed in a case control study evaluating urethral closure pressure and bladder neck movement assessed with ultrasound [32]. Eighty primiparous women complaining of de-novo stress incontinence 9-12 months after delivery were compared with 80 primiparous continent and 80 nulliparous continent women. Lower maximal urethral closure pressure followed by vesical neck mobility was most likely to be associated with de novo stress incontinence after first vaginal birth.

2.2. Role of childbirth, vaginal prolapse and urethral position

2.2.1. Role of childbirth

Childbearing is an established risk factor UI among young and middle-aged women. It has been suggested that vaginal delivery is the main contributing factor, possibly because of damage to important muscle tissue or nerves. However, pregnancy itself may cause mechanical changes, hormonal changes, or both that can lead to UI.

The Swedish Pregnancy, Obesity and Pelvic Floor (SWEPOP) study demonstrated that 20 years after one birth, vaginal delivery was associated with a 67% increased risk of urinary incontinence (UI), and UI > 10 years increased by 275% compared with caesarean section. [44] These data showed also that the prevalence of all three subtypes of UI (stress urinary incontinence (SUI); urgency urinary incontinence (UUI) and mixed urinary incontinence (MUI)) 20 years after one delivery was higher after vaginal delivery (VD) compared with caesarean section (CS). This was also the case for the prevalence of bothersome UI, the severity of UI and the severity of each subtype of UI. Moderate to severe incontinence occurred in two-thirds of women with MUI, in every second woman with UUI, whereas two-thirds of women with SUI had mild symptoms. [45] LEVEL OF EVIDENCE: II

The largest community-based study (EPICONT study) [46] evaluated the risk of incontinence associated with CS and VD on the 15,307 women < 65 years and who either were nulliparous or had only caesarean deliveries or only vaginal deliveries. The prevalence of any incontinence was 10.1% in the nulliparous group; age standardized prevalences were 15.9% in the CS group and 21.0% in the VD group. As compared with nulliparous women, women who had CS had an adjusted OR for any incontinence of 1.5 (95 % CI, 1.2 to 1.9) and an adjusted OR for moderate or severe incontinence of 1.4 (95 % CI, 1.0 to 2.1). Only SUI and MUI were significantly associated with CS. The adjusted OR for any incontinence associated with VD as compared with CS was 1.7 (95 % CI, 1.3 to 2.1), and the adjusted OR for moderate or severe incontinence was 2.2 (95 % CI, 1.5 to 3.1). Only SUI (adjusted OR, 2.4; 95% CI, 1.7 to 3.2) was associated with the mode of delivery. The authors concluded that the risk of UI is higher among women who have had CS than among nulliparous women and is even higher among women who have had vaginal deliveries. CS seems to decrease the postpartum UI, but its protective effect seems to diminish over time and disappears after multiple deliveries. [46,47] LEVEL OF EVIDENCE: II

In a systematic review and metanalysis Tahtinen *et al.* [48] looked for the long-term effects of childbirth on urinary leakage. From 15 eligible studies, they found that compared with CS, VD was associated with an almost twofold increase in the risk of long-term SUI, with an absolute increase of 8%, and the effect is largest in younger women. LEVEL OF EVIDENCE: II

In the cohort study extracted from national Swedish Medical Birth Registry between 1973 and 1982 [49], two groups were identified: 30,880 women who had their first and all subsequent deliveries by CS vs. an age-matched sample of 60,122 women who delivered vaginally only. SUI surgery was observed in 0.4% of the CS group and 1.2% of the VD group (follow-up time 26.9 years), and the risk of SUI was estimated to be 2.9 times higher after VD compared with women after CS. Among women with VD, rates of SUI surgery increased with the number of births, whereas in the CS cohort it slightly decreased. Compared with CS, the risk of SUI was more than doubled for VD with vacuum extraction and tripled for a vaginal non-instrumental delivery. After VD, the incidence rates for SUI surgery steadily increased, reaching a peak close to 3 decades after the first delivery. For CS, the incidence of SUI increased more slowly and started to diverge from the curve for vaginal delivery very early (Figure 1). LEVEL OF EVIDENCE: III

The group of Tähtinen [50] recruited 13,694 women > 20 years after a VD for two surveys addressing SUI and UUI: of these 12.7% reported SUI. Among women <50 years, there was a statistically significant difference in the risk of SUI for forceps delivery (OR 1.42, 95% CI) but not for vacuum (OR 0.80, 95% CI) when compared with spontaneous VD. Among women <50 years, forceps also had increased risk for SUI (OR 1.76, 95% CI) when compared with vacuum. In this large population-based study of women across a wide age range, forceps delivery was associated with a significantly increased long-term risk of SUI among women <50 years, but there was no longer a measurable impact for women >50 years. LEVEL OF EVIDENCE: III

In a prospective study, Hansen *et al.* [51] investigated the impact of the first pregnancy and delivery on the prevalence and types

of UI during pregnancy and 1 year after delivery. The prevalence of SUI during pregnancy was 3.3 times higher compared with a control group of nulliparous women. After 1 year, the difference was reduced, but still 2.5 times higher in the primiparous group. LEVEL OF EVIDENCE: II

Twelve risk factors associated with postpartum SUI have been identified: vaginal delivery (OR 2.08, 95% CI 1.72–2.52), advanced age at gestation (OR 1.06, 95% CI 1.04–1.08), advanced maternal BMI (OR 1.04, 95% CI 1.03–1.06), excess weight gain during pregnancy (OR 1.13, 95% CI 1.00–1.26), advanced current BMI (OR 1.32, 95% CI 1.02–1.70), diabetes (OR 1.91,95% CI 1.53–2.38), episiotomy (OR 1.76, 95% CI 1.06–2.94), forceps delivery (OR 2.69, 95% CI 1.25–5.76), gestational UI(OR 5.04, 95% CI 2.07–12.28), gestational SUI (OR 4.28, 95% CI 2.61–7.01), prenatal UI (OR 8.54, 95% CI 3.52–20.70), and early postpartum UI (OR 3.52, 95% CI 1.61–7.69). [56] LEVEL OF EVIDENCE: II

Although most women with postpartum SUI regain continence within 1 year but they have a greater predisposition to develop recurrent SUI years later: among women with postpartum SUI, 92% had recurrent SUI 5 years later. [52] Indeed, trauma to the pelvic floor nerves, muscles, and connective tissue during pregnancy and vaginal delivery may persist even in the absence of SUI symptoms and could become an underlying risk factor for later development of SUI. [29] That is demonstrated by the fact that transient antepartum or postpartum SUI is predictive of later development of recurrent SUI. [53]

These findings suggest that even with functional recovery from postpartum SUI, there are latent pathophysiologic changes in the continence mechanism, which could lead to later development of recurrent SUI. LEVEL OF EVIDENCE:III

In a multicentre trial including 2305 twin pregnancies without history of SUI, women in the planned caesarean group had lower SUI rates compared with women in the planned vaginal birth group [8.11% versus 12.25%; OR, 0.63; 95%CI, 0.47–0.83; P = 0.001]. However, among those with problematic SUI, quality of life was not different for planned caesarean vs planned vaginal birth groups. The authors concluded that among women with a twin pregnancy and no prior history of SUI, a management strategy of planned CS compared with planned VD reduces the risk of problematic SUI at 2 years postpartum. These findings show that the likelihood but not the severity of SUI was associated with mode of birth. [54] LEVEL OF EVIDENCE: II

Data for the rates of incontinence after elective and emergency CS areinconsistent and it remains unclearwhether caesarean performed before labour confers greater protection than caesarean performed after labuor.

To understand the true impact of CS on UI, future studies must compare incontinence by planned delivery modes, consider a woman's entire reproductive career, focus on urinary leakage severe enough to be problematic or bothersome, consider other bladder symptoms in addition to incontinence, and take into account other risk factors, particularly antepartum UI. [55] GRADE OF RECOMMENDATION C

2.2.1.1. Pathophysiologic mechanism of birth injury to UI

During the process of childbirth, the vaginal wall and muscles, ligaments and connective tissue of the pelvic floor can be compressed and overstretched. [57] In addition, the pudendal nerve in Alcock's canal is vulnerable to trauma during delivery, particularly with associated increased duration of second stage of labour, forceps delivery, or a large birthweight baby.[58] LEVEL OF EVIDENCE: III

The major mechanism by which vaginal delivery might contribute to pelvic floor trauma are muscle trauma, nerve injury, connective tissue damage and vascular damage.

Muscle trauma

The pelvic floor muscles (PFMs), including the levator ani muscles (LAMs), coccygeus muscle, perineal muscles, striated urethral sphincter and external anal sphincter, form the base of the abdominal-pelvic cavity and contribute to the support of the pelvic contents and continence control. The LAMs are considered a functional unit which provides support to the pelvic organs in the transverse plane (lifting) and compresses the urethra against the anterior vagina in the mid-sagittal plane (squeezing). Damage to, or dysfunction of the LAMs is thought to be a contributor to SUI. [1] LEVEL OF EVIDENCE: II

A computer model quantified the pelvic floor muscle stretch induced during the second stage of labour as a model in which the fetal head progressively engaged and then stretched the iliococcygeus, pubococcygeus and puborectalis muscles. The authors demonstrated that the medial pubococcygeus muscles undergo the largest stretch of any LAMs during vaginal birth and it is therefore at the greatest risk of stretch-related injury. [59] LEVEL OF EVIDENCE: II

The occurrence rate of postpartum levator injuries in primiparae after VD is reported between 15-39.5%. [60-69] LEVEL OF EVIDENCE: III

The aetiological role of LAM integrity in bladder dysfunction is still not completely clear. A weakly significant association between levator avulsion and worsening or de novo UI has been reported 3 months postpartum. [70] LEVEL OF EVIDENCE: III

However, recent evidence questions this link, reporting that women with a major levator defect are less likely to experience SUI [71], and that puborectalis trauma is not associated with an increased risk of SUI or urodynamic stress incontinence [72]. Brincat et al [73], found no significant association between maximal urethral closure pressure (MUCP) and urethral closure pressure with a pelvic floor contraction or Kegel (KUCP) in women with or without LA defects, illustrating the involvement in urethral functon in the generation of SUI. Additionally, there was no correlation between MUCP and vaginal closure force ($r = 0.06$, $p = 0.41$), and only a weak correlation between KUCP and vaginal closure force ($r = 0.20$, $p = 0.01$). The authors concluded that urethral pressure profiles are unrelated to LAM defect status after vaginal birth, indicating that the mechanism responsible for LAM damage spares the urethra. Also, Shek *et al*. [70] demonstrated that except at the bladder neck, there was no significant association between urethral mobility and levator avulsion. LEVEL OF EVIDENCE: III

However, it has been showed that stress-incontinent women had less skeletal muscle content, fewer muscle fibres in each LAM fascicle and higher connective tissue content in their LAMs than were observed in continent women. [74, 75] LEVEL OF EVIDENCE: III

On study showed also that asymmetry of the puborectalis muscles was more common in stress incontinent women. [76] Li *et al.* [77] recently demonstrated that there were no differences between women with and without SUI in terms of overall levator defects (asymmetry, hypertrophy or disruption) but in the study of Stock-

er *et al.* [78] a significantly greater percentage of pubococcygeal muscle defects was found in stress incontinent women (45–66%) than in their continent counterparts (10–28%). During maximal effort pelvic floor muscle (PFM) contraction, one study showed greater elevation of the proximal urethra in incontinent women versus continent controls [33] while another showed the opposite [79]. In one study, the midurethra rose higher in women without than with SUI when performing a PFM contraction [80] but in another study there was no difference in bladder neck elevation between groups performing the same task [81]. These conflicting results, as well as the detection bias associated with LAM strength measurement and an overall lack of assessor blinding in studies comparing LAM strength between women with and without SUI, lead us to conclude that there is limited evidence for the integrity and strength of the LAM and its correlation with the pathophysiology of SUI. LEVEL OF EVIDENCE: III

Nerve damage

Studies of the effect of vaginal birth on the urethral sphincter mechanism show decreases in urethral closure pressure. [82-84] These decreases have been ascribed to damage to the pelvic nerves showing delayed conduction in the pudendal nerve as well as single fibre recordings. [85, 86]

The role of vaginal birth in the denervation process has been clarified by Allen's electromyographic studies performed before and after vaginal birth. [87] Allen *et al.* found that most women have signs of neurologic injury after vaginal birth (but not after caesarean section), as shown increased motor unit potential and increasing amounts of damage correlate with more evidence of SUI.

Animal models have been used to better understand the mechanisms of postpartum SUI: a study simulating dilation of the vagina during the second stage of labour of human vaginal delivery, shown that vaginal distension leads to hypoxia and disruption of external urethral sphincter muscle fibres. The crushing of bilateral pudendal nerves results in external urethral sphincter dysfunction, caused by denervation injury to the external urethral sphincter. [88]

A rat model of simulated childbirth injury demonstrated that pudendal nerve crush and vaginal distension cause a more severe and durable damage to EUS, pudendal nerve and connective tissue than either injury alone. [89, 90]

Although urethral resistance to leakage, as measured by leak point pressure (LPP), recovers 4–6 weeks after pudendal nerve crush and vaginal distension, EUS electromyography does not recover over this time. [91] Insufficient innervation of the EUS may account in part for clinical development of recurrent SUI, [29] since recurrent SUI occurs later in life when the continence threshold is reached due to the compounding effects of aging, such as reduction of the number of muscle fibres in the EUS, loss of elasticity of supportive tissues, and denervation of smooth and striated muscles. [92]

Neurophysiological testing has revealed nerve damage in 36% of women with persistent SUI at 3 months postpartum. Compared with nulliparous control subjects, patients with SUI and pelvic organ prolapse (POP) had changes in the levator ani and external anal sphincter consistent with either motor unit loss or failure of central activation, or both [92]. LEVEL OF EVIDENCE: III

2.2.1.2. Epidural Analgesia and SUI

Meyer *et al.* [93] assessed the effects of epidural analgesia on pelvic floor function. Eighty-two primiparous women (consisting of 41 given an epidural and 41 not given an epidural) were investigated during pregnancy and at 2 and at 10 months after delivery by a questionnaire, clinical examination, and assessment of bladder neck behaviour, urethral sphincter function and intravaginal/intra-anal pressures. Ten months after spontaneous delivery, there were no significant differences in the prevalence of SUI and decreased sexual vaginal response, or in bladder neck behaviour, urethral sphincter function and pelvic floor muscle strength between women who had or had not had epidural analgesia.

LEVEL OF EVIDENCE: III

2.2.1.3. Episiotomy and SUI

In a recent study of Bø et al. [94], comparing vaginal resting pressure, pelvic floor muscle strength and endurance and prevalence of urinary incontinence at 6 weeks postpartum in women with and without episiotomy, concluded that PFM function and prevalence of postpartum UI were not affected by a lateral or mediolateral episiotomy. LEVEL OF EVIDENCE: III

2.2.2. Role of Pelvic Organ Prolapse (POP)

Failure of bladder, bladder neck, and urethral support is often part of more extensive defective pelvic organ support. Poor pelvic organ support can lead to pathological pelvic relaxation in one or more compartment(s). Marinkovic and Stanton [95] published a review of 97 articles regarding incontinence and voiding difficulties associated with POP. The authors concluded that POP appears to have significant clinical effects on urethral and voiding function; that should be quantified preoperatively to allow appropriate surgical intervention, with the aim of restoring vaginal function and correcting concurrent incontinence, whether overt or occult. Not uncommonly, POP can lead to bladder outlet obstruction, detrusor overactivity , and latent SUI that is unmasked only with reduction of the POP (potential, occult, latent, or unmasked SUI). [96] It is recognized that POP surgery can improve voiding dysfunction and unmask SUI by alleviating the urethral kinking causing outlet obstruction. [97] The findings of Karjalainen *et al.* [98] , showed that odds for occult SUI is 10.9 times higher with the cystocele with an intact retrovesical angle than with the cystocele with an open retrovesical angle. LEVEL OF EVIDENCE: III

Burrows *et al.* [99] described symptoms of bladder, bowel, and sexual function in 330 women with POP, comparing different degrees of prolapse staged by POP-Q system. Women with SUI symptoms had less advanced prolapse (median 5 cm less prolapse in apical compartment) than those without SUI. In a large community-based questionnaire survey, 44% of women who had prolapse symptoms also complained of SUI and 37% of overactive bladder. [100] LEVEL OF EVIDENCE: II

SUI can be functionally masked by POP. SUI may be uncovered by POP surgery and clinically continent women are at risk for developing symptomatic SUI after surgery.

The prevalence of latent SUI occurring after POP surgery is between 40 and 50% according to two large prospective randomized clinical trials. [101,102] LEVEL OF EVIDENCE: II

The large survey study using a validated SUI specific quality of life questionnaire completed by an unselected population of patients undergoing POP surgery followed up between 1 and 3 year after surgery, noted a 42% prevalence of SUI. [101] The degree to which these patients were bothered by their incontinence and how and when they seek therapy was less clear. The 2-year post-op questionnaire survey noted that 1/3 of their patients were moderately or severely bothered by their incontinence but only 5% sought further

surgical correction. From this study it is clear that 40-50% of patients develop SUI but it is less clear on how bothersome this is, and whether patients seek further surgical interventions. LEVEL OF EVIDENCE: II

This is an area that needs more investigation as the ultimate goal is to reduce the need for further procedures following POP surgery.

The pathophysiology of latent SUI has not been studied extensively. There are a few older studies involving small numbers of subjects suggesting that patients with advanced prolapse experience an obstructive effect of the prolapse on the urethral closure mechanism. One of these studies noted that maximal urethral closure pressures (MUCP) dropped from75 cm H_2O to 45 cm H_2O when the prolapse was reduced during urodynamic testing. [103] In another study subjects with prolapse beyond the introitus had an increase in their MUCP when they performed Valsalva, suggesting that as the prolapse was pushed out the urethra became more obstructed. [104]

In a more recent study Mueller *et al.* [105] noted that, although prolapse reduction significantly decreases MUCP, it does not alter intrinsic neuromuscular activity of the striated urethral sphincter: prolapse reduction resulted in a clinically and statistically significant decrease in maximum urethral closure pressure (31%) but it had no impact on quantitative urethral electromyography.

A more anatomic description of this phenomena was conducted using videourodynamics and a Gehrung pessary to support the POP during the exam. In this study the investigators demonstrated a hypermobile open bladder neck of SUI subjects with POP when the prolapse was reduced by the pessary. They did not study these same patients with the prolapse unreduced to describe the anatomy of the prolapse related continence mechanism. This points to the prolapse acting as an external force obstructing the urethral lumen and either through kinking or compression against the inferior pubic symphysis. [106]

Evidence of reduced peptide-containing innervation of perineal and periurethral muscles in women with SUI and POP has emerged [107], suggesting a neural abnormality in their pathogenesis. Connective tissue alterations such as decreased a-1 antitrypsin expression and altered elastin metabolism [107] , decreased collagen concentration [108], and decreased oestrogen receptors [109, 110] have been described in women with urinary incontinence and POP. LEVEL OF EVIDENCE: III

The role of urodynamic studies (UDS) before prolapse surgery remans contentious and hotly debated. Currently, it has been impossible to reach a universal consensus on the role of UDS before prolapse surgery in women with concomitant symptomatic or occult SUI. It is clear that UDS has an important role in preoperative identification of occult SUI, could add some information in women undergoing POP surgery and could facilitate counselling of patients as recently demonstrated by Martin *et al.* [111] LEVEL OF EVIDENCE: III. Weber *et al.* [112] showed that urodynamic testing in this setting is not cost-effective relative to basic office evaluation. They claimed that is possible that UDS could better identify and define some lower urinary tract dysfunction, such as a preoperative detrusor overactivity or occult SUI, but this information rarely leads to either a change in the management plan or in the type of surgical procedure. LEVEL OF EVIDENCE: III

Two randomized trials evaluated whether or not UDS may improve objective and subjective surgical outcomes in the treatment of SUI with mid-urethral sling procedures. [113, 114] However, these studies included a very selected population of women with SUI, the so called “uncomplicated” patients. LEVEL OF EVIDENCE: II.

Serati et al. [115] showed that “uncomplicated” patients represent a minority among female SUI patients evaluated before surgery. In “complicated” patients, the role of urodynamics has not been challenged and remain mandatory. LEVEL OF EVIDENCE: III

Other studies have identified different urodynamic variables (such as the median Valsalva Leak Point pressure (VLPP) and Maximum Urethra Closure Pressure (MUCP) > 40 cm H2O) as able to predict efficacy of anti-incontinence procedures and post-surgical voiding dysfunction risk [116, 117]

In 2009 Digesu *et al.* [118] showed that UDS could demonstrate that 20% of women with a history of pure SUI might not need any surgery at all. Serati *et al.* [119] showed that UDS are able to demonstrate that several patients with symptoms of pure SUI were affected by underlying detrusor overactivity and thus were ineligible for surgery.

UDS may be a useful tool in the preoperative work-up of all patients with SUI, predicting postoperative outcomes and avoiding unnecessary surgical procedures. [120] LEVEL OF EVIDENCE: III

New well-designed randomized studies are necessary to improve our understanding and to identify additional risk factors to facilitate tailoring a patient´s preoperative assessment and surgical counselling.

The surgical management of women with POP and latent SUI remains controversial and challenging. Maher *et al.* [121] determined the effects of surgery in the management of POP by searching the Cochrane Incontinence Group trials register (as of June 2004) for randomized or quasi-randomized controlled trials. The resulting metanalysis on the impact of POP surgery on continence was ‘limited and inconclusive’, but they report that 10% of women developed new incontinence symptoms postoperatively. LEVEL OF EVIDENCE: I

Levin *et al.* [122] prospectively evaluated 313 women who underwent TVT procedure for overt (228 women) or occult (85 women) SUI. Of them, about 50% also underwent POP surgery concurrently. Overall, for 241 women with at least a follow-up of 12 months, 6.6% had persistent mild SUI, an additional 7% had urodynamic evidence of asymptomatic sphincteric incontinence, whereas 8% developed de-novo UUI. LEVEL OF EVIDENCE: III

Among 130 women who underwent surgical treatment for an enterocele (75% the vaginal wall protruded through the introitus), 77% presented with SUI or detrusor instability. Sixty-seven percent of patients underwent Burch colposuspension with enterocele repair. Postoperative SUI requiring further treatment occurred in 10% after a mean period of follow up of 10 months, and cystocele developed in 1.5%. [123] LEVEL OF EVIDENCE: III

Urologists and urogynaecologists are faced with the challenge of determining which women with POP associated with SUI will benefit from concurrent surgical intervention for the UI. A comprehensive and anatomical approach to pelvic floor reconstruction is recommended, but no high-level evidence-based studies exist in the contemporary literature.

The intended goal of surgical correction of SUI and POP is durable restoration of normal anatomy and function, with symptomatic

relief and avoidance of morbidity. At present, few evidence-based conclusions can be drawn about when to surgically intervene for SUI in women who present with POP. The recent Cochrane Review published in 2018 by Baessler *et al.* [124] aiming to determine the impact of surgery for symptomatic POP with or without concomitant or delayed two-stage continence procedures to treat or prevent SUI on postoperative bladder function, included 19 RCTs (2717 women): the authors concluded that in women with POP and SUI (symptomatic or occult), a concurrent mid-urethral sling (MUS) probably reduces postoperative SUI and should be discussed in counselling. It might be feasible to postpone the MUS and perform a delayed (two-stage) continence procedure, if required. Although an abdominal continence procedure (Burch colposuspension) during abdominal POP surgery in continent women reduced de novo SUI rates in one underpowered trial, another RCT reported conflicting results. Adding a MUS during vaginal POP repair might reduce postoperative development of SUI. An anterior native tissue repair might be better than use of transobturator mesh for preventing postoperative SUI; however, prolapse recurrence is more common with native tissue repair. LEVEL OF EVIDENCE: I

Ramanah *et al.* [125] compared changes in urinary symptoms before and after POP surgery, using either laparoscopic sacrocolpopexy or transvaginal porcine dermis hammock placement with sacrospinous ligament suspension. Out of the 151 patients included, 87 patients underwent laparoscopic sacrocolpopexy, and 64 sacrospinous ligament suspension. Overall, after a median follow-up of 32 months, POP surgery improved urinary frequency, voiding difficulty, SUI, but not urinary urgency. Sacrospinous ligament suspension was more effective in treating SUI while laparoscopic sacrocolpopexy was more effective on voiding difficulty. Postoperative de novo symptoms were observed in 35.8% of patients with no difference between the two groups. The authors concluded that most preoperative urinary symptoms decreased after POP surgery with equivalent proportion of de novo symptoms after vaginal and laparoscopic approaches. LEVEL OF EVIDENCE: III

A recent study from Bideau *et al.* [126] demonstrated that preoperative SUI was the most important risk factor for postoperative SUI. However, given the higher risk of postoperative complication with concomitant MUS and the acceptable rate (29%) of the novo SUI without it, two-stage surgery seems preferable for patients with pre-operative SUI. LEVEL OF EVIDENCE: III

Recommendations for treatment of occult SUI have been recently summarized by Edenfield et al. [127]:

1) In women with prolapse and no SUI symptoms who are undergoing a vaginal prolapse repair, consider performing a MUS if the reduction cough stress test is positive preoperatively or the patient has a high risk of latent SUI. GRADE OF RECOMMENDATION C

2) If the reduction cough stress test is negative preoperatively or the patient has a low risk of latent SUI, defer a concurrent sling in women with prolapse and no SUI symptoms who are undergoing a vaginal prolapse repair. However, if the patient prioritizes decreasing the risk of latent UI, after discussion of risks and benefits, then it is reasonable to consider a concurrent sling in these women. GRADE OF RECOMMENDATION D

3) In women with prolapse and no SUI symptoms who are undergoing an abdominal mesh sacral colpopexy, a concurrent Burch retropubic urethropexy should be considered independent of preoperative reduction cough stress testing, if the surgeon's choice of anti-incontinence procedure is indeed a Burch. GRADE OF RECOMMENDATION B

4) If an anti-incontinence procedure is deferred at the time of a prolapse repair, it is still important to discuss the rate of postoperative latent UI with the patient as an interval procedure can be considered. This may indeed be some patients'preference. GRADE OF RECOMMENDATION D

2.2.3. Urethral position

Cohorts of stress incontinent women have demonstrated shorter and more cranial positioning of the urethral sphincter complex at rest [128] and smaller area and circumference of the sphincter muscles compared to continent controls [129]; the latter is consistent with MRI findings that stress incontinent women had significantly thinner striated urethral sphincter than continent women. [76] Authors reported both shorter [76, 130,15], longer [131] and no difference [80] in urethral length between stress incontinent and continent women.

Functional urethral length, defined as the length of the urethra along which urethral pressure exceeds intravesical pressure, presumably represents the location of the urethral sphincters. Several studies [15, 130, 132, 133], but not all [134] found greater functional urethral length in continent than in stress incontinent women. Shorter functional urethral length appears to be associated with greater severity of SUI. [15, 135] A metanalysis showed that functional urethral length was 3.58 mm (95% CI −5.83 to −1.33 mm) shorter in stress-incontinent women (n = 521) compared with continent women (n = 109). [1]

Another metanalysis of six studies suggests that bladder neck funneling (or dilation) is five-fold (risk ratio = 5.04, 95% CI 2.12–11.97) more prevalent at rest and 5.52 (95% CI 0.60–50.54) times more prevalent during straining among stress incontinent than continent women. [1] LEVEL OF EVIDENCE: III

2.2.3.1. Urethral support

Para-urethral connective tissues

Dense connective tissue arises primarily from the vagina and periurethral tissues and attaches to the pelvic wall laterally at the arcus tendineus fasciae pelvis and to the medial edge of the LAM (these supportive tissues are often referred to as the "pubo-urethral ligaments," although they do not insert exclusively into the pubic bone or attach directly to the urethra). Lesions of the urethral support structures were more prevalent in stress-incontinent than in continent women. [76, 77, 136]

In one study, defects in the periurethral ligament were found in 76% of stress incontinent women and in 32% of parous controls [76]. While greater pubovaginal distance and periurethral ligament disruption were significantly associated with SUI, in a multivariable model, only periurethral ligament disruption was significantly more common in incontinent than in continent women. [137] Among 31 middle-aged women, periurethral ligament symmetry reduced the odds of incontinence by 87%. (98) The urethropelvic ligaments were significantly thinner in stress-incontinent women, but the length of the pubourethral "ligaments" was similar between women with and without SUI. [138] LEVEL OF EVIDENCE: III

2.2.3.2. Bladder neck position

Compared to their continent counterparts, women with SUI demonstrated shorter distances between the bladder neck and the lower margin of the symphysis pubis at rest and during straining [139] and

shorter distances from the bladder neck to the central axis of the symphysis pubis in standing, but not in supine position. [134, 140] In women with SUI, a larger distance from the symphysis pubis to the urethra at rest in supine position was observed, and the bladder neck tended to sit in a more posterior and caudal position [141] compared to continent women. Another study showed no difference in the resting position of the bladder neck in the horizontal or vertical plane between continent women and those with SUI [142]. Falah-Hassani et al. [1] were unable to conduct a meta-analysis for bladder neck position because of the variation in measurement approaches in the different trials (e.g., using the central axis of the symphysis pubis vs. a line through the apex and measuring the direct vs. perpendicular distance from the bladder neck to symphysis pubis). LEVEL OF EVIDENCE: III

2.2.3.3. Urethral angular orientation

Compared to continent women, women with SUI had larger rotation (α) angles (defined as the angle between the axis of the proximal urethra and central axis of the symphysis pubis [143, 144], the angle between a line drawn through the bladder neck parallel to the probe and a line through the apex of the pubic bone [145] or the proximal urethral rotation angle, with a lack of clarity regarding the task [146] at rest and during straining.

However, when defined as the angle between the vertical axis and the urethral axis (a.k.a. the urethral axis angle), there was no difference in α angles at rest between women with and without SUI, and, while during Valsalva there was no difference in one study, there were larger α angles in a stress-incontinent group in another study. [136, 147] The β angle (also referred to as the posterior urethrovesical angle, posterior vesicourethral angle or retrovesical angle) was measured as the intersection between lines drawn along the urethra and the bladder base, the angle from the bladder base to the symphysis pubis, the angle from the bladder neck to the vaginal wall or undefined. Regardless of definition, women with SUI typically had larger β angles at rest than continent women, with the exception of one study [15]. The metanalysis of Falah-Hassani *et al.* [1] showed there was a large effect of incontinence on the β angle, with larger β angles observed among stress incontinent than continent women.

Urethral mobility is assessed clinically using a cotton swab inserted into the distal urethra (Q-tip test) while women are supine and at rest. Although this test has limited accuracy, women with SUI demonstrated larger angular deviations of the cotton swab from horizontal compared to those without SUI [79]. Other findings include that, compared to continent women, women with SUI demonstrated a larger retropubic space [76] and a larger bladder neck symphyseal angle at rest [144], but iliococcygeal angles and levator plate angles [136] did not differ. LEVEL OF EVIDENCE: III

2.2.4. Summary of evidence:

a) Vaginal delivery (VD) is associated with a 67% increased risk of UI compared with caesarian section (CS) 20 years after one birth. LEVEL OF EVIDENCE: III
b) UI is higher among women who had CS than among nulliparous and even higher among women who had VD. CS seems to decrease postpartum UI but its protective effect seems to diminish over time and disappears after multiple deliveries. LEVEL OF EVIDENCE: II
c) Risk of SUI after forceps delivery is 1.4 times higher compared with spontaneous delivery and 1.7 higher compared with vacuum. LEVEL OF EVIDENCE: III
d) Planned CS for twin pregnancy reduced the risk of problematic SUI. LEVEL OF EVIDENCE: II
e) Rates of UI after elective and emergency CS are mixed. LEVEL OF EVIDENCE: III
f) There is limited evidence for levator ani muscle integrity and correlation with the pathophysiology of SUI. LEVEL OF EVIDENCE: III
g) Damage to the pelvic nerves (particularly the pudendal nerve) after VD has been demonstrated in women with stress incontinence. LEVEL OF EVIDENCE: III
h) Epidural analgesia and episiotomy seem to have no effect on the postpartum UI. LEVEL OF EVIDENCE: III
i) Latent SUI develops in roughly 40% of continent women with advanced POP following surgery to correct their prolapse. LEVEL OF EVIDENCE: II
j) External compression or urethral kinking aids the continence mechanism in women with advanced POP. LEVEL OF EVIDENCE: III
k) Only about 5% of patients who develop latent SUI will undergo interval surgical management of their incontinence. LEVEL OF EVIDENCE: II

2.2.5. Recommendations for practice

a) UDS should be considered for all women for preoperative identification of occult SUI. GRADE OF RECOMMENDATION B
b) Discuss with women with POP and SUI (symptomatic or occult) that a concurrent MUS probably reduces postoperative SUI. It is possible to postpone the MUS procedure and perform two-stage surgery. GRADE OF RECOMMENDATION A

3. ROLE OF CONNECTIVE TISSUE

Collagen is the main constituent of endopelvic fascia and abnormalities in the quantity, type and quality of collagen have been observed in women with stress incontinence. Several studies have reported a decrease in the total collagen content in women with SUI [148,149,150]; moreover, a defect in endopelvic fascia is also likely to be of functional significance given that the urethra is indirectly attached to the levators by endopelvic fascia and an intact arrangement assists in urethral positioning [151]. Collagen is mainly synthesized by fibroblasts in periurethral vaginal wall tissue. Type I collagen content is significantly decreased in periurethral vaginal wall tissues and cultured vaginal fibroblasts from women with SUI. Furthermore, fibroblasts from women with SUI exhibit significant decreases in the expression levels of TIMP-1, TIMP-2 and TIMP-3, while the mRNA expression levels of MMP-1, MMP-2, and MMP-9, which reportedly increase collagen degradation in stress incontinence, are significantly increased. [152]

Stress incontinence may be acquired through conditions causing changes in connective tissue:

- SUI is more common with increasing age. In postmenopausal women, there is loss of muscle in the urethra and formation of collagen cross-links in the urethra stabilizes prevents remodelling and flexibility [153].
- Stress incontinence is more common in multiparous women. There is also evidence to suggest that trauma during childbirth may cause neuromuscular injury. However, changes in connective tissue also occur during pregnancy. Fascia becomes more elastic and vulnerable and women who have antenatal stress incontinence might have a greater degree of fascial weakness compared with those who remain continent [154]. Women who develop antenatal stress incontinence, even when it resolves

in the postnatal period, are twice as likely to develop it again in the future compared with those without antenatal stress incontinence [30]. The hormonal changes during pregnancy or abnormal remodelling of collagen may be important in the development of these conditions. The fact that incontinence may be seen during pregnancy might also be consistent with the hypothesis that the normal mechanical and hormonal effects of pregnancy unmask women with an inherently weak continence mechanism.

4. ROLE OF URETHRA AND ISD

Recent symposia sponsored by the National Institutes of Health [155] have highlighted the growing evidence that urethral failure is a primary factor in the cause of stress incontinence. The idea that primary urethral weakness could cause urinary incontinence independent of weakness in urethral support appeared in a classification proposed by Blaivas *et al.* [156]. In their classification, they named this Type III incontinence to distinguish it from Types I and II, based on bead-chain cystourethrograms, each of which showed movement, while Type III did not. This remains in the contemporary literature, although it has now been largely replaced by the term intrinsic sphincter deficiency (ISD), focusing attention on urethral elements which appear to be independent of vaginal position and mobility. These elements include pudendal innervation, striated sphincter mass and function, and urethral smooth muscle, mucosa and submucosal cushions.

When ISD was first introduced as a concept to explain surgical failures and the presence of stress incontinence in the absence of vaginal mobility, the diagnostic tendency was to consider the cause of stress incontinence as a dichotomy, due either to hypermobility (displacement, or prolapse of the vaginal wall) or ISD. The typical patient with ISD was described as having low urethral closure pressures, a “stovepipe” appearance on cystoscopy, and opening or funnelling of the urethra under resting or minimal increases in intra-abdominal pressures on radiographic images. The common causes were thought to be surgical injury, ischaemia following previous pelvic or vaginal surgery or radiation damage. The evidence that weakness in the ability of the urethral muscles to maintain closure, is very strong and it appears that the examples of “pure” ISD may have represented the most advanced or extreme forms.

4.1. Hypermobility Vs. Isd: From Dichotomy To Continuum

Currently, there appears to be a shift away from the idea that stress incontinence as being due either to hypermobility or ISD. This has arisen in part because of the of the concept of Valsalva Leak Point Pressure (VLPP) [157,158] and more recent analyses of long term results of stress incontinence surgery [159]. Most importantly, there are strong data from case control studies of well-matched continent and incontinent women showing that reduced urethral closure pressure explains 50% of the occurrence of stress incontinence and that adding urethral support parameters increases this prediction by an additional 11% showing that both factors are important.

VLPP emerged as an alternative method to study urethral closure during stress for studies of urethral bulking with collagen. Investigators recognized that improvements in continence following urethral bulking did not correlate with urethral closure pressures but did correlate with the amount of pressure required to produce leakage in the absence of intrinsic detrusor contraction. Although VLPP still lacks specific anatomic or theoretical grounding, problems related to standardization of recording methods and associated prolapse remain, low VLPP (without specified or established values) has been widely embraced as an indicator of ISD.

Just as the concept of VLPP blurred the previous distinction between simple ISD and simple hypermobility, long term outcome studies of correction of hypermobility have suggested that there may be more urethral weakness among patients with hypermobility than previously considered.

Long term outcome studies of stress incontinence surgery show a greater failure rate of many of the commonly performed stress incontinence operations than had been generally appreciated, and that slings providing direct sub-urethral support seemed to give the greatest long term protection against recurrence of incontinence [159]. Since slings had traditionally been the procedure of choice for recurrent incontinence or “Type III” (now ISD) incontinence, the possibility that ISD was more common than previously thought was more widely considered. Recently, Horbach and Ostergaard have found that age is a significant, independent predictor of ISD in the setting of urodynamic stress incontinence [160], suggesting that age-related reduction in muscle mass, slowed reflexes or repeated episodes of prolapse may all contribute to the condition.

Perucchini *et al.* [161, 162] showed that aging is associated with a decrease in the number and density of urethral striated muscle fibres at the bladder neck and along the ventral wall of the urethra [241]. The clinical correlate of this is the 15% per year decline in urethral closure pressure in nulliparous women where age effects can be determined without the confounding effect of childbirth [163].

These two developments have led to a growing clinical impression that some degree of ISD may exist in many patients who, until recently, were thought to have only hypermobility as a cause of their incontinence. Atypical expression of this approach can be found in the conclusion of Kayigil *et al.* [164] following examination of 50 patients; “The high rate of intrinsic sphincter deficiency in patients with urethral hypermobility indicates that the incidence with stress incontinence may be greater than previously believed, and may influence the apparently higher failure rates after bladder neck suspension.” In contemporary clinical practice, this impression has given rise to a growing tendency to recommend suburethral sling surgery as a form of primary surgical treatment for all women with stress incontinence, whereas formerly this approach was reserved almost exclusively for patients with recurrent stress incontinence or significant ISD [165, 166].

4.2. Direct studies of Urethral Function and Support

As recognition of the importance of urethral function has increased, so too have the number of investigations of urethral position, urethral closure and transmission pressure profiles, Valsalva leak point pressure measurements and electromyographic examinations of the pudendal nerve and the striated sphincter.

4.2.1. Studies Of Urethral Position

Stress incontinence is frequently associated with loss of urethral position. This has been the primary pathophysiological paradigm since the observations of Hodgkinson and Jeffcoate and Roberts. Similar observations are still reported today [167, 168]. Even when some displacement is seen in continent nulliparous females, incontinent women show a greater degree of mobility [169].

This pathophysiological mechanism has been supported by different authors [170, 171] using a rat model. Both and induced trauma on structured supporting the urethra (such as the pubourethral ligaments) and uretherolysis resulted in SUI in short and long term because of increased urethral mobility.

Successful suspensory operations, whether by sling or paraurethral suspension stabilize urethral position [42] and, when studied, increase pressure transmission during stress. It is not clear if the active contraction of urethral support seen in the female is restored after surgery, nor is it known if it is necessary for continence. It has been suggested that passive support alone is what restores continence after suspension. Caution is needed before assuming surgical success proves a specific causal mechanism to avoid the "post hoc, ergo proctor hoc fallacy." Application of this logic would for example, suggest that success of bariatric operations in causing weight loss "proves" that obesity is caused by a large stomach.

4.2.2. Studies of urethral pressure and resistance

Stress incontinence is thought to be characterized by a decrease in urethral transmission profiles and resting closure pressure. The correlation between low resting pressures and low leak point pressures is still controversial. With a bladder filled up to 200ml, Almeida *et al.* [172] reported a significant correlation between MUCP and LPP. Patients with a LPP of 60 cm H_2O or less also had shorter urethral functional length and lower sphincter activity. Moreover Sinha *et al.* [173] showed that women with urodynamic stress incontinence were more likely to leak at cough leak point pressure than the Valsalva manoeuvre, with the opposite happening for women with detrusor overactivity. On the contrary Martan *et al.* [174] found no significant correlation between MUCP and VLPP.

Different urodynamic parameters have also been posited to assess urethral function in with women with stress incontinence. Digesu *et al.* [175] showed that urethral resistance pressure (URP) and pressure flow parameters were reduced in women with stress incontinence. Salvatore *et al.* [176] found that reduction in opening vesical pressure was significantly correlated with ISD. Sonographic studies have recently shown a relationship between low urethral resistance and decreased urethral smooth and skeletal muscle layers [177].

Improvement in transmission pressures is associated with successful outcomes after suspensory operations for stress urinary incontinence [12, 16, 19, 20, 178,179]. The exact mechanism for this increase in transmission is not clear. Increased exposure to intra-abdominal forces [21, 180,181] and compression against the pubis by the pelvic viscera [260] has also been suggested but is anatomically implausible. The final position of the urethra may not be the key variable [182].

4.2.3. Electrophysiological studies of urethral function

Snooks and Swash [183, 184] first brought attention to the importance of urethral denervation after childbirth and its possible contribution to urinary and faecal incontinence. Stress incontinence is frequently associated with a decline in the electrophysiological function of the pudendal nerve [185], the striated urethral sphincter [186], and the pelvic floor muscles. More recent studies continue to support the finding of prolonged pudendal nerve terminal motor latency in SUI [187].

With the use of animal models simulating intrinsic urethral deficit through periurethral cauterization, urethral sphincterectomy or pudendal nerve transection, different authors reported a decrease of LPP lasting for weeks [188-190]. Injury of the pudendal nerve determined a dramatic decrease of urethral resistance causing urinary loss during an intrabdominal pressure increase.

Electromyographic studies of normal sphincter function show that in continent women, pressures begin to rise in the urethra before rising in the bladder, suggesting an active muscular component in generating this pressure [191].

Women with stress incontinence have an altered pattern of pelvic floor muscle response during successive coughing efforts [192] with a sharp decrease in MUCP after repeated coughs [193]. EMG studies have also shown that women with persistent stress incontinence after previous surgery have poorer urethral neuromuscular function than naïve stress incontinent women [194]. Experimental studies of urethral function and the role of Onuf's nucleus in the sacral spinal cord have led to recent practical innovations in the development of serotonin uptake inhibitor agents in the treatment of stress incontinence [195]. Most electrophysiological studies have concentrated on motor rather than sensory innervation, however, and the role of urethral sensation in urodynamic stress incontinence is unknown.

Needle electromyographic studies to assess urethral sphincter function have been performed by Takahashi *et al.* [186] to determine the electromyographic features of the striated urethral sphincter due to intrinsic sphincter deficiency (ISD). Myogenic dominant damage of the striated sphincter were suggested to contribute to the etiology of ISD [196]. Heesakkers *et al.* proposed circumferential sphincter surface electromyography (CSS-EMG), a less invasive and, therefore more patient friendly procedure, of the urethral sphincter and to identify CSS-EMG parameters for diagnosing ISD [197]. The authors found that the Average Rectified Value of the Motor Unit Action Potential, a measure of strength of the urethral rhabdosphincter, at 12 o'clock at 100% squeeze of the urethral sphincter, could discriminate between ISD and non ISD.

4.2.4. Genetic Factors

Recent research is now focusing on the identification of factors related to stress incontinence which might be genetically determined. Chen *et al.* [198] reported that genes involved in elastin metabolism were differentially expressed in vaginal tissue from women with stress incontinence, suggesting that elastin remodelling may be important in the molecular aetiology of stress incontinence. Wen *et al.* [199] recently reported a decreased expression of alpha2-M mRNA and protein and protease inhibitor activity in the vaginal wall tissues of women with stress incontinence. Wu *et al.* provided strong evidence that

microRNA-214 (miR-214) could promote fibroblast differentiation of adipose-derived mesenchymal stem cells (ADMS Cs) by down-regulating mitofusin-2 (Mfn2) to improve pelvic floor dysfunction in Sprague Dawley rats with birth trauma. [200] Whether these effects are mediated by altering the connective tissues supporting the urethra or those in the urethral wall itself is yet to be determined.

There is a need for a hypothesis which would integrate these various observations regarding hypermobility, ISD and pudendal nerve function, place them within the context of an abnormal pelvic floor and provide a model to guide research and studies of the natural history of the condition.

4.2.5. Role of advanced imaging in understanding pathophysiology

Many imaging modalities have been used to improve our knowledge of pelvic floor dysfunction, such as: radiographic imaging, ultrasound, computed tomography and magnetic resonance imaging (MRI).

Radiographic imaging has provided considerable insight into the pathophysiology of stress incontinence, ever since the advent of bead chain cystograms and simple static and straining lateral cystograms.

MRI and real time ultrasonography, in addition to showing the events of stress incontinence on both a global pelvic and local urethral scale, have suggested a relationship of the proximal urethra to vaginal wall movement.

4.2.6. Magnetic resonance imaging

Dynamic fastscan MRI can visualize all compartments of the female pelvis during increased intraabdominal straining [201]. MRI is comparable to standard cystography in demonstrating cystocele defects [202] and in determining the structural failures that are responsible [203]

Using the pubococcygeal line or Pelvic Inclination Correction system (PICS) [204] as a reference marker, the normal displacement of the bladder base, cervix or cervical cuff and the rectum can be identified and compared to women with prolapse. The urethra is shown in the context of global pelvic relaxation [205]. These studies show more soft tissue detail than earlier radiographic studies and continue to offer promising research opportunities. Recent studies have utilized an endovaginal coil to obtain higher resolution images of the urethra [206] but improving magnet strength and software has now largely rendered this unnecessary.

Dynamic MRI with cine-loop reconstruction produces vivid, intuitively appealing images which can show movement of all compartments of the relaxed pelvis during straining [205]. Static MRI shows details of urethral and peri-urethral anatomy and the striated sphincter can be clearly seen [207]. Pending further improvements in resolution, MRI remains a most promising tool for studying details of urethral movement [208].

Functional MRI has recently been evaluated to assess the efficacy of pelvic floor muscle training with EMG- biofeedback in women with stress incontinence. After a 12-week training period a more focused activation in the primary motor and somatosensory cortical representation sites of the lower urogenital tract was found [209].

Madill *et al.* have recently proposed another clinically promising aplication of MRI. They hypothesized that the Pelvic Floor Muscle (PFM) rehabilitation program would also exercise the striated urethral sphincter and that this would be demonstrated by hypertrophy of the sphincter on MRI [210, 211]. Their results appear to demonstrate that MRI is able to show that PFM training for SUI also trains the striated urethral sphincter and that improvement in incontinence signs and symptoms is associated with sphincter hypertrophy in older women with SUI. These findings support previous ultrasound (US) data showing an increase in urethral cross-sectional area following PFM training and extend the previous findings by more specifically assessing the area of hypertrophy and by demonstrating that older women present the same changes as younger women when assessed using MRI data. Similar data on the role of hypertrophy of the urethral sphincters after effective PFM training, and therefore in the pathophysiology of SUI, were observed also by McLean *et al.*, using a two- and three-dimensional ultrasound imaging of the pelvic structures [212].

Very recently, Macura *et al.*, stated that MRI might play an important role in assessing the contribution of hypermobility and sphincteric dysfunction to SUI in women when considering treatment options; however, the study sample was only small [213].

Ultrasonography is simpler and less expensive in comparison with MRI, and, for now, provides better visualization of moving structures.

4.2.7. Real time ultrasonography

Ultrasonography offers the advantage of capturing organ movements in real time. Several sonographic approaches have been used for the study of stress incontinence: suprapubic, translabial and transperineal.

As resolution of sonographic probes has improved, the detail previously best seen with the transrectal approach may now be seen by a transperineal approach. Earlier studies with a transrectal approach have shown that funnelling of the proximal urethra was the sonographic sign most-frequently associated with loss of urine [214].

In the study of Schaer *et a.l* in about half the patients with stress incontinence. funnelling was seen only with straining. In the other half, some degree of funnelling was already present at rest, increasing with straining and present with actual leakage. [215], Enhanced views of the urethra were possible with sonographic contrast material.

Most recently, 3-D reconstruction from translabial views of the urethra has been used to compare findings in normal volunteers and those with ISD [216].

A recent sonographic study of women with stress urinary incontinence found funnelling at rest in 109 of 330 patients and found that the degree of vaginal relaxation as well as the parameters of intrinsic urethral function, including VLPP and urethral closure pressures were worse in patients with funnelling than without. The authors of this study concluded that: “In primary genuine stress incontinence, bladder neck funnelling on ultrasound cystourethrography implies the potential coexistence of poor anatomic support and an intrinsic sphincter defect [217].” Ghoniem *et al.* [218] also found that urethral funnelling was more likely to be associated with low closure pressures, low

VLPPs, and a higher incidence of ISD in patients with stress urinary incontinence. However, recently, Tunn *et al.* [219] reported no association between the ultrasound findings of urethral funnelling with stress incontinence using an introital approach, demonstrating it only in 59% of the patients with stress urinary incontinence. Issues of whether authors are discuss funneling at rest or during stress events needs to be kept in mind as they are different things.

Improved soft tissue detail seen with ultrasound has permitted an extension of these original observations. The anterior and posterior walls of the proximal urethra appear to move differently during increases in intra-abdominal pressure. At first, they appear to move together: the urethra begins its descent as a single unit. At some point, however, the anterior urethra becomes arrested in its rotational movement and appears to move more slowly. The posterior portion of the urethra continues to descend along with the vaginal wall [214,220].

This difference in movement suggests a shearing apart of the two walls, leading to the appearance of funnelling, which can be seen as urine leaks out of the urethra.

On Valsalva, the proximal urethra rotates in a postero-inferior direction approximating to the symphysis pubis. This movement can be measured by comparing the angle of inclination between the proximal urethra and any other fixed axis. No normal values of bladder neck descent have been defined but cutoffs of 20, 25 and 30 mm have been reported to classify urethral hypermobility [221 222]. The anatomical and functional integrity of the PFM have an important role in the urethral support system and, therefore, in the continence mechanism. Women with UI, compared to continent subjects, have less effective PFM in terms of: strength, reduced endurance, reduced thickness, coordination of PFM and lower abdominal muscles, and altered elletromyographic activity [223-225]. With transperineal ultrasound it is possible to evaluate the urethral displacement towards the pubic bone caused by pelvic floor muscle contractions [226]. This mechanism is involved in maintaining urinary continence by determining a good efficacy in intraurethral pressure transmission [227].

These anatomical considerations, combined with current knowledge about pudendal nerve activity in normal, prolapse or stress incontinence, suggest an inter-relationship regarding urethral closure and vaginal movement. As intra-abdominal pressure increases, the proximal urethra experiences two kinds of forces, which may lead to opening. The first of these is a shearing force produced by the unequal separation of the anterior and posterior urethral walls from the pubis during straining. This is the effect of vaginal mobility on urethral closure. The second is an expulsive force, produced by the transmission of intra-abdominal forces to the bladder, which must be resisted by the urethra if opening is to be prevented.

The urethra resists this primarily by intrinsic closure of the pudendally innervated striated sphincter, aided by vaginal support.

3D ultrasound has introduced new insights in the image of urethral sphincters. Athanasiou *et al.* [228], using a transvaginal approach, reported a close correlation between the urethral sphincter volume and the degree of incontinence assessed on videocystourethrography (r = .-65; P <0.001). This author reported that this group of women have urethral sphincters that are shorter, thinner, and smaller in volume compared to controls.

Urethral vasculature has also been postulated to play a role in the continence mechanism and different Doppler parameters have been studied to evaluate correlation with stress urinary incontinence. Tsai *et al.* [229] reported that urethral vasculature, and in particolar the anterior branch of the middle urethral vessels, is less likely to be seen after menopause (89.1% vs. 79.2% pre- and postmenopause, P = 0.030). In postmenopausal women hormone replacement therapy did not affect the appearance of the urethral vessels. However, some authors [205] reported fewer periurethral vessels and lower flow in women suffering from stress urinary incontinence whereas others [230] could find no difference in the appearance of the urethral vasculature in subjects with or without stress urinary incontinence.

It is likely that shearing and expulsive forces are generated simultaneously as intra-abdominal pressure rises. One can easily imagine that the urethra can be brought to a continence threshold beyond which closure cannot be maintained. One can further imagine that repeated episodes of prolapse may eventually stretch, tear or attenuate sphincter mass and contribute to a chronically weakened urethra manifested by low VLPP or low urethral closure pressures, characteristic of ISD. After severe or prolonged untreated prolapse and stress incontinence, vaginal support alone may not be sufficient to correct the deficiencies of an exhausted sphincter. Although theoretical rather than evidence-based, such considerations may direct future research efforts towards a more integrated hypothesis regarding stress incontinence in women. The relative contributions of abnormal vaginal mobility and intrinsic urethral function should be considered as part of a continuum rather than a dichotomy. Current research interest has concentrated mostly on ISD as the primary cause of SUI in women, but the relationship of the many factors affecting urethral support and function need consderation in interpreting emerging findings.

Recently, Najjari *et al.* [131], using perineal ultrasound, compared the anatomical length of the urethra with the urodynamic functional urethral length to detect anatomical insufficiency of the urethra. The authors showed perineal sonographically measured urethral length was significantly longer in incontinent compared to continent patients and functional uretral length was significantly shorter in incontinent patients than in the control group.

Using ultrasound, evaluation of Levator Ani Muscles (LAM) found asymmetry of the puborectalis muscles more common in stress incontinent women in one study [206], and, while there were no differences between women with and without SUI in terms of overall levator defects (asymmetry, hypertrophy or disruption) in a subsequent study [78], a significantly greater percentage of pubococcygeal muscle defects was found in stress incontinent women (45–66%) than in their continent counterparts (10–28%). There is no high level evidence of significant morphological differences or in terms of strength between continent women and incontinent women.

5. OTHER PATHOPHYSIOLOGICAL MODELS

Reviewing all the available evidence on the pathogenesis of SUI, DeLancey tried to produce a new model to describe the interaction between the different possible mechanisms. Despite

progress made to date, our understanding is far from complete. The urethra is a dynamic structure with variation in closure from second to second, minute-to-minute, day to day and year to year. The role of the submucosal vascular plexus is still poorly understood; the complex neural control mechanisms that allow for temporary and total relaxation during voiding, that somehow know when to re-establish normal muscle function are still not entirely understood. In addition, although urethral support is not as important as previously thought, it is one of the contributing factors for stress incontinence. Understanding what it is about urethral support that lessens continence is vital. However, the finding that maximal urethral closure pressure, and not urethral support, is the factor most strongly associated with stress incontinence implies that improving urethral function may have therapeutic promise. Racial disparities exist in incontinence, and the biological basis for these differences should help our understanding [33, 231.].

5.1. Pathophysiology Of Stress Urinary Incontinence In Obese Women

Obesity has become one of the most worldwide prevalent pathologic conditions; this may be a relevant cause of several chronic diseases, such as hypertension, diabetes, dyslipidemia, many types of cancers, cardiovascular diseases [232, 233]. There is a strong relationship between obesity and urinary incontinence (UI) and weight gain is associated with a higher prevalence and severity of symptoms of UI, and in particular of Stress Urinary Incontinence (SUI)[234]. However, the pathophysiological mechanisms which explain this correlation are not completely clear and well-demonstrated.

Several studies have showed that BMI is strongly correlated with intra-abdominal pressure, and that increases in intra-abdominal pressure also increase intravesical pressure and exerts an increased stress on pelvic floor muscles, a risk factor for SUI [234, 235]. Moreover, the increase of abdominal pressure might also impair the innervation of these muscles [236]. Unfortunately, in most cases, obese patients also have many other concomitant risk factors for SUI, such as multiparity, oestrogen deficiency and history of surgical procedures for the treatment of pelvic organ prolapse. However, some studies showed that, in these women, obesity is an independent risk factor for SUI [237].

Obesity seems to be related to a higher prevalence of every type of UI, but a recent study of Brucker *et al.* demonstrated that SUI is significantly more prevalent in obese patients than Urinary Urgency Incontinence (UUI) (25% vs 15%) and that this finding is even more evident in the subgroup of younger patients (<50 years) (27% vs 11%) [238]. Waetjen *et al.*, in a study that compared the characteristics and baseline factors associated with prevalent and incident urinary incontinence in a diverse cohort of midlife women found that a BMI increase of 5 kg/m^2 increased SUI by 30% and UUI by 15% [239]

Several authors have demonstrated that increased sagittal abdominal diameter was associated with elevated abdominal pressure in obese compared to non-obese patients [240, 241]. Moreover, urodynamic evaluations may also highlight the association between increased BMI and increased abdominal pressure in female patients with SUI [236, 242]. It seems that abdominal pressure at maximum cystometric capacity significantly increases by 0.4 cm H_2O per Unit of BMI and of 0.4 cm H_2O per 2 cm increase in abdominal circumference in incontinent obese women [243]. Swenson *et al.*, in a recently published secondary analysis of a case-control study, assessed the effect of BMI on the components of the continence mechanism. The authors showed that the primary association between obesity and SUI is higher cough pressures which place increased demands on the continence system, rather than changes in urethral function or urethrovaginal support. They concluded that obese women have higher resting intravesical pressures and generate more pressure during maximal cough compared to women with BMI in the normal or overweight range [244].

Other authors, based on the systemic impact of obesity, supposed that the correlation between weight gain and SUI may not be solely due to increased abdominal and vesical pressure. Specifically, the association between obesity and neurogenic diseases has been proposed. Obesity has been shown to be a risk factor for peripheral nerve dysfunction, in terms of conduction in the median, peroneal, sural, and tibial nerves [245-247]. Additionally, obesity as a component of metabolic dysfunction or metabolic syndrome may negatively influence neural function. Callaghan *et al.* found a prevalence of polyneuropathy of 3.8% in lean controls, 11.1% in the normoglycemic obese, 29% in the prediabetic obese, and 34.6% in the diabetic obese participants ($p < 0.01$ for trend) [248]. Finally, the obese have a higher risk for lumbar intervertebral disc herniation than normal weight women [249]. Although there is an association between obesity and neurological impairment, it is not clear how much this may really influence the pathophysiology of SUI in obese women.

Lee *et al* , investigated the contractile properties of the urethral striated sphincter in obese and lean female rats in an *ex vivo* organ bath study.Ten 12-week-old Zucker Fatty (ZF) and 10 Zucker Lean (ZL) female rats were used in this experiment. Compared to ZL controls, ZF rats had significantly impaired muscle contractile activity (MCA). Also, ZF rats presented early fatiguing of MCA and had a significantly greater percentage of MCA decline from baseline in the fatiguing test. This study showed that obese female rats had significantly impaired contractile properties of the striated urethral sphincter, suggesting urethral dysfunction could be an important contributor to SUI in obesity [250].

In conclusion, there is a significative association between obesity and SUI, and that the most relevant mechanism to explain this correlation is that over-weight and obese patients have a higher resting intravesical pressures and produce more pressure during maximal cough compared to women with a normal BMI. It is plausible that neurological and metabolic factors are involved in the pathophysiology of SUI in this group of patients but more data are needed.

6. CONCLUSIONS

A recent systematic review with meta-analysis perfectly summarizes the information and knowledge on the pathophysiology of stress urinary incontinence as a multifactorial condition. The authors demonstrated that deficits in urethral and bladder neck structure and support, neuromuscular and mechanical function of the striated urethral sphincter (SUS) and levator ani muscles all appear to be associated with SUI [1].

A lower functional urethral length was significantly associated to SUI. This anatomic parameter was 3.58 mm (95% CI −5.83

to −1.33 mm) shorter in stress-incontinent women (n = 521) compared with continent women (n = 109) [77; 131].

They also considered the role of bladder neck funneling (or dilation), measured using USS, MRI or cystourethrography and demonstrated that funneling is five-fold more prevalent among stress incontinent (n = 1195 and n = 181 for rest and straining, respectively) than continent women (n = 775 and n = 193 for rest and straining, respectively) [136, 146, 251]. However, they included studies affected by biases and confounding.

Urethral resistance and competence, measured in terms of maximal urethral pressure (MUP) and maximal urethral pressure closure (MUPC), is a highly relevant factor for urinary continence. MUP was lower in stress-incontinent (n = 1034) compared to continent (n = 336) women, and MUCP was lower in stress-incontinent (n = 1122) compared with continent (n = 342) women.

The role of the Levator Ani Muscle (LAM) is controversial. Conflicting results as well as the detection bias associated with LAM strength measurement and an overall lack of assessor blinding in studies comparing LAM strength between women with and without SUI, lead us to conclude that there is limited evidence for LAM strength impairment in SUI [252]

7. SUMMARY

We are approaching a new classification of stress incontinence which will integrate hypermobility and urethral dysfunction as inter-related elements. Certain concepts have stood the test of time, and they are included below:

- Many patients with urodynamic stress incontinence show urethral mobility (Level 2), though it is not yet known what it is about that mobility which permits urethral opening during stress.
- Some patients who present with minimal urethral mobility or who have recurrent stress incontinence after successful surgery have primary or residual sphincter insufficiency.
- Sphincter insufficiency is related to a decline in striated sphincter muscle mass and function as measured by electrophysiological studies of pudendal nerve and sphincter function, and MRI and sonographic estimates of muscle mass. If repeated episodes of vaginal traction can be shown to enhance sphincter damage, then the effect of early treatment of stress incontinence and prolapse on future development of ISD should be investigated, since advanced ISD remains difficult to treat.
- Successful operations can restore urethral position but probably do not restore urethral function. A good surgical outcome probably requires a certain reserve of urethral function. It is in the area of functional understanding of urethral anatomy that the greatest progress is likely to be made.

III. IDIOPATHIC OVERACTIVE BLADDER AND URGE INCONTINENCE

1. INTRODUCTION

The International Continence Society (ICS) defines urinary incontinence (UI) as an involuntary loss of urine experienced during the bladder storage phase [1-3]. Urgency urinary incontinence (UUI) is defined as complaint of involuntary loss of urine associated with urgency [1-3]. Urgency is defined as the complaint of a sudden compelling desire to pass urine, which is difficult to defer [1-3].

The overactive bladder (OAB) is a storage symptom syndrome which is defined by urgency, usually accompanied by increased daytime frequency and/or nocturia, with urinary incontinence (OAB-wet) or without (OAB-dry), in the absence of urinary tract infection or other detectable disease [1-3]. Therefore, urgency is the defining symptom of the OAB syndrome. A better understanding of the genesis of urgency and its relationship to other aspects of bladder function is required to unravel the pathophysiology of OAB and to develop more effective treatments [4]. Owing to the difficulty in identifying the underlying pathology for the development of OAB in most patients, it is often labelled as “idiopathic”.

The ICS acknowledged that these symptoms are usually “suggestive of urodynamically demonstrable detrusor overactivity (DO) but can be due to other forms of urethra-vesical dysfunction” [1]. DO is defined as a urodynamic observation characterized by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [1]. However, OAB is not interchangeable with DO. only about half of patients with DO experience urgency [5,6], whereas among patients with urgency 44–69% exhibit DO during cystometric studies [7-10].

The definition of urgency as a complaint implies that it can only be measured in patients sufficiently cognitively intact to report it [4,11]. Quantifiable and objective demonstration of urgency is difficult, and thus surrogate measures are often used as outcome measures in OAB, leading to inconsistency between clinical trials. Urgency is a pathological sensation and does not necessarily involve the same mechanisms as those underlying the physiological urge to void upon bladder filling. Therefore, comparisons between urinary urge in healthy people and urgency in patients may help our understanding of the mechanisms involved in the latter but, in fact, may be misleading [11].

The emphasis on urgency, rather than DO, as the defining element of OAB gives the condition a subjective foundation which renders derivation of basic science insights challenging. The subjective nature of urgency makes development of animal models impossible. Despite of these limitations, most studies on mechanisms related to urgency/OAB have employed the use of isolated tissues and experimental animals. Non-voiding contractions remains the most frequently used surrogate parameter in experimental animal studies [11].

The pathophysiology of OAB and DO is still incompletely known, but most probably multifactorial and results from multiple potential pathophysiological mechanisms. Identification of

the underlying causes on an individual basis may lead to the identification of OAB phenotypes, paving the way for personalized medical care [12].

This section focuses on pathophysiology of idiopathic OAB and reviews studies that have provided insight into the mechanisms underlying OAB symptoms and DO.

DO may be further characterized as neurogenic in the presence of a relevant neurological condition [13]. The dependence of lower urinary tract (LUT) functions on complex central neural networks makes these susceptible to a variety of neurological disorders. Non-neurogenic aetiologies may be related to different mechanisms relating to the role of the urothelium, suburothelium, urethra, and central nervous system (CNS) in the pathogenesis of OAB [4]. This suggests that a "bladder afferent signaling" mechanism contributes to the OAB symptom complex. Each one of these mechanisms exerts their effect at different levels of the bladder afferent pathway, and we outline these various hypotheses below. (Figure 1). Recently, Peyronnet et al reviewed the a potential classification of OAB phenotypes according to urodynamic demonstration of DO and to pathophysiological factors; this section will widely cite this elegant and useful review that is the most recent and complete paper on the topic [12] (Table 1).

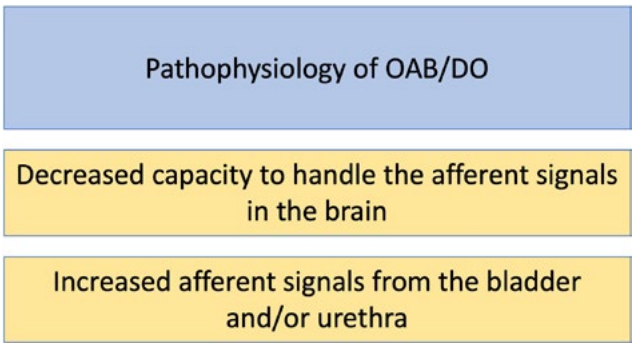

Figure 1: *Two possible origins of OAB symptoms: 1) decreased capacity to handle the afferent signals in the brain and, 2) abnormally increased afferent signals from the bladder and/or urethra.*

Table 1: Possible OAB phenotypes according to Peyronnet B, et al. Eur Urol. 2019 Jun;75(6):988-1000.

Peyronnet B, Mironska E, Chapple C, Cardozo L, Oelke M, Dmochowski R, Amarenco G, Gamé X, Kirby R, Van Der Aa F, Cornu JN. A Comprehensive Review of Overactive Bladder Pathophysiology: On the Way to Tailored Treatment. Eur Urol. 2019 Jun;75(6):988-1000. doi: 10.1016/j.eururo.2019.02.038.

Phenotyping according to pathophysiological factors	Phenotyping according to urodynamic demonstration of detrusor overactivity
Metabolic syndrome	Myogenic
Affective disorders	Urotheliogenic
Sex hormone deficiency	Urethrogenic
Urinary microbiota	Supraspinal
Functional gastrointestinal disorders	Urotheliomyogenic: detrusor underactivity
Autonomic nervous system dysfunction	
OAB = overactive bladder.	

2. PATHOPHYSIOLOGY OF INCREASED AFFERENT ACTIVITY

Different hypothetical mechanisms probably contribute in varying proportion to the complex mechanisms underlying the genesis of DO and the associated storage symptoms such as urgency composing OAB [12], have been put forward (Figure 2)

- The urothelium-based hypothesis: urgency originating from the bladder urothelium/suburothelium,
- The myogenic hypothesis: urgency originating from the detrusor,
- The urethrogenic hypothesis: urgency originating from the urethra,
- The detrusor underactivity hypothesis.
- Other factors

2.1. The Urothelium-based Hypothesis

2.1.1. Context [12]

OAB may be related to changes in urothelial receptor function and neurotransmitter release as well as in the sensitivity and coupling of the sub-urothelial interstitial cell network leading to enhancement of involuntary contractions [14,15].

In 1991, Creighton *et al.* reported that either DO or an abnormal perception of bladder filling could provoke the sensation of urgency [16]. Since then, several studies have shown abnormal detrusor sensory function in patients with OAB [17-19]. The role of increased activity of bladder afferents is well described [5,20] and supports the idea [5,21] of urgency resulting from urothelial/sub-urothelial dysfunction in some patients, which may not manifest as DO. UUI may indeed be less frequent in this subgroup of patients, but urinary frequency may be more common [18,22], and this is thought to be mediated by abnormal sensory and signaling properties of the urothelium and sub-urothelial fibroblasts [5,20] as well as possibly sympathetic dysfunction.

2.1.2. Molecular basis

There is increasing evidence that urothelial cells play an important role in modulation of bladder activity by responding to local chemical and mechanical stimuli and then sending chemical signals to bladder afferent nerves. Urothelial cells express various sensor molecules such as receptors of bradykinin, neurotrophins, purines (P2X and P2Y), norepinephrine (NE), acetylcholine ACh (nicotinic and muscarinic), epithelial sodium-channels (ENaC), and a number of transient receptor potential (TRP) channels.

These sensor molecules respond to mechanical as well as chemical stimuli and in turn release chemicals such as ATP, prostaglandins (PG), nerve growth factor (NGF), ACh, and NO. These transmitters are known to have excitatory or inhibitory actions on afferent nerves, which are located close to or in the urothelium [15].

The urothelium interacts closely with the underlying sub-urothelial layer, in particular the interstitial cell network contained within it, so that the whole structure can be regarded as a functional

unit [14]. The suburothelium is composed of nerves, blood vessels, and connective tissue in intimate contact with the urothelium. The roles of the urothelium and suburothelial myofibroblasts in afferent activation have been emphasized with intense interest. The C fibres afferents generally have endings in the suburothelial layer of the bladder wall, but in some cases, they also penetrate the urothelium [13].

ATP was the first neurotransmitter demonstrated to be released directly from the urothelium [24]. Non-vesicular ATP release is evoked by chemical stimuli or by stretch proportional to the extent of bladder distension [25-28]. ATP is released from the urothelium submitted to stretch or inflammation. ATP has been proposed as a major link to transduce bladder information into suburothelium nerve fibres, which express purinergic receptors [12]. Both P2X and P2Y purinergic receptor subtypes have been identified in the bladder urothelium. It is now thought that these purinergic receptors may respond to urothelial-derived ATP release in autocrine and paracrine signaling [25, 29-32]. By acting on structures such as nerves [33] and interstitial cells in the suburothelial space, urothelial-derived ATP may trigger the underlying afferent signaling of bladder fullness and pain and possibly even the micturition reflex [34]. The increase of ATP may result not only from an excessive release of the neurotransmitter, but also from reduced extracellular hydrolysis of the molecule [12]. Urothelial ATP may therefore contribute to DO and the emergence of storage symptoms [12].

In an additional study, including women with OAB, urinary ATP levels increased with age [35]. One should take into consideration that ATP is also released from purinergic nerves in the detrusor layer and contributes to non-adrenergic, noncholinergic smooth muscle contractions [36]. Thus, the manipulation of ATP release through pathways regulated by cyclic nucleotides offers a route for therapeutic management of OAB [37]. After successful treatment with botulinum toxin injection, a reduced P_2X3-immunoactive suburothelial nerve fibres correlated with a reduction in urgency [38]. Sugaya *et al*. reported that improvement of OAB symptoms with antimuscarinic treatment was significantly correlated with a decrease in urinary ATP level in female s with OAB [35].

The presence and localization of muscarinic receptor protein and mRNA in the human [39-44] and mouse [45] urothelium have been studied. All five muscarinic subtypes are expressed throughout the urothelial layers with a specific localization of the M2 subtype to the umbrella cells and M1 to the basal layer, with M3 receptors more generally distributed. Release of Ach from human urothelial and suburothelial sites increases with age, as well as during bladder stretch, and represents a functional, non-neuronal, alternative cholinergic system [41]. At therapeutic doses, antimuscarinics act mainly during the filling phase and exert little effect on detrusor contraction during emptying [46-48]. This lends support to the suggestion that urothelial muscarinic receptors might be involved in the generation of afferent impulses.

Urothelial cells express also both adrenoceptor subtypes, stimulation of which has been shown to trigger the release of ATP and nitric oxide (NO), respectively [49, 50]. Stimulation of urothelial adrenoceptors also triggers a urothelially-derived inhibitory factor [51]. However, β3-adrenoceptor agonists may be more potent in decreasing nerve-evoked ACh release than in producing direct relaxation of human bladder smooth muscle [52,53]. This is in line with the observed abundance of β3-adrenoceptor immunoreactivity on ACh-containing nerve fibres coursing the suburothelium and the detrusor of the human bladder, leading to the hypothesis that β3-adrenoceptor agonists act, at least in part, through inhibition of ACh release from cholinergic, most probably parasympathetic, nerve terminals through a prejunctional mechanism [54]. According to this theory, β3-adrenoceptor agonists may preferentially inhibit pathologically increased detrusor tone during bladder filling over physiological detrusor contraction during voiding and enabling them to inhibit an increased cholinergic tone in OAB [55]. Because purinergic transmission is more evident in pathological human bladders, attenuation of ATP release may be more relevant [37]. Moreover, β3-adrenoceptor agonists have more pronounced inhibitory effects on purinergic than cholinergic transmission [56].

In addition to the changes in ACh-release, several specific alterations in urothelial function and ultrastructure have been demonstrated in OAB. Expression of the mechanosensitive ENaC is increased significantly in human obstructed bladders in comparison with unobstructed controls and correlates significantly with storage symptom scores [57]. It is possible that increased expression of mechanosensitive channels such as ENaC in the urothelium enhances substance release upon bladder stretch. Levels of PG, which are locally synthesized in bladder muscle and mucosa, and levels of NGF are increased in subjects with OAB in comparison with controls; and in symptomatic patients, levels of PGE2 are positively correlated with OAB symptoms and maximum cystometric capacity [58,59].

Several channels of the TRP (transient receptor potential) family have a role in nociception and mechanosensory transduction in the lower urinary tract (LUT) [37]. A number of these channels, including vanilloids TRPV1, TRPV4, TRPM8, TRPA1, and TRPM4, have been suggested from animal studies to be able to treat OAB/DO, bladder underactivity and bladder pain disorders [60,61].

Bladder biopsies from patients with both idiopathic detrusor overactivity (IDO) [62] and neurogenic detrusor overactivity (NDO) [63] showed increased urothelial TRPV1 expression. This may be in accordance with the fact that intravesical vanilloids (resineferatoxin) have been shown to improve OAB symptoms in patients with (IDO) as well as with hypersensitivity disorders [64,65]. TRPV4 channels are present in urothelium and detrusor muscle cells and in urothelium are proposed to have important mechanosensory functions during bladder distension [37,66]. TRPM8 channels are expressed in bladder mucosa and their abundance is positively associated voiding frequency in samples from patients with idiopathic DO. This has led to the proposal that this channel subtype contributes to the pathophysiology [37,67]. TRPA1 channels have also been identified on urethral C-fibre afferents and urothelial cells as well as detrusor myocytes from human tissue. Furthermore, intravesical application of TRPA1 channel activators initiates DO-like activity. Together, it has been proposed that they have a role in modulating both efferent and afferent fibre activity in both the bladder and outflow tract [37,61].

It is clear that the sensory process is more complex than originally thought. Suburothelial myofibroblasts (interstitial cells) in the bladder wall form a functional syncytium through connexin 43 gap junction [68,69]. These myofibroblasts are in close apposition to unmyelinated nerves (afferent C-fibre nerves) [70]. Studies investigating human myofibroblasts show that these

cells can respond to ATP by generating an intracellular Ca2+ transient, which is mediated by a P2Y receptor, most likely including P2Y6 [71]. On the basis of these observations, it has been hypothesized that the close relation between nerves and myofibroblasts allows an amplification of the afferent system in its response to stimulatory mediators such as ATP.

2.2. Myogenic Hypothesis

2.2.1. Context

OAB may be related to changes to the excitability and coupling of smooth muscle cells with other myocytes or interstitial cells leading to the generation of uninhibited contractions [72,73]. Brading and Turner have suggested that myogenic changes (regardless of aetiology) may contribute to the pathophysiology of IDO [72,73]. On the basis of observation that denervation is consistently found in detrusor biopsy specimen from patients with various forms of DO, it has been proposed that partial denervation of the detrusor may alter the properties of smooth muscle, leading to increased excitability and increased coupling between cells [74]. Drake *et al.* [6] later proposed that DO may result from histological changes within the detrusor [75], leading to abnormal electrical coupling of smooth muscle cells so that physiological micromotions become synchronized into active involuntary detrusor contractions [76]. However, other data suggest that increased afferent signaling resulting from urothelial/suburothelial dysfunction may contribute to uninhibited detrusor contractions [20] or that DO could be initiated from changes in central neural control of the micturition reflex [12].

Thus, local contraction (activity) that occurs somewhere in the detrusor will spread throughout the bladder wall, resulting in coordinated contraction of the whole bladder. In addition, this local contraction in the bladder wall has been shown to generate afferent discharge [77,78]. Localized bladder activity was assessed by the micromotion detection method, demonstrating that women with increased bladder sensation on filling cystometry had a significantly higher prevalence of localized activity than the control group [79]. This observation suggests that localized distortion of the bladder wall simulates afferent activity, which would precipitate a feeling of urgency and (DO) [80,81] (Figure 3).

2.2.2. Molecular basis

Although the relationships between intercellular communication and spontaneous mechanical activity and the degree of involvement of different types of connexins (Cxs) need further study, Cx45 and Cx43 appear to be the most prominent Cxs expressed in human detrusor smooth muscle tissue and cultured cells. Observations in tissue biopsies from patients with NDO and urgency symptoms clearly demonstrated an increase in the presence of Cx43-derived gap junction channels in detrusor muscle [82].

Another population of cells in the bladder, known as interstitial cells, has been proposed for a pacemaking role in spontaneous activity of the bladder [83,84]. The number of interstitial cells is increased in a guinea-pig model of bladder outlet obstruction (BOO) [85] and that c-kit tyrosine kinase inhibitors, which inhibit interstitial cell activity, decreased the amplitude of spontaneous contractions in the guinea-pig and human bladder [86,87], interstitial cells may also be involved in the emergence of (DO) because of enhanced autonomous detrusor muscle activity.

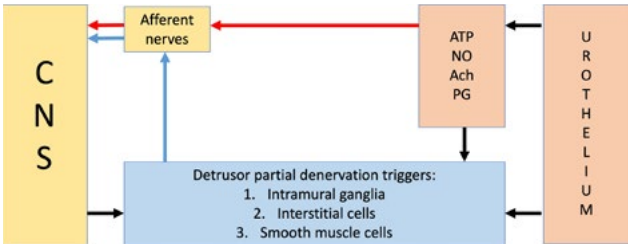

Figure 1: *Mechanisms involved in increased afferent input from the bladder: the urothelium-based and myogenic theories.*

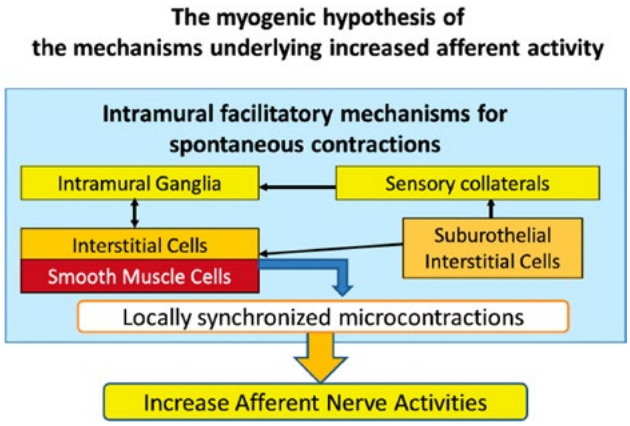

Figure 3: The myogenic hypothesis of the mechanisms involved in increased afferent input from the bladder.

2.3. Urethrogenic hypothesis [12]

In the early 20th century, Barrington described component reflexes of micturition evoked by running water through the urethra which resulted in a strong bladder contraction mediated through pudendal and pelvic afferent and efferent signals [88]. Using an animal model, Jung *et al.* hypothesized that entry of urine into the proximal urethra in patients with SUI may stimulate urethral afferents, inducing and/or increasing DO [89]. Their findings were confirmed a few years later in healthy human volunteers leading to generation of the hypothesis of an urethrovesical reflex [90].

Moving from a sitting or lying position to a standing position can cause urgency in many patients. This is considered a clinical feature of OAB originating from the urethra [91]. Urodynamics is not so useful to detect DO in these patients, as the investigation is usually performed only in the sitting position, the catheter might partially seal the bladder neck and patient positioning during filling cystometry may influence involuntary detrusor contractions. Valsalva-induced involuntary detrusor contractions may provoke DO in these patients [92].

Surgical repair of SUI improves storage LUTS in some patients with mixed incontinence [93]. However, *de novo* urgency is reported to occur in over 10% of patients undergoing any form of SUI surgery. In patients with pelvic organ prolapse, urgency may result from a prematurely activated micturition reflex caused by inability to support bladder neck/proximal urethral stretch receptors, which could explain the high rates of OAB symptom resolution after surgical correction of pelvic organ prolapse [94].

While primary deterioration of urethral tone has been advocated as a possible cause of OAB, the concept of urethral instability (i.e., urethral pressure variation during bladder filling) has been proposed as another mechanism of urethra-driven urgency, which may be due to a lack of pudendal or central neurological control [95]. Some evidence supports the role of SUI surgery in patients with urethral pressure variation [96].

Two other mechanisms of OAB symptoms due to severe SUI might be encompassed in this urethrogenic hypothesis [12]. First, constant leakage in patients with severe SUI may result in a chronically underfilled, "defunctionalized" bladder. Such patients may develop artifactual DO or impaired compliance generating urgency [97]. These abnormalities have been shown to resolve in many cases after surgical correction of SUI by restoring the physiological cycles of bladder storage and voiding [97]. The second mechanism appears to be related to pre-emptive urinary frequency voluntarily undertaken to prevent incontinence episodes in patients with severe SUI [12].

2.4. Detrusor underactivity [12]

Underactive bladder is currently a subject of considerable research [98]. While underactive bladder is considered to be the clinical correlate of urodynamicdetrusor underactivity, the voiding symptoms associated with detrusor underactivity overlap with OAB. Urgency was reported to be the most common symptom in patients with urodynamically proven detrusor underactivity (seen in over 50% of patients) [99]. In a survey-based epidemiological study including 977 patients underactive bladder symptoms were urgency, UUI, and nocturia [100]. The occurrence of urinary urgency in patients with DO can also be attributed to the well-known DO/impaired contractile function entity [101], which, in this context, is no doubt related to increased postvoid residuals and the subsequent reduced functional bladder capacity. In addition, urgency in detrusor underactivity can be attributed to urinary tractinfections (UTIs) secondary to chronic urinary retention [102] or the impact of such retention on the urinary microbiota. Current data suggest that detrusor underactivity may result from urothelial/suburothelial dysfunction (urotheliogenic hypothesis) and/or from detrusor muscle dysfunction (myogenic hypothesis) [103].

2.5. Other Factors

Several other processes may factor in development of DO/OAB. This includes ageing, bladder outlet obstruction (BOO), bladder ischaemia and mucosal injury.

Ageing and BOO may have a common pathway in contribution to DO/OAB development. Remodeling of the micturition circuits caused by ageing and BOO both involve a) ischaemia/reperfusion and oxidative stress, and b) chronic inflammation [104, 105] (Figure 4). In addition, there is an increasing evidence for the role of the urinary microbiome in relation to DO/OAB (See section I: Microbiota in incontinence and pelvic floor dysfunctions). BOO-induced bladder remodeling: hypertrophy, compensation (increased detrusor contractility during the voiding phase, often in combination with filling phase DO) followed by the phase of decompensation (detrusor underactivity) [105].

2.5.1. Process of ischaemia and reperfusion

Ischaemia/reperfusion has been proposed as a pathophysiological factor underlying DO/OAB. Recent studies suggest that macrovascular and microvascular disease may lead to OAB in both men and women via ischeemia, hypoxia and oxidative stress in the bladder [106-109]. DO associated mitochondrial stress may also have a role in epithelial damage, smooth muscle cell injury and neurodegeneration. Superoxide dismutase and aldose reductase up-regulation in OAB suggests an intrinsic defensive reaction against free radicals that apparently fails to prevent oxidative damage and neurodegeneration [108]. Up-regulation of HIF, TGFB, VEGF and NGF in the ischaemic bladder is accompanied by the loss of mitochondrial structural integrity, fibrosis, and the degeneration of microvasculature and nerve fibres [110,111]. These observations may suggest the role of ischaemia in OAB with impaired contraction, as reported in elderly patients without obstruction. Ischaemia may be a key factor in age associated LUTS.

2.5.2. Inflammation

By definition, the presence of bladder inflammation precludes a clinical diagnosis of OAB. However, there are increases in the amount of pro-inflammatory mediators within the bladder and urine of OAB patients [112-114].

Different studies have inflammation in bladder biopsy specimens from OAB patients [110, 115]. Increases in cytokines, chemokines, and growth factors have been reported in the urine of OAB patients [116]. Consistent association of increasing serum C-reactive protein (CRP) levels and OAB has been demonstrated in the literature [117-119]. Moreover, Liu *et al.* demonstrated increased levels of serum adipokines (adipose tissue secreted cytokines), including IL- 6, IL-8, and TNF, refractory to antimuscarinic therapy compared to the control subjects [119]. In this study, no significant difference was found in adipokine levels between OAB-dry and OAB-wet, while serum CRP and NGF levels were significantly higher in OAB-wet, compared to controls. The prevalence of OAB increased with increasing CRP levels in both men and women, supporting the role of inflammation in the development of OAB. These findings suggest that some OAB patients might have pathophysiology linked to urinary or systemic inflammatory conditions.

Serum monocyte chemotactic protein-1 (MCP-1) levels have been shown as significantly higher only in OAB-dry compared to controls [119]. This suggests that more systemic inflammatory disorders exist among OAB-dry patients, as MCP-1 provokes mast cell activation and has chemotactic activity for monocytes that mature into macrophages at the site of inflammation.

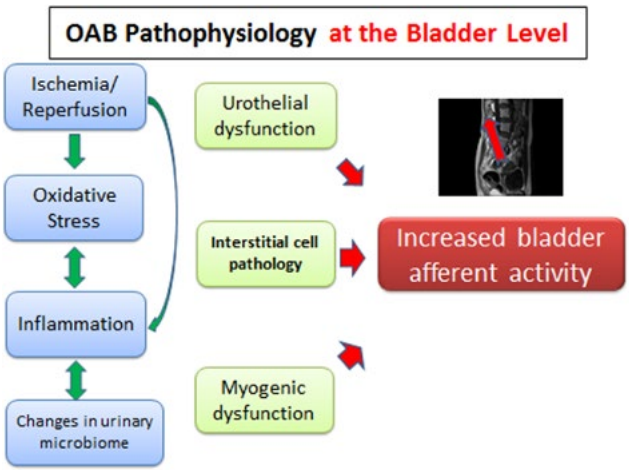

Figure 4: Potential factors involved in OAB pathophysiology at bladder level.

Age-associated biochemical changes may accentuate the inflammation associated with OAB. A study on urinary chemokines in OAB patients showed an age-associated elevation of NGF, suggesting a homeostatic response to counter the senescence of bladder nerves and arrest the progression of OAB into detrusor hyperactivity with impaired contractile finction [120]. All together, these findings support the hypothesis for the role of chronic inflammation at the local and systemic levels in the development of OAB.

3. NEUROPATHOLOGY: ABNORMAL HANDLING OF AFFERENT SIGNALS IN THE BRAIN

Among the theories contributing to the complex mechanisms underlying the genesis of DO/OAB we report the supraspinal hypothesis with urgency originating from the brain and brainstem [12].

3.1. Supraspinal hypothesis

Control of the LUT by the brain has received increasing attention over the past 15-20 years, and investigation with imaging techniques has revealed several brain centres associated with control of urine storage and voiding [121]. Theories have evolved regarding interconnection of these centres and further control of micturition by “circuits” associated with: a) the decision “to void or not to void” following contextualization of bladder sensory information with preconscious and conscious control over bladder filling and voiding (circuit 3, frontal brain); b) pattern/environmental recognition and relation of urinary status to emotional state (circuit 2, subcortical/limbic system); and c) the registration of bladder sensory information and preparation of motor responses (circuit 1, relation to desire to void) [122].

Since the late 1990s the decreased capacity to functionally integrate afferent information or reduced supraspinal inhibitory control of the micturition reflex has been suggested as a possible pathophysiological mechanism of OAB with the emergence of functional brain imaging [12, 123]. Increasing evidence supports the idea of two distinct subtypes of “brain OAB”: one with and one without DO [124]. Activity in the insula (lower bladder volumes) and anterior cingulate gyrus/supplementary motor area (higher volumes) may be neural characteristics of urgency without DO, while the neural signature of DO seems to be deactivation in the prefrontal cortex [124]. The difference in supraspinal activity between OAB patients with or without DO was confirmed by Tadic *et al.* [125], demonstrating that older age and a greater burden of white matter damage in patients with DO are associated with more severe functional urinary impairment. Several reports support the hypothesis that this “white matter disease” could be the anatomical substrate for the brain aetiology of OAB associated with DO, maybe through frontal hypoperfusion [122].

Blood oxygen level-dependent (BOLD) fMRI is a functional neuroimaging modality that has emerged as a useful tool in the study of the central pathways of micturition and bladder dysfunction [126]. As recently reported by Smith [127], the anterior cingulate gyrus, insula, and frontal cortices have been implicated as areas of increased activation in women with OAB [123, 128]. Furthermore, studies using bladder filling to provoke urgency suggest a neural correlate of the experience of urgency [124]. The cerebellum and parietal lobe have demonstrated increased activation during inhibition of voiding and contraction of the pelvic floor muscles [129]. Increased connectivity between the cerebellum and parietal lobe and the right insula and anterior cingulate gyrus has been demonstrated in women with UUI compared with controls [125].

Neurogenic Detrusor Overactivity (NDO) is a urodynamic observation characterized by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked in the setting of a clinically relevant neurologic disease [2,13]. The pathophysiology of NDO is described elsewhere. (See section V: Neurological patients: neurogenic basis of overactive bladder).

4. OAB PHENOTYPING ACCORDING TO PATHOPHYSIOLOGICAL COFACTORS

According to Peyronnet et al [12], different pathophysiological factors may configure different OAB types. The relation between OAB phenotypes according to urodynamic demonstration of DO and according to pathophysiological factors are shown in Figure 5.

4.1. Metabolic syndrome [12]

A link between metabolic syndrome and OAB has been demonstrated in many studies, especially between obesity and OAB [130,131]. While this association was initially thought to be driven through benign prostatic hyperplasia/chronic prostatic inflammation [131], increasing evidence has shown that OAB occurs equally in both men and women with metabolic syndrome [130,131]. OAB may have its own pathophysiology in patients with metabolic syndrome, relying on increased mechanical load stimulating sensory afferents of the trigone and bladder neck, but also on oxidative stress, systemic inflammation, and insulin resistance that promote chronic pelvic ischaemia and urothelial dysfunction [130,131].

4.2. Affective disorders [12]

Recent data demonstrate the influence of emotional stress and affective disorders on the natural history of OAB [132]. Hence, there may be a bidirectional association between affective disorders and OAB. Corticotrophin- releasing factor (CRF) has been investigated as a possible common pathophysiological contributor to OAB and anxiety/depression [133]. The concomitant decrease in serum CRF levels and improvement of depression induced OAB observed using a CRF receptor type 1 antagonist in a recent animal model study confirms this possible mechanism, while highlighting a possible therapeutic pathway for social stress induced OAB [134]. Serotonin depletion has been postulated as another shared pathophysiological candidate for both anxiety/depression and OAB, as its role in affective disorders is well established and several experimental studies have demonstrated that lowering of serotonin levels in the CNS was accompanied by urinary frequency and DO [135-137].

4.3. Sex hormone deficiency [12]

Sex hormone deficiency has been described as having a role in the pathogenesis of LUTS, with up to 70% of women relat-

ing the onset of UI to their final menstruation [138]. Oestrogen deprivation may lead to urgency with increased detrusor contractility through Rho-kinase pathway activation, increased acetylcholine release, changes in urothelial afferent signaling, or increased connexin-43 expression [138,139].

4.4. Urinary microbiota

The urinary microbiota may play a role in the pathogenesis of OAB. (See section I: Microbiota in incontinence and pelvic floor dysfunctions).

4.5. Functional gastrointestinal disorders [12]

The gastrointestinal condition that has most frequently been -related to OAB is irritable bowel syndrome (IBS) [140–142], with a prevalence as high as 33.3% in patients with OAB [143]. Both disorders are characterized by increased frequency of visceral emptying due to increased sensation (urgency for OAB; pain and discomfort for IBS) [144]. Central sensitization has been hypnotized as a primary dysfunction affecting the concurrence of both gastrointestinal and urological functional disorders alongside affective disorders (e.g., anxiety and depression) as part of a brain-gut-bladder axis [145]. This possible brain-gut-bladder axis–OAB phenotype might be induced by stress due to either psychological factors (e.g., a previous traumatic event) or physical factors (e.g.,internal/external physical threat) [12].

4.6. Autonomic nervous system dysfunction [12]

In several neurological conditions, sympathetic, parasympathetic, and somatic nerves dysfunction hasbeen associated with N-LUTS (See section V: Neurological patients: neurogenic basis of overactive bladder). Blanc *et al.* were the first authors to hypothesize that subclinical autonomic nervous system dysfunction may be a causative factor of “idiopathic” OAB [146]. Hubeaux *et al.* suggested that bladder filling induces a global sympathetic response in women with OAB [147]. The same group reported that sympathetic dysfunction might be predominant over parasympathetic dysfunction in OAB patients and that OAB patients with autonomic dysfunction maybe less likely to exhibit DO on urodynamics [148].

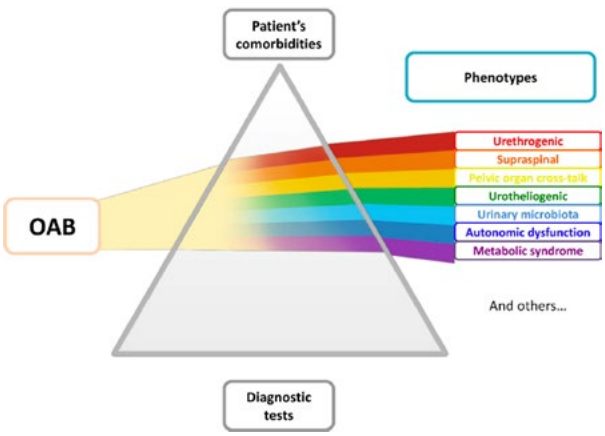

Figure 5: The diagnosis “prism” approach of OAB phenotypes. The new diagnostic approach should seek for the underlying pathophysiological phenotypes, which could probably be achieved through a thorough clinical examination (though the clinical hallmarks of some phenotypes are still to be identified), eventually associated with urodynamics and other testing in selected cases.

IV. NEUROLOGICAL PATIENTS: NEUROGENIC BASIS OF OVERACTIVE BLADDER

1. INTRODUCTION

This chapter deals with basic information related to neurologic urinary and faecal incontinence; Literature searches were undertaken with keywords; “neurologic”, neurogenic”, “bladder”, “bowel”, “lower urinary tract”, “anorectal”, “incontinence “, “continence”, “urinary”, “faecal”, “paralysis”, “dysfunction”, “retention”, “constipation”. Searches for specific neurologic diseases were undertaken, looking into selected neurological diseases of particular relevance to neurourology, comprising those more prevalent or more challenging in terms of continence diagnosis and treatment.

Continence relates to reservoir functions of the bladder and rectum, and closure of their respective outlets by contraction of smooth muscle (bladder neck and internal bowel sphincter) and striated muscle (urethral and anal sphincters). Expulsion requires relaxation ofthe sphincters , and contraction of the musculature of the reservoirs, to permit evacuation of urine or faeces.

The lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically, bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lie in close proximityand close to the muscular structures of the pelvic floor. Both are innervated by autonomic and somatic nerves (Table 1), and have similar principles underlying central control [2, 3].

The lower bowel tract (LBT) differs from the urinary bladder in having an enteric nervous system [4]. Interactions between the two organ systems are increasingly recognized, and their activity is coordinated. Voiding can occur without defecation [5], and the initiation of micturition often precedes that of defecation, even if both organs are considered equally full [6]. The filling status of the bladder influences sensation in the rectum and vice versa [7], and the potential for mutual influence in pathology is emerging [8]. Nonetheless, little information is available on co-ordination of both functions in patients with neurological pathology.

Table 1: Overview of function of the abdominal sympathetic, the pelvic parasympathetic and somatic nerves in the LUT and LBT.

	Sympathetic T10-L1	Parasympathetic S2-4	Somatic S3-5
Bladder	-	+	
Bladder neck	+	-	
External urethral sphincter	exp	exp	+
Bowel		+	
Internal anal sphincter	+	-	
External anal sphincter	exp	exp	+
Pelvic floor			+

Exp= only suggested in animal experiments, no definite clinical evidence.
Suggestion to take exp = experimental out because it is for the common reader misleading and it is depending to the chosen animal model.

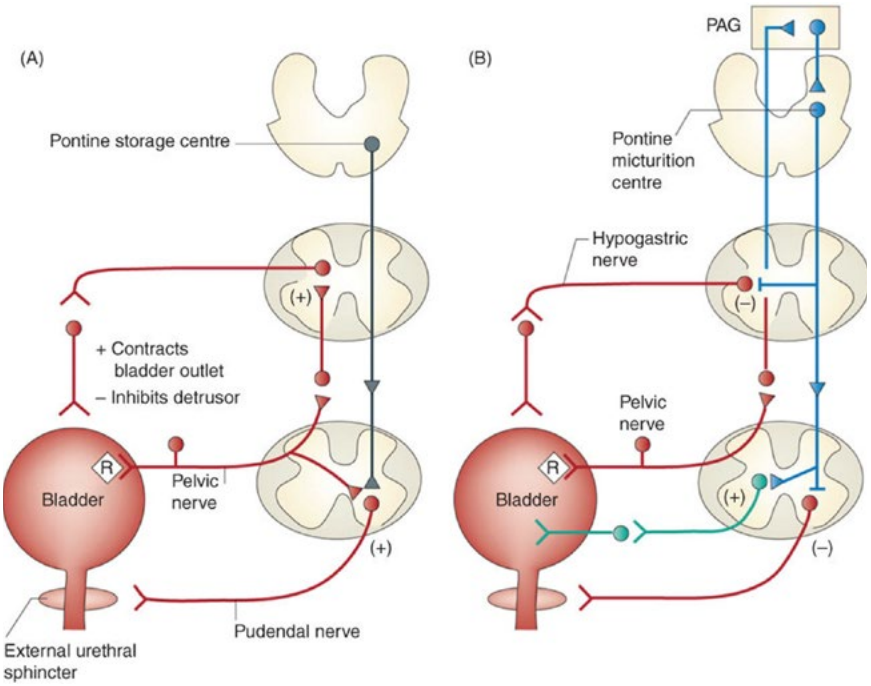

Figure 1: Neural circuits that control continence and micturition. (A) Urine storage reflexes. During the storage of urine, distention of the bladder produces low-level vesical afferent firing. This in turn stimulates the sympathetic outflow in the hypogastric nerve to the bladder outlet (the bladder base and the urethra) and the pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways and represent guarding reflexes, which promote continence. Sympathetic firing also inhibits contraction of the detrusor muscle and modulates neurotransmission in bladder ganglia. A region in the rostral pons (the pontine storage centre) might increase striated urethral sphincter activity. (B) Voiding reflexes. During the elimination of urine, intense bladderafferent firing in the pelvic nerve activates spinobulbospinal reflex pathways (shown in blue) that pass through the pontine micturition centre. This stimulates the parasympathetic outflow to the bladder and to the urethral smooth muscle (shown in green) and inhibits the sympathetic and pudendal outflow to the urethral outlet (shown in red). Ascending afferent input from the spinal cord might pass through relay neurons in the periaqueductal gray (PAG) before reaching the pontine micturition centre. Note that these diagrams do not address the generation of conscious bladder sensations, nor the mechanisms that underlie the switch from storage to voluntary voiding, both of which presumably involve cerebral circuits above the PAG. R represents receptors on afferent nerve terminals.

(original from: de Groat WC1, Griffiths D2, Yoshimura N3. Neural control of the lower urinary tract. Compr Physiol. 2015 Jan;5(1):327-96. doi: 10.1002/cphy.c130056 .)

Any disturbance of the nervous system can result in signs and symptoms of lower urinary tract dysfunction (LUTD). [9] The extent and location of the neurological dysfunction will determine the type of LUTD, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function. [10]

Neurogenic LUTD (nLUTD) applies to a spectrum of clinical conditions and refers to the presence of LUTD symptoms 'when there is a relevant neurological condition'.[11] Urodynamics (UDS) can measure LUTD caused by a lesion in the brain and or spinal cord or peripheral nerves; associated with a congenital condition (e.g.myelomeningocele), an acquired, stable condition (e.g., stroke, spinal cord injury), or an acquired, progressive condition (e.g., multiple sclerosis [MS], Parkinson's disease, dementia).[12] Because not all patients with neurogenic conditions develop LUTD or have abnormal UDS findings, a specific understanding of the dysfunction in each individual is a prerequisite for the correct choice of therapy.

2. NEUROPATHOLOGY

2.1. Pathophysiology

With a neurologic lesion the type of dysfunction that follows in LUT (and LBT) will depend on the site, the extent and the evolution of the deficit. Traditionally neuro-urological pathology has been divided into the upper motor neuron lesions (UMNL), comprising suprapontine (cerebral) and suprasacral (brainstem, and spinal cord); and lower motor neuron lesions (LMNL), comprising sacral and subsacral (cauda equina and peripheral nerve). Brainstem lesions are rarely compatible with more than short-term survival, so they are only infrequently encountered in neurourological practice.

Powell proposed a new step in classification of the neurogenic bladder: SALE (Stratify by Anatomic Location and Etiology). [13] The classification is based on seven categories, each having a neurologic defect in a distinct anatomic location. In addition, the presence or absence of bowel dysfunction and autonomic dysreflexia is reported. In the future, as more definite prognostic information can be gleaned from biomarkers [14], urinary nerve growth factor (NGF) and urinary brain-derived neurotrophic factor (BDNF) levels were hoped to be added to the classification. The SALE system should efficiently describe a patient suffering from neurogenic bladder (NGB) and simultaneously inform the most appropriate treatment, follow-up regimen, and long-term prognosis. [15]

2.2. Neurogenic Detrusor Overactivity

Damage to the central inhibitory pathways, or sensitization of afferent nerves, may lead to the unmasking of primitive voiding reflexes, which may trigger involuntary detrusor contractions [89,90]. In addition, increased release of nerve growth factor (NGF) in DO has been reported, which may alter the neural regulation of detrusor muscle [16-18]. Plasticity in peripheral innervation and within the central nervous system (CNS) may both play a pathophysiological role in DO [19]. Peripherally, neurological diseases might cause a sensitisation of C-fibres that are silent under normal circumstances, thereby leading to the emergence of a C-fibre-mediated reflex.

While many neurological diseases predispose patients to NDO, the only populations that have been systematically studied are adults with multiple sclerosis, adults with SCI and children and young adults with myelodysplasia [20].

3. STROKE, CEREBRAL INFARCTION

3.1. Suprapontine lesions

It is generally accepted that suprapontine lesions such as stroke and Parkinson's disease produce DO. The patient with a suprapontine lesion loses voluntary inhibition of micturition, which corresponds to uninhibited overactive bladder according to a classification by Fall *et al* [21, 22]. Higher brain centres provide an additional level of urinary control, which is responsible for conscious sensation, volition and emotional response. Key higher centres include the prefrontal cortex, insular cortex and anterior cingulate gyrus, and functional brain imaging has shown changes in higher CNS activity in OAB [20, 23, 24]. Although such observations have been made infrequently, they do point to some key areas for consideration. For example, the participation of several brain areas in urinary control may explain why brain disease and cerebral atrophy are risk factors for lower urinary tract dysfunction. [20, 25]

Variation in observations between individuals implicates a diversity of processes in the mechanisms that underly OAB, although these are manifest clinically in OAB symptoms. The increased activity observed in certain regions of the brain in patients with OAB may actually be compensatory, to counteract urgency, rather than being responsible for the symptom [20]. This confounds interpretation of function, and there are many questions that still need to be answered.

Brain transection studies in animals with an intact neuraxis show that suprapontine areas generally exert a tonic inhibitory influence on the pontine micturition center (PMC). [25-27] [Figure 1] In humans, the cerebral cortex (medial frontal lobes) and the basal ganglia are thought to suppress the micturition reflex. Thus, damage to the brain induces DO by reducing suprapontine inhibition.

In the CNS,a glutamatergic pathway plays a role in both excitatory and inhibitory regulation of micturition. Results from animal models indicate that bladder overactivity induced by cerebral infarction occurs in two phases, both of which depend on activation of NMDA glutamatergic receptors. The cerebral infarction model demonstrates that bladder overactivity is mediated by NMDA glutamatergic and D2 dopaminergic excitatory mechanisms, suggesting that cerebral infarction may alter a balance between the facilitatory and inhibitory mechanism that results in up-regulation of an excitatory pathway and down-regulation of a tonic inhibitory pathway. [27]

4. PARKINSON'S DISEASE

Parkinson's disease (PD) has been long characterized by the degeneration of dopamine-producing cells in the substantia nigra of the midbrain and Lewy body formation, leading to motor dysfunction such as bradykinesia or akinesia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes also have influence on

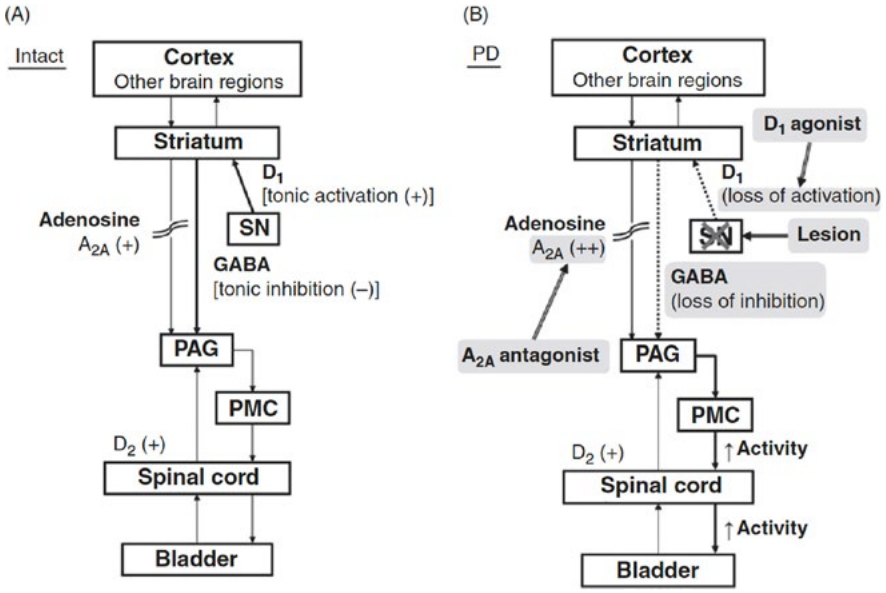

Figure 2: Hypothetical diagram showing dopaminergic and adenosinergic mechanisms inducing bladder dysfunction in Parkinson's disease (PD). The micturition reflex is controlled by the spinobulbospinal pathway passing through the PAG in the midbrain and the PMC in the pons. This neural circuit is under the control of higher centers including the striatum and the cortex region. A. Under normal conditions (Intact), tonic firing (+) of dopaminergic neurons in the SN activates dopamine D, receptors expressed on GABAergic inhibitory neurons in the striatum to induce tonic GABAergic (-) inhibition of the micturition reflex at the level of the PAG. At the same time, D, receptor stimulation suppresses the activity of adenosinergic neurons, which exert an excitatory effect on micturition via adenosine A2A receptors (Adenosine A2a (+)]. B. In PD, dopaminergic neurons in the SN are lost (lesion), leading to the loss of dopamine D1 receptor activation [D1 (loss of activation)], which results in reduced activation of inhibitory GABAergic neurons in the striatum (GABA (loss of inhibition)]. At the same time, reduced D1 receptor stimulation enhances the adenosinergic mechanism to stimulate adenosine A2A receptors [Adenosine A2A (++)], leading to facilitation of the spinobulbospinal pathway controlling the micturition reflex (activity). Administration of dopamine D, receptor agonists (D, agonist) can restore the GABAergic nerve activity and suppress Aza receptor-mediated activation to reduce bladder overactivity in PD. Also, administration of adenosine A2A receptor antagonists (A2A antagonist) can suppress A2A receptor-mediated activation of the micturition reflex to reduce bladder overactivity in PD. Dopamine D2 receptors [D2 (+)] expressed in the spinal cord enhance the micturition reflex. Abbreviations: dopamine Di receptor (D1); dopamine D2 receptor (D2); gamma-aminobutyric acid (GABA); periaqueductal gray (PAG); pontine micturition center (PMC); substantia nigra pars compacta (SN).

(original from: de Groat WC1, Griffiths D2, Yoshimura N3. Neural control of the lower urinary tract. Compr Physiol. 2015 Jan;5(1):327-96. doi: 10.1002/cphy.c130056 .)

autonomic function; the most common problems are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary system.

However, the symptomatology of Parkinson's disease is heterogeneous, with clinically significant non-motor features. Similarly, its pathology involves extensive regions of the nervous system, various neurotransmitters, and protein aggregates other than just Lewy bodies. The cause of Parkinson's disease remains unknown, but risk of developing Parkinson's disease is no longer viewed as primarily due to environmental factors. Instead, Parkinson's disease seems to result from a complicated interplay of genetic and environmental factors affecting numerous fundamental cellular processes.[28]

PD patients often exhibit overactive bladder symptoms such as urinary urgency, frequency, and incontinence which are induced by DO, estimated to be as high as 50% to 70%. [27]

The most widely accepted theory of pathophysiology of DO in PD is that basal ganglia inhibits the micturion reflex in the normal situation via D1 receptors, and that cell depletion in the substantia nigra in PD results in loss of D1-mediated inhibition and consequently DO. (Figure 2, [27])

LUT dysfunction in PD is estimated to occur in 50-70% [27]. Among these, Hattori et al. [29] (LOE3) reported 60% of PD patients with urinary symptoms, which could be divided in three categories: storage LUTS in 28%, voiding in 11%, and mixed in 21%. Prevalence correlated with PD severity, but not with duration of illness. Gray et al. [30] (LOE3) reported that LUT functional disturbances in PD were not disease-specific and only correlated with age.

In controlled studies [31-34] (LOE2) the prevalence of LUT symptoms (LUTS) was 27-64%, significantly higher than healthy controls. The majority of patients had onset of bladder dysfunction after the appearance of motorsymptoms. Bladder dysfunction substantially affects the quality of life in patients with PD. Bladder dysfunction in PD correlates with neurological disability, and stage of disease, both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of older PD patients, as in healthy populations. Among LUTS, nocturia (nighttime urinary frequen-

cy) is the most prevalent symptom (>60%) [33, 34] (LOE2). Patients also complain of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 26% of males and 28% of females. These figures are almost the same in untreated, early PD patients [35]. Although less common than storage symptoms, PD patients also report voiding symptoms. Sakakibara *et al.* [36] (LOE2) reported significantly higher rates of delay in initiating urination (44% of men), prolongation/poor stream (70% of men), and straining (28% of women) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals. Impaired detrusor contractility is reported in urodynamic studies in PD and is related to the degree of motor impairment [37]; impaired detrusor contractility was observed in 66% of women and 40% of men. [38, 39] (LOE2)

4.1. Pathology and disease-specific urinary tract problems

Deep brain stimulation in the subthalamic nucleus results in amelioration of the motor disorder as well as increased bladder capacity and decreased post-void residuals [40] (LOE2).

Related to the recent COVID-19 pandemic urinary issues and fatigue were notice in a Community-Based Case-Control Study, the most prominent nonmotor issues.**[41]**

4.2. Conclusions

In Parkinson's disease, LUT symptoms are associated with degeneration of dopaminergic neurotransmission (LOE2). The most common LUT disturbances are detrusor overactivity during storage, and impaired detrusor contractility during voiding (LOE2). The effect of levodopa on LUTS in PD patients remains to be fully elucidated (LOE3).

5. MULTIPLE SYSTEM ATROPHY (MSA)

Multiple system atrophy (MSA) is a rare and fatal neurodegenerative disorder characterized by a variable combination of parkinsonism, cerebellar impairment, and autonomic dysfunction.[42] Some MSA patients survive as little as 2 years, whereas a few survive much longer, up to 20 years. [43, 44]. The term MSA was introduced by Graham and Oppenheimer in 1969 to describe a disorder of unknown cause affecting extrapyramidal, cerebellar, and autonomic pathways [45]. The exact mechanisms leading to neurodegeneration still remain elusive – a accumulation of aggregated α-synuclein in oligodendrocytes forming glial cytoplasmic inclusions (GCIs), which qualifies MSA as a synucleinopathy together with Parkinson's disease (PD) and dementia with Lewy bodies (DLB). MSA-specific α-synuclein species have yet to be formally identified from oligodendrocytes of MSA patients. [42]

Autonomic failure (AF) is almost invariably present and can be an initial manifestation (AF-MSA) [46]. Autonomic failure occurs in other neurodegenerative diseases, for example in a subset of patients with IPD (AF-PD), as well as in pure autonomic failure (PAF), both of which are considered Lewy body diseases.

5.1. Pathology and disease-specific LUT problems

In male erectile dysfunction is often the first presentation [47-49] possibly preceding the occurrence of urinary dysfunction in MSA. Both OAB and large post-void residuals occur in MSA. The second consensus statement on the diagnosis of MSA recognizes that the disease frequently begins with bladder dysfunction (although erectile dysfunction usually precedes that complaint).

Reports of focal lesions have shown that postural hypotension occurs in lesions below the medulla, whereas urinary dysfunction occurs in lesions at many sites in the neuroaxis. These might be investigated by a brain 18-FDG-PET [50]. MSA lesions involve the pons, the hypothalamus, and the basal ganglia, all of which might affect LUT function. Urinary dysfunction also precedes the motor disorder, approximately 60% of patients with MSA develop urinary symptoms either prior to or at the time of presentation with the motor disorder [51]. Many of these patients may seek urological advice early in the course of their disease.

Patients may present with urinary incontinence, urinary retention, or a combination of incontinence and incomplete bladder emptying and other common causes of poor bladder control are excluded [52, 53]. For example, the prevalence of troublesome urinary symptoms in 256 patients with MSA compared with 158 aged matched control subjects [54] showed that MSA patients had significantly higher increased daytime frequency (45% of women, 43% of men), night time frequency (65%, 69%), urinary urgency (64% of men), and urgency incontinence (75%, 66%) than the controls. They also had more hesitancy of micturition (62%, 73%), prolonged poor stream (71%, 81%), or intermittent stream (61%, 47%), or the need to strain to void (48%, 55%). The quality of life (QOL) index in the MSA group was significantly worse in MSA patients for bladder dysfunction (70%, 76%) than that in controls. Many show larger post-void residual urine volumes > 100 ml. Therefore, as reported in the initial publications. both overactive bladder and large post-void residuals are common in MSA [55, 56]

Of various symptoms of autonomic failure (erectile dysfunction, urinary dysfunction, postural hypotension, respiratory stridor) in patients with MSA, urinary dysfunction has attracted less attention than postural hypotension, although urinary dysfunction may result in recurrent urinary tract infection and cause morbidity.

If severity of urinary symptoms is severe enough for surgical intervention, males with MSA may undergo surgery for prostatic outflow obstruction before the correct diagnosis has been made. The results of such surgery are often transient or unfavourable because of the progressive nature of the disease. In addition, UI results in impaired self-esteem, stress on the caregiver, and considerable financial cost..

Gallien *et al.* found urinary symptoms (96%) to be more common than orthostatic symptoms (postural faintness (43%), blurred vision (38%) and syncope (19%)).[57] The most frequent urinary symptom was voiding difficulty (79%) followed by nocturnal urinary frequency in 74%. Other symptoms included urgency (63%), urgency incontinence (63%), diurnal urinary frequency (45%), nocturnal enuresis (19%), and urinary retention (8%) as reported by others. [58, 59]

The urologist confronted with a patient with these features should be cautious about embarking on an operative approach. The neurologist encountering a patient with marked urinary symptoms might consider future investigation by brain MRI and sphincter EMG. Since motor disorders in MSA mostly mimic those in IPD, the urogenital distinction between these two dis-

eases is worth considering, although a number of earlier studies on 'Parkinson's disease and the bladder' might inadvertently have included patients with MSA. The prevalence of urinary dysfunction and urgency incontinence in MSA is higher than that reported in IPD. Urinary dysfunction is almost never the initial presentation in IPD.

6. SPINAL CORD LESIONS (NOT INCLUDING NEWBORN AND CHILDREN)

A spinal cord lesion above the lumbosacral level eliminates voluntary and supraspinal control of micturition, leading to DO mediated by spinal reflex pathways [60]. Disruption below the level of the pons leads to unsustained and uncoordinated detrusor contractions often associated with uncoordinated sphincter overactivity (detrusor-sphincter dyssynergia, DSD). [61] Impairment or loss of bladder sensation is a typical feature.

On the bladder level: increased TRPV1, P2X3 and pan-neuronal marker (PGP9.5) staining in suburothelial nerves and increased TRPV1 staining in the basal layer of the urothelium have been observed in patients with neurogenic bladder due to SCI and multiple sclerosis [62].

These results indicate that an abnormality of the C-fibre afferent innervation contributes to NDO [63].

Upregulation of TRPA1 protein and mRNA levels, in bladder and in dorsal root ganglia (DRG; L6-S1) has been reported in rats with SCI. Moreover, HC-030031 (a TRPA1 antagonist) treatment decreased the number and the amplitude of DO contractions, suggesting that the TRPA1 activation and upregulation seem to exert an important role in DO following SCI [64].

Following SCI, changes in the electrophysiological properties of bladder afferent neurons have also been observed consisting of multiple action potentials (tonic firing) in response to long depolarizing current pulses [65, 66]. In addition, A-type K^+ channels are suppressed in parallel with an increased expression of TTX-sensitive Na^+ currents, thereby increasing excitability of C-fibre bladder afferent neurons [67]. These electrophysiological changes contribute to the emergence of the C-fibre-mediated spinal micturition reflex following SCI.

Sacral reflex testing has been studied extensively and is used to prove objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-/clitoro-cavernosus reflex) was shown to be a complex response, often forming two components.

The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response. [68] The second component has latency similar to the sacral reflexes evoked by stimulation peri-anally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation.During voiding sacral reflexes are un-elicitable but in presence of spinal cord lesions such as myelodysplasia this normal suppression is lostSacral reflex responses recorded with needle or wire electrodes can be analyzed separately for each side from the EAS or bulbocavernosus muscle.

6.1. Spinal cord lesions

Spinal cord injury (SCI) can be a devastating consequence of a variety of insults to the spinal column including road traffic accidents, gunshot wounds, surgical injuries, disc lesions or sports injury. It can be accompanied by vertebral fractures. Unlike other neurological diseases, once established the neurologic status generally remains stable.

6.2. Epidemiology and prevalence

SCI epidemiology has evolved over the last three decades. The incidence in women has increased over time. The male/ female ratio is now is 3.5:1. Taking into account that traumatic SCI occur mostly at a young age below 30 years [69] and nontraumatic spinal cord disease affects people at an olderage, i.e., above 55 years, the average age of persons at the time of injury is steadily increasing, but has increased in average from 29 years during the 1970s to 43 by 2015. This comprises incomplete quadriplegics (47.2%), complete paraplegics (20.2%), complete quadriplegics (13.3%) and incomplete paraplegics (19.6%). [70]

There has been a steady improvement in life expectancy and quality of life after SCI. At present, the life expectancy of paraplegic patients is similar to the general population. This has been accomplished by development of multidisciplinary teams, introduction of clean intermittent self-catheterization (CSIC) and an improved and protocol driven follow-up plan.

The SCI is classified using the American Spinal Injury Association (ASIA) impairment scale of motor and sensory function [71].

6.2.1. ASIA Impairment scale

A = Complete: No motor or sensory function is preserved in the sacral segments S4–S5.

B = Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4–S5.

C = Incomplete: Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.

D = Incomplete: Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 of more.

E = Normal: Motor and sensory function are normal.

It separates into 5 clinical syndromes [4] as follows:

- **Central cord syndrome** is most commonly due to hyperextension injury and results in haemorrhagic necrosis of the central gray matter and some of the medial white matter. Arm function is less at risk than legs because more caudal fibres of the corticospinal and spinothalamic tract are localized in the spine more laterally so are better protected. Bladder dysfunction is also less common.

- **Brown–Séquard syndrome** is a unilateral cord condition. It presents as ipsilateral motor weakness and contralateral sensory impairment of pain and temperature. Bladder dysfunction in the pure condition is uncommon.
- **Anterior cord syndrome** is characterized by injury to the anterior aspects of the cord. The posterior columns and dorsal horns are preserved. There is a motor deficit and loss of pain and temperature sensation below the level of the injury.
- **Conus medullaris and cauda equina syndrome** result from damage to the conus and spinal nerve roots, leading to flaccid paraplegia and sensory loss. Sacral reflexes can be partially or totally lost.

American Spinal Injury Association/International Spinal Cord Society published the first guideline and International Standards to document remaining Autonomic Function after Spinal Cord Injury (ISAFSCI). [72] This guideline should be used as an adjunct to the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI), including the ASIA Impairment Scale (AIS), which documents the neurological examination of individuals with SCI. The Autonomic Standards Assessment Form is recommended to be completed during the evaluation of individuals with SCI, but is not a part of the ISNCSCI. This scale involves an assessment of general autonomic function, lower urinary tract, bowel, sexual function and urodynamic evaluation. The impact of SCI on the pelvic organ function constitutes a major part of this classification [73].

6.3. Bladder dysfunction after SCI

SCI can be divided into two phases; spinal shock and a chronic phase, and can be categorized according to the level of injury.

6.3.1. Spinal shock

Spinal shock is the period just after the injury. It lasts on average three months. It is characterised by loss of muscle tone and segmental spinal reflexes caudal to the SCI. There is detrusor areflexia and the bladder is acontractile but the bladder neck and proximal urethra remains closed. This areflexia cannot be reversed with bethanechol, which is relevant in the way to describe the pathology – but although a diagnostic tool. [74]. The only reflex activity that rapidly returns are the anal or bulbocavernosus reflexes. Spinal shock is initially managed with an indwelling urinary catheter. Recently it has been demonstrated that bladder overdistension during the acute phase deteriorates lower urinary tract storage function in patients with SCI during the later phase. [75] The recovery of bladder function usually follows that of skeletal muscle reflexes. The removal of an indwelling urinary catheter and initiation of self-catheterization should be instituted as soon as practical

6.3.2. Neurogenic Bladder Dysfunction in the chronic phase

6.3.2.1. Suprasacral lesions

The spinal shock phase is followed by the appearance of a segmental spinal bladder reflex. This relates to emergence of unmyelinated C-fibre afferent function [76]. As a result, some stimuli can influence bladder and sphincter activity that were seemingly irrelevant prior to injury [77, 78]. The sacral micturition centre is disconnected from the control of higher centres and produces what is functionally an isolated spinal cord segment. This results in neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD). DSD is defined as intermittent or complete failure of relaxation of the urinary sphincter during a bladder contraction and voiding. It has been reported to occur in 96% of individuals with suprasacral lesions. In addition to DSD, internal sphincter dyssynergia also

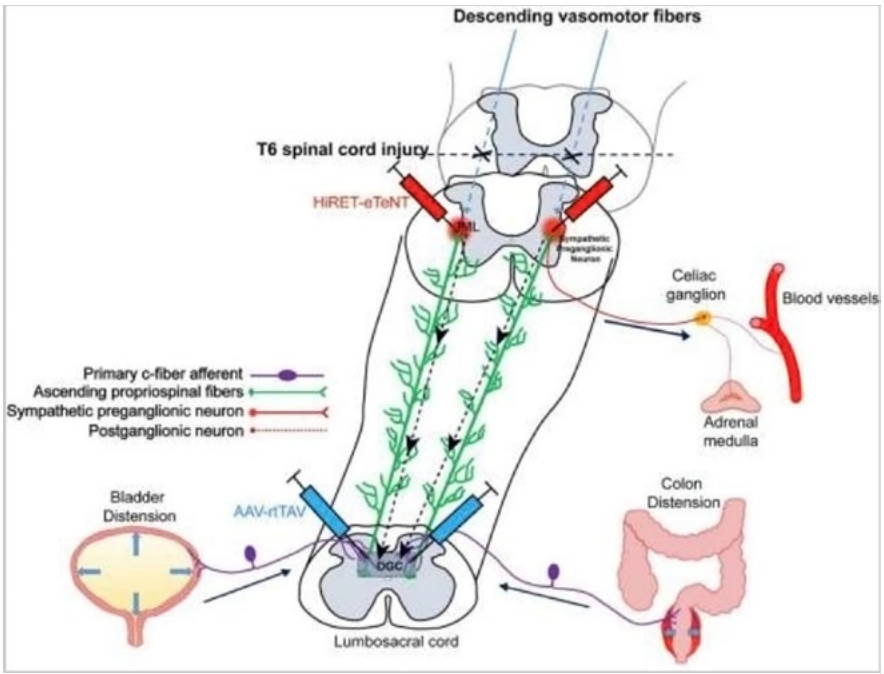

Figure 3: Eldahan KC1, Rabchevsky AG2. Autonomic dysreflexia after spinal cord injury: Systemic pathophysiology and methods of management. Auton Neurosci. 2018 Jan;209:59-70. doi: 10.1016/j.autneu.2017.05.002. Epub 2017 May 8. (original from: de Groat WC1, Griffiths D2, Yoshimura N3. Neural control of the lower urinary tract. Compr Physiol. 2015 Jan;5(1):327-96. doi: 10.1002/cphy.c130056 .)

has been reported, often occurring at the same time as DSD. Patients present with both storage and voiding dysfunction [79].

DSD can manifest with both complete and incomplete lesions. However, complete injuries are significantly more often associated with DSD. This leads to high voiding pressure, dis-coordinated voiding, residual urine and incontinence. If left untreated, this can lead to recurrent urinary infections, hydronephrosis and renal failure. Ambulatory patients with incomplete spinal cord may have significantly less urinary tract dysfunction, but the urodynamic parameters may still be abnormal.

6.3.2.1.1. Detrusor-(external) sphincter dyssynergia

Schurch *et al.* [80] assessed types of DSD in 105 chronic SCI males and evaluated change in the pattern over time. Those with an incomplete sensory and motor SCI presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. At medium to long-term follow-up, a significant change was found in the DSD type.

6.3.2.1.2. Autonomic dysreflexia

Autonomic dysreflexia (AD) is a clinical emergency in patients who have a SCI, usually at level of T6 or above. It is caused by a massive sympathetic discharge triggered by either a noxious or non-noxious stimulus originating below the level of the SCI (Figure 3, [81]. Bywater *et al.* revealed an unfavourable urodynamic parameters in 63% of the investigated patients within the first 40 days after SCI. [82]

The mechanism might be changes occurring within the spinal and peripheral autonomic circuits. There is a loss of inhibitory and excitatory supraspinal input to the sympathetic preganglionic neurons secondary to the destruction of the descending vasomotor pathways. [83] AD is characterized by severe hypertension and reflex bradycardia, though tachycardia also may occur.

An increase in systolic blood pressure greater than 20 to 30mmHg is considered a dysreflexic episode. The other symptoms could be severe headache, feeling of anxiety, profuse sweating, flushing and piloerection above the injury level with dry and pale skin below. It might also cause blurred vision, nasal congestion, cardiac arrhythmias and atrial fibrillation. It can vary in intensity, from mild discomfort to life-threatening. Untreated episodes may cause intracranial haemorrhage, retinal detachment, seizures, and death.

The severity of AD symptoms increases with completeness of injury and higher level of lesion (27% of patients with incomplete quadriplegia vs 91% of patients with complete tetraplegia) [84]. The commonest trigger for AD is bladder or bowel distention. Immediate recognition and reversal of trigger factors is essential [85.

6.3.2.2. Infrasacral lesions

In patients with injury to the sacral pathways there is decentralization of parasympathetic pathways to the detrusor with the loss of somatic innervation to the external sphincter. This results in loss of conscious awareness of bladder filling. In some people there is partial preservation of pain sensation transmitted via hypogastric nerves. Patients present with hesitancy, slow and interrupted stream, feeling of incomplete emptying, and are often in retention. The bladder has little or no contractile ability. Nevertheless, because of loss of compliance of the bladder wall, the bladder may still be subject to high intravesical pressure during filling, especially in individuals with conus medullaris lesions or with partial injuries. In the chronic state there is an increase in adrenergic innervation to the detrusor, resulting in change of functional role from beta- mediated adrenoreceptor relaxation to alpha-mediated contraction [86, 87]. The sympathetic nervous system supplies the main innervation to the urethra. However, there may be a contribution of the somatic innervation to external sphincter [88, 89]. The perineal floor electromyography shows denervation of the perineal floor and an underactive urethral sphincter in infrasacral cord lesions.

6.3.3. Natural History of Neurogenic bladder after SCI

SCI usually causes impairments of urinary function such as UI and/or difficulty in urination. Podnar *et al.* [90] studied 55 patients with chronic cauda equina or conus medullaris injury: 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear regression analysis, perianal sensory loss and female gender had a significant positive effect on urinary incontinence score.

6.3.4. Disease-specific LUT mechanisms

Pontari *et al.* [91] analyzed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC) and compared them with bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction alters, and found that whereas normal detrusor contractions are mediated by the M3 receptor subtype, in patients with neurogenic bladder dysfunction, contractions can be mediated by the M2 muscarinic receptor subtype.

Drake *et al.* found a marked reduction in the range of transmitters expressed in bladder nerves in SCI [92]. Haferkamp et al. [93] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients, concentrations were significantly increased in SCI, and the lowest concentrations of urinary 8-iso PGF2alpha were observed in the areflexic group. [94] According to the study of viscerosensory pathway of the lower urinary tract (LUT) by Schmid *et al.* [95], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2ms, 2 to 3- fold sensory threshold, 60mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients.

Schmid *et al.* [96] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with incomplete SCI, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses

were normal, and the ratio (5.5) was increased. Those with a complete SCI showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a spinal cord lesion. Ten patients with incomplete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots.

According to Dai and Xiao [97], the thresholds of stimulation on ventral roots were 0.02 ms duration, 0.2-0.4 mA, (mean 0.3 mA+/-0.07 mA), compared with 0.2-0.4 ms duration, 1.5-3 mA (mean 2.3 mA+/- 0.5 mA) for dorsal root (P<0.01) to cause evoked potentials and EMG. Continuous stimulation for about 3-5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz,and 0.4 mA) could result in bladder detrusor contraction, but the strongest bladder contraction was usually caused by stimulation on the S3 ventral root in 7 of the 10 patients.

Beside the electrophysiological changes the detrusor undergoes a significant morphological change after complete SCI, which had been investigated in the pig model. They demonstrated the shift towards intercellular tissue and loss of contractile tissue. [98]

6.3.5. Assessment/investigations (different to diagnostics)

6.3.5.1. Urodynamic studies

Ersoz and Akyuz [99] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to examine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were significant differences between three groups with respect to bladder sensation category. About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before Pves reached 25 cmH2O and simultaneous bladder capacity of more than 150 ml was present in 61.2%, 41.2% and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had a second cystometric examination.

To measure bladder mucosal sensory function quantitatively, Ukimura *et al.* [100] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete suprasacral SCI, the bladder CPT value (4.0+/-1.9) at 5Hz was significantly lower than that in the controls (26.2+/-17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infrasacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz (p<0.05), 250Hz (p=0.07), and 2000Hz compared to the controls. No fibre specificity has so far been found depending on frequency of current used or current type.

6.3.6. Vesicoureteral Reflux (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer *et al.,* there was an association of posterior position of ureteral orifices and reflux but no differences were found with regard to bladder capacity, bladder wall compliance, or voiding pressures between the reflux group and non-reflux group. [101]

6.3.7. Bacteriuria

Levendoglu *et al.* prospectively studied 27 SCI patients who applied CIC during the initial rehabilitation with 40 controls. [102] E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli; and Pseudomonas was colonized more in male patients. Waites et al. found that among 77.1% of men with bacteriuria, uropathogens were shown in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria. [483] Over the time the changes in the bacterial spectrum and resistance for in- as well as for outpatients is seen where strategies to control urinary tract infections need to be further developed[103]

6.3.8. Urinary Microbiome

In the LUT, influence on the microbiome as a result of SCI and other neurogenic cases influencing the LUT has been examined. [104, 105] Urinary microbiome variations were also observed using 16S rRNA sequencing analysis for male and female patients with normal bladder function compared to NBD patients. [106] Urine samples from healthy control bladders had significant enrichment in Lactobacillus and Corynebacterium genera, whereas other bacterial general such as Klebsiella, Enterococcus, and Escherichia were predominant in NBD urine. Bacteriuria is associated with a range of LUT symptoms, and the role of a putative bladder microbiome in the sensitization of spinal neurons needs to be further explored. [107] Although recent research is focused on the gut-brain-axis, the bladder-brain-axis remains an area of interest related to the significant changes in uroepithelial morphology as early as two hours post-injury and catheterization. [108, 109] The understanding of the urinary microbiome will hopefully not only help to understand but develop treatment options to control the growth of more virulent bacteria and potential protective treatment against UTIs [110].

7. SPECIFIC NEUROLOGICAL DISEASES: DEMENTIA

The dementias can be categorized according to clinical presentation, neuropathology and/or aetiology into four major dementia groupings, (I) the Alzheimer's group (Alzheimer's disease, AD); (II) the vascular group (including large and small vessel disease, particularly white matter disease); (III) the Parkinson's group (including Parkinson's disease dementia complex (PDD, being regarded as identical to DLB), and dementia with Lewy bodies (DLB), (IV) the frontotemporal group (including Pick's disease and Semantic dementia) [111] (II-III were grouped into the non-AD dementia syndromes [112]). Normal pressure hydrocephalus (NPH) is a less common pathology, but nonetheless important.

7.1. Alzheimer's disease [113]

Alzheimer's disease (AD) [113] is the most common type of dementia in clinical and autopsy surveys. AD mostly affects older adults. AD affects more than 40 million people globally, this is expected to reach 75.6 million by 2030. It is the biggest killer in women at 15.3% and the second biggest killer in men at 8%. [114] The symptoms include worsening of memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and mobility, incontinence and motor dysfunction. The onset of incontinence usually correlates with disease progression (LOE 3) [115] and almost inevitably occurs in the advanced stage of disease, while UI is less common in the early stage of AD. This is in contrast with early occurrence of urinary urgency and incontinence in vascular dementia and dementia with Lewy bodies. The prevalence of incontinence in AD is between 23 % and 48 % (LOE 3) [116, 117]. However, most previous studies do not mention the type of dementia. The prevalence of incontinence in advanced, institutionalized individuals with dementia reaches more than 90% (of) (LOE 3) [118].

Pathology and disease-specific urinary tract problems in AD at the outset was identified by its unique pathology, the amyloid plaques and neurofibrillary tangles containing phosphorylated tau that Alzheimer referred to as "a clotting of fibrils…. in addition to an extraordinary number of peculiar patches disseminated throughout the entire cortex". Omega-3 fatty acids might be a potential therapeutic tool to reduce the burden of accumulated protein. They appearto be a competitive inhibitor of ARA and reduce the production of inflammatory lipid mediators'and hence reduce the inflammatory condition. [119] Amyloid and tau can now be measured in vivo by positron emission tomography and/or examination of the cerebrospinal fluid (CSF). New research demonstrated the first evidence for the capacity of extracellular DNA from certain bacterial species to substantially promote tau misfolding and aggregation identified in the CSF, amyloid plaques, or brains of patients with AD (*B. burgdorferi, P. gingivalis, C. albicans*, and *E. coli.)*. Orally localized bacteria (Microbiome) may gain access to the brain via multiple pathways. Notably, the DNA of *T. alzheimeri* (belonging to *Brucellaceae;* together with that of *E. coli*) evinced the highest promoting activity relative to other bacteria. This can possibly lead to tau protein misfolding and aggregation, suggesting their potential role in the initiation and progression of pathological abnormalities responsible for AD. [120]

The clinical hallmark of AD is memory impairment. Memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation. AD has a gradual and progressive course, and duration is typically 10 years from diagnosis to death. The advent of central cholinesterase inhibitors and glutamate receptor antagonists has had a positive effect on the memory symptoms of AD [121-123].

In early stages of AD, the prevalence of urgency incontinence is lower than in dementia with Lewy bodies [124, 125]. During stage III (advanced) AD, urinary and faecal incontinence occur due to loss of sphincter control [125]. In a study by Del Ser *et al.* (LOE 3) urinary incontinence was associated with severe cognitive decline in pure AD but usually preceded severe mental failure in patients with dementia due to diffuse Lewy body disease [125]. Nobili *et al.* (LOE 3) performed quantitative EEG in AD patients, finding that incontinence was predicted by alpha power in the right hand side [126]. In another study by Nobili *et al.* (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [127].

A brain computer tomography study done by Sugiyama *et al.* (LOE 3) in AD patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity (DO) than those withoutDO was found in 40-61 % of patients. [128] (LOE 3). The incidence of DO in AD patients is low as compared with vascular dementia and dementia with Lewy bodies [129]. Haddad *et al.* (LOE 3) described two patients with vesicoureteral reflux, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprostatic and urethrovesical reflux as a consequence of the neurologic dysfunction [130]. In a study of 144 patients with AD reportingUI , the most common type of UI was urgency urinary incontinence. Clinical Dementia Rating and Barthel's Activities of Daily Living predicted the severity of detrusor overactivity in urodynamics [131].

7.1.1. Guidance for further research

We are still lacking studies evaluating LUT disorders in AD. Recently Averbeck *et al.* published a systematic review regarding medical management (both pharmacological and behavioural) of incontinence. [132] The role of surgery for LUT problems in these patients andthe issue of perioperative careremain unaddressed. [133]

7.1.2. Conclusions

Detrusor overactivity seems to be the most common underlying cause of lower urinary tract dysfunction patients with Alzheimer's disease (AD) (LOE 3), while the incidence is low as compared with vascular dementia and dementia with Lewy bodies.

UI in AD is also commonly as a result of disability associated incomtinence resulting from cognitive and physical impairment (LOE 3)

EEG studies, occurrence of developmental reflexes and regional blood flow studies can predict the development of incontinence in AD patients (LOE 3)

7.2. Non-AD dementia syndromes [134]

7.2.1. Vascular dementia

7.2.1.1. Epidemiology and prevalence

Vascular dementia is the second most common form of dementia after Alzheimer's disease (AD) among the elderly. The Rotterdam Study found that 72% of dementia cases were AD, 16% were VaD, and 12% other dementias, [135] while the Cardiovascular Health Study (CHS) found that 12% of the all cases met criteria for VaD, and of that group 27% met criteria for "pure" VaD, and 63% exhibited different degrees of cerebrovascular disease associated with other disease processes, mainly AD. [136] Pooled prevalence from eight European countries was 1.6% for vascular dementia in subjects older than 65, compared to a prevalence of 4.4% for AD (LOE 3) [137]. A meta-analysis of the European studies on the incidence of dementia showed vascular dementia constituted 17.6% of all incident dementia (LOE 3) [138].

Population-based MRI (MRI measures, [139]) studies suggest that moderate white matter disease (WMD, a major cause of

vascular dementia) affects around 10% (7.6–24%) of the general population of persons over 55 years of age [140], comparable to type 2 diabetes. WMD is associated with three different geriatric syndromes; 1) vascular dementia (usually mild in the Mini-Mental State Examination and other general cognitive function), 2) vascular parkinsonism, and 3) so-called vascular incontinence, i.e. urinary frequency/ urgency with or without incontinence [141]. Among these three syndromes, urinary and gait disorders are more prominent than dementia, and usually precede dementia. Coexistence of Alzheimer's disease (a degenerative disease) and WMD (a vascular disease) is not uncommon.

Vascular dementia may be the result of a single infarct, particularly involving the thalamus and left angular gyrus, or multiple cortical or subcortical infarcts. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2) [142]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer's disease (LOE 3) [143]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [144].

7.2.1.2. Pathology and disease-specific urinary tract problems

In patients with WMD, diffuse abnormalities are seen in the small deep perforating vessels of the hemispheric white matter, basal ganglia and brain stem. Pathological changes range from lipohyalinosis to fibrinoid necrosis and disintegration of small vessels. Disruption of the blood brain barrier is likely to precipitate or worsen progression of WMD [145] (LOE 3). Positron emission tomography imaging with 18F-fluoromisonidazole showed higher susceptibility to ischaemia of white matter than gray matter in stroke [146]. Cortical WMD in MRI looks diffuse. However, within the brain, detailed pathology studies confirmed that the frontal lobe is most severely affected [147]. This is in line with documented frontal lobe atrophy on MRI volumetry, where glucose metabolism was also most severely reduced [148] (LOE 3). Corresponding to this, brain perfusion is most reduced in the frontal lobe of subjects with WMD [149] (LOE 3), a finding that remains to be fully explained. In patients with WMD reporting incontinence ("vascular incontinence"), performance on the frontal assessment battery suggests that performance on an inhibitory control task is decreased in patients with detrusor overactivity [150] (LOE 3). The frontal cortex is an important higher centre for micturition: damage to the prefrontal cortex, medial superior/middle frontal gyri, anterior cingulate cortex, supplemental motor area and insula result in marked lower urinary tract dysfunction in humans [151] (LOE 3), corroborated by functional neuroimaging [152, 153] (LOE 3). It seems that the density of the frontal **white matter** hyperintensity predicts lower **urinary tract** dysfunction. [154]

Altered spinobulbospinal micturition reflex control may contribute to DO emergence in lesions of the brain [155] (LOE 3). Functional neuroimaging studies show that the prefrontal cortex was deactivated in elderly subjects with urinary frequency/ urgency (LOE 3). [156], [154] Jirovec *et al.* (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [157]. When the variables were examined together, mobility, followed by cognitive impairment emerged as the best predictor of the patient's urine control.

The prevalence of DO in WMD is reported as 70-91%. In Sakakibara's study, urodynamic studies in 33 subjects found DO more commonly in grade 1-4 white-matter lesions (82%) than grade 0 white-matter lesions (9%). [153] Yoshimura *et al.* (LOE 3) found a 47% prevalence of DO which correlated with the presence of dementia [158], confirmed by Ogama *et al.* with a predominance to the age and the athrophy of the front lobe. [154]

7.2.1.3. Recommendations for further research

Since dementia is not a homogeneous disease, a population study specifically reviewing disorders of lower urinary tract function is needed. A study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

7.2.1.4. Conclusions

Incontinence occurs in 30-100 % of patients with dementia (LOE 3).

The degree of incontinence is strongly associated with the patient's general status and mobility(LOE 3).

There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant proportion of incontinence (LOE 3).

7.2.2. Dementia with Lewy bodies

7.2.2.1. Epidemiology and prevalence

Dementia with Lewy bodies (DLB) is thought to be the third most common type of dementia, accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of DLB was found to be 0.7%. [159] The epidemiology of DLB is sparse; age and gender distribution, and potential risk factors have yet to be defined.

Pathology and disease-specific urinary tract problems in DLB primarily affects the basal ganglia (as in Parkinson's disease) and the cerebral cortex. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein (SNCA), a ubiquitously-expressed synaptic protein that has been implicated in vesicle production [160]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alphasynuclein is the most sensitive and specific method for detecting Lewy bodies and can be used in a semiquantitative grading of severity of Lewy-related pathology [161]. Alpha-synuclein can now be measured in vivo by positron emission tomography and/or in the cerebrospinal fluid.

Many patients with DLB also have Alzheimer's disease pathology, which alters the clinical presentation. DLB patients who also have numerous neurofibrillary tangles display more core clinical features of AD [162]. Conversely, Lewy bodies also occur in more than half of patients with sporadic and early-onset AD [163]. The essential feature for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal, from almost normal to markedly confused or hypersomnolent) are a core feature of dementia with Lewy bodies. In DLB, autonomic dysfunctions occur and are included as a supportive feature for clinical diagnosis [164].

Horimoto *et al.* (LOE 3) found a 97% incidence of UI amongst patients with DLB. From the urological point of view, patients with DLB tend to develop urgency and urgency incontinence

more often than do patients with Parkinson's disease (PD) or AD. Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in each disease; DO was more prevalent in DLB than in PD and in AD [165]. Urinary symptoms were recorded in 35 % of patients with DLB, compared to 70 % in MSA and 25 % in PD patients. No detrusor-sphincter-dyssynergia (DSD) was observed. DLB patients with DO had significantly higher Hoehn and Yahr scores than those without. Since the prevalence of frequency, urgency, urgency incontinence and DO is markedly lower in AD than in DLB, LUTS may contribute to the differential diagnosis of these two entities.

7.2.3. Frontotemporal dementia (FTD)

7.2.3.1. Epidemiology and prevalence

FTD commonly presents in oounger patients and the average age of onset is 56. [166] The estimated prevalence is 0.16-31.04 per 1000 persons and incidence (0.0-0.3 per 1000 person-years). FTD accounted for an average of 2.7% (range 0-9.1%) of all dementia cases. [167] A high familial occurrence of FTD is reported [168]. In such cases, a combination with parkinsonism, and rarely amyotrophic lateral sclerosis, also occurs. The distribution of FTD is almost equal between men and women (52.5:47.5). The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years.

7.2.3.2. Pathology and disease-specific urinary tract problems

Frontotemporal dementia (FTD), also known as Pick's disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioural changes, but a language disorder, usually in the form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient's premorbid behaviour. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetrical [63]. At autopsy, markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histological examination the salient features include neuronal loss, micro-vacuolization and astrocytes gliosis centred on cortical layer II.

Molecular pathology of FTD has identified four subtypes: [169]
- classical FDT (Pick's disease; Pick body with accumulation of 3-repeat tau);
- mutations in the MAPT (microtubule-associated protein tau) gene;
- accumulation of TDP-43 (TAR DNA binding protein-43) with mutations in the PGRN (progranulin) gene; and,
- accumulation of FUS (fused in sarcoma) protein

FTD is subdivided in Behavioral Variant FTD (bvFTD) and Frontotemporal Dementia-Motor NeuronDisease (FTD-MND) associated with a shorter survival (2.4 years from symptom onset) compared with bvFTD alone (6.6 years). [170]

There are no published data on LUTS in patients with FTD, but due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, or they may urinate in inappropriate places. They may also be affected by constipation, diarrhoea or faecal incontinence.

8. NEUROLOGICAL URINARY INCONTINENCE

8.1. Introduction

NLUTD may be caused by a variety of neurological diseases and/or events affecting the various parts of the nervous systems controlling the LUT. The resultant dysfunction depends grossly on the location, extent, and nature of the causative neurological lesion or lesions. Overall prevalence estimates for NLUTD in the general population are scarce, but data are available on the prevalence of the underlying conditions and, in some cases, the relative risk for the development of NLUTD. It is important to realize that most of these data show a very wide range of prevalence figures, due to low level of evidence in most published data and smaller sample sizes.

Nevertheless, worldwide estimates of the prevalence of spinal cord injury (SCI) are at over 2.5 million, multiple sclerosis (MS) considerably greater than 1.5 million and Parkinson's disease (PD) approximately 6 million [171-174]. Spinal cord injuries are common, with an estimated between 10.4 and 83 per million people per year which represents an absolute annual number of 80,000–630,000 new cases worldwide sustaining a traumatic spinal injury every year in the Western world [175]. Non-traumatic injury (vascular, infection, tumour) is more common, and cancer alone is estimated to cause more SCI than trauma [176]. The incidence of nontraumatic SCI varies between 6 and 76 per million population per year. [177-179] Nontraumatic SCI is attributed in 41% of the cases to degenerative spine diseases with consecutive spinal canal stenosis, 26% to tumours compressing the spinal cord, 20% to infectious diseases, and 16% to ischaemia and in most cases is an incomplete injury. [180]

Traumatic injury mostly affects young men, and advances in rehabilitation medicine mean that the longevity of paraplegics is similar to the general population while that of tetraplegics is 10 years shorter [181]. The prevalence of MS varies from North America and Europe (more than 100 cases per 100,000 population) to low levels in Eastern Asia and Sub-Saharan Africa (2 cases per 100,000 population). [182]

Mobility, pain and bladder dysfunction in neurological patients has been relatively well studied, while bowel and pelvic floor dysfunction has been neglected by comparison. With rapid advances in rehabilitation medicine resulting in increased survival of patients, these individuals are experiencing bladder and bowel symptoms for ever-longer periods.

The conclusions and recommendations on epidemiology of the previous ICI report therefore remain unchanged.

8.2. Conclusions

- Dysfunction of the LUT occurs in patients with a variety of neurological diseases but precise epidemiological data are seldom available
- Common manifestations of NLUTD include urinary incontinence, voiding difficulties, and urinary retention.
- Because neurological disease is often present in older populations, it is frequently difficult to discriminate if LUTS are due

to aging alone, or due to the presence of neurological disease. This difficulty is reflected in widely varying prevalence estimates.

8.3. Recommendations

Patients with neurological disease known to be associated with NLUTD should be evaluated for the presence of lower urinary tract symptoms.

- In certain neurologic disease states, NLUTD may be relatively asymptomatic, yet represent a risk of upper urinary tract impairment.
- In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic severe LUTS after proper office evaluation for common aetiologies.
- Prevalence estimates of NLUTD would be improved by multicentreco-operative studies from large tertiary centres utilizing established outcomes and evaluation tools.

V. PELVIC ORGAN PROLAPSE

1. INTRODUCTION

The most accounted model describing the pathophysiology of pelvic floor disease (PFD) is the chronic disease life span approach, which emphasizes the chronological impact of different types of exposure variables as well as their interrelationship [1, 2].

According to DeLancey, three specific phases can be identified [2]. Phase I accounts for predisposing factors such as genetic predisposition and growth. Phase II corresponds to provoking factors, in which birth-induced damage to the pelvic floor has a major role. Phase III accounts for intervening factors such as aging, obesity and lifestyle practices.

A new study supports a multifactorial aetiology for pelvic organ prolapse considering altered smooth muscle, vasculature, and connective tissue content as crucial for pelvic support structures [3]. Histological phenotypes exist in pelvic support ligaments that can be distinguished using the pelvic organ prolapse histologic quantification system and principle component analysis. Vaginal delivery is associated with aberrant adipose accumulation in uterosacral ligaments. The prolapse ligaments in the premenopausal group had significantly more loss of smooth muscle fibres within the fascicles, increased inflammatory infiltrates of neutrophils within the tissue and perineural inflammatory cells and reduced neointimal hyperplasia. Prolapse ligaments in the postmenopausal group exhibited elevated adipose content compared with that of the control group. Amount of fibrillar collagen, total nonvascular smooth muscle, and muscle fibre vesicles of prolapse ligaments did not differ in either the premenopausal or postmenopausal group compared with that of the control group. Unbiased principal component analysis of the histological scores separated the prolapse ligaments into 3 phenotypes: (1) increased adipose accumulation, (2) increased inflammation, and (3) abnormal vasculature, with variable overlap with controls. *Post hoc* analysis of these subgroups demonstrated a positive correlation between increasing number of vaginal deliveries and BMI with increasing adipose content in the adipocyte accumulation and inflammatory phenotype and increasing neointimal hyperplasia in the vascular phenotype [3].

2. ANATOMY

A basic understanding of pelvic floor anatomy is essential for adequate anatomical and functional evaluation of the pelvic floor. For purposes of clinical evaluation, the female pelvis is classically divided into 3 compartments: the anterior compartment containing the bladder and urethra; the middle compartment containing the uterus, cervix, and vagina; and the posterior compartment containing the rectum and anal canal. These compartments are closely interrelated, and patients often present with multicompartment dysfunction [4-6].

The compartments of the pelvic floor are supported by a complex network of fascia, ligaments, and pelvic floor muscles that form 3 layers of support:
- the endopelvic fascia (superior),
- the pelvic diaphragm (middle),
- the perineal membrane or urogenital diaphragm (inferior).

The fascia and ligaments provide passive support, whereas the musculature of the pelvic diaphragm provides the underlying tone and can be recruited for active support.

2.1. Endopelvic Fascia

The endopelvic fascia is a sheet of connective tissue that extends across the pelvic floor from the bony pelvis on one side to the other and forms the superior-most layer of support of the pelvic floor. It covers the levator ani muscles and pelvic viscera. Various components of the endopelvic fascia are named according to their location:

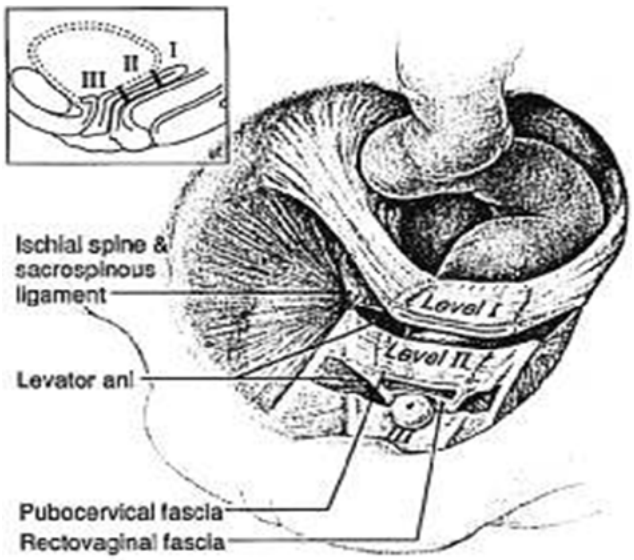

Figure 1. Level I (suspension) and level II (attachment). In level I the paracolpium suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and also posteriorly towards sacrum. In level II vagina is attached to arcus tendineus fasciae pelvis and superior fascia of levator ani. From DeLancey et al, Clin Obstet Gynecol,1993 [7].

- the pubocervical fascia between the bladder and vagina or cervix
- the parametrium extending from the cervix to the lateral sidewalls
- the paracolpium extending from the vagina to the pelvic sidewalls
- the rectovaginal fascia between the vagina and rectum.

The cardinal and uterosacral ligaments arise from condensations of the endopelvic fascia superiorly. Laterally, the endopelvic fascia coalesces to form the arcus tendineus along the bony pelvis, which serves as an attachment site for the muscles that form the pelvic diaphragm.

The endopelvic fascia provides 3 levels of support in relation to vagina: level I (vaginal apex), level II (mid vagina), level III (distal vagina), and defects in each level may present with unique physical signs and symptoms (Figure 1) [7].

Deficiencies within different portions of the fascia may determine the degree of prolapse in each compartment. For example, defects in the uterosacral ligaments or the paracolpium/parametrium may result in cervical or vaginal prolapse; tears in the pubocervical fascia or urethral ligaments may result in cystocele and urethral hypermobility; and defects in the perineal body or rectovaginal fascia may present with anterior rectocele or enterocele [8].

2.2. Pelvic Diaphragm

The pelvic diaphragm provides the middle layer of support of the pelvic floor and consists of the ischiococcygeus muscles and the levator ani muscles.

The levator ani is a vaselike or hourglass-shaped group of striated muscles composed of the iliococcygeus, pubococcygeus,

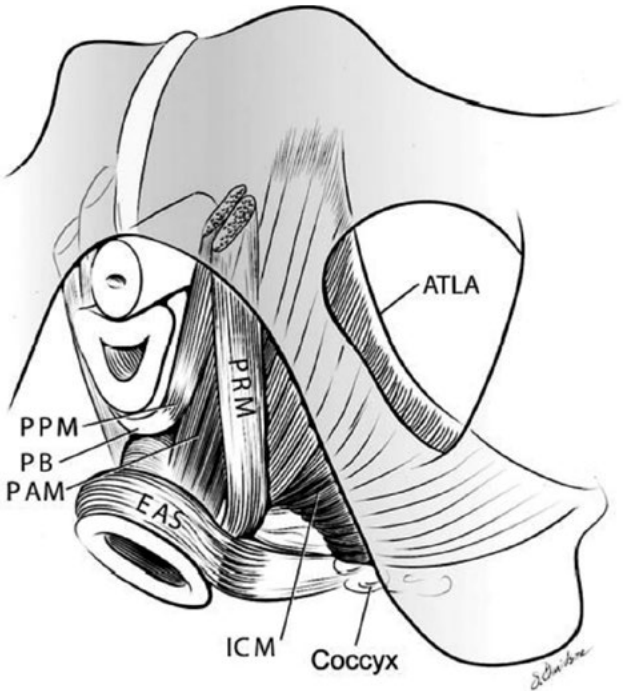

Figure 2: Schematic view of the levator ani muscles from below after the vulvar structures and perineal membrane have been removed showing the arcus tendineus levator ani (ATLA); external anal sphincter (EAS); puboanal muscle (PAM); perineal body (PB); uniting the 2 ends of the puboperineal muscle (PPM); iliococcygeal muscle (ICM); puborectal muscle (PRM). Figure 3: The levator ani muscle seen from above looking over the sacral promontory (SAC) showing the pubovaginal muscle (PVM). The urethra, vagina and rectum have been transected just above the pelvic floor. PAM = puboanal muscle; ATLA = arcus tendineus levator ani and ICM= iliococcygeal muscle (The internal obturator muscles have been removed to clarify levator muscle origins). Copyright © DeLancey 2003. [11]

and puborectalis muscles. These muscles normally maintain a convex appearance superiorly. The relatively thin iliococcygeus muscle attaches anteriorly to the pubic bone, laterally to the arcus tendineus, and inferiorly to the external anal sphincter. The thicker pubococcygeus muscle is more medially located relative to the iliococccygeus; it arises from the superior pubic rami and wraps around the bladder, urethra, vagina, and rectum. Posteriorly, the iliococccygeus and pubococcygeus form a thick condensation of tissue called the levator plate, which inserts upon the sacrum and coccyx. The iliococccygeus and pubococcygeus muscles are difficult to differentiate on imaging owing to the overlap in fibres and morphology. The most caudal component of the levator ani muscle group is the puborectalis, which attaches anteriorly to the pubic symphysis and forms a U-shaped sling around the anorectum. The level of the puborectalis impression upon the posterior rectum demarcates the anorectal junction, and the margins of the puborectalis form the urogenital or pelvic floor hiatus. Superiorly, the puborectalis muscle fibres overlap with the pubococcygeus. The ischiococcygeus or the coccygeus muscle is a relatively minor part of the pelvic diaphragm, extending from the coccyx in the midline to the ischial spine bilaterally [8-10] (Figure 2, Figure 3).

The pelvic diaphragm provides continuous tone to the pelvic floor, but can be contracted or relaxed actively.

2.3. Perineal Membrane/Urogenital Diaphragm

The perineal membrane (also referred to as the urogenital diaphragm) forms the caudal-most layer of the pelvic floor and comprises primarily the deep transverse perineal muscle and connective tissue that extend from ischial rami laterally to the perineal body in the midline. The perineal membrane attaches anteriorly to the pubic symphysis, giving the perineal membrane a triangular shape (Figure 4).

Anatomical support of pelvic viscera is mainly provided by the levator ani muscle complex and connective tissue attachments of the pelvic organs: vaginal support arises from the connective tissue attachments between the vagina and the pelvic sidewall, the vaginal wall, and the levator ani muscles [12, 13].

Two mechanical principles explain how the uterus and vagina are normally held in place. First, the uterus and vagina are attached to the walls of the pelvis by the endopelvic fascia that suspends the organs from the pelvic sidewalls. Second, the levator ani muscles costrict the lumen of these organs closed, forming an occlusive layer on which the pelvic organs may rest [14].

The levator ani complex consists of the pubococcygeus, the puborectalis, and the iliococcygeus muscles [11]. These muscles are tonically contracted at rest and act to close the genital hiatus, providing a stable platform for the pelvic viscera. Decline of normal levator ani tone by denervation or direct muscle trauma, results in an open urogenital hiatus, weakening of the horizontal orientation of the levator plate, and a bowl-like configuration [15, 16].

The supportive connective tissues are a continuous, highly interdependent sheet in which all members interact to achieve support of the vagina and, therefore, of the pelvic organs. DeLancey has introduced the concept of dividing the connective tissue support of the pelvis into three levels, with level I, II and III representing apical, midvaginal and distal support respectively. The upper portion of the paracolpium (Level I) consists of

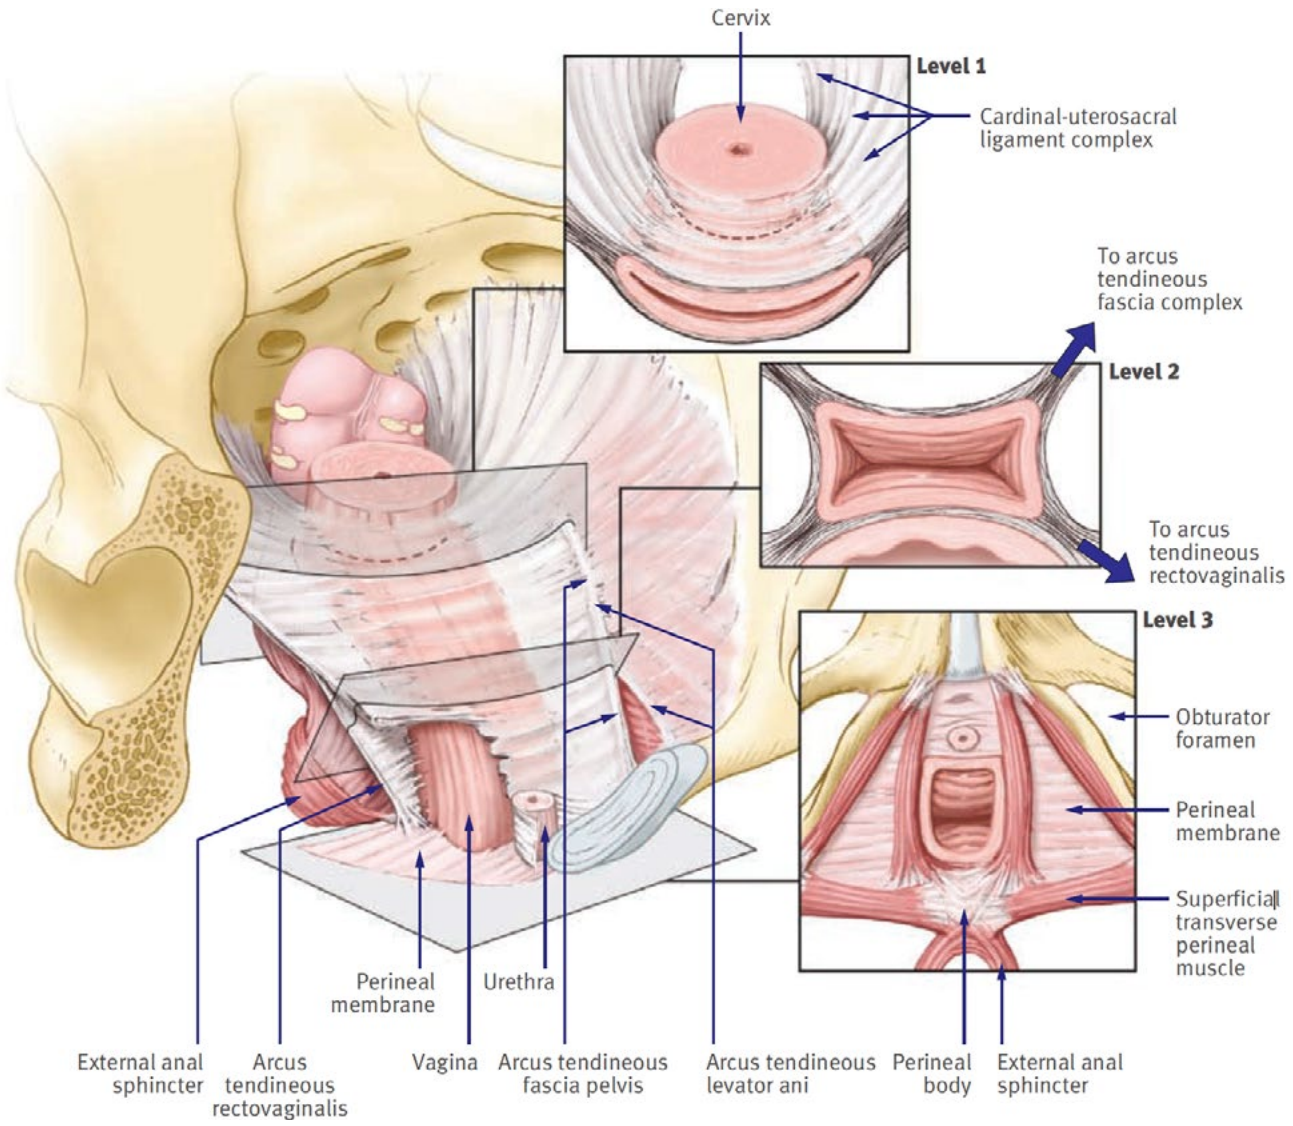

Figure 4: DeLancey´s three level of pelvic support. Reprinted from Barber [18], with permission from the Cleveland Clinic Foundation [19].

a relatively long sheet of tissue that suspends the vagina by attaching it to the pelvic wall, and it is responsible for suspending the apex of the vagina after hysterectomy. In the middle third of the vagina, the paracolpium attaches the vagina laterally, to the arcus tendineus and fascia of the levator ani muscles (Level II). This attachment stretches the vagina transversely between the bladder and the rectum. The structural layer that supports the bladder (pubocervical fascia) is composed of the anterior vaginal wall and its attachment through the endopelvic fascia to the pelvic wall. Similarly, the posterior vaginal wall and endopelvic fascia (rectovaginal fascia) form the restraining layer that prevents the rectum from protruding forward. The vagina´s lower third (Level III) fuses with the perineal membrane, levator ani muscles and perineal body, without any intervening paracolpium (Figure 4) [14, 17]. Damage to the upper suspensory fibres of the paracolpium causes a different type of prolapse from damage to the mid-level supports of the vagina. Defects in the support provided by the mid-level vaginal supports (pubocervical and rectovaginal fascia) result in cystocele and rectocele, while loss of the upper suspensory fibres of the paracolpium and parametrium is responsible for the development of vaginal and uterine prolapse. These defects usually occur in varying combinations and this is responsible for the diversity of clinical problems encountered within the overall spectrum of pelvic organ prolapse [14].

For conceptual purposes the supportive connective tissue has been related with structural elements of pelvic floor: the uterosacral ligaments (level I); the paravaginal attachments (endopelvic fascia) that connect the lateral vaginal walls to the arcus tendineous fascia pelvis (ATFP) and the fascia of the levator ani muscles (level II); the perineal membrane and the perineal body (level III) [17].

Table 1: lists the structural elements of pelvic organ supports, their possible damage and subsequent site of pelvic organ prolapse. The integrity of muscular, connective and nerve structures is essential to guarantee a normal pelvic organ support. If one of these factors fails, the other might be able to compensate to a certain degree.

Structural elements of pelvic organ support, their possible damage and subsequent site of pelvic organ prolapse. The levels of support and anatomical defects are derived from the anatomical studies of DeLancey [14, 17].

	Structure	Failure/Defects	Anatomical results
Level 1	Uterosacral ligaments	• Disruption • Overdistension • Elongation	• Uterine prolapse • Vault prolapse
Level 2	• Anterior endopelvic fascia (pubocervical fascia) • Posterior endopelvic fascia (rectovaginal fascia)	• Central impairment of fascia • Lateral detachment of fascia from ATFP • Impairment of fascia	• Midline cystocele • Paravaginal defect-cystocele • Rectocele
Level 3	Perineum	• Disruption from endopelvic fascia • Disruption of bulbocavernosus muscles	• Excessive perineal descent • Rectocele

3. AETIOLOGY

In an American gynaecologic clinic population (18-83 years), approximatively 3-6% of women had pelvic organ prolapse descending beyond the vaginal opening on routine pelvic examination [20]; an estimated 11% of women will undergo surgery for pelvic organ descent and urinary incontinence sometime in their life [21].

The aetiology of pelvic organ prolapse (POP) is thought to be multifactorial with contributions from both environmental and genetic risk factors. Environmental factors that contribute to POP include vaginal delivery, chronic increases in intra-abdominal pressure, obesity, advanced age and oestrogen deficiency [22, 23]. Evidence for a genetic contribution to pelvic organ prolapse has been found in family-based studies, candidate gene association studies, expression studies and linkage studies [24].

Vaginal delivery has been considered the main causal factor in the development of pelvic organ prolapse for some years [21, 25-29]. However, if it is true that all women undergo pelvic floor stretching during vaginal delivery, not all of them develop a further prolapse; moreover, pelvic floor dysfunction has also been described in women who gave birth by caesarean section only [23, 26] and in nulliparous women [30]. Therefore, the vaginal delivery does not totally explain the origin and progression of pelvic floor descent in all women. This supports the hypothesis

Table 2: lists anatomical and functional determinants of normal pelvic organ support. It also summarizes the possible nature of failure and its potential causes as well as the established and theoretical risk factors.

Determinants of normal pelvic organ support. Possible sites of failure and possible causes, established and theoretical risk factors. LE= LEVEL OF EVIDENCE

Normal support	Failure	Possible cause/risk factors
Normal connective tissue including normal tone (smooth muscle cells)	• Reduced tone • Pathological type and cross linking (LE 2) • Disruption (LE 2)	• Genetic (LE 2) • Pregnancy (connective tissue remodelling) (LE 3) • Vaginal birth (mechanical) (LE2) • Chronic pelvic floor stress 8straining, constipation, asthma) • Obesity
Normal attachment of connective tissue and pelvic floor musculature	• Disruption, detachment (LE2)	• Vaginal birth (LE 1) • Hysterectomy, pelvic operations (LE3) • Chronic pelvic floor stress (LE3) • Pelvic trauma (accidents, falls) (LE3)
Normal tone of the pelvic floor muscle	• Hypotonic pelvic floor muscle (LE4)	• Pregnancy, childbirth (ischemic, mechanical, hormonal) (LE2) • Reduced connective tissue tone • Chronic pelvic floor stress
Normal, nearly horizontal, axis of the vagina	• Vertical course of the vagina (LE3)	• Hysterectomy, pelvic operations including Burch colposuspension (LE3) • Chronic pelvic floor stress • Vaginal birth (LE2)
Normal innervations and pre-programming of abdominal capsule and pelvic floor muscle	• Denervation/re-innervation (LE1) • Loss of pre-programming (LE4)	• Vaginal birth (LE1) • Pelvic trauma/pain • Delayed or lack of pelvic floor contraction during increased abdominal pressure (LE3)

that other causes, besides obstetrics, are involved in the aetiology of the pelvic organ prolapse: connective tissue deficiencies, genetic predisposition, sexual hormones, pregnancy, ageing, menopause, obesity, neuropathies, ethnicity and family history.

Miedel *et al.* [31] showed that age and parity are the dominating risk factors for symptomatic pelvic organ prolapse, but significant independent associations with markers suggestive of congenital susceptibility (family history and conditions signaling weak connective tissue) and non-obstetric strain on the pelvic floor (overweight/obesity, heavy lifting and constipation) imply that individual predisposition and lifestyle/environment also may play an important role. (LEVEL OF EVIDENCE: II)

In the last decade, attention has increasingly focused on understanding of the molecular basis of POP and the recognition of the potential molecular markers and their modulators in pelvic floor supportive tissues in order to identify the women predisposed to develop POP.

3.1. Inheritance, Genetic and Ethnic Predisposition
Several studies have focused the attention on the inheritable predisposition for pelvic organ prolapse.

A recent metanalysis showed that positive family history of POP is on average associated with 2.3- to 2.7-fold increased risk for POP as well as a 1.4-fold increased risk for POP recurrence [32]. Positive family history has been recently identified as independent risk factor (OR 8.016) for prolapse [33].

The findings of high concordance in the POP stage between nulliparous women and their parous sisters strongly support the hypothesis of a familial basis for POP. Buchsbaum *et al.* [34] investigated the role of familial factors in the development of pelvic organ prolapse by comparing the prevalence of this condition in nulliparous postmenopausal women and their parous sisters. By compartment, there was a 74.3% to 91.1% concordance in prolapse stage within sister pairs. In discordant sister pairs, the parous sister was found to have the more advanced prolapse 88% of the time. Based on these results, the authors conclude that a high concordance of pelvic organ prolapse in nulliparous and parous sister pairs suggests a familial predisposition toward developing this condition. However, vaginal delivery appeared to confer a risk for more advanced pelvic organ prolapse. LEVEL OF EVIDENCE: II-2.

In the large case-control study carried out by Chiaffarino *et al.* [35], a higher risk of prolapse was reported in women whose mother (OR: 3.2; 95% CI: 1.1-7.6) or sister (OR: 2.4; 95% CI: 1.0-5.6) were affected by the same condition; also their data support that first-degree family history of prolapse is a risk factor for POP.

The systematic review by Lince *et al.* [36] found a substantially greater likelihood of SUI in family members with women with POP compares with women without POP, indicating that genetic predisposition play an important role in the development of POP. In a study of nulliparous women, Dietz *et al.* [37] showed also the heritability of bladder-neck mobility.

Jack *et al.* [38] demonstrated that the risk of POP among siblings of young women (average age: 37 years) with stage III and IV POP was five times higher than in the general population. Genetic analysis of the inheritance pattern within these families showed that POP segregated in a dominant fashion with incomplete penetrance. Some studies have drawn attention to the incidence of pelvic organ prolapse amongst identical twins. In the large Swedish twin registry of 3,376 monozygotic and 5,067 dizygotic female twin pairs, a greater twin similarity among the monozygotic twins was found, indicating the influence of a genetic component to the aetiology of pelvic organ prolapse. Genetic and non-shared environmental factors seemed to contribute equally to the development of pelvic floor disorders in these women, about 40% for each factor [39]. A study of twins by Altman *et al.* [39] on SUI and POP analyzed 3,376 monozygotic and 5,067 dizygotic female twins and found a greater similarity in outcomes in monozygotic twins.Buchsbaum *et al.* [40] even reported that vaginal delivery was not associated with clinically relevant differences in relaxation of the pelvic support system within four sets of postmenopausal identical twins with different parity status.

Genetic variants that run in families with an increased incidence of pelvic organ prolapse have been documented.

A recent genome-wide association study of POP using data from Iceland and the UK biobank found eight sequence variants at seven loci associating with POP; seven common (minor allele frequency >5%) and one with minor allele frequency of 4.87%. Some of the variants associating with POP also associated with traits of similar pathophysiology. Of these, rs3820282, which may alter the oestrogen-based regulation of WNT4, also associates with leiomyoma of the uterus, gestational duration and endometriosis. Rs3791675 at EFEMP1, a gene involved in connective tissue homeostasis, also associates with herniae and carpal tunnel syndrome. These results highlight the role of connective tissue metabolism and oestrogen exposure in the etiology of POP [41].

Allen-Brady *et al.* [42], using a genome-wide association study, demonstrated that 6 single-nucleotide polymorphisms (SNPs) are significantly associated with POP in high-risk familial case group participants. LEVEL OF EVIDENCE: II. Their results showed that two of the six SNPs are located within the genes ZFAT and COL18A1, both with Mendelian inheritance. The ZFAT has been found to play a transcriptional regulator role for immune regulation and apoptosis and, hence, may affect development of the muscle and connective tissue of the pelvic floor. The COL18A1 gene (precursor of the collagen XVIII) may play a role in the structural organization of basement membranes. The other four SNPs identified are intergenic, but one of them is close to the ANTXR2 gene, which binds intravenously to collagen and laminin, suggesting that it may be involved in extracellular matrix adhesion. The authors identified at least three strong candidate genes for POP that warrant follow-up. Another genome-wide linkage analysis to identify pelvic organ prolapse predisposition genes using a resource of high-risk POP pedigrees, provided evidence that loci on the chromosomes 10q and 17q may contribute to POP aetiology [43].

Further data suggest a role of genetic influence in early onset of POP. In a family in which three generations of female relatives suffered from prolapse at a very young age, a polymorphism in the promoter of LAMC1 gene has been found that seems to increase the susceptibility to early onset pelvic organ prolapse, as an autosomal dominant transmission [44]. A recent study on Chinese population strongly supports the involvement of LAMC1 in POP development [45].

A metanalysis of genetic association studies provided moderate epidemiological credibility for association of variation of COL1A1 gene with prolapse [46]. The authors suggested that clinical testing for these polymorphisms cannot be recommended based on current evidence. A recent study lack of association between DNA polymorphisms rs1800012 of COL1A1 and rs1800255 of COL3A1 with advanced POP [47].

One study examined gene expression of structural proteins that are related to actin and myosin in five women with, and five women without, pelvic organ prolapse in the pubococcygeal muscle. Several genetic differences between subjects and controls with gene under- and overexpression were found [48]. In mice, HOXA11 has been identified as an essential gene for the development of the uterosacral ligaments [49]. In HOXA11-null mice, the uterosacral ligaments were absent. Women with POP might have weakened connective tissue due to changes in a signaling pathway involving HOXA11 [49].

Increasing evidence supports a genetic aetiology of POP, also with respect to abnormal extracellular matrix remodeling [50]. A genetic predisposition to POP specific to elastin metabolism was noted in the rodent model, in which genetic mutation of the LOXL1 or the fibulin-5 gene in mice are involved in the altered elastic fibre assembly and then in the pathogenesis of the pelvic prolapse [51]. Altered gene expression of elastin has also been described in women with POP [52].

The study carried out by Wang *et al.* [53] supported the view that the polymorphism of the matrix metalloproteinase-10 (MMP-10) gene may be associated with an increased risk of POP.

Genetic screening may be a future tool for identifying the woman at risk for POP and for refining the counseling of women deemed to be at elevated risk; with the aim of preventing the condition and providing a targeted treatment. Primary prevention could be the adaptation of the delivery mode in at-risk groups. These patients could also benefit from changing management, such as whether surgery should be considered early or late in the woman´s lifespan.

Race is another demographic factor that seems to be associated with the development of POP. Some studies reported that Hispanic and European women appear to be at higher risk for POP than those of African, Asian or other descent [20, 23, 28, 54, 55]. This is also supported by evidence suggesting that women of Asian descent have reduced inherent pelvic organ mobility. In a cadaveric study, Zacharin [56] reported that Chinese women have stronger and thicker pubourethral ligaments, endopelvic fascia and endopelvic attachment to the obturator fascia compared to Caucasian women. More recently, Dietz *et al.* [55] confirmed these results using pelvic floor ultrasound, showing that Asian women have significantly less pelvic organ mobility than Caucasian women both antepartum and postpartum. In a cohort analysis of 27,342 women, Hendrix *et al.* [28], confirmed previously reported differences between white and African-American women. Hispanic women had the highest rate of uterine prolapse (OR: 1.24, 95% CI: 1.01-1.54) and an increased risk for cystocele (OR: 1.20, 95% CI: 1.05-1.36) but not rectocele (OR: 0.95, 95% CI: 0.82-1.11). The reasons for these ethnic differences are unclear; however, some evidence indicates that African-American women have smaller pelvic outlets than those of European descent [57].

Other connective tissue deficiencies such as herniae may share common pathophysiological mechanisms with POP. In a group of 60 women with advanced prolapse, the total prevalence of hiatal and inguinal herniae was significantly higher than in a control group of 60 women with mild or no prolapse (31.6% vs. 5%, $p<0.001$) [58].

A Stockholm population-based, cross-sectional study of 5,489 women found an OR of 1.8 for a positive association with symptomatic prolapse in women with a history of conditions suggestive of deficient connective tissue (varicose veins/herniae/haemorrhoids) [31].

McLennan *et al.* [59] demonstrated that the risk of prolapse was 1.4 (95% CI 1.2-1.8) times higher in women with a family history of prolapse and/or hernia, after adjusting for vaginal deliveries, hysterectomy and incontinence. The authors confirm that heredity is a risk factor for prolapse and suggest that history taking should include both male and female family members.

Taken together, this evidence suggests that exists a familial or genetic basis for POP in some women, and that heritable or genetic factor plays a role in its development.

3.2. Role of connective tissue

Young women with POP are more likely to have connective or neurological tissue diseases and congenital abnormalities [60]. Women with Marfan or Ehlers-Danlos syndrome have high rates of POP. Intrinsic joint hypermobility is another well recognized connective tissue disease that is associated with pelvic descent [61-64]. This finding supports the hypothesized aetiological role of connective tissue disorders as a factor in the pathogenesis of this conditions [65].

The vaginal wall is comprised of four layers: a superficial layer of non-keratinized stratified squamous epithelium; a subepithelial dense connective tissue layer composed primarily of collagen and elastin; a layer of smooth muscle referred to as the muscularis; and a layer of adventitia, composed of loose connective tissue. The subepithelium and muscularis together are thought to confer the greatest tensile strength to the vaginal wall. In the normally supported vagina, the supportive connective tissues pull the vagina up and back away from the vaginal introitus over the levator ani muscles. A normally supported vagina, in turn, provides support to the bladder, urethra, uterus and rectum. Disruptions of, or damage to, these connective tissue structures and injury to the vaginal wall are thought to be two important mechanisms causing prolapse.

The connective tissue of the vagina and supportive tissues contains a fibrillar component (collagen and elastin) and a non-fibrillar component (non-collagenous glycoproteins, hyaluronan, and proteoglycans). In addition, and with the exception of the arcus tendineous, these tissues contain a significant amount of smooth muscle. The fibrillar component is thought to contribute the most to the biomechanical behaviour of these tissues. The quantity and quality of collagen and elastin are maintained through a precise balance between synthesis, post-translational modification, and degradation.

Therefore, the integrity of the vagina and its supportive connective tissues are essential for keeping the pelvic organs in their normal anatomic position. Evaluation of these tissues from a biochemical perspective enables us to better discern the com-

plex interplay between structural composition and supportive capacity.

Collagen types I, III and V are the main structural components of vaginal epithelium and endopelvic fascia and they are thought to be the principal determinants of tissue strength. Type I collagen confers strength to tissues while type III contributes to elasticity. Type III collagen is the primary collagen subtype in the vagina and its supportive structures. The ratio of collagen I to III is an indicator of tensile strength: the higher the amount of collagen type III, the lower is the mechanical strength. To our knowledge the role of type V collagen, which is found in small quantities in the vagina, is still unknown.

The turnover of connective tissues throughout the body is maintained by a family of highly conserved, zinc-dependent endopeptidases referred to as matrix metalloproteinases (MMPs). The MMPs are involved in both normal physiological and pathological proteolytic processes, which are an integral part of tissue remodeling in both women with and without prolapse. An excessive tendency toward connective tissue degradation may underlie the predisposition of some women to prolapse.

Interstitial collagens (types I, II and III) are cleaved by MMP-1, 8 and 13. The cleaved collagen fragments are susceptible to rapid gelatinase (MMP-2 and 9) degradation into amino acids. These gelatinases (MMP-2 and 9) also degrade elastin.

Reports of decreased total collagen in pelvic tissue from women with POP suggest that collagen degradation may contribute to POP. Collagen degradation depends on the activity of MMPs produced by connective tissue cells. MMP proteolytic activity is specifically regulated by their inhibitors, TIMPs, which bind stoichiometrically to MMPs to inhibit their activity. The balance between MMPs and TIMPs defines the collagenolysis.

In women with prolapse, MMP-2 mRNA expression is increased with a concurrent decrease in the inhibitor TIMP-2 [66]. Recent data also indicate increased MMP-1 expression and decreased collagen I in the uterosacral ligaments of women with POP [67]. In contrast, collagen I and III mRNA expression was increased in vaginal tissue from women with POP [68]. Discrepancies in the literature can be due to the different methodological issues (different tissues targeted or a different method of protein quantification) used. Mismatches between mRNA and protein data are often found when examining proteins in the extracellular matrix. Thus, gene expression should always be confirmed with protein expression. These issues contribute to significant variations in the reported data and underscore the importance of careful research method. These discrepancies also suggest the possibility that different pathways in the extracellular matrix may be activated depending on injury type and severity, mechanical load and environmental factors [50].

Despite discrepancies in the precise MMP/TIMP or collagen type, the mentioned data and numerous other publications indicate that women with POP show an abnormal pelvic extracellular matrix metabolism with increased collagen remodeling.

Recent data suggested that oxidative stress (a well-recognized mechanism involved in fibre metabolic disorders) may be involved in the pathophysiology of POP by contributing to collagen metabolic disorders in a severity-dependent manner in human uterosacral ligaments fibroblasts, possibly through the regulation of metalloproteinase (MMPs), tissue inhibitor of metalloproteinase (TIMPs) and transforming growth factor (TGF)-ß1 indirectly [69]

Takano *et al.* [70] demonstrated that the general amount of collagen in the parametria is reduced in pre- and postmenopausal women with pelvic organ prolapse compared with women without prolapse. Moalli *et al.* [71] showed that collagen III is increased in vaginal subepithelium and muscularis in patients with prolapse relative to patients without prolapse, independent of age and parity. LEVEL OF EVIDENCE II-2. Increase in collagen III has been reported also in the uterosacral and cardinal ligaments of women with prolapse [72, 73]. The Moalli's group [74] demonstrated that collagen III is the primary subtype in the arcus tendineus fascia pelvis; a decrease in the ratio of collagen I/(III+V) is associated with menopause in the absence of hormone therapy and a restoration of this ratio to premenopausal levels with hormone therapy. From these data the authors suggested that sex steroid hormones may improve the biomechanical properties of the supportive tissues of the vagina. Recent findings report that decreased β-catenin in the anterior vaginal wall tissues may play an important role in the onset of POP by affecting collagen anabolism [75]. As all studies involving the procurement of human tissue are by necessity cross-sectional, it is impossible to determine whether the increase in collagen III reflects the causes or effects of prolapse. In either case, the increased flexibility and distensibility plus the decreased tensile strength associated with an increase in collagen III very likely contribute to the progression of POP.

Elastin is primarily laid down during fetal development and rarely synthesized in adult tissues. In contrast to the other tissues in which elastin fibres do not experience a turnover in a lifespan, there is cyclical remodeling of elastin fibres in the reproductive tract. A massive degradation of elastin occurs at the time of parturition, followed by postpartum resynthesis, allowing recovery of reproductive tissues to their pre-pregnancy state [76]. Mice deficient in LOX (lysyl oxidase) fail to replenish mature elastin fibres in the reproductive tract following parturition and develop spontaneous prolapse [77][52] found a marked decrease in elastin mRNA and tropoelastin protein in the cardinal ligaments of women with pelvic organ prolapse relative to women without prolapse. Chen *et al.* [78] demonstrated a significant decrease in the endogenous inhibitors of elastases with increase in elastolytic activity in vaginal tissue from women with stress urinary incontinence and pelvic organ prolapse compared with control subjects. Therefore, these data suggest that the proper degradation, synthesis, and regeneration of elastic fibres are essential for maintaining pelvic organ support.

If damaged or destroyed, metabolically repaired elastin frequently results in malformed and dysfunctional repair products. Proteolytic enzymes capable of degrading elastin include the serine proteases, such as neutrophil elastase, the cysteine proteases, and MMP-2, 9 and 12. Marked decreases in elastin gene transcripts and elastin synthesis in pelvic fibroblasts were noted in women with POP [52], suggesting that altered elastin metabolism may contribute to prolapse. In rodent models with genetic disruption to LOXL1 or fibulin-5 gene, prolapse develops due to failure to synthesize and assemble functional elastic fibres [77]. Elastin content was decreased in the uterosacral ligaments of women with POP, as were LOX, and LOXL1 and LOXL2 gene expression [79].

A recent study by Moon *et al.* [80], evaluated the alteration of elastin metabolism in women with pelvic organ prolapse in a

prospective case-control study: their results showed that expression of neutrophil elastase and matrix metalloproteinase-2 mRNA was higher in women with than in those without POP. Compared to before menopause, neutrophil elastase and matrix metalloproteinase-2 showed a significant decrease in postmenopausal women without POP, although they remained increased in postmenopausal women with POP. Alpha-1-antitrypsin was significantly lower in postmenopausal women with pelvic organ prolapse than in postmenopausal women without. The activities of neutrophil elastase, matrix metalloproteinase-2 and matrix metalloproteinase-9 were increased in women with POP, and these trends were similar to neutrophil elastase and matrix metalloproteinase-2 expression even after adjusting for age, parity and menopausal status. This study demonstrates that after menopause increased elastolytic protease has a significant role in the development of POP.

In a recent clinical trial of de Landsheere *et al*. [81], the authors shown that biomechanical testing highlights the hyperelastic behavior of the vaginal wall: at low strains, vaginal tissue appeared stiffer when elastin density was low, with a significant inverse relationship between low strains and the elastin/collagen ratio in the lamina propria. They suggested that elastin density deserve consideration as a relevant factor of vaginal stiffness in women with POP.

The strongly heritable connective tissue diseases, in which pelvic organ prolapse predominates as a result of an elastinopathy, highlight the importance of elastic fibres for maintaining vaginal support. Marfan's syndrome, characterized by mutations in the fibrillin-1 gene, and cutis laxa with mutations in the elastin and fibulin-5 genes, are notable for an increased incidence of POP in affected women [82-85].

Childbirth is an important risk factor for POP, not only for the mechanical trauma that the pelvic floor is submitted to: also inflammatory pathways are activated during the complex process of tissue healing after birth trauma. During healing proteinases, growth factors such as TGF-β, cytokines and chemokines are secreted into the extracellular matrix by surrounding cells. TGF-β is one of a family of 25 kDa polypeptide growth factors that is currently viewed as the most important fibrosis promoting cytokine. It is responsible for extracellular matrix synthesis in fibroblasts, the differentiation of fibroblasts to myofibroblasts and the inhibition of matrix degradation by inhibiting MMP expression and up-regulating TIMP expression. Thus, it is important in extracellular matrix metabolism and affects tissues or organs in various ways. There is sparse but growing evidence of TGF-β modulation in pelvic connective tissue. Large quantities of TGF-β1 are stored in readily available form in the extracellular matrix. Release and activation of stored latent TGF-β1 by proteases can generate rapid, highly localized signals. Therefore, the modulation of TGF-β1 activity by extracellular proteases provides faster signal transduction than alterations in gene expression. This is important for tissue remodelling during pregnancy and repair after birth trauma [50] .

3.3. Pregnancy and Delivery

3.3.1. Effect of pregnancy on pelvic floor function

Pregnancy has significant effect on lower urinary tract function. By the sixties, it was demonstrated that in uncomplicated pregnancy, micturition frequency is influenced by the physiological state of the bladder. Frequency has been described as diurnal changes, which maybe up to seven times or more of normal, and slight nocturnal changes of one or more times during the night. The incidence is the same in both primigravidae and multigravidae women. The first trimester is the most common time of onset. The uterine weight is the most important factor affecting frequency throughout the pregnancy. Uterine weight not only exerts pressure on the bladder but also irritates the bladder. Normal bladder capacity in the first trimester is 410 ml [86]. In late pregnancy, descent of the presenting part of fetus has an additional effect on bladder irritation. Bladder capacity in the third trimester reduces to 272 ml in conjunction with increased irritability of detrusor muscles [86]. Alternative causes include nervous and hormonal influences. Indeed, the onset of frequency in late pregnancy is a common symptom of engagement of the fetal head [86]. Approximately 80% of pregnant women, both primigravidae and multigravidae, experience increased micturition frequency at some time during pregnancy [86]. Increased frequency usually begins in early pregnancy but can occur in the later stage; it disappears in mid pregnancy, which maybe due to the increase in bladder capacity to 460 ml in the second trimester, and returns in the later weeks [86]. Once increased frequency has occurred, it is nearly always progressive and becomes increasingly worse until term [86]. Increased frequency during pregnancy results in polyuria and is associated with increased fluid intake. However, which is the cause and which the effect remains an unsolved issue. Average daily excretion, output, and fluid intake are highest in the second trimester and lowest in the third. Uterine position also plays a significant role. The impacted retrovert gravid uterus causes fluid retention because it interferes with the obliteration of the posterior urethrovesical angle [86].

Pregnancy is associated with bladder-neck descent, increased bladder-neck mobility, increased POP, decreased urethral resistance and loss of pelvic floor contractility (111). These changes are compatible with changes in mechanical properties of fascial tissue and can be considered a physiological adaptation to mechanical and hormonal alterations in pregnancy [87, 88].

Several of the changes occurring prior to delivery are in all likelihood normal physiological changes and may be secondary to hormone-induced collagen alterations. Hormonal alterations are essential to prepare the body and to adjust the musculature and connective tissue for vaginal birth.

Changes in relaxin and progesterone levels during pregnancy may have a significant role in the development of SUI [89]. The high progesterone levels during pregnancy influence the pelvic floor structures: progesterone has smooth muscle-relaxing and estrogen-antagonizing effects, reducing the tonus in ureters, bladder and urethra [90].

Progesterone increases during pregnancy from 24 ng/ml at the 8th week to 150 ng/ml at the 36th week [91]. Increased progesterone may relax smooth muscles in the urinary system [92], result in reduced ureter, bladder, and urethral tone [93]. Values urethral pressure profile parameters below the median value and defective transmission of pressure over the urethra were observed in almost all pregnant women who experienced SUI during pregnancy. These observations suggest that an inherent weakness of the urethral sphincter mechanism plays a key role in the pathogenesis of SUI during pregnancy. However, correlation between alterations in hormone levels during pregnancy and changes in urethral pressure profile measurements has not been demonstrated [91].

Relaxin increases markedly during pregnancy and it modifies the connective tissue: its collagenolytic effect, that allows appropriate stretching during vaginal birth, has been demonstrated in guinea pigs [94]. As a likely result of connective tissue remodeling in preparation for birth, Landon *et al.* [95] found that the connective tissue of the rectus sheath fascia and the obturator fascia could be stretched to greater length during pregnancy, but it is also much weaker. In some women, these changes may be irreversible and further stretching beyond physiological limits may result in permanent dysfunction.

Relaxin, which plays an important role in maintaining urinary continence during pregnancy [96], could stimulate tissue growth in the lower urinary tract and increase urethral pressure. There is a marked increase in relaxin concentration to peak at a gestational age of 10–14 weeks and then decrease to a stable level of approximately half the peak value at the 17th–24th week of pregnancy, resulting in decreased growth of the urethral epithelium [97, 98]. This may lead to a decrease in urethral pressure [99]. As pregnant women with SUI have lower urethral pressure than continent pregnant women [100], lower relaxin concentrations in late pregnancy, therefore, correlate with a higher prevalence of SUI at the second and third trimesters [96]. Collagen changes included modifications of tensile properties. Changes in tensile properties contribute to reduced functional support of PFM, and reduced total collagen content may result in joint laxity and stretching of pelvic ligaments [99]. The effect of the pregnancy on pelvic soft tissues was investigated through animals' studies [101, 102]: these researches has shown that along the reproductive statuses, the pelvic floor soft tissue undergoes profound histological changes. Particularly, during pregnancy the vaginal wall tissue and cervix became very compliant. This is associated with significant decrease in total collagen and a significant increase of elastin and smooth muscle cell content.

When the pregnant woman coughs, sneezes, laughs, or moves, intra-abdominal pressure increases, and this pressure is transmitted to the bladder. When pressure inside the bladder is greater than urethral closure pressure, incorporated with weakness of the urethral sphincter, SUI is the result.

Pregnancy is one of the main risk factors for the development of SUI in young women [103-106]. In fact, a significantly higher prevalence of SUI in pregnant women than in non-pregnant women has been demonstrated [26, 107, 108]. Pregnant women with SUI have significantly decreased PFM strength than continent pregnant [109]. It is known that PFM weakness causes bladder-neck and urethral mobility, leading to urethral sphincter incompetence [103, 110] .

Reduced PFM strength and SUI development in pregnant women are supposed to be due by weight. The growing uterus and fetus weigh solely on PFM, which contributes to chronic stress on PFM throughout pregnancy and results in PFM weakness. That lead to increased pressure on the PFM and bladder, which may result in greater urethral mobility [111, 112]. Furthermore, excess maternal weight gain may impair blood flow and innervations to the bladder and urethra [113]. Sphincter strength and its supportive function of PFM are consequently jeopardized [26, 103, 114] . Furthermore, multigravidity causes a decrease in PFM strength at a rate of 22–35% beginning at a gestational age of 20 weeks and lasting until 6 weeks postpartum [110].

During the last 20 years, several researches have focused on the effect of pregnancy on the pelvic floor and on the development of prolapse. Rahn *et al.* [115] identified pregnancy-induced changes in biomechanical properties of the vaginal wall and compare these with fibulin-5 knockout mice (Fbln5−/−) with and without prolapse. Compared with non-pregnant mice, vaginas of pregnant and Fbln5−/− (with prolapse) mice exhibited decreased maximal stress, increased distensibility and strain, plus decreased stiffness. Tissues from Fbln5−/− mice without prolapse were similar to nonpregnant wild-type animals. The authors conclude that pregnancy confers remarkable changes in the vaginal wall that include increased distensibility, decreased stiffness and maximal stress.

O'Boyle *et al.* [116] showed in a series of 135 nulliparous pregnant women that POP-Q stage increase during pregnancy and does not change significantly following delivery. These findings suggest that significant changes may be objectively demonstrated prior to delivery. In fact, in nulliparous women pregnancy is associated with increased POP-Q stage compared with non-pregnant control subjects [117].

These findings were confirmed by the data of Sze *et al.* [118] reporting that 46% of 94 nulliparous women had pelvic organ prolapse at their 36-week antepartum visit and of them, 26% had a stage II prolapse.

A recent prospective cohort study assessing 300 nulliparous pregnant women [119], showed that vaginal POP-Q points made a cranial shift from mid to late pregnancy, a caudal shift following delivery, and again a cranial shift after 6 weeks postpartum. Postpartum change was present following both vaginal and caesarean deliveries, but was more pronounced following vaginal delivery. The perineal body and genital hiatus became longer from mid to late pregnancy, and shortened after 6 weeks postpartum. At 12 months postpartum all POP-Q points, except cervix, had recovered to baseline in the vaginal delivery group. The authors considered good the short-term ability to recover after the first pregnancy and delivery.

Gachon *et al.* [120] in their review concluded too that pelvic organ mobility, ligamentous laxity, levator hiatus and urethral mobility change in a similar way during pregnancy (increase of mobility or distension) and postpartum (recovery). Clinical assessments performed in the reviewed studies showed an increase of pelvic organ mobility and perineal distension during pregnancy followed by a recovery phase during postpartum.

A recent review of Soave *et al.* [121] evaluated the efficacy of PFMT for prevention and treatment of UI during pregnancy and after childbirth and its effect on urinary system and supportive structures assessed by objective measurement techniques. They concluded that at the present time there is insufficient evidence to state that PFMT is effective in preventing and treating UI during pregnancy and in the postpartum. However, based on the evidence provided by studies with large sample size, well-defined training protocols, high adherence rates and close follow-up, a PFMT program following general strength-training principles can be recommended both during pregnancy and in the postnatal period.

3.3.2. Obstetric and maternal factors

In 1997 the Oxford Family Planning Study showed that increasing vaginal parity was the strongest risk factor for pelvic organ prolapse in women <60 years [27]. Compared with nulliparous individuals, the relative risk of developing prolapse was 8.4 for a woman who had delivered two children and 10.9 (95% CI: 4.7–

33.8) for someone with four or more children [27]. The Women's Health Initiative reported that single childbirth was associated with raised odds of uterine prolapse (OR 2.1;95% CI: 1.7–2.7), cystocele (OR 2.2; 95% CI: 1.8–2.7), and rectocele (OR 1.9; 95% CI: 1.7–2.2) [28]. Every additional delivery up to five births increased the risk of worsening prolapse by 10–20% [28]. The Progetto Menopausa Italia study confirmed that risk of pelvic organ prolapse increases with the number of vaginal births [122].

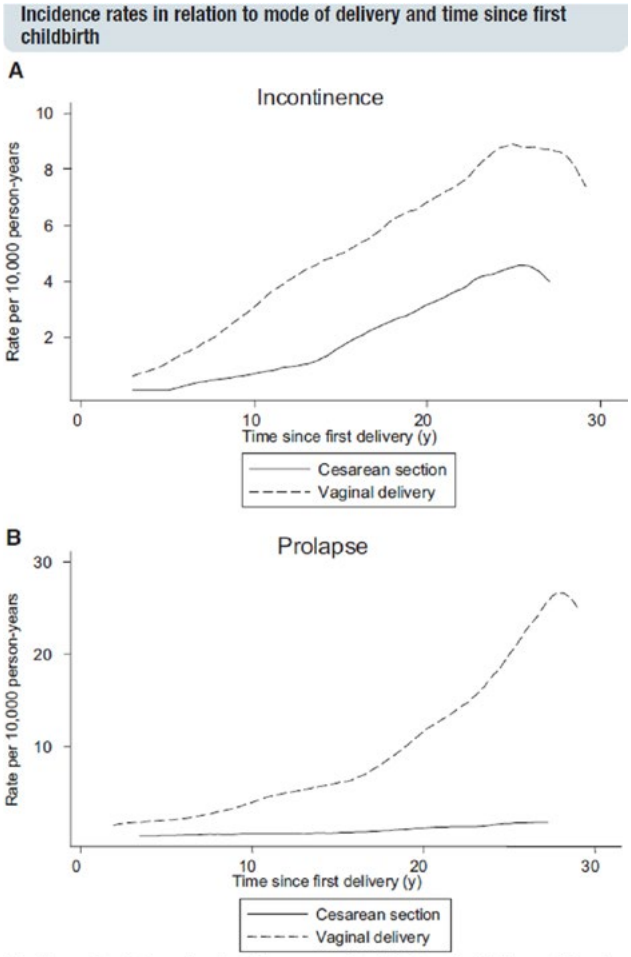
To ascertain the effect of a second delivery on pelvic floor anatomy, Horak *et al.* [123] showed that a second pregnancy and delivery do not seem to have a major effect on bladder support and/or levator function. However, findings of a cross-sectional study of 3050 women randomly selected from a large southern California Health Maintenance Organization, showed that women who had undergone one or more vaginal deliveries had a significantly greater risk of developing symptomatic pelvic organ prolapse than did those who had only caesarean sections (OR 3.21; 95% CI: 1.96–5.26) [124]. The attributable risk of vaginal delivery for development of symptomatic prolapse, or the proportion that could have been prevented with a policy of routine elective caesarean section, in this population was 46%. LEVEL OF EVIDENCE: II-2 [124].

The association between caesarean section and POP was investigated by Larsson *et al.* [125]: the Swedish Hospital Discharge Registry was used to identify women with an inpatient diagnosis of pelvic organ prolapse, and the data were linked to the Swedish Medical Birth Registry. A total of 1.4 million women were investigated. A strong and statistically significant association between caesarean section and pelvic organ prolapse was found (Adjusted OR 0.18 [95% CI: 0.16-0.20] and overall hazard ratio=0.20 [95% CI: 0.18-0.22]). The authors concluded that caesarean section is associated with a lower risk of pelvic organ prolapse than vaginal delivery.

In another study from the Swedish Medical Birth Registry [126], POP surgery was observed in 2.2% of vaginal deliveries and 0.2% of caesarean sections (follow-up time 25.9 years). Among women only having had vaginal deliveries, rates of POP surgery increased with number of childbirths. In the caesarean delivery cohort, rates of POP surgery slightly decreased with increasing parity number. Compared with a caesarean delivery, the risk of POP surgery was increased nine-fold both after non-instrumental vaginal delivery and after vacuum extraction, whereas among women with forceps delivery a twenty-fold increase in risk was observed. The incidence rate of POP in women with caesarean deliveries showed very little variation over time, but started to diverge more notably from the vaginal delivery cohort 10 years after the first birth (Figure 5B).

Another registry-based national cohort study [127], confirmed that the prevalence of symptomatic POP was doubled after vaginal delivery compared with caesarean section, two decades after one birth.

A clear link between vaginal delivery and symptoms and signs of pelvic organ prolapse in urogynecological patients was demonstrated by Trutnovsky *et al.* [128]: nulliparae showed the lowest prevalence of POP, followed by women exclusively delivered by caesarean section. Highest prevalences were consistently found in women delivered at least once by forceps, although the differences between this group and women delivered by normal vaginal delivery and/or vacuum extraction were significant in three out of eight POP-Q measures only. Compared with women in the caesarean section group, the adjusted odds ratios for reporting symptoms of prolapse were 2.4 (95% CI 1.30-4.59) and 3.2 (95% CI 1.65-6.12) in the normal vaginal delivery/vacuum extraction group and forceps group, respectively.



A, Incidence rates of stress urinary incontinence surgery in relation to mode of delivery and time since first childbirth; B, Incidence rates of pelvic organ prolapse surgery in relation to mode of delivery and time since first childbirth.

Figure 5: [126] From: Leijonhufvud et al. Incontinence and prolapse surgery after childbirth. Am J Obstet Gynecol 2011 [126]

A register-based national cohort study [129] of primiparae who delivered between 1985 and 1988 and had no further deliveries confirmed these results: 20 years after the birth the late prevalence of UI, symptomatic POP and faecal incontinence were almost identical between vacuum extraction (VE) and spontaneous vaginal delivery (SVD).

Lisonkova *et al.* [130] designed a retrospective analysis to examine age-specific trends in vaginal and caesarean delivery, obstetric trauma, and surgery for pelvic organ prolapse among all women in Washington State. From 1987 through 2009, caesarean delivery rates among women aged 15-44 years increased from 12.7-18.1 per 1000 women, vaginal delivery rates remained stable, and instrumental vaginal delivery rates declined from 6.3-3.9 per 1000 women. Obstetric trauma decreased from 6.7 in 1987 to 2.5 per 1000 women aged 15-44 years in 2009. Surgery for pelvic organ prolapse decreased

from 2.1 in 1987 to 1.4 per1000 women aged 20-84 years in 2009. Obstetric trauma rates in 1987 through 1999 among women 15-44 years old were strongly correlated with the rates of surgery for pelvic organ prolapse among women 25-54 years of age 10 years later in 1997 through 2009 (correlation coefficient 0.87, P<.001). Similarly, rates of midpelvic forceps delivery in 1987 through to 1999 were correlated with the rates of surgery for pelvic organ prolapse 10 years later (correlation coefficient 0.72, P<.01). Regression analyses showed a strong effect of age on surgery for prolapse, temporal decline in surgery, and an effect of birth cohort, as younger cohorts (women born in ≥1965 vs 1940) had lower rates of surgery for pelvic organ prolapse. The authors concluded that temporal decline in instrumental vaginal delivery and obstetric trauma may have contributed to the reduction in surgery for pelvic organ prolapse.

Blomquist *et al.* [131] recruited women from a community hospital for a cohort study 5 to 10 years after their first delivery and followed up annually for up to 9 years. Among 1528 women (778 in the caesarean birth group, 565 in the spontaneous vaginal birth group and 185 in the operative vaginal birth group), after a median follow-up of 5.1 years, there were 138 cases of SUI, 117 cases of OAB, 168 cases of AI, and 153 cases of POP. For spontaneous vaginal delivery (reference), the 15-year cumulative incidence of POP was 30.0% (95% CI, 25.1%-34.9%). Compared with spontaneous vaginal delivery, caesarean delivery was associated with significantly lower hazard of POP (aHR, 0.28 [95% CI, 0.19-0.42]), operative vaginal delivery was associated with significantly higher hazard of POP (aHR, 1.88 [95% CI, 1.28-2.78]). Stratifying by delivery mode, the hazard ratios for POP, relative to a genital hiatus size less than or equal to 2.5 cm, were 3.0 (95% CI, 1.7-5.3) for a genital hiatus size of 3 cm and 9.0 (95% CI, 5.5-14.8) for a genital hiatus size greater than or equal to 3.5 cm. The authors concluded that, compared with spontaneous vaginal delivery, caesarean delivery was associated with significantly lower hazard pelvic organ prolapse, while operative vaginal delivery was associated with significantly higher hazard pelvic organ prolapse. A larger genital hiatus was associated with increased risk of pelvic organ prolapse independent of delivery mode.

The occurrence rate of pelvic organ prolapse stage ≥2 in the first 3-6 months postpartum has been described in literature between 18.1-56% [132-134].

In a cross-sectional study of 382 primigravid women, pelvic organ support was explored 6 months postpartum: POP-Q stage ≥II was present in 7.7%, 18.1% and 29% of women who delivered by caesarean section, spontaneous and instrumental vaginal delivery, respectively. Spontaneous vaginal delivery increased the risk by more than three times (OR 3.19) while instrumental vaginal delivery increased it more than five-fold (OR 5.52) in comparison with caesarean section. Instrument-assisted delivery did not increase the risk of prolapse in women who delivered vaginally. The authors concluded that caesarean section is associated with a lower prevalence of pelvic organ prolapse after delivery and instrument assisted delivery is not associated with an increased risk of postpartum prolapse among women who delivered vaginally [132].

Other obstetric factors that have been associated with an increased risk of pelvic organ prolapse, albeit less consistently, are delivery of a macrosomic infant, prolonged second stage of labour, age and BMI [135-137].

To date, the studies are controversial considering younger age (25 versus 28 years of age) [136] as well as older age (more than 30 years) [138] at first delivery as a risk factor to develop pelvic organ prolapse. Another large study did not reveal any association at all [23].

Somewhat more controversial is whether pregnancy itself, distinct from mode of delivery, alters the risk of pelvic organ prolapse. In a small case-control study, pregnancy was associated with worsening prolapse compared with non-pregnant controls matched for age and ethnic origin [117]. A substantial proportion of pregnant nulliparous women show progression from stage 0 or I support in the first trimester to stage I or II in the third trimester [116]. This loss of vaginal support does not seem to return to baseline in the postpartum period. Significant risk factors from Chen *et al.* (n=108) were POP during pregnancy (OR 8.2, 95% CI 3.07-21.9) and higher first-trimester body mass index (BMI) (OR 1.31, 95% CI 1.01-1.70) [139].

Significant risk factors from Reimers *et al.* (n=284) were a more caudal position of the anterior vaginal wall (point Ba measured with the POP-Q) at gestation week 21 (OR 2.45, 95% CI 1.29-4.67), a longer distance from the meatus urethra to the anus (Gh + Pb measured with the POP-Q) (OR 1.58, 95% CI 1.05-2.38), a more distensible levator ani muscle at gestation week 21 (OR 1.13, 95% CI 1.03-1.23), and an episiotomy (OR 19.84, 95% CI 6.18-63.73) [140].

Handa *et al.* [141] investigated whether episiotomy, perineal laceration and operative delivery are associated with pelvic floor disorders after vaginal childbirth. Episiotomy was not associated with pelvic floor disorders. Forceps delivery increased the odds of prolapse (OR 1.95, 95%CI 1.03 - 3.70). In contrast, women with a history of more than one spontaneous perineal laceration were significantly more likely to have prolapse to or beyond the hymen (OR 2.34, 95% CI 1.13 - 4.86). Few others studies investigate the relationship between POP surgery and episiotomy. Abdel-Fattah *et al.* [142], in a large register linkage study, reported a POP surgery rate of 44% irrespective of previous episiotomy. The difference between groups was not significantly different (OR 1.05, 95% CI 0.94–1.18). Similarly, Uma *et al.* [143] did not show any difference between patients who underwent episiotomy and controls in terms of POP surgery rates (21.1% vs 19.2%; CI 0.99–2.10; p = n/a). Recently Frigerio *et al.* [144], confirmed that episiotomy does not seem to negatively influence genital prolapse development and might even be protective with respect to prolapse severity and prevalence without affecting surgery rates. Based on these studies, episiotomy does not seem to affect POP surgery rates. Lovejoy *et al.* [145] recently demonstrated that breastfeeding after vaginal childbirth was not associated with the development of stress urinary incontinence, pelvic organ prolapse, or anal incontinence 1-2 decades after the first vaginal delivery.

3.3.3. Pathophysiologic mechanism of childbirth injury to the pelvic floor

Undoubtedly, vaginal delivery constitutes a traumatic event for the pelvic floor: it affects the pelvic nerves, the pubococcigeus-puborectalis muscle complex, the pelvic fascial structures and the anal sphincter. However, all women sustain the trauma of their pelvic floor during vaginal birth, but only some of them experience injury.

The first vaginal delivery is when most women are likely to sustain pelvic floor damage, such as, neurogenic injury, change in

bladder-neck position and mobility, levator ani trauma, increase in levator hiatus, and anal sphincter disruption. In most women, the pelvic floor muscle function recovers during the year following delivery. In a minority, symptoms persist and may finally lead to PFD in later life [146].

Several attempts have been made to define the fascial trauma after vaginal delivery. In the anterior compartment, the childbirth may result in disruption of the 'endopelvic fascia', in particular of the paraurethral and paravaginal structures. Analogous to increased bladder descent after childbirth, there is a highly significant increase in caudal displacement of the rectal ampulla after childbirth [147]. The rectovaginal septum and the Denonviller's fascia are the connective structures involved in the posterior compartment damage that appears as a rectocele. It has been shown that vaginal childbirth also results in an increased prevalence of true rectocoele, i.e. presumptive defects of the rectovaginal septum [148]. Such defects are strongly associated with symptoms of pelvic organ prolapse and obstructed defecation [149].

Specific features of injury during vaginal birth influence whether a woman develops prolapse later in life. Several factors, that can be grouped together as descriptors of difficult vaginal delivery, are associated with increased occurrence of prolapse: forceps delivery, a prolonged second stage of labour, and large infant birth weight. Unfortunately, because of the overlapping nature of these different factors, it is difficult to determine which of them is causal and which of them is associated (e.g., forceps delivery is used when there has been a prolonged second stage of labour, and both of these factors increase in large-sized infants).

A mechanical model study has shown that even an apparently uneventful vaginal delivery inflicts injuries to the pelvic floor muscles, particularly during the extension of the fetal head, having been obtained more than 10% of damaged fibres; the puborectalis component of the levator ani muscle (LAM) is the most prone to be damaged [150].

The role of childbirth in causing damage to the LAM, which is associated with both vaginal delivery and with pelvic organ prolapse, is probably the mediating mechanism in these injuries. In the last decades the imaging techniques such as magnetic resonance imaging and 3D and 4D ultrasound have focused on the morphology of the levator ani complex and its integrity after delivery.

The occurrence of levator trauma after vaginal delivery (Figure 12) is reported to be between 15-39.5% when investigated with ultrasound [151-158] and between 17.7%-19.1% when assessed with MRI [159-161]. This difference in occurrence rate is probably due to the different postpartum assessment of levator ani muscle (which varies in these studies between 24-72 hours to 12 months postpartum). In fact, it has been demonstrated by Staer-Jensen *et al.* [162] that the LAM has the ability to recover after pregnancy and delivery and most of the recovery occurs during the first 6 months postpartum (LEVEL OF EVIDENCE: II). These results are consistent with other research evaluating levator morphology using either MRI or ultrasonography: 26 primiparous women demonstrated major levator ani defects at 6 weeks, but at 12 months postpartum, 10 of these 26 women no longer had a major defect. Others similarly have found that avulsion injuries of the levator ani after childbirth resolve in 10-20% of women [160, 163, 164]. On the other hand, Valsky *et al.* [165] showed that a sonographic finding of LAM defect identified in the period immediately postpartum persists months or year after delivery; therefore this test may be performed following the delivery, or may be delayed without impact the result. Also the Delancey´s group demonstrated that the magnitude of LAM tear did not substantially change by 8 months postpartum, but LAM edema and bone injuries showed total or near total resolution [166].

The following risk factors for levator trauma after vaginal delivery have been described in the literature: obstetric anal sphincter injuries (OR: 4.4-8.1); prolonged active second stage of labour per hour (OR: 2.2); forceps delivery (OR: 14.7); fetal head circumference (OR: 3.3); episiotomy (OR: 3.1); increased maternal age [151, 153, 158, 161, 164, 167-169].

Memon *et al.* [170] showed that ten years after delivery, the prevalence of levator avulsion is almost tripled after forceps compared with vacuum-assisted vaginal delivery (LEVEL OF EVIDENCE II).

An observational study done in women 2–4 weeks before and 2–6 months after vaginal childbirth provided a direct proof for the hypothesis that childbirth is responsible for certain morphologic abnormalities of LAM observed in parous women and suggests that older age at first delivery is a risk factor for such trauma (LEVEL OF EVIDENCE II-3) [155].

Third-fourth-degree perineal tears were found to be independent clinical indicators of an increased risk of levator trauma. Such clinical markers may become useful in the identification of women at high risk of levator trauma and future pelvic floor disorders [171].

Kamisan Atan *et al.* [172] investigated in a prospective randomized study if the antepartum use of a birth trainer (Epi-No®) may prevent such injuries by altering the biomechanical properties of the pelvic floor. 504 women were assessed with 4D translabial ultrasound in the late third trimester, and again 3-6 months postpartum, after randomization to control or intervention (use the Epi-No® device from 37 weeks of gestation until delivery) groups. The results of this trial showed no significant difference in the incidence of levator avulsion, irreversible hiatal overdistension, clinical anal sphincter trauma and perineal tears. A marginally higher rate of significant defects of the external anal sphincter on ultrasound was observed in the intervention group. The authors concluded that the antenatal use of Epi-No® device is unlikely to be clinically beneficial in the prevention of intrapartum levator ani damage, or anal sphincter and perineal trauma.

The systematic review of pelvic floor interventions during pregnancy published on 2018 by Schreiner *et al.*, [173] confirmed that pelvic floor muscle training and perineal massage improved childbirth-related parameters and pelvic floor symptoms, whereas Epi-No® showed no benefit.

To estimate the risk of prolapse associated with levator avulsion injury among a urogynaecological clinic population, Dietz *et al.* [174] considered 781 women retrospectively, with a mean age 53 years (range 15-89 years), and a median parity of 2 (range 0-12). Significant prolapse (stage II or higher) was diagnosed in 415 (53%) women, and 181 (23%) women were found to have levator avulsion defects. Prolapse was seen in 150/181 (83%) women with avulsion and in 265/600 (44%) women without

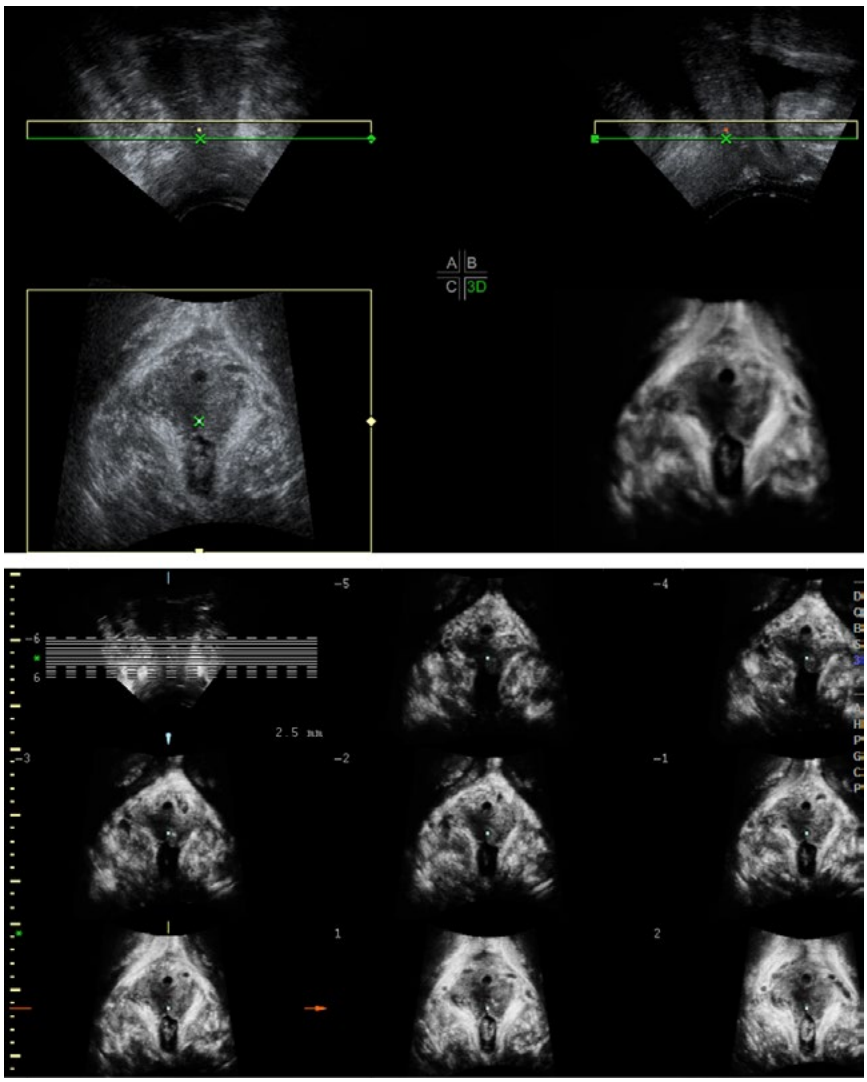


Figure 6: Levator ani defect early postpartum in a patient had spontaneous vaginal delivery (acquisition screen GE Voluson-e ® System). A) In the multiplanar mode, the axial plane (lower left) and the rendered image (lower right) show an unilateral levator discontinuity (**) on the right side of pubococcigeal-puborectalis muscle. B) Eight slices obtained with TUI in coronal-C plane in the same patients: the discontinuity (arrow) is demonstrated in at least three consecutive slices at and above the plane of minimal hiatal dimension (frames *,-1,-2,-3). From Albrich et al, BJOG 2011 [156] with permission

avulsion, giving a RR of 1.9 (95% CI: 1.7-2.1). The association was strongest for cystocele (RR 2.3, 95% CI: 2.0-2.7) and uterine prolapse (RR 4.0, 95% CI: 2.5-6.5). The authors concluded that women with levator avulsion defects were about twice as likely to show pelvic organ prolapse of stage II or higher than those without, with an increased risk of cystocele and uterine prolapse. A cystocele with an intact rectovesical angle is more likely to be associated with avulsion injury of the LAM and thus more likely to be caused by birth-related trauma [175]. Puborectalis avulsion injury and levator hiatal ballooning are independent risk factors for symptoms and sign of prolapse. The role of avulsion in the pathogenesis of prolapse is not fully explained by its effect on hiatal dimensions. It likely that avulsion implies not only muscular trauma but also damage to structures impossible to assess clinically or by imaging, i.e. myofascial and connective tissue [176]. Pelvic organ prolapse has a considerably lower incidence after caesarean section [26, 57]; however pelvic organ prolapse has been described in 35% of 26 women after caesarean section during active labour in comparison to 32% of 41 women who had spontaneous vaginal deliveries [118]. On the other hand, one epidemiological study using validated questionnaires negated the influence of labour versus no-labour pure caesarean delivery on pelvic organ prolapse [124] (LEVEL OF EVIDENCE: II-2). Others studies [156, 177] reported cases of early levator abnormalities after emergency caesarean section, and hypothesized a possible role of the active labour in the occurrence of lesions of the pelvic muscular floor.

A recent study of Leijonhufvud *et al.* [126] considered a cohort study of all women having their first and all subsequent caesarean deliveries (n = 33,167), and an age-matched sample of women having only vaginal deliveries (n = 63,229). Women who had only vaginal deliveries had an overall increased risk of prolapse surgery (HR, 9.2; 95% CI: 7.0-12.1) compared with women who had only having caesarean deliveries. They con-

clude that having only vaginal childbirths was associated with a significantly increased risk of pelvic organ prolapse surgery later in life compared with only having caesarean deliveries. There seems to be sufficient proof that pelvic organ support can be impaired by vaginal childbirth. It is unclear whether this effect is due to stretching or avulsion of structures and whether the observed changes are primary (i.e. directly due to childbirth) or the medium-term or long-term consequence of the levator impairment. Several mechanisms may well coexist in one individual [178].

Furthermore, it has been shown that any delivery-related changes occur against the background of marked variations in pelvic organ support in young nulliparous women [179]. As the most significant changes are observed in those with the least antenatalorgan mobility [180], the effect of childbirth may be a partial equalization of those interindividual differences.

A recent systematic literature review confirmed that the PMFT during pregnancy shortened the second stage of labor and reduced the urinary incontinence, whereas the perineal massage reduced perineal pain. [173]

3.3.4. Perineal trauma

Since the current literature suggests that childbirth and in particular vaginal childbirth has the strongest association with PFD and childbirth is significantly associated with POP, the identification of modifiable risk factors such as obstetric interventions during vaginal childbirth is of the utmost importance.

The role of episiotomy in the prevention of future PFD is still controversial.

The study of Sartore *et al.* [181] showed that mediolateral episiotomy does not protect against genital prolapse and is associated with a lower pelvic floor muscle strength compared with spontaneous perineal lacerations.

However, a recent systematic review of Frigerio *et al.* [144] reported that episiotomy does not seem to negatively influence genital prolapse development and might even be protective with respect to prolapse severity and prevalence without affecting surgery rates.

The episiotomy, a surgical incision in the perineum made to enlarge the vaginal opening and facilitate delivery, was originally introduced as a method assumed to improve maternal and neonatal outcomes and rapidly became a part of standard obstetric care. However, since the 1980s, routine use of episiotomy has been challenged, based on the lack of evidence of benefits of the procedure [182] and the publication of multiple studies reporting increased blood loss at delivery, perineal scar breakdown and infection, postpartum pelvic pain, and dyspareunia [183-186]. . Various types of episiotomy have been described in the past (median, modified median, J-shaped episiotomy, mediolateral, lateral, radical lateral and anterior) in papers and textbooks. Routine episiotomy is no longer recommended

Some studies deal with the different use of various episiotomies in different countries (e.g. UK, Finland and Greece) [188-191]. However randomized trials comparing alternative methods or position of episiotomy are lacking, resulting in Level 2b or Level 3 of evidence. To ensure Level 1 evidence from randomized trials, a standardization of the practice and reporting of the episiotomy incision is required . However, a standardized classification system has not been introduced yet, making it difficult to compare the various techniques. Even in the last Cochrane review of episiotomy, an exact classification or definition of episiotomies is lacking [192].

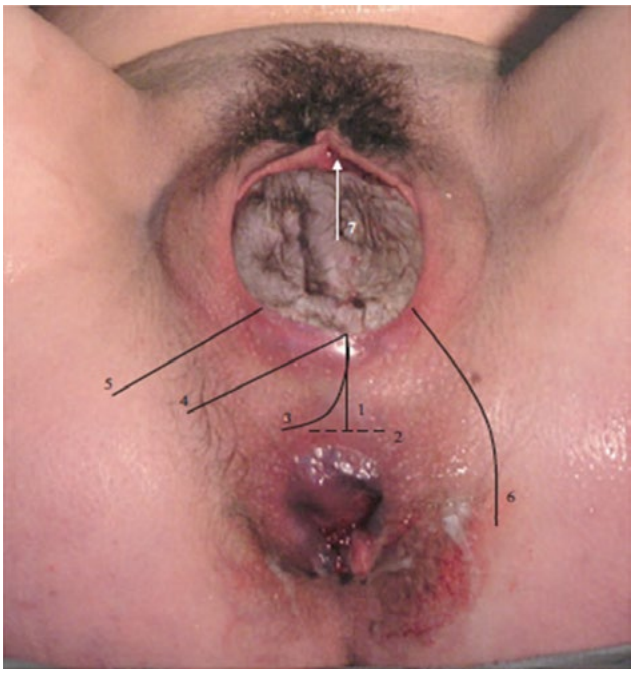

Figure 7: The description of mediolateral episiotomy (the most frequently used in Europe) in standard obstetrics textbooks differs widely: some publications provide only descriptive terms, the angle of incision varies between 31° and 63°, suggesting the wide potential variation in the practice of episiotomy worldwide.
Types of episiotomy. 1: median episiotomy, 2: modified median episiotomy, 3. 'J'- shaped episiotomy, 4: mediolateral episiotomy, 5. lateral episiotomy, 6: radical lateral (Schchardt incision), 7: anterior episiotomy (white arrow). From Kalis et al. Classification of episiotomy: towards a standardization of terminology. BJOG 2012 [187].

Some studies have demonstrated increased incidence of third and fourth-degree lacerations associated with the use of midline episiotomy [193, 194]. The resulting damage to the internal and external anal sphincters can lead to devastating long-term sequelae, including faecal incontinence and rectovaginal fistulae [195].

To support the benefits of episiotomy, some clinicians have claimed that meticulous repair of a surgical episiotomy yields improved wound healing when compared with an unpredictable spontaneous laceration [183]. This assertion has not been substantiated by empiric evidence [196].

Kalis *et al.* [197] evaluated the results of mediolateral episiotomy with incision angle of 60°: the study group comprised 60 consecutively recruited primiparous women who required episiotomy during delivery. The results showed that the angles differed significantly among the incision (60°), repair (45°), and 6-month (48°) measurements ($P < 0.001$). There was a poor correlation between the suture angle and the angle measured at 6 months postpartum. No severe perineal tear was diagnosed in the cohort. At 6 months postpartum, only one woman reported mild symptoms of de novo anal

incontinence, whereas seven women reported perineal pain related to episiotomy.

Many institutions and individual obstetric practitioners have decreased their performance of episiotomy over the past 20 years, most likely as a result of practicing evidence-based medicine.

An electronic audit of the medical procedures database at Thomas Jefferson University Hospital from 1983 to 2000 was completed to determine if practice patterns have been altered by the large body of literature strongly advocating the selective use of episiotomy. Overall episiotomy rates in 34,048 vaginal births showed a significant reduction from 69.6% in 1983 to 19.4% in 2000. Significantly decreased risk of episiotomy was seen based upon year of childbirth (OR 0.87, 95% CI: 0.86-0.87), black race (OR 0.29, 95% CI: 0.28-0.31), and spontaneous vaginal delivery (OR 0.40, 95% CI: 0.36-0.45). Increased association with episiotomy was seen in forceps deliveries (OR 4.04, 95% CI: 3.46-4.72), and with third or fourth-degree lacerations (OR 4.87, 95% CI: 4.38-5.41). This study demonstrated a statistically significant reduction in the overall episiotomy rate between 1983 and 2000 [186].

A population-based register of 514,741 women with singleton vaginal deliveries recorded in the Finnish Medical Birth Register was reviewed. Primiparous and multiparous women who had undergone episiotomy were compared to women who had not undergone episiotomy, for possible risk factors. The occurrence of episiotomy decreased from 71.5% in 1997-1999 to 54.9% in 2006-2007 among primiparous women, and from 21.5% in 1997-2001 to 9.2% in 2006-2007 among multiparous women. The use of episiotomy decreased not only in low-risk but also in high-risk women who had operative vaginal or breech deliveries, macrosomic newborns, and oxytocin augmentation. The ratio of episiotomy use remained relatively unchanged in different subgroups even though episiotomy policy became increasingly restrictive over time. The authors concluded that the spectrum of episiotomy indications has not changed over time, and use of episiotomy has declined arbitrarily to a similar extent among high and low-risk women [198].

To identify the risk factors for obstetric anal sphincter rupture (OASR), a retrospective population-based register study was carried out. A total of 514,741 women with singleton pregnancy and vaginal delivery between 1997 and 2007 in Finland were recruited. Episiotomy decreased the likelihood of OASR for the primiparous [OR 0.83, 95% CI: 0.75-0.92], but not the multiparous women (OR 2.01, 95% CI: 1.67-2.44). Episiotomy was associated with decreased risks for obstetric anal sphincter rupture in vacuum assisted deliveries (OR 0.70, 95% CI: 0.57-0.85). These results support the restrictive use of episiotomy, since 909 episiotomies appear to be needed to prevent one OASR among primiparous women. The equivalent estimate in vacuum assisted deliveries among primiparous women was 66, favoring routine use of episiotomy in such cases [190].

Robinson *et al.* [199], carried out a study to identify factors associated with the use of episiotomy at spontaneous vaginal delivery. They studied 1576 consecutive term, singleton, spontaneous vaginal deliveries; the association of demographic variables and obstetric factors with the rate of episiotomy use were examined. The overall rate of episiotomy was 40.6% (640 of 1576). Midwives performed episiotomies at a lower rate (21.4%) than faculty (33.3%) and private providers (55.6%) (P =0.001). After controlling for confounding factors with logistic regression, private practice provider was the strongest predictor of episiotomy use (OR 4.1, 95% CI: 3.1-5.4) followed by faculty provider (OR 1.7; 95% CI:1.1-2.5), prolonged second stage of labor (OR 1.8; 95% CI: 1.2-2.7), fetal macrosomia (OR 1.6; 95% CI: 1.1-2.5), and epidural analgesia (OR 1.4 95% CI: 1.1-1.8). The authors conclude that the strongest factor associated with episiotomy at delivery was the category of obstetric provider. Obstetric and demographic factors evaluated did not readily explain this association.

A study was carried out to lower the episiotomy rate through physician education and to document the indication when episiotomy was performed. The intervention consisted of an evidence-based lecture recommending limited usage of episiotomy and requesting documentation of any indication for episiotomy. Data 3 monts prior to the intervention were compared to those of the following year. For all vaginal deliveries, there was a 17% decrease in the rate of episiotomy, from 46.9% to 38.8%. For spontaneous vaginal deliveries, there was a 25% decrease in the episiotomy rate, from 40.8% to 30.8%. The most common indications for episiotomy reported were routine/elective, 41.0%; vacuum, 18.6%; forceps, 16.4%; and nonreassuring fetal heart tracing, 10.9% [200].

A review was conducted of women with consecutive vaginal deliveries at Magee-Women's Hospital between 1995 and 2005 to evaluate the episiotomy exposure at first vaginal delivery. A total of 6,052 patients were included, of whom 47.8% had episiotomy at first delivery. Spontaneous second-degree lacerations at the time of second delivery occurred in 51.3% of women with history of episiotomy at first delivery, compared with 26.7% without history of episiotomy (P<0.001). Severe lacerations (third or fourth- degree) occurred in 4.8% of women with history of episiotomy at first delivery compared with 1.7% without history of episiotomy (P<0.001). Prior episiotomy remained a significant risk factor for second-degree (OR 4.47, 95% CI: 3.78-5.30) and severe obstetric lacerations (OR 5.25, 95% CI: 2.96-9.32) in the second vaginal delivery after controlling for confounders. Based on these findings, for every four episiotomies not performed, one second-degree laceration would be prevented. To prevent one severe laceration, performing 32 fewer episiotomies is required. Episiotomy at first vaginal delivery increases the risk of spontaneous obstetric laceration in the subsequent delivery. This finding should encourage obstetric providers to further restrict the use of episiotomy. LEVEL OF EVIDENCE II [201].

In a biomechanical analysis on the impact of episiotomy during childbirth, Oliveira *et al.* [202] demonstrated that a mediolateral episiotomy has a protective effect, reducing the stress on the muscles, and the force required to delivery successfully up to 52.2%. The intervention also has benefits on muscle injury, reducing the damage to a small zone.

Handa *et al.* [141] demonstrated that forceps deliveries and perineal lacerations, but not episiotomies, were associated with pelvic floor disorders 5–10 years after a first delivery. Women with perineal lacerations in two or more deliveries were at significantly higher risk of prolapse. In contrast, even among women with multiple episiotomies across multiple pregnancies, the odds for incontinence and prolapse were not elevated. The data do not suggest a "dose response" relationship between perineal laceration and prolapse. Specifically, the increase in prolapse was statistically significant only in women with at least two lacerations. The observed association between spontaneous laceration and the later development of prolapse is biologically plausible, given recent evidence of the role of levator ani injuries in the genesis of prolapse. Magnetic resonance imaging suggests that avulsion of the levator from the pubis is associated with prolapse later in life [2]. Biomechanical models of the pelvic floor predict that avulsion of the levator ani occurs with

excessive stretching of the levator hiatus during crowning of the fetal head [203]. The hypothesis that spontaneous perineal laceration may be a marker of excessive stretch at the time of delivery has been later demonstrated by Shek *et al.* [171]: vaginal sidewall and third-/fourth-degree perineal tears were found to be independent clinical indicators of an increased risk of levator trauma, as diagnosed by 4D translabial ultrasound 3-6 months postpartum. Such clinical markers may become useful in the identification of women at high risk of levator trauma and future pelvic floor disorders.

Lisankova *et al.* [130] showed that the decline from 1987 through to 2009 in instrumental vaginal delivery and obstetric trauma may have contributed to the reduction in surgery for pelvic organ prolapse.

A recent review and meta-analysis by Driusso *et al.* showed that there was no difference in short-term PFM strength after childbirth between primiparous women who underwent caesarean section or vaginal delivery, as assessed through vaginal manometry. However, they identified reduced PFM strength in women who underwent an episiotomy or instrumented vaginal delivery compared with those who underwent caesarean section. [204] Eisenberg *et al.* aimed to verify the functional interaction that exists between the pelvic floor and the abdominal wall. The study was aimed to investigate the clinical and morphological relationships between diastasis rectus abdominus (DRA) and pelvic floor trauma in primiparous women. Their results showed that the diastasis rectus abdominus does not correlate with morphological changes in the pelvic floor, but does correlate with higher scores in the urinary symptoms portion of the PFDI-20. Women suffering from DRA do not endure more pain or greater lumbar disability than non-DRA women. In extended DRA, the abdominal muscles are significantly compromised and weaker. [205]

3.4. Age

Both incidence and prevalence of pelvic organ prolapse increase with advancing age. In a cross-sectional study of 1004 women (age 18–83 years) who came for their yearly examination, the relative prevalence of this disorder rose by about 40% with every decade of life [20]. In the Women's Health Initiative, American women aged 60–69 years (OR 1.2; 95% CI: 1.0–1.3) and 70–79 years (OR 1.4; 95%CI: 1.2–1.6) had a higher risk of prolapse than did those aged 50–59 [28]. Similarly, findings of a cross-sectional study of 21449 menopausal Italian women showed an augmented risk of pelvic organ prolapse in women aged 52–55 years (OR 1.3; 95% CI:1.1–1.5) and those 56 years or older (OR 1.7; 95% CI: 1.5–2.0) compared with those younger than 51 years [122]. Surgery for prolapse is uncommon in people younger than 30 and older than 80 years; for women between these ages, incidence rises steadily [21].

A recent nationwide epidemiological survey on 55477 Chinese women confirmed that the odds for each type of symptomatic POP increased with age (>50 vs 20-29 years old in symptomatic POP-Q stage II or higher, OR increased from 1.34 [95% CI 1.32-1.45] to 7.34 [95% CI 4.34-12.41]) [206].

3.5. Hormones

As age has been clearly shown to affect the prevalence and progression of POP, it is intuitive to believe that declining sex hormone levels observed with ageing may contribute to biochemical changes observed within tissue. However, several researchers studying hormonal status and prolapse have failed to find an association between oestrogen status and the disorder [27, 35, 57, 122].

The female lower urinary tract is a target organ for the action of the two sex steroid hormones, oestrogen and progesterone.

Steroidal hormones exert their effect on tissue through an interaction with specific intracellular receptors. Hormone receptor affinity may be at the root of the differences between women with pelvic floor diseases and normal controls. Progesterone receptors have been found to be more expressed in women with POP than in women without POP [207]. Several polymorphisms are present in the progesterone receptor gene that can alter its expression. A specific genotype (PGR rs484389) was significantly associated with the risk of having POP [208]. Similarly, the oestrogen receptor β gene also contains multiple single nucleotide polymorphisms that affect its expression. A case-control study of 69 women with POP and 141 control subjects found that a specific haplotype for the estrogen receptor β gene was associated with an increased risk of POP [209].

Studies have shown lower serum oestradiol (E2) levels in premenopausal women with SUI, with [210] and without concurrent POP [211], compared with control subjects. The impact of oestrogen on tissue may be related to its systemic or local levels, or altered sensitivity from a decreased amount of receptors noted in genitourinary tissues [210, 212].

Skala *et al.* [213], evaluates the expression of oestrogen receptor (ER) alpha (α) and beta (β) and progesterone receptor (PR) in vaginal and periurethral tissue in women with genital prolapse. The expression of PR and ER varied with the extent of prolapse. For patients with prolapse >stage 1 (n=32), there was a significantly greater amount of PR in periurethral tissue (p=0.007) and a significantly lower expression of ER β in vaginal tissue (p=0.008) compared to patients with a low stage prolapse (n=15). Patients with stage II and III prolapse did not differ in their amount of receptor expression. The authors concluded that the expression of PR in periurethral and ER in vaginal tissue varied with prolapse extent.

In a cross-sectional study aiming to determine whether there is a change in the number of vessels in the lamina propria of the vagina after menopause in parallel to ER- α expression on the vaginal wall, Lara *et al.* [214] showed that postmenopausal women with genital prolapse have a smaller number of vessels and a lower ER- α expression on the vaginal wall compared to normoestrogenic premenopausal controls.

Recent findings showed that the significant low hormonal levels in cases with high POP-Q stage as well as the significant higher estradiol levels in patients with strong Oxford Grading Scale may indicate that endogenous circulating sex steroids might have a potential role in the severity and progression of POP [215].

Oestrogen seems to have a profound influence on the synthesis and metabolism of pelvic connective tissues, and may have the ability to both prevent POP and improve prognosis if used therapeutically [216].

The current status of the literature is controversial: if some results suggest a hormonal impact on pelvic floor disease, recent findings suggest that hormone deficiency following menopause is unlikely to play a major role in pelvic organ prolapse sup-

port and levator ani function [217]. The weak level of evidence emphasizes the necessity for future research endeavors in this field to elucidate these complex relationships.

Moreover, there is limited research regarding the role of androgens and progesterone and their receptors in POP and results so far have also been contradictory, warranting further study to determine whether changes in androgen and progesterone receptor expression are a cause or effect of POP [216].

3.6. Obesity

Elevated BMI is an important lifestyle factor affecting pelvic prolapse. The most probable mechanism of POP development among obese women is the increase in intraabdominal pressure that causes weakening of pelvic floor muscles and fascia. Obesity is associated with significant pelvic floor symptoms and impairment of quality of life. Weight loss is likely not associated with anatomic improvement, but may be associated with prolapse symptom improvement. Weight loss should be considered a primary option in obese women for its beneficial effects on multiple organ systems and reducing pelvic floor disorder symptoms. Although the operation time in obese women is significantly longer than in healthy weight women, the complication rate of surgery has not been shown to be increased compared to nonobese patients, regardless of route of surgery. There are data to support the vaginal approach in obese women. Some studies have shown that women with high body weight are associated with an increase in the risk for both anatomical and functional recurrence, and other studies have shown no difference [218].

An high BMI increases the risk for prolapse [20, 27, 136, 219, 220] and specifically for progressive rectoceles [221]. Increased waist circumference was associated with more pelvic organ prolapse in some studies [57, 221]. Handa et al. [221] demonstrated this for cystoceles. Women who are overweight (body mass index 25–30 kg/m²) and obese (>30 kg/m²) are at high risk for developing pelvic organ prolapse [28, 135]. Similarly, women with a body mass index of more than 26 kg/m² are more likely (OR 3.0; 95%CI: 1.6–5.7) to undergo surgery for prolapse than are those with a lower value [136].

A review of 22 studies reported that women in the overweight and obese categories had meta-analysis risk ratios of at least 1.36 (95% confidence interval, 1.20-1.53) and at least 1.47 (95% confidence interval, 1.35-1.59), respectively. Subgroup analyses showed effect estimates for objectively measured clinically significant pelvic organ prolapse were higher than for self-reported pelvic organ prolapse [222].

Obesity is a prevalent modifiable condition that impacts PFDs including pelvic prolapse. Patients should be counseled using clinical judgment, knowledge of the literature and with the goal of improving QOL [218].

3.7. Previous surgery

Although hysterectomy might heighten the risk of subsequent POP, prolapse symptoms typically develop many years after this procedure [21, 27, 136, 223, 224]. In the Oxford Family Planning Study, surgical incidence for prolapse in women who had under gone a previous hysterectomy was 29 per 1000 women-years versus 16 per 1000 women-years for the entire cohort [27]. The cumulative risk of surgery for pelvic organ prolapse rose from 1% at 3 years after hysterectomy to 5% at 15 years. Risk was highest in women who had undergone a previous hysterectomy for prolapse (158 per 1000 women-years). In a retrospective cohort study of 149.554 women aged 20 and older, the mean interval between hysterectomy and surgery for pelvic organ prolapse in those who developed the disorder was 19.3 years [21, 225]. Contrary to findings of many other studies, the prevalence of prolapse in women with a uterus in the Women's Health Initiative was slightly higher than for those who had undergone hysterectomy, suggesting that previous prolapse of pelvic organs might have been repaired at the time of the procedure in this study population [28]. The surgical technique performed during hysterectomy, including performance of prophylactic culdoplasty, can lessen the development of a subsequent prolapse [226].

3.8. Chronic pelvic floor stress

Low socioeconomic status [227] and a labour-intensive occupation [35, 227, 228] are two demographic factors identified as risk factors for the development of POP. Housewives, who perform more physically demanding work, seem more likely to have prolapse (OR: 3.1; 95% CI: 1.6–8.8) than do professional managerial women [35]. Similarly, people with occupations involving heavy lifting might have a higher chance of undergoing surgery for pelvic organ prolapse [228].

A recent study on 448 Nepali women [229] showed that using a patuka (a special piece of cloth worn around the waist by heavy workers and mountain porters in Nepal), occupation and body position during work significantly associated with uterine prolapse.

3.9. Constipation and anorectal function

Repetitive straining, such as that seen in patients with chronic constipation or workers whose jobs entail heavy lifting, has also been associated with pelvic organ prolapse. Spence-Jones *et al.* [230] reported that stool straining as a young adult was more typical in women with prolapse than in those without the disorder (61% vs 4%; p<0.001). Individuals with stage II or greater pelvic organ prolapse had an increased risk of constipation (OR 3.9; 95% CI: 1.4–11.9) compared with women with stage 0 or 1 prolapse [231]. However, findings of larger studies have disputed this association, and several groups have shown that neither overall stage of prolapse nor stage of the posterior vaginal wall correlate with bowel function [232-234]. Additionally, women with only urinary incontinence and no prolapse seem to meet Rome II criteria for constipation with the same frequency as those with advanced pelvic organ prolapse [234].

Prolapse of the posterior vaginal wall, alone or in combination with other compartment defects, can be challenging for the pelvic surgeon. Pelvic pressure, vaginal/ perineal splinting to defecate, difficult defecation, faecal incontinence and impaired sexual relations are some of the symptoms associated with posterior POP. Whether the prolapse is the cause of the symptoms or is a result of straining and stretching of support structures in women with defecation disorders, remains unclear.

Bowel symptom like incontinence of flatus and obstructed defecation are common in women with POP. In several surveys, the incidence of anal incontinence ranges from 15-50% [232, 235-243]. Faecal incontinence was reported in 5-22% of women with prolapse [39, 235, 242] which was significantly more than bowel symptoms in a control group [242]. There were no associations found between prolapse stages and symptoms after adjusting for age and BMI [232, 241].

Meschia *et al.* [237] reported that among 881 women with symptoms of urinary incontinence and pelvic organ prolapse, the prevalence of anal incontinence was 20%. Urinary incontinence and severe rectocele were found to be associated with anal incontinence.

Disparities have been shown between the degree of pelvic organ prolapse, pelvic floor symptoms and defecography results [39, 244]. Two series of defaecographies in consecutive patients with prolapse and/or evacuation disorders described defaecographic findings that changed the patients diagnosis (though not always the management) in 46 of 62 of cases and noted enteroceles that were not found on physical exam in approximately 50% of cases [245-247]. Sigmoidoceles are present in 4-11% of reported series, and are nearly always missed on physical examination [247, 248]. Their clinical impact and management remain however unclear. Defaecography is not a routine investigation in women with POP and interpretation may be difficult in some cases since normal asymptomatic women may have focal defecographic abnormalities [244]. The prevalence of abnormal colonic transit time is approximately 20% in patients presenting with evacuation disorders [249]. An abnormal preoperative colonic transit study is the most consistently cited risk factor for failure of rectocele repair to relieve evacuatory symptoms, regardless of the surgical technique [250-252]. Goh *et al.* [253] reviewed the management of rectocele and clearly describe the complexity of clinical conditions resulting from the possible combination of various gynaecological and colorectal symptoms with anatomical abnormalities and the different surgical approaches.

Ramanah *et al.* [254] evaluated changes in anorectal symptoms before and after pelvic organ prolapse surgery, using laparoscopic sacrocolpoperineopexy. Preoperative and postoperative anorectal symptoms, colorectal-anal distress inventory (CRADI) and colorectal-anal impact questionnaire (CRAIQ) scores were prospectively compared from 90 consecutive women undergoing laparoscopic sacrocolpoperineopexy. After a median follow-up of 30.7 months, laparoscopic surgery significantly worsened CRADI (p=0.02) with no effect on CRAIQ (p=0.37) scores. Post-operative and *de novo* straining (27%) and the need for digital assistance (17%) were the most frequent anorectal symptoms. No correlation was found between laparoscopic surgery and anorectal symptoms after multivariate analysis (OR 2.45, p=0.05). The authors conclude that anorectal symptoms are not improved after POP surgery by laparoscopic sacrocolpoperineopexy.

Anorectal symptoms do not correlate with the degree of posterior vaginal wall prolapse, nor does the presence of prolapse equate to abnormal objective measures of anorectal function [255].

Recently Groenendijk *et al.* [256] studied the pathophysiology of defaecation disorders in patients with primary POP and the diagnostic potential of anorectal function testing including endosonography in the work-up of these patients. They concluded that anorectal function testing indicates the presence of neuromuscular damage of the anorectal region in patients with POP. Anorectal function testing is not useful in the work-up of patients with POP and constipation, because it fails to discriminate between symptomatic and asymptomatic patients. In cases of faecal incontinence, anorectal function testing and endosonography are helpful to distinguish between functional and anatomical problems.

3.10. Bony pelvis

There is evidence from several case control studies that variations in axial and pelvic skeletal structure can be associated with increased POP risks. These include increasing severity of thoracic kyphosis, a decrease in lumbar lordosis and in vertical orientation of the pelvic inlet, and an increase in the transverse diameter of the pelvic inlet [257-259]. In a case control study, Handa [260] compared 59 women with pelvic floor disorders with controls using standardized pelvimetry techniques during MRI. After controlling for age, race and parity and using a multiple logistic regression analysis, pelvic floor disorders were significantly associated with a wider transverse inlet (OR 3.4) and a shorter obstetrical conjugate (OR 0.23). The association between early age, advanced stage POP and severe disruption of pubic bone and pelvic muscle structure in women with bladder exstrophy is well recognized [261].

Recently Yang *et al.* [262] investigated the association between bony pelvis dimensions and anterior, apical, and posterior compartment POP: women with apical compartment POP are more likely to have a smaller anteroposterior diameter. Larger interspinous and intertuberous diameters were associated with anterior and apical POP, and smaller intertuberous diameter was associated with posterior POP.

3.11. LUTS and bladder function

So far, the relationship between LUTS and pelvic organ descent however, are not completely understood. Costantini et al. [263] retrospectively reviewed 256 patients presented with POP and LUTS and underwent POP surgery. Most of 50% of patients reported two or more symptoms and only 4.2% were asymptomatic for LUTS. 73.8% patients had voiding symptoms, 15% a urodynamic detrusor overactivity, 5% suffered from hydronephrosis. 57.8% showed SUI. The authors concluded that urologists and gynecologists should be aware of the high frequency of the association of POP and LUTS. POP repair my restore a normal anatomical situation but LUTS symptoms may last after the surgery or develop “de novo.”

In a large community-based questionnaire survey, 44% (104/239) of women who had prolapse symptoms (239/3799) also complained of SUI and 37% of overactive bladder [240]. SUI can be functionally masked by POP. SUI may be uncovered by POP surgery and clinically continent women are at risk for developing symptomatic postoperative SUI.

The role of urodynamic studies (UDS) before prolapse surgery is contentious and a hotly debated topic in urogynaecology. Previous studies in women with prolapse and women with uncomplicated SUI have focused on women without preoperative incontinence. Currently, it has not been possible to reach a universal consensus on the role of UDS before prolapse surgery in women with concomitant symptomatic or occult SUI. It is clear that UDS could add some information in women undergoing pelvic organ prolapse surgery and could facilitate counselling of patients. However, there is no evidence that the outcome of surgery is altered by prior UDS [264]. In fact, *Weber et al.* [265] showed that urodynamic testing before surgery in women with prolapse and stress urinary incontinence symptoms is not cost-effective relative to basic office evaluation. It is possible that UDS could better identify and define some urinary dysfunctions, such as a preoperative detrusor overactivity or occult SUI, but this information rarely leads to a change in the management plan or the type of surgical procedure. We have no data to show that the UDS can improve subjective or objective outcomes of

surgery for prolapse. New well-designed randomized studies are necessary to improve our understanding of this topic.

Evidence of reduced peptide-containing innervation of perineal and periurethral muscles in women with SUI and POP has emerged [78], suggesting a neural abnormality in their pathogenesis. Connective tissue alterations such as decreased a-1 antitrypsin expression and altered elastin metabolism [78], decreased collagen concentration [266], and decreased oestrogen receptors [212, 267] have been described in women with UI and/or POP.

Failure of bladder, bladder neck, and urethral support is often part of a more extensive defective pelvic organ support. Poor pelvic organ support can lead to pathological pelvic relaxation in one or more compartment(s). Marinkovic and Stanton [268] published a review of 97 articles regarding incontinence and voiding difficulties associated with POP: they described the incidence, pathophysiology, anatomical changes and resultant consequences, evaluation and imaging of cystocele, rectocele, enterocele, and uterine and vaginal vault prolapse in combination with UI. The authors concluded that POP appears to have significant clinical effects on urethral and voiding function that should be quantified preoperatively to allow appropriate surgical intervention, with the aim of restoring vaginal function and correcting concurrent incontinence, whether overt or occult. Not uncommonly, POP can lead to bladder outlet obstruction, detrusor instability, and latent SUI that is unmasked only with reduction of the POP (potential, latent, or unmasked SUI) [269]. It is recognized that POP surgery can improve voiding dysfunction and unmask occult SUI by alleviating the urethral kinking causing outlet obstruction [270].

Burrows *et al.* [271] described symptoms of bladder, bowel, and sexual function in 330 women with POP, comparing different degrees of prolapse staged by POP-Q system. Women with SUI symptoms had less advanced prolapse (median 5 cm less prolapse in apical compartment) than those without SUI. Women who needed to manually assist urination had more advanced prolapse (median 3.5 cm more prolapse in the most severe compartment) than those who did not. Women with urgency and urgency incontinence had less advanced prolapse (median 3 cm or less) but the differences were smaller than those for SUI. Severity of prolapse was not associated with bowel or sexual symptoms in this study. The most important finding is that there are few strong associations between specific symptoms and severity of prolapse. LEVEL OF EVIDENCE: II-2.

Women without anterior prolapse on POP-Q exam rarely (<10%) report urinary splinting but ranged between 23 and 36% for stage III and IV. Urinary splinting is 97% specific for anterior prolapse. Seventy-seven percent of women with stage II POP report a symptomatic bulge, and report of a bulge has an 81% positive predictive value and a 76% negative predictive value [272]. It seems therefore that if women present with symptoms of vaginal/perineal bulge, then careful assessment for POP is warranted. If a woman with SUI, however, presents with no symptoms of POP, then surgical treatment of asymptomatic and incidental anterior POP does not seem to be indicated.

Ramanah *et al.* [273] compared changes in urinary symptoms before and after POP surgery, using either laparoscopic sacrocolpopexy (LSC) or transvaginal porcine dermis hammock placement with sacrospinous ligament suspension (VS). Out of the 151 patients included, 87 patients underwent LSC, and 64 VS. Overall, after a median follow-up of 32.4 months, POP surgery improved urinary frequency ($P = 0.006$), voiding difficulty ($P = 0.001$), stress urinary incontinence ($P = 0.001$), but not urgency ($P = 0.29$). VS was more effective in treating SUI ($P < 0.001$ vs. 0.52) while LSC more effective on voiding difficulty ($P = 0.01$ vs. 0.08). Postoperative *de novo* symptoms were observed in 35.8% of patients with no difference between the groups ($P = 0.06$). UDI ($P = 0.04$) and UIQ ($P = 0.01$) scores were significantly lower after surgery. However, LSC significantly improved UDI ($P = 0.03$) with no effect on UIQ ($P = 0.29$) scores while VS significantly improved both scores (P=0.02 and 0.001, respectively). Upon multivariate analysis, only the improvement in the impact of urinary symptoms on daily living was independently associated to VS (OR 5.45, P=0.01). The authors concluded that most preoperative urinary symptoms decreased after POP surgery with equivalent proportion of *de novo* symptoms after vaginal and laparoscopic approaches.

The surgical management of women with POP and with latent SUI remains controversial and challenging. Maher *et al.* [274] aimed to determine the effects of surgery in the management of POP by searching the Cochrane Incontinence Group trials register (as on June 2004) for randomized or quasi-randomized controlled trials that included surgical procedures for POP. The metanalysis on the impact of POP surgery on continence was 'limited and inconclusive', but they report that 10% of women developed new incontinence symptoms postoperatively. Levin *et al.* [275] prospectively evaluated 313 women who underwent TVT procedure for overt (228 women) or occult (85 women) SUI. About 50% women also underwent POP surgery concurrently. Overall, for 241 women with at least a follow-up of 12 months, 6.6% had persistent mild SUI, an additional 7% had urodynamic evidence of asymptomatic sphincteric incontinence, whereas 8% developed *de novo* urgency incontinence.

Among 130 women who underwent surgical treatment for an enterocele (75% the vaginal wall protruded through the introitus), 77% presented with SUI or detrusor instability. Sixty-seven percent patients underwent Burch colposuspension with enterocele repair. Postoperative SUI requiring further treatment occurred in 10% after a mean period of follow up of 10 months, and cystocele developed in 1.5% [276].

Urologists and urogynaecologists are faced with the challenge of determining which women with POP associated with SUI will benefit from concurrent surgical intervention for POP. A comprehensive and anatomical approach to pelvic floor reconstruction is recommended. The intended goal of surgical correction of SUI and POP is durable restoration of normal anatomy and function, with symptomatic relief and avoidance of morbidity.

At present, the conclusions based on 19 RCTs (2717 women) are summarized in the Cochrane Systematic Review of Baessler *et al.* [277]: in women with POP and SUI (symptomatic or occult), a concurrent mid-urethral sling probably reduces postoperative SUI and should be discussed in counselling. It might be feasible to postpone the MUS and perform a delayed (two-stage) continence procedure, if required. Although an abdominal continence procedure (Burch colposuspension) during abdominal POP surgery in continent women reduced *de novo* SUI rates in one underpowered trial, another RCT reported conflicting results. Adding a mid-urethral sling during vaginal POP repair might reduce postoperative development of SUI. An anterior native tissue repair might be better than use of transobtu-

rator mesh for preventing postoperative SUI; however, prolapse recurrence is more common with native tissue repair.

The prevalence of OAB symptoms in relation to POP is reported to be between 22.5-36.8% in community based studies [240, 278-280] and between 16-88% in hospital based studies [269, 281-283]. By and large, the prevalence of OAB with POP is greater in the hospital-based studies than in the community-based studies, which is not surprising, given the selected nature of the hospital samples. Only three studies, one community-based and two hospital-based, were identified that presented data specified per compartment and showed conflicting results: in the study by Miedel *et al.* [280], there is a clear relationship between anterior and posterior compartment prolapse and OAB symptoms, in contrast to central compartment prolapse. In the studies by Bradley and Nygaard [284] and Sobhgol and Charandabee [285] such a relationship could not be identified. In a study by Ellerkmann *et al.* [286] no correlation between worsening of the anterior compartment and urgency incontinence could be found. Data regarding the relationship between the stage of prolapse and OAB are very sparse. Burrows *et al.* [271] found that urgency and urgency incontinence occurred more often in women with a less advanced overall prolapse. Another study using ultrasound reached the same conclusion; women with a higher grade of bladder descent were less likely to suffer from urgency incontinence [287].

The pathophysiology of OAB in women with POP is unclear. Several theories exist: bladder outlet obstruction; release of various chemical factors (ATP, Ach, and P2X3) by bladder distension stimulating the detrusor receptors; traction on the urethra due to prominent cystocele resulting in an open urethra with urine entering the urethra that causes detrusor contractions. Bladder outlet obstruction is likely to be the most important mechanism by which POP induces OAB symptoms and DO signs. However, several other mechanisms might also play a role. However, strong indications show a causal relationship between OAB and POP [288].

Pelvic organ prolapse is a common condition that often leads to lower urinary tract symptoms (LUTS) and may require surgical intervention to alleviate those symptoms. Therefore, the clinical evaluation of the women with POP symptoms also requires necessarily the assessment of urinary symptoms. Physicians, who examine women seeking care for one condition, should inquire about the symptoms of other disorders.

3.12. Neurological factors

Integrity of the pelvic innervation is essential to the normal pelvic function. The changes in neurophysiological parameters seen after childbirth were interpreted to reflect neuromuscular injury caused by forces exerted on the sacral plexus, pudendal nerves, and pelvic floor muscles.

Abnormal tests have also been found in women with prolapse or stress incontinence. Histologically, there are smaller and fewer nerve bundles in women with posterior vaginal wall prolapse compared with women without prolapse [289]. The density of peptide-containing nerves in the periurethral tissue and in the levator ani muscle in women with prolapse is reduced [290, 291].

Between 1985 and 1987, Allen *et al.* [292] found that 80% of primigravidae developed evidence of partial denervation of the pelvic floor following delivery. However, evidence of reinnervation and increased fibre density 2 months after vaginal delivery has been detected [292, 293]. Snooks *et al.* investigated 14 multiparous women from their previous studies [293, 294] 5 years after first vaginal delivery and demonstrated that pelvic floor striated sphincter musculature denervation progressed, indicating that age is a contributory factor [295]. Similarly, progressive denervation with time up to 15 years postpartum was found in another prospective study, corroborating the ageing factor [296].

The pudendal nerve innervates the voluntary urethral and anal sphincters, but it does not innervate the levator ani muscles, which receive their own nerve supply from the sacral plexus. Therefore, there is currently no clear evidence whether the neurological damage is responsible, together with the mechanical damage of stretching, of the visible levator defects.

Information from electrodiagnostic studies has demonstrated that birth causes changes in mean motor unit duration after vaginal birth and changes in pudendal nerve conduction patterns [292, 295, 297-299]. Prolongation of the pudendal nerve terminal motor latency (PNTML) is thought to be a result of pudendal nerve damage during vaginal delivery. Significantly prolonged mean PNTMLs have been found in women two to three days after vaginal delivery, compared to a multiparous [294] and a nulliparous control group [293]. At follow-up five years later, prolongation of PNTML persisted [295]. Two prospective analyses demonstrated a prolongation of PNTML antenatally to six to eight weeks after vaginal delivery, particularly after the first delivery [300, 301]. But, again, many of these changes seem to be temporary, as two-thirds of the women with an abnormally prolonged PNTML after delivery had normal measurement six months later [300]. Little recent electrophysiological work has been added in literature, probably due to the technically difficulty of the nerve function tests in clinical practice.

Although it has not been proven, it is reasonable to assume that periods of pain and discomfort after childbirth (e.g., due to perineal tears and episiotomy) and especially the pain related to attempted PFM contraction, could lead to a temporary non-activation of the PFM. This could be the origin of disturbances in behavioural patterns, which would need to be readjusted. In combination with a particularly vulnerable pelvic floor neural control, whose complexity only evolved phylogenetically after the attainment of the upright stance, such a temporary disturbance of neural control after childbirth may persist, although the lesion(s) would have fully recovered. Therefore, the effects of vaginal delivery on pelvic floor nerves remain not fully understood. While it seems logical that vaginal delivery causes some neuromuscular injury and this would be at risk for development of pelvic organ dysfunctions, many details are far from be resolved.

Due to weakened pelvic floor muscles, the risk of POP may increase after SCI; Elmelund *et al.* [302] investigated the occurrence of POP after SCI and evaluated the need for urogynecological consultations offered to women with spinal cord injury. From their results women with spinal cord injury are not in increased risk of developing anatomical POP. Nonetheless, the high occurrence of other urogynaecological issues supports the need for specialized urogynaecological consultations offered to women with SCI.

3.13. Sexual function

Sexual dysfunction associated with POP motivates women to seek medical help. Women with POP are likely to restrict sexual activity owing to a perceived of loss of attractiveness and fear of incontinence. Patients who present with pelvic organ prolapse symptoms should be questioned about their sexual function. Surgical treatment in these patients may cure their sexual disorders (e.g., by solving incontinence in patient with coital incontinence) but may also have undesired effects on sensation, blood flow, and anatomy. These effects can affect sexual arousal and orgasm or cause dyspareunia.

Dyspareunia, coital incontinence and vaginal dryness are common complaints in women with pelvic floor disorders [303, 304]. Although sexual dysfunction appears to be more frequently observed in these women, pelvic organ prolapse seems not negatively impact on sexual satisfaction when controlled for confounders like age [304-306].

Clinical populations are likely to have more severe pelvic floor symptoms and more advanced pelvic organ prolapse, with a greater potential for discernible impact on sexual function, whereas community populations may have mild symptoms and prolapse, with minimal impact. These conflicting results may also be the result of population differences in other related factors, such as age, menopause, or the status of the woman's intimate relationship. Other challenges in studying the factors associated with sexual function in women with POP include a limited characterization of female sexual function in some studies and difficulties assessing sexual function among women who do not have intercourse.

Handa *et al.* [307] reported that, with respect to anatomical prolapse, women with stage III–IV prolapse were more likely to report decreased libido and infrequent orgasm than women with stage 0 support. Adjustment for other characteristics attenuated the strength of these associations, although the association between prolapse and infrequent orgasm remained statistically significant. In the final adjusted model, the odds of infrequent orgasm were increased more than three times for women with stage III–IV prolapse (P=0.02). The authors conclude that women the anatomical prolapse (stage III–IV) were more likely to report infrequent orgasm but they were not at increased risk of other sexual problems. An important observation is that women with stage II support were not more likely to report any sexual complaint than women with stage 0 support. This suggests that the physical presence of stage II prolapse alone is not associated with sexual dysfunction. In contrast, women with prolapse symptoms (as reflected by a high score on the prolapse scale of the Pelvic Floor Distress Inventory) were much more likely to report sexual complaints.

Sexual function is worse in women with symptomatic prolapse. LEVEL OF EVIDENCE II.

In 305 women over 40 years seeking outpatient gynaecologic care the association between sexual complaints and perceived sexual distress has been investigated. Women with sexual distress were also more likely to report sexual difficulty related to pelvic floor symptoms, sexual avoidance due to vaginal prolapse (13.9% vs. 1%, P=0.001) [308].

Conservative (pelvic floor muscles training or pessary) or surgical management (transabdominally or transvaginally) can be offered to treat POP but questions remain regarding sexual outcome. Recent findings showed a significantly improved sexual function 1 year after pelvic floor surgery, and the improvement was predicted by other social and physical factors in addition to normal functional anatomy [309].

Despite the usual improvement in sexual function after surgery, a risk of *de novo* dyspareunia exists irrespective of the procedure used with slightly increased risk after transvaginal repair. Preoperative patient counselling, ideally with a cross-disciplinary approach is an important part of management of POP [310].

A better understanding of the anatomy of this area and of the sexual function it is necessary for a more targeted approach to manage these conditions.

4. CONCLUSIONS

The aetiology of POP is multifactorial. Vaginal delivery is the major risk factor but growing evidence underlines the possible genetic influence and familial predisposition in the aetiology of POP. LEVEL OF EVIDENCE II

Even though vaginal delivery is the major traumatic event for the pelvic floor during lifespan, caesarean section seems not to be completely protective. LEVEL OF EVIDENCE II.

Hormonal and mechanical physiological alterations during pregnancy affect the pelvic floor support. LEVEL OF EVIDENCE III

Forceps, vaginal parity, prolonged second stage of labour, and fetal macrosomia are obstetric risk factors for development of POP. LEVEL OF EVIDENCE II

Declining sex hormone level, ageing, obesity, constipation, chronic pelvic floor stress are associated with pelvic organ prolapse. LEVEL OF EVIDENCE III

The evaluation of POP requires the assessment of urinary, anorectal and sexual functions. LEVEL OF EVIDENCE II

VI. MICROBIOTA IN INCONTINENCE AND PELVIC FLOOR DYSFUNCTIONS

1. INTRODUCTION

For a long time, urine was thought to be sterile. It has only been recently understood that the bladder contains its own microbiome. Consequently, a whole novel field of research within urology has opened up with regard to the physiological role of the lower urinary tract microbiome and its pathophysiology. Over 50% of women will experience at least one urinary tract infection (UTI) during their life, with a yearly prevalence of 11% [1]. In addition, UTIs are responsible for substantial morbidity in frailolder adults. Amongst community dwelling older women, UTIs compromise the second most common cause of infection. In long-term care facilities and hospitalised subjects, UTIs represent the most common cause of infection [2]. Aside from the patient's burden this results in significant health care expenditure. UTIs are estimated to be responsible for more than 100,000 hospital visits and $3.5 billion annually in the United States of America [3]. An analysis 456,586 German patients with Type 2 diabetes mellitus showed a prevalence of 48,337 UTI episodes over a mean observation period of 665 days. Additional multivariable cost analysis in this group showed a UTI cost-increasing effect of 3.916 euro per patient year [4]. These UTI related additional costs might even be higher in frail older adults; UTIs in this group led more often to hospitalisation [5]. During a 90-day follow-up period Turner *et al.* showed that in-hospital treatment led to significantly more costs during treatment but also at follow-up 90 days post-treatment [5].

1.1. Terminology

Microbiome: The microbiome represents the genes and genomes of the microbiota. In addition, it represents the products of microbiota and the host environment. The microbiome incorporates biotic and abiotic factors (including archaea, viruses and fungi and products of microbiota) and refers to the whole environment including [32].

Metagenome: The metagenome refers to the genes and genomes of the microbiota and highlight the genetic potential of a population.

Microbiota: Identification of the microorganisms in an environment by the use of molecular techniques (such as 16S ribosomal RNA sequencing). The term microbiota refers to the microbial taxa associated with an environment [32, 33].

Table 1: Registration of Urinary tract microbiota in different studies. The presented strains are highlighted by the authors of the original studies as predominant or more prevalent than other populations. The microbiota are listed as genera unless otherwise specified. STI: sexually transmitted infection, NBD: neurogenic bladder dysfunction, IC: interstitial cystitis, POP: pelvic organ prolapse, OAB: overactive bladder, MUI: mixed urinary incontinence; UUI: urgency urinary incontinence, UTI: urinary tract infection, UCPPS: urological chronic pelvic pain syndrome, SUI: Stress Urinary Incontinence.

	Patient groups	n	Predominant strains	Urine Sample collection
Nelson et al. 2010 [6]	Men with STI Men without STI	10 9	Lactobacillus, Sneathia, Gemella, Aerococcus, Corynebacterium, Streptococcus, Veillonella, Prevotella, Anaerococcus, Propionibacterium, Atopobium, Staphylococcus	First-void
Dong et al. 2011 [7]	Men with STI Men without STI	10 22	Lactobacillus, Sneathia, Gemella, Aerococcus, Corynebacterium, Streptococcus, Veillonella, Anaerococcus, Propionibacterium, Atopobium, Staphylococcus, Ureaplasma, Mycoplasma, Enterococcus, Finegoldia, Neisseria, Ralstonia	First-void
Siddiqui et al. 2011 [8]	Healthy women	8	Lactobacillus, Prevotella, Gardnerella, Peptoniphilus, Dialister, Finegoldia, Anaerococcus, Allisonella, Streptococcus, Stahpylococcus	Clean-catch midstream
Fouts et al. 2012 [9]	Healthy controls Patients with NBD	26 (58% women) 27 (48% women)	Lactobacillus, Enterobacteriales, Actinomycetales, Bacillales, Anaerococcus, Allisonella, Clostridiales, Bacteroidales, Burkholderiales, Pseudomonadales, Bifidobacteriales, Coriobacteriales	Midstream, catetherisation
Nelson et al. 2012 [10]	Healthy adolenscent men	18	Lactobacillus, Streptococcus, Sneathia, Mycoplasma, Ureaplasma	First-void
Siddiqui et al 2012 [11]	Women with IC	8	Lactobacillus, Gardnerella, Corynebacterium, Prevotella, Ureaplasma, Eterococcus, Atopobium, Proteus, Cronobacter	Clean-catch midstream
Wolfe et al. 2012 [12]	Healthy women Women with POP/UI	23 11	Lactobacillus, Actinobaculum, Aerococcus, Anaerococcus, Atopobium, Burkholderia, Corynebacterium, Gardnerella, Prevotella, Ralstonia, Sneathia, Staphylococcus, Streptococcus, Veillonella	Clean-catch midstream, Suprapubic
Lewis et al. 2013 [13]	Healthy men Healthy women	6 10	Jonquetella, Parvimonas, Proteiniphilum, Saccharofermentans Phyla: Actinobacteria, Bacteroidetes	Clean-catch midstream
Fricke et al. 2014 [14]	Patients receiving 1st renal transplant	60 (37% women)	Lactobacillus, Enterococcus, Pseudomonas, Streptococcus Families: Bifidobacteriaceae, Corynebacterineae	Not described
Hilt et al. 2014 [15]	Healthy women Women with OAB	24 41	Lactobacillus, Corynebacterium, Streptococcus, Actinomyces, Staphylococcus, Aerococcus, Gardnerella, Bifidobacterium, Actinobaculum	Transurethral catheterisation
Pearce et al. 2014 [16]	Healthy women Women with urgency UUI	58 60	Gardnerella, Lactobacillus, Actinobaculum, Actinomyces, Aerococcus, Arhrobacter, Corynebacterium, Oligella, Staphylococcus, Streptococcus	Transurethral catheterisation
Willner et al. 2014 [17]	Patients with uncomplicated UTI	50 (76% women)	Anaerococcus, Peptoniphilus, Streptococcus, Lactobacillus, Staphylococcus, Escherichia, Pseudomonas	Midstream
Pearce et al. 2015 [18]	Women UUI	182	Lactobacillus, Aerococcus, Bifidobacterium, Enterobacterium, Prevotella, Staphylococcus	Transurethral catheter
Nickel et al 2015 [19]	Men UCPPS Aged-matched controls	110 115	Lactobacillus, Listeria, Staphylococcus, Streptococcus, Propionibacterium, Finegoldia, Burkholderia, Bifidobacterium	Initial stream urine, midstream, after prostate massage
Nickel et al 2016 [20]	Women UCPPS and flare Women UCPPS without flare	127 86	Lactobacillus, Staphylococcus, Streptococcus, Finegoldia, Bifidobacterium, Corynebacterium, Escherichia	Initial stream urine, midstream
Karstens et al 2016 [21]	Women UUI Healthy controls	10 10	Lactobacillus, Lachnospiria, Enterobacterium, Comamonadacium, Micrococcus, Bifidobacterium, Provotella, Flavobacterium	Transurethral catheter

	Patient groups	n	Predominant strains	Urine Sample collection
Thomas-White et al 2016 [22]	Women UUI Healthy controls	74 60	Lactobacillus, Streptococcus, Enterobacterium, Staphylococcus, Actinobaculum, Bifidobacterium, Alloscardovia, Atopobium, Micrococcus	Transurethral catheter
Thomas-White et al 2016 [23]	Women with SUI	197	Lactobacillus, Streptococcus, Bifidobacterium, Corynebacterium, Atopobium, Prevotella,	Transurethral catheter, midstream
Curtiss et al. 2017 [24]	Women with OAB Controls	60 35	Staphylococcus, Streptococcus, Corynebacterium, Lactobacillus, Escherichia, Peptoniphilus, Fusobacterium, Enterococcus, Anaerococcus, Campylobacter, Bifidobacterium, Serratia, Proteus, Gardnerella, Prevotella	Midstream
Chen et al. 2018 [25]	Refractory DO and rUTI	39	Anaerococcus, Atopobium, Bifodobacterium, Corynebacteriaceae_family, Eneterobacteriaceae_other, Enterococcus, Escherichia, Finegoldia, Gardnerella, Janthinobacterium, Lactobacillus, Prevotella, Pseudomonas, Staphylococcus, Streptococcus	Midstream
Komesu et al. 2019 [26]	MUI Controls	123 84	Lactobacillus, Gardnerella, Prevotella, Tepidomonas, Serratia, Streptococcus	Transurethral catheter
Meriwether et al. 2019 [27]	UCPPS Controls	23 18	Lactobacillus, Prevotella, Shuttleworthia, Bifidobacterium, Streptococcus, Coriobacteriaceae, Dialister, Megasphaera, Anaerococcus, Rhodococcus	Midstream
Bresler et al. 2019 [28]	UCPPS Controls	18 20	Lactobacillus, Bifidobacteriaceae, Bifidobacterium, Corinebacterium, Megasphhera, Prevotella, Streptococcus	Midstream
Price et al. 2020 [29]	Women with UUI Women with SUI Continent Controls	61 54 47	Lactobacillus, Streptococcus, Staphylococcus, Aerococcus, Gardnerella, Actinotignum, Corinebacterium	Transurethral catheter
Garretto et al. 2020 [30]	Women with UTI Wonen with OAB Women with UUI Women without LUTS	42 5 13 6	Escherichia, Lactobacillus, Staphylococcus, Streptococcus, Klebsiella, Gardnerella,	Transurethral catheter
Jacobs et al. 2020 (31)	UCPPS Controls	15 13	Lactobacillus, Streptococcus, Gardnerella, Actinomyces, Staphylococcus, Enterobacteriaceae	Transurethral catheter

2. MICROBIOTA AND URINARY TRACT: PHYSIOLOGY

The significance of microbiome in maintenance of health and development has been extensively explored in organ systems other than the urinary tract and it has only been recently accepted that most of the human body is colonised with bacteria. The Human Microbiome Project (HMP) is a large mapping study of the human microbiome sampling 300 individuals at five body sites (gastrointestinal tract, mouth, vagina, skin and nasal cavity) using culture independent methods [34]. Specific microbial sites have been linked to diseases,for example, gastrointestinal misbalance in microbiota has been related brain abnormalities [35], problems in the musculoskeletal system [36] and linked to metabolic processes [37].

In addition to the Human Microbiome Project multiple studies have suggested that the lower urinary tract contains a unique microbiome that is vastly different from gastrointestinal and vaginal colonisation (Table 1) [12, 15, 38]. In contrast to traditional bacterial culturing of urine which only allows identification of fast-growing pathogens, progress has been made possible by advanced culture and molecular techniques (PCR and 16S ribosomal RNA sequencing). The initial disadvantage of the molecular techniques was that they were unable to distinguish live from dead bacteria. However, by combining RNA sequencing with expanded cultures Hilt *et al.* were able to show that most bacteria in the bladder were alive [15].

Is there a “core” set of microbiota? In 2013 Lewis and colleagues presented a catalogue of bacterial DNA from a small cross-sectional sample of healthy adults. In addition, they proposed the concept of a set of bacteria that exist across different age groups but may fluctuate in association with age [13]. However, with regard to the variations in detected microbiota amongst the different studies presented in Table 1, larger longitudinal studies will be needed to confirm the existence of a core set of microbiota in the bladder. Moreover, evolvement of the bladder’s microbiome over time and factors influencing these specific microbiota need further investigation.

The specific role of microbiota and the microbiome in the urinary tractremains unclear. In contrast to other organ systems

the homeostatic role of bacteria in the lower urinary tract has only received minimal attention. However, specific key roles of the urinary tract's microbiome have been suggested, based on research in other organ system: 1) Regulation and maintenance of barrier function of the bladder wall and functioning as the prime urothelial defence mechanism. For example, through competition with pathogens for common resources. This is true for other sites of the body such as the gut and vagina [39, 40]. 2) Products of microbiota may kill pathogens and degrade certain harmful compounds. 3) Involvement of microbiota in the development of the urinary tract, including the connected peripheral nervous system. There is only little known about the link between microbiota and development of the nervous system. Through production of neurotransmitters microbiota might be needed for correct development the bladder's signalling system. Incorrect development of these signalling systems might be related to lower urinary tract dysfunctions such as OAB or DUA. Gastrointestinal studies on germ-free mice show that absence of microbes correlated with behavioural and neurological disorders [27]. However, the exact role of microbiota in the bladder and its relation to signalling systems in the bladder-brain axis is still unknown due to the lack of studies in this specific area of research.

3. THE PATHOPHYSIOLOGICAL ROLE OF MICROBIOTA IN THE URINARY TRACT

Acknowledgement of the suggested physiological role of the urinary tract microbiome does raise questions about the pathophysiological role of microbiota in different urological entities. For example, microbiota have suggested to be involved in development of urolithiasis and as treatment for recurrent superficial bladder cancer. However, both of these topics are beyond the scope of this chapter. Here, the link between microbiota and functional lower urinary tract disorders will be furtherdiscussed.

3.1. Stress Urinary Incontinence

To date only one study considers relationship between urinary microbiota and the characteristics of women with stress urinary incontinence. This cross-sectional study in 197 women showed no association between stress urinary incontinence symptoms and the bacterial diversity [23]. Based only on these results, the involvement of the urinary microbiome in SUI seems of lesser importance compared to other lower urinary tract dysfunctions. However, more research is needed to confirm these initial conclusions.

3.2. Urgency Urinary Incontinence

Urgency urinary Incontinence is a widespread disorder affecting many adult women. It is only recently that the potential role of the microbiome has been explored. In 2014 Pearce *et al* compared microbiota of women with and without UUI using molecular sequencing. Results showed that women with UUI had decreased Lactobacillus taxa and higher Gardnerella presence. In addition, Actinobaculum, Actinomyces, Aerococcus, Arthrobacter, Corynebacterium, Oligella, Staphylococcus and Streptococcus were found more frequently in the UUI group [16]. Curtiss *et al*. too showed Lactobacillus to be less common in patients with OAB compared to controls, with Proteus found statistically more commonly in patients with OAB. No difference in microbial diversity was found [24].

Thomas-White demonstrated how 12 weeks of vaginal oestrogen treatment resulted in a significant increase in Lactobacillus in postmenopausal women's urine, with a modest but significant improvement in OAB symptoms. However, also in this case, no difference was found in microbial diversity [41].

Komesu *et al.* showed how Lactobacillus predominance did not differ between women affected by Mixed Urinary Incontinence (MUI) and controls, but it did distinguish between MUI and controls in women younger than 51 years. Indeed, younger MUI patients more commonly had Moderate-Lactobacillus or Mixed communities rather than a High-Lactobacillus community. Whether the high preponderance of health-associated bacteria (Lactobacillus) or the shift in the balance of MUI-associated bacteria (e.g., Gardnerella, Prevotella) contributes to bladder symptoms warrants further investigation [26].

In one of studies describing the variability in female microbiota in patients with UUI, an association between certain microbial characteristics (i.e. taxa and variety of microbes) and symptom severity was found. An increase in UUI symptom severity may be associated with a loss of microbial diversity in women with UUI [21]. Price *et al.* showed how, in adult women, the detection and richness of culturable urobiome was associated with UI, regardless of incontinence subtype (SUI or UUI) in comparison with the continent cohort. Furthermore, the two UI groups were more similar to each other than the control cohort, and each UI cohort differed significantly from the control cohort. Moreover, the richness indices were associated with worsening of incontinence symptom severity [29].

In a follow-up study, Pearce *et al* compared sequencing in positive and negative UUI groups before oral drug treatment for UUI. They found that positive sequencing was associated with more severe UUI and a better response to treatment [18].

In 2016 Thomas-White *et al* reported a 12 weeks anticholinergic follow-up study in women with UUI suggesting that less diversity in microbiota tended to be associated with fewer UUI symptoms and with better treatment response to an anticholinergic drug [22]. Non-responders had a more diverse microbial population than population found in responders. An additional study in women with stress urinary incontinence showed consistent results. Increased microbial diversity was associated with a higher urgency index score [23]. In addition to finding differences between women with UUI and healthy controls several studies have shown a relationship between urinary microbiota and response to oral drug treatment. The variations in outcome between the studies might be related to the sampling method. However, in general the results highlight the potential clinical importance of the urinary microbiome in UUI.

Chen and Phan demonstrated that rUTI are common in patients with refractory urgency incontinence, with either the same persistent strain or a new infecting strain. This may suggest the existence of a chronic reservoir (i.e. bladder, urethra, vagina or bowel flora) and that the composition of the microbiota might have an impact on the incidence of rUTI and the refractoriness to antimuscarinics drugs on DO patients [25].

A genomic survey of *Escherichia coli* bladder colonization in individuals with or without LUTS (OAB, UUI and UTIs), showed no correspondence between different genomic content of different types of E. coli and symptoms. Furthermore, the presence of E. coli alone was not sufficient to distinguish between the

urobiomes of patients with and without LUTS, making E. coli a weak predictor of LUTS, highlighting that symptoms are more likely to be a result of urobiome composition [30].

Hence, recent research gives clues regarding the potential role of urinary microbiota diversity in the aetiology and treatment of women with UUI. However, a major flaw in research is the variability in sampling methods between the different studies. This makes replication and clinical utility difficult[42].

3.3. Urological Pain Syndromes Painful Bladder Syndrome(PBS) / Interstitial Cystitis (IC)

The role of microbiota in different urological pain syndromes has been explored, for example in PBS/IC and chronic pelvic pain syndrome (CPPS). Saddiqui *et al.* collected urine samples of women with interstitial cystitis and compared this with healthy volunteers. They were able to show that IC patients had lower bacterial diversity and an increase in Lactobacillus compared to healthy volunteers (92 vs 57%) [11]. Reduction of bacterial diversity in general is seen in chronic inflammatory states such as inflammatory bowel disease [43]. Although, Jacobs *et al.* showed Lattobacillus to be the most common urotype, without any difference between IC/PBS individuals and controls. Presence of Lattobacillus or not did not affectIC/PBS symptoms. Furthermore, bacteria were not isolated from most of the IC/PBS patients, suggesting that bacteria may not be an aetiological factor for IC/PBS [31]. Furthermore, Bresler *et al.* compared the urinary microbiota of women affected by IC/PBS with a group of asymptomatic controls, highlighting that IC/PBS symptoms may not be related to differences in the female urinary microbiota, at least not its bacterial components [28].

In one study, premenopausal women with IC/BPS were not found to have significantly different urinary and vaginal microbiomes compared to women without IC/BPS andLactobacilli was the most abundant genus in both cohorts, while anaerobic or fastidious predominance was similar between groups [27]. The relative abundance of Lactobacillus however is yet to be confirmed in other studies and the question is whether this is truly associated with IC in women.

The Multidisciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) research network compared women with Urological Chronic Pelvic Pain (UCPPS), a group in which they gathered women with IC/PBS, with and without flare to examine differences in microbiota. The results revealed no difference in bacterial prevalence in the urine samples. However, the group with flare had a significantly greater prevalence of fungi (Candida and Saccharomyces sp.) [20]. This agrees with an earlier study from the same group in which they performed a 2-year follow-up of IC/PBS patients to identify bacterial culture status using only standard culture techniques [35]. The same MAPP research network studied male PBS/IC/chronic prostatitis patients and compared the microbiota with aged-matched controls. The study group showed higher presence of *Burkholderia cenocepacia* in the UCPPS group of patients in the initial stream urine [19]. However, these differences were not reproducible for the midstream urine samples or after prostate massage.

A recent study examining stool samples of female UCPPS patients identified potential stool-based microbial and metabolome markers for UCPPS, with specific interest for *Colinsella aerofaciens* and the metabolite glyceraldehyde. In this pilot study these biomarkers were altered in the gut of 18 women with UCPPS compared to 16 healthy controls [44]. Shoskes *et al.* analysed gut microbiota in men with UCPPS and showed a decreased microbial diversity in the gut in men with UCPPS compared to controls [45].

In theory the bladder microbiome might be involved in aetiology or development of IC/PBS/UCPPS, however different studies show largely varying results. Up until now there is no compelling evidence to support the specific role of the microbiome in patients with urological pain syndromes and more research is needed in this specific area.

VII. CHILDBIRTH AND FAECAL INCONTINENCE

1. INTRODUCTION

Pregnancy and childbirth have a significant impact on the emotional and physical wellbeing of a woman. As many as 91% of women report at least one new symptom eight weeks post-partum [1.]. A fall in maternal mortality accompanied by an increase in female life expectancy (86 years in Japan) has now shifted the focus of attention towards identification of factors that may minimise morbidity. Although pre-existing bowel symptoms may be aggravated during pregnancy and childbirth, the development of symptoms *de novo* is a more frequent occurrence. Obstetric trauma is the most common cause of FI. However, the onset of symptoms may occur many years after delivery with a peak incidence in the perimenopausal years. This may reflect the effect of contributory factors such as aging, the effect of menopause or progression of neuropathy. This section focuses on the association between obstetric trauma and FI. The term 'anal incontinence' is used to include incontinence to flatus, liquid and solids.

Anal incontinence (AI) has been reported to occur between 5 [2,3] to 26 [4] percent of women during the first year following vaginal delivery. In a Canadian study [5] involving 949 consecutive women who delivered vaginally, 26% reported AI while 3% reported FI. They identified forceps delivery and third/fourth degree tears as independent risk factors. In a population based study of 8774 women in Oregon, USA, more than 25% reported FI within 6 months of childbirth [6].

The prevalence of anal incontinence among women who sustained OASIS 1–5 years previously has been found to be 18–53% for flatus and 3–23% for stools [7-11]. Among parous women without OASIS, the prevalence of incontinence to flatus was 15–32% and incontinence to stools 5–7% at 4–5 years postpartum [7,8]

2. NEUROGENIC TRAUMA

The mechanism that maintains continence is complex and affected by various factors such as mental function, lack of a compliant rectal reservoir, rectal hypersensitivity, enhanced colonic transit and changes in stool consistency and volume. However, the ultimate barrier is the anal sphincter. AI may ensue if there is mechanical disruption to the anal sphincter muscles, disturbance in neurological function or a combination of both factors. In about 80% of women with presumed "idiopathic" anorectal incontinence there is histological evidence of denervation of the striated pelvic floor muscles, particularly the puborectalis and external anal sphincter (EAS) [12]. This feature has also been demonstrated electro-physiologically by means of an increased fibre density in patients with idiopathic FI indicating re-innervation following denervation [13]. Another finding in these patients is a conduction delay in pudendal nerves as measured by pudendal nerve terminal motor latency (PNTML) [14].

Hertz in 1909 suggested that pelvic floor damage may result from a normal vaginal delivery, objective scientific evidence for this was only produced in 1984 [15] and a follow-up of 14 patients 5 years later [16.]. These authors studied 122 women, 71 after delivery with manometry, perineometry, PNTML and EMG, and 51 before and after delivery with EMG. This study demonstrated an increase in anal sphincter striated muscle fibre density in the vaginal delivery group at 2 months post-partum indicating evidence of re-innervation following denervation. The fibre density was not altered following elective caesarean section. Thirty three percent of primiparae and 50% of multiparae had prolonged PNTML within 48 hours of delivery. However, by 2 months, the PNTML had returned to normal in 60% of these women, indicating that damage to pudendal nerve conduction is reversible. Multiparity, forceps delivery, increased duration of the second stage of labour, third degree perineal tears and high birth weight were important factors leading to pudendal nerve damage. In the five year follow-up study of 14 women, only multiparae who did not have a forceps delivery were selected; the denervating process was found to be progressive in the majority of women and 5 women suffered from stress incontinence of urine, 3 of whom were also incontinent to flatus.

In another prospective neurophysiological study, Allen *et al.* [17] studied 96 nulliparous women with EMG, PNTML and vaginal pressure measurements during pelvic floor contraction. They found evidence of re-innervation in the pelvic floor muscles of 80% of primiparae 2 months after vaginal delivery. The only obstetric factors associated with re-innervation were a high birth weight and a longer active stage of labour. Forty five of the original 96 women were studied again 6 years later and they concluded that changes in pelvic floor neurophysiology occur with time and do not appear to be related to further childbearing [18].

A third prospective study [19] measured anal pressures, anal sensation and the perineal plane in 72 antenatal women and repeated 72 hours post-partum and in 41 women 2 months postpartum. Anal sensation was unchanged. Cornes *et al.* [20] measured anal sensation in 96 primiparae within 10 days after delivery and measurements were repeated in 74 women 6 months after delivery. They found that at 6 months anal sensation had returned to normal. Anal sensation remained unchanged after caesarean section. In women who had a torn EAS, only impairment of sensation in the upper anal canal persisted at 6 months. More than half the women who admitted to persistent anal incontinence had normal anal sensation. Chaliha *et al.* [21] measured anal electro-sensitivity before and after childbirth and found it unchanged. Anal sensation in isolation therefore probably plays a minor role in the development of obstetric related faecal incontinence.

A cross-sectional study of 175 women with FI and 19 healthy volunteers [22] concluded that fa

Faecal incontinence in women is mainly associated with mechanical sphincter dysfunction related to either muscle damage or, to a lesser extent, impaired efferent conduction at pudendal nerves. Impaired conduction through afferent anorectal pathways is also very prevalent in women with FI and may play an

important role as a pathophysiological factor and as a potential therapeutic target.

Broens *et al.* [23] reported that the puborectal muscle is able to contract involuntarily during rectal dilatation and described a new regulatory mechanism "puborectal continence reflex", which controls faecal continence by involuntary contraction of the puborectal muscle. It seems to be initiated by dilatation at the level of the puborectal muscle. Presumably, the puborectal continence reflex protects many patients with anal sphincter dysfunctions from faecal incontinence.

Jonker *et al*. [24] showed that voluntary contractions of the puborectal muscle are significantly decreased in patients with pudendal nerve damage, while involuntary contractions of the puborectal muscle are comparable to those of patients without nerve damage. They concluded that the puborectal continence reflex, which controls involuntary contractions of the puborectal muscle, is not regulated by the pudendal nerve. Although there are no relevant studies on women with postpartum faecal incontinence, it is possible that puborectal continence reflex plays a part in faecal continence women with pudendal neuropathy following childbirth.

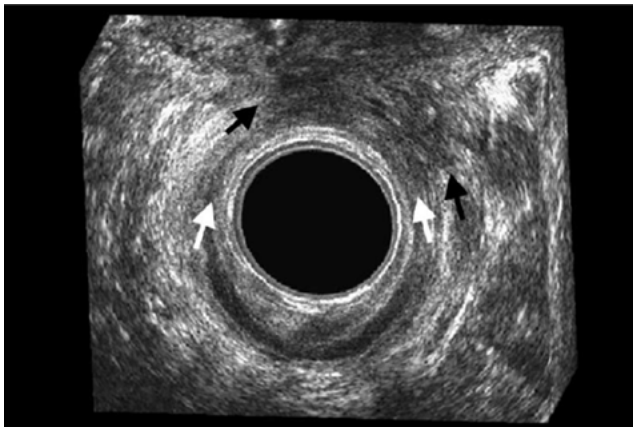

Figure 1: Anal ultrasound image of the mid anal canal. EAS = external anal sphincter. IAS = internal anal sphincter. The area between the black arrows at 11 and 2 o'clock represents an external anal sphincter defect while the area between the white arrows between 9 and 3 represent an internal sphincter defect.

3. MECHANICAL TRAUMA

Until the advent of anal endosonography, mechanical trauma to the anal sphincters was only suspected when there was a history of third or fourth degree tears collectively known as obstetric anal sphincter injuries (OASIs). Consequently, when anal endosonography was performed in patients believed to be suffering from "neurogenic" FI unsuspected internal anal sphincter (IAS) and EAS defects were identified [25]. The sonographic appearance of EAS defects has been verified histologically to represent fibrosis [26.] while the appearance of IAS defects have been validated prospectively in patients undergoing lateral internal anal sphincterotomy [27]. Trauma as identified by ultrasound may represent unrecognised OASIs (previously referred to as occult) or the consequence of recognised and repaired OASIs.

3.1. Unrecognised ("occult") anal sphincter trauma

Sultan *et al.* [2] performed the first prospective study (before and after childbirth) to demonstrate both "occult" anal sphincter trauma (**Figure 10**) and pudendal nerve damage during childbirth in both primiparous and multiparous women (n=150). In 35% of primiparous and 44% of multiparous women anal sphincter defects were identified at 6 weeks postpartum by anal endosonography that were not present before vaginal delivery. Thirteen percent and 23% respectively developed defecatory symptoms (faecal urgency and/or AI) after delivery. Only two of the 150 women (both primiparous) had recognised tears of the anal sphincter at the time of delivery. A strong association was demonstrated between the presence of any defect and the development of symptoms. Only 4% of multiparous women sustained new sphincter damage following a subsequent delivery. The single independent factor associated with anal sphincter damage was forceps delivery. The 23 women delivered by caesarean section remained asymptomatic and none developed sphincter defects. No relationship was demonstrated between PNTML measurements and defecatory or urinary symptoms.

Donnelly *et al.* [28] interviewed 219 nulliparae in the third trimester regarding bowel habits and performed anal vector manometry. At 6 weeks postpartum, 184 women returned and the same bowel symptom questionnaire was completed and anal vector manometry plus PNTML measurements were performed. Anal endosonography was performed in 81 women with altered faecal continence or abnormal physiology. Instrumental vaginal delivery and a passive second stage of labour prolonged by epidural analgesia were significantly associated with the greatest risk of anal sphincter trauma and impaired faecal continence. As instrumental delivery is a known risk factor (8 fold increased risk of sphincter trauma), early use of oxytocin was recommended to shorten the second stage. A continuation of the same study [29.] reported that PNTML was prolonged and the squeeze pressure increment was reduced in women who had a caesarean section in the late first stage (>8cm cervical dilatation) or second stage.

Chaliha *et al.* [21] measured anal sensation and manometry in 286 nulliparae during the third trimester and repeated in 161 women postpartum when anal endosonography was also performed. Anal endosonography revealed sphincter defects in 38% of women and this was associated with the presence a lowering of anal squeeze and resting pressures. Threshold anal electrosensitivity remained unchanged and bore no relationship to symptoms. Postpartum sphincter defects were associated with perineal laceration and vaginal delivery.

Abramowitz *et al.* [30] performed a prospective study of 233 women who had anal endosonography performed before and 6 to 8 weeks after childbirth. Of the 233 women (118 primiparae), 202 had a vaginal delivery. Postpartum AI in the 233 women was reported by 13% of primiparae and 8.5% of multiparae and anal sphincter defects in 21% and 12% respectively. However, the prevalence of anal sphincter defects amongst those who had a vaginal delivery (n=202) was 26% and 13% respectively. Previous studies [31,32] including others mentioned in **Table 3** and **7** have shown that the first delivery is at greatest risk for anal sphincter trauma but this study is at variance as it claimed that secundiparous females have the same risk as primiparous women. However, this finding remains unsubstantiated and is further disputed by a subsequent prospective study [32].

Fynes *et al.* [33.] undertook a prospective study of 59 previously nulliparous women through 2 successive pregnancies and found that 34% had anal sphincter injury after their first delivery but only 2 new injuries occurred after the second delivery confirming the findings in Sultan's study [2.]. An important finding in this study was that 42% of women (5 of 12) who had a severe 'occult' sphincter injury during their first delivery (squeeze pressure increment < 20mmHg or anal sphincter defect > one quadrant) developed AI after the second delivery.

Willis *et al.* [34] performed anal vector manometry, endosonography, PNTML and rectal sensibility at the 32 weeks and 6 weeks postpartum. Using the Kelly-Holschneider score they reported AI in 5% and identified occult injuries in 19%. PNTML and rectal sensibility was unaffected by vaginal delivery.

Nazir *et al.* [35] performed vector manometry and endoanal ultrasound in 73 nulliparous woman at 25 weeks and 5 months postpartum (**Table 3**). There was no correlation between vector manometry and anal endosonography or clinical variables.

Belmonte-Montes [36] performed anal endosonography in 98 nulliparous women 6 weeks before and 6 weeks after delivery and after excluding 20 third degree tears found occult sphincter injuries in 13%. Seventy five percent of women with defects were symptomatic and there was a good correlation between defects and symptoms. However, it is not clear as to how many with 'occult' defects were symptomatic (**Table 3**).

In 3 further studies [37, 40, 41] anal ultrasound was performed only after delivery and defects were identified in 11.5 to 34% (**Table 4**). Varma *et al.* [37] studied 159 postnatal women (105 primiparous and 54 secundiparous) and found occult anal sphincter defects in 11.5% of primiparous and 19% of secundiparous vaginal deliveries but 80% of forceps deliveries. None of their patients suffered FI but only 72% of questionnaires were returned. However, their cohort was recruited before 1998 and had a high caesarean section rate (25%) and a low forceps rate (4%).

Williams *et al.* [42] performed a prospective study in 45 nulliparous women before and after vaginal delivery using 3 dimensional endosonography. There was evidence of perineal trauma in 29% (external sphincter 11%, puboanalis 20%, transverse perineal muscle 7%). Sudoł-Szopińska *et al.* [43] performed 3 dimensional endoanal ultrasound in 112 primiparous women and found only 2.6% sonographic injuries. However, their obstetric practice was different in that they had a 77% episiotomy rate and a 59% epidural rate.

Oberwalder *et al.* [44.] performed a meta-analysis of 717 vaginal deliveries and found a 26.9% incidence of anal sphincter defects in primiparous women and an 8.5% incidence of new sphincter defects in multiparous women. Although two thirds of these women with "occult" defects were asymptomatic in the postpartum period, the probability of FI associated with a sphincter defect was 76.8 to 82.8%.

Some 15 years after having first coined the term "occult" OASIs based on anal endosonography, Sultan [2] began questioning whether the 28% sonographic anal sphincter defects (**Table 5**) identified some weeks after delivery were really genuine occult defects that were unidentifiable clinically at delivery. They therefore conducted a prospective study [49.] in which 241 women having their first vaginal delivery had their perineum re-examined by an experienced research fellow and endoanal ultrasound was performed immediately after delivery and repeated 7 weeks postpartum. When OASIs were identified by the research fellow, the injuries were confirmed and repaired by the duty registrar or consultant. The prevalence of clinically diagnosed OASIs increased from 11% to 25% (n=59). Every clinically diagnosed injury was identified by postpartum endoanal ultrasound. However, there were three women with sonographic defects in whom the injury was not identified clinically. Two of these had only small IAS defects that were not considered clinically significant. The other was a combined defect of both the IAS and EAS and while this could be classified as an occult tear, it is most probably a tear that was not recognised by the research fellow. At 7 weeks postpartum, no *de novo* defects were identified by ultrasound. This study concluded that virtually all sphincter defects that have previously been designated as "occult" injuries (**Table 5**) were in fact OASIs that could have been identified by a trained clinician [50] and that less than one percent are genuine occult OASIs (if indeed they exist). Interestingly, 87% of midwives and 27% of junior doctors failed

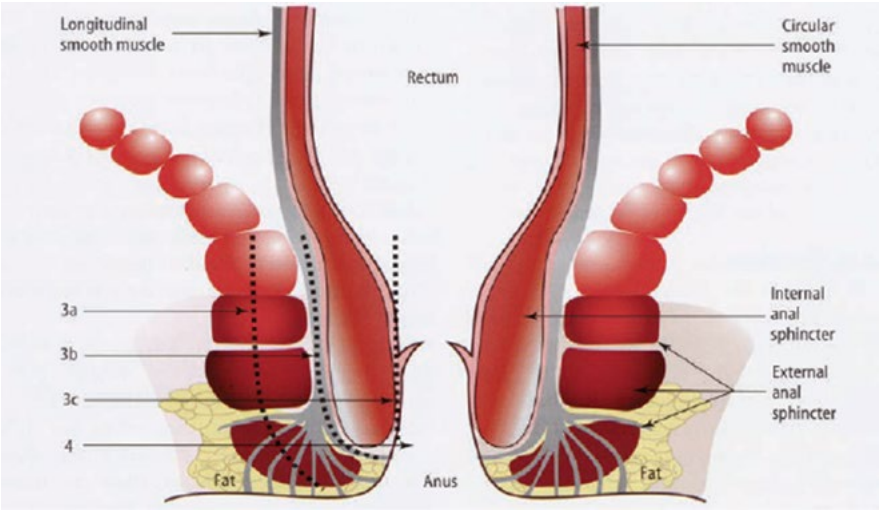

Figure 2: Schematic representation of the classification of 3rd and 4th degree tears (with permission from Springer)

Figure 3: An isolated "buttonhole" tear of the rectal mucosa (arrow) inferior to which is an intact anal sphincter. (From 65. Roper, J.C., Thakar, R. & Sultan, A.H. Isolated rectal buttonhole tears in obstetrics: case series and review of the literature. Int Urogynecol J (2020)

to recognise OASIs clinically. Although it is likely that some of these injuries would have been detected at the time of suturing the tear, it is concerning that clinical recognition of OASIs is suboptimal [50.]. However, this finding is not unique as Groom and Patterson [51] also found that the rate of third degree tears rose to 15% when all "2nd degree tears" were re-examined by a second experienced person.

These studies [49, 51] confirm the lack of adequate training as previously highlighted by Sultan *et al.* [52] who reported that 91% of doctors who had done at least 6 months of training in obstetrics and 60% of midwives indicated inadequate training in perineal anatomy and 84% and 61% respectively reported inadequate training in identifying 3rd degree tears. Another possible reason for under-diagnosis is that tears of the anal sphincter have been wrongly classified and therefore anal sphincter tears have been under-reported. Any involvement of the anal sphincter should be classified as a third degree tear. However 41% of doctors and 16% of midwives classified a torn anal sphincter as a 2nd degree tear [52]. Sultan and Thakar [53] reviewed every relevant text book (n=65) in the library of the Royal College of Obstetricians and Gynaecologists (RCOG) and found that there was a lack of consistency in classification and in about 40% the classification was omitted or wrong. Furthermore, previous classifications were incomplete because they did not incorporate depth of EAS rupture or involvement of the IAS. This therefore has epidemiological, clinical and medicolegal implications. If a third degree tear is incorrectly classified as second degree, then inappropriate repair could result in sub-optimal outcome (see below). Sultan [54] therefore proposed the following classification (**Figure 11**) that has been incorporated into the 29th RCOG green top guidelines

Table 1: Prospective studies before and after vaginal delivery of "occult" anal sphincter injury (using 2d ultrasound) and anal incontinence but excluding fecal urgency.

Study	Parity	Vaginal delivery (n)	FU in weeks postpartum	Sphincter Defects	Anal Incontinence

Table 4: Summary of studies using Sultan classification of OASIS and anal incontinence symptoms score following primary repair.

Authors, year and country	n	FU	Mean AI Score according to degree of OASIS				Questionnaire used and statistical significance
			3a	3b	3c	4th	
Patton et al [68] 2019 Australia	265	6m	1.2	2.1	3.3	2.9	Mean St Mark's score Significant
Ramage et al [69] 2017 UK	117	6-12m	4.1	5.1	5.2	4.6	Mean Wexner score Not significant
*Linneberg et al [70] 2014 Denmark	54	7 Yrs	1	1.5	Not documented	3	Median St Mark's Not significant
*Visscher et al [71] 2014 Netherlands	16	3m	4.4 (combined 3a & 3b)		9.7	-	St Mark's (3a & 3b) v 3c Significant
			3.5 (combined 3a & 3b)		8.3	-	Wexner (3a & 3b) v 3c Significant
*Cerro et al [72] 2017 Spain	95	6m	1.8	1.6	6.7 (3c + 4)		Mean Wexner (3a &3b) v (3c & 4) Significant
*Anglim et al [73] 2019 Ireland	437	12m	0 (0-2) 3a+3b		2 (0-5) 3c+4		Median St Mark's (IQR) Significant
*Roos et al [74] 2010 UK	531	9 w	Faecal urgency - 2.24 (SD, 0.94)		2.04 (SD, 0.94),		Mean Manchester Significant
			Flatus inc (1.95 (SD, 1.14)		1.66 (SD, 0.92),		Significant
			Loose FI 1.12 (SD, 0.44)		1.05 (SD, 0.30),		Significant
			Solid FI (1.04 (SD, 0.25)		1.02 (SD, 0.21),		Not significant

**Linneberg did not document 3c tears where as Vicscher, Cerro, Anglim and Roos combined different degrees of OASIS due to small numbers.*

[55.], adopted by The American College of Obstetricians and Gynecologists (ACOG) [56.] and included in this ICI textbook since it first edition in 2002,:

First degree: laceration of the vaginal epithelium or perineal skin only.

Second degree: involvement of the perineal muscles but not the anal sphincter.

Third degree: disruption of the anal sphincter muscles and this should be further subdivided into:

3a: <50% thickness of external sphincter torn.

3b: >50% thickness of external sphincter torn.

3c: internal sphincter torn also.

Fourth degree: a third degree tear with disruption of the anal epithelium.

Isolated tears of the rectal mucosa without involvement of the anal sphincter (Figure…) is a rare event but the true incidence is not reported. By definition, it is not a fourth-degree tear because the anal sphincter muscles are not torn and therefore should not be labelled as such. It can also occur concurrently with an OASIS, i.e. an isolated rectal tear occurs in conjunction with a separate tear involving the anal sphincter. However, this is extremely rare. Usually, the presentation is with an intact perineum at delivery or a first/second-degree tear, and consequently it can remain undiagnosed, without a structured and careful combined vaginal and rectal examination [65] If unrecognised and therefore unrepaired, a rectovaginal fistula can persist [66,67].

Since the introduction of new classification in 1999 there have been several studies looked at the anal incontinence rates with 3a, 3b, 3c and 4th degree tears. Table 6 summarises the anal incontinence rates with different degrees of OASIS

Table 6 shows that except for Ramage *et al.* [69] and Linneberg *et al.* [70] all the other studies which used the Sultan classification showed a significantly worse Anal Incontinence score with higher degrees of OASIs.

Ramalingam and Monga [108] analysed 255 patients' symptoms at 6 months classified according to the Sultan classification. Twenty-three patients (9 %) reported symptoms at 6-month follow-up. Eight patients reported anal incontinence of liquid or solid stool. Among patients who sustained 3a tears, 8 patients were symptomatic: 7 had urgency and 1 had flatus incontinence. None of the patients who sustained 3a tears reported incontinence of solid/liquid stool. They concluded that as the vast majority of patients are asymptomatic irrespective of the degree of OASIs, with effective primary care follow-up, there may be a place to follow up patients with 3a tears in the community during the routine 6- week postnatal check and refer the symptomatic patients to the hospital for further review.

Reid *et al.* [109] analysed 344 women who had OASIs classified using the Sultan classification followed up at 3 years showed that compared to 9 weeks, there was a significant improvement in urgency and flatus incontinence for both minor (3a & 3b) and major tears (3c & 4) at 3 years. There was no significant change in presence of faecal incontinence in women sustaining minor and major tears. However, they did find that 10% of women developed symptoms for the first time between these two time periods and all these women had persistent sphincter defects

A meta-analysis of 103 studies involving 16,110 women [110] showed that in those who delivered vaginally, OASIS were diagnosed on ultrasound in 26 % (95 %CI, 21–30, I 2 = 91 %), and 19 % experienced anal incontinence (95 %CI,14–25, I 2 = 92 %). In women without clinical suspicion of OASIS (n = 3688), sphincter defects were observed in 13 % (10–17, I 2 = 89 %) and anal incontinence experienced by 14 % (95 % CI: 6–24, I 2 = 95 %). Following primary repair of OASIS, 55 % (46–63, I 2 = 98 %) of 7549 women had persistent sphincter defects with 38 % experiencing anal incontinence (33–43, I 2 = 92 %). There was a significant association between ultrasound diagnosed OASIS and anal incontinence (RR 3.74, 2.176.45, I 2 = 98 %). However this meta analysis did not specify the type of OASIS classification used.

4. RECOGNISED OBSTETRIC ANAL SPHINCTER INJURIES

4.1. Introduction

The rate of OASIs is increasing and in England alone there has been a 3 fold increase between 2000 and 2012 from 1.8 to 5.9% in primiparous vaginal deliveries [57]. This has been attributed to improvements in understanding anal sphincter anatomy and clinical diagnosis [50]. Primary repair of OASIs are usually performed by obstetricians using the end-to-end repair technique [58]. However, as shown in **Table 5**, AI occurs in 37% (range 10 to 67%) and in addition, urgency can affect a further 6 [58] to 28% [59]. Frank FI affected 12% (range 2 to 42%). The reasons for persistent symptoms are unclear but there are at least six studies [58, 59, 61, 63, 64, 76.] demonstrating anal sphincter defects following repair in 40 to 91% of women. Although the extent of the sphincter injury appears to be related to outcome of repair, in some studies (**Table 5**) the data was not interpretable [77], incomplete [76] or inclusive of symptoms other than anal incontinence [79]. Nulliparity, instrumental delivery especially forceps without episiotomy, large baby >4 kg, shoulder dystocia and a persistent occipito-posterior position and prolonged second stage of labour have been identified as the main risk factors for the development of OASIs [30, 31, 55, 58, 75].

Traditionally, the technique described to repair the torn anal mucosa (4th degree tear) was to insert interrupted sutures with the knot tied within the anal canal [58]. However, this was recommended when catgut was in use to minimise tissue reaction and infection. With the availability of polyglactin suture material this is no longer necessary as it dissolves by hydrolysis. Figure of eight sutures should be avoided during repair of the anal mucosa as they can cause ischaemia and therefore a continuous non-locking suture is adequate [58].

The most popular method of EAS repair is the end-to-end technique, but colorectal surgeons prefer the overlap technique for secondary repair because of a better outcome [111]. Similar to other operations for incontinence, the outcome can deteriorate with time and one study has reported continence in 50% of women at 5-year follow-up [112]. However, at least one third of women in this study had more than one attempt at sphincter repair and therefore these findings cannot be extrapolated to that following primary repair of acute injury [112]. In 1999,

Sultan *et al.* [111] were the first to explore the feasibility of the overlap technique of repair for acute EAS rupture but more importantly advocated the identification and separate repair of the torn IAS [55]. Until then, very little importance was given to the torn IAS during primary repair. However, subsequently in a study involving 500 consecutive women with OASIs it has been shown that sonographic evidence of IAS injury was predictive of FI [113]. Roos *et al.* [114] studied 531 consecutive women with OASIs and found that women who sustained an IAS tear were significantly more likely to suffer incontinence, have lower anal pressures, persistent IAS defects and a reduced quality of life. Increasing IAS defect size has also been shown to be related to symptoms of AI [92]. Reid *et al.* [115] performed a prospective study using validated outcome measures at 9 weeks and 3.2 years after primary repair involving 539 women with OASIs. All those who had an internal sphincter injury were classified as major tears (including 4th degree tears). There was no significant difference in outcome between minor and major tears in relation to urgency (10%), flatus (7%) or FI (0.9%). In fact there was a significant improvement in symptoms over time confirming that good outcomes can be achieved when the internal sphincter is repaired as a primary procedure. Oude Lohuis *et al.* [59] have shown that only 10% (26 of the 29) of women who sustained internal anal sphincter injuries (3c and 4th degree tears) had no persistent internal sphincter defects at 3 months follow up indicating adequate repair. Dickinson *et al.* [116] followed up 136 women who sustained OASIs (25 women sustained 3c/4th degree tears) and found internal sphincter defects in 32% of women but this could have included undiagnosed internal sphincter injuries.

When a patient presents with FI months or years after delivery, it is almost impossible to perform a successful IAS repair, highlighting the importance of identification and repair immediately after delivery [62, 111]. Compared to matched historical controls [58] who had an end-to-end repair, Sultan *et al.* [111] found that the rate of AI was reduced from 41% to 8% when the overlap technique was used for EAS repair with separate repair of the torn IAS [111] and therefore recommended the performance of a randomized controlled trial.

The first published randomised trial by Fitzpatrick *et al.* [61] reported no significant difference between end-to-end and overlap repair although there appeared to be trend towards more symptoms in the end-to-end group. However, there were methodological differences in that the torn IAS was not identified and repaired separately and they used a constipating agent for 3 days after the repair. Unfortunately, they included partial EAS tears in their randomised study. A true overlap [62, 111] is not possible if the sphincter ends are not completely divided and it would be expected that if an overlap is attempted, the residual intact sphincter muscle would have to curl up and hence there would be undue tension on the remaining torn ends of muscle that would be overlapped. This technique would therefore go against the general principles of surgery of deliberately placing tissue under avoidable tension [55, 62].

Garcia *et al.* [98] also performed a randomized trial of the two techniques and took great care to include only complete ruptures of the EAS (full thickness 3b,3c and 4th degree tears). There were 23 women in the end-to-end group and 18 in the overlap group. Unfortunately, only 15 and 11 women respectively returned for follow-up which was only at 3 months. No significant difference was found between the groups in terms of symptoms of FI or transperineal ultrasound findings. However, the authors have acknowledged that the major limitations of their study were that the randomization process was flawed and that their study was underpowered.

Williams *et al.* [117] performed a factorial randomized controlled trial (n=112) in which women were randomized into 4 groups: overlap with polyglactin (Vicryl; Ethicon, Edinburgh, UK); end-to-end repair with Vicryl; overlap repair with polydiaxanone (PDS; Ethicon, Edinburgh, UK); end-to-end repair with PDS. This trial was specifically designed to test the hypothesis regarding suture related morbidity (need for suture removal due to pain, suture migration or dyspareunia) using the two techniques. At six weeks, there were no differences in suture related morbidity. The authors claimed that there were no differences in outcome based on repair technique. Unfortunately, the majority of patients included in this trial were partial tears of the EAS (70% were 3a tears) and as mentioned above, a true overlap [62, 111] cannot be performed if the EAS is only partially torn. Furthermore, their follow up rate at 12 months was only 54%. This data therefore needs to be interpreted by caution.

Fernando *et al.* [118] performed a randomised controlled trial of end-to-end vs overlap technique. The study had adequate power (n=64) and the primary outcome was FI at one year. All repairs were performed by two trained operators and Grade 3a EAS were excluded. At 12 months (81% follow-up rate), 24% in the end-to-end and none in the overlap group reported FI (p=0.009). Faecal urgency at 12 months was reported by 32% in the end-to-end and 3.7% in the overlap group (p=0.02). There were no significant differences in dyspareunia and quality of life between the groups. At 12 months 20% reported perineal pain in the end-to-end and none in the overlap group (p=0.04). During the 12 months period 16% in end-to-end and none in the overlap group reported deterioration of defecatory symptoms (p=0.01). Further calculation revealed that four women need to be treated with the overlap technique to prevent one woman with OASIs developing FI. On the basis of this randomized trial it would appear that the overlap technique of EAS repair accompanied by separate repair of the torn internal sphincter, performed by trained clinicians is associated with a good outcome. In 2006, the Cochrane review [98] concluded that as the surgeon's experience was not addressed in two of the three randomised studies, it would be inappropriate to recommend one type of repair over the other.

Farrell *et al.* [119] performed a randomised controlled trial with a 6 month follow-up of end-to-end (n=62) vs overlap (n=63) EAS repair in primiparous women. They reported significantly higher rates of flatal but not FI in the overlap group. However, there were more 4th degree tears in the overlap group and therefore more IAS injury that could explain the increased flatal incontinence in this group [120]. At 3 year follow up there was no significant difference in AI between the groups [121]. This supports the findings of Fernando *et al.* [118, 122] who demonstrated a significantly higher risk of deterioration in AI over time in the end-to-end group and highlights the importance of longer term follow-up.

Rygh and Korner [123] performed another randomized controlled trial (n=101) with the primary outcome measure 'of at least weekly solid stool incontinence'. They concluded that the overlap technique was not superior to the end-to-end repair. However, there were more women with symptoms of AI with the end-to-end repair (34% vs 20%).

The Cochrane Review concluded, "The data available show that at one-year follow-up, immediate primary overlap repair of the external anal sphincter compared with immediate primary end-to-end repair appears to be associated with lower risks of developing faecal urgency and anal incontinence symptoms. At the end of 36 months there appears to be no difference in flatus or faecal incontinence between the two techniques. However, since this evidence is based on only two small trials, more research evidence is needed in order to confirm or refute these findings" [122]. Although there are indications from two studies [92, 121] that compared to the end-to-end technique, the overlap technique appears to be more robust over time, longer term follow up of a larger cohort is required.

More recently, 3 and 4 dimensional transperineal ultrasound techniques have been used to image the anal sphincter and 40% residual defects were identified following OASIs repair and levator avulsion in 17% [46].

4.2. Management of subsequent pregnancy after OASIs

All women who sustained OASIs should be assessed in hospital by a senior obstetrician 6 to 12 weeks after delivery. Some centres have established dedicated multidiscliplinary perineal clinics. In a survey conducted in 2010 [124], 30% of hospitals in the UK had such a dedicated clinic. It is important that a comprehensive history is taken regarding bowel, bladder and sexual function. As these symptoms are embarrassing, a structured questionnaire may be useful. A proper vaginal and rectal examination should be performed to check for complete healing, scar tenderness and sphincter tone [49, 62, 125]. Mild incontinence (faecal urgency, flatus incontinence, infrequent soiling) may be controlled with dietary advice, constipating agents (Loperamide or Codeine Phosphate), physiotherapy or biofeedback. However, women who have severe incontinence should, in addition, be offered secondary sphincter repair by a colorectal surgeon. Asymptomatic women must be advised to return if symptoms develop [62].

It is known that the risk of recurrence of anal sphincter injury in centres that practice mediolateral episiotomy is 4.4% [126, 109] to 7.1% [127 ,128]. Two large cohort studies showed the rate of recurrent OASIs to be 7.2% -10% [129] for women who had previously sustained OASIS during their first vaginal delivery, compared with a rate of 1.3% for women who did not sustain OASIS [130]

The management of a subsequent pregnancy after OASIs has been largely based on obstetrician opinion. It has been suggested that a caesarean section should be performed even after transient anal incontinence· but this has been questioned [131].

In order to counsel women with previous OASIs appropriately, Sultan *et al.* [62] find it useful to have a symptom questionnaire, anal ultrasound (**Figure 10**) and manometry results (**Figure 13**). It has been shown that clinical assessment alone has a poor sensitivity for detecting anal sphincter defects [132]. If vaginal delivery is contemplated then these tests should be performed during the current pregnancy unless performed previously and found to be normal. In a prospective study over a 5 year period, Scheer *et al.* [128] followed the protocol shown in **Figure 13** and found that when women who had no evidence of significant anal sphincter compromise based on anal endosonography and manometry were allowed a vaginal delivery (the others were offered caesarean section) there was no deterioration in symptoms, anorectal function or quality of life. Other units have also reported favourable outcomes when vaginal delivery and caesarean section were offered on selected criteria [133, 134, . 135]. Although 11% of textbooks recommend a prophylactic episiotomy [53] there is limited evidence that an elective episiotomy prevents subsequent anal sphincter disruption [90] while other studies have indicated that episiotomy may increase the prevalence of anal sphincter disruption. However, there is no study that has been done evaluating outcome in subsequent pregnancies in which the angle of episiotomy has been controlled for [136].

A RCT by Abramowitz *et al.* [137] where 222 women who had a 3rd degree tear and / or a forceps delivery in their first pregnancy with no symptoms of anal incontinence were randomised to have a vaginal birth or a planned caesarean section. The authors concluded that a caesarean section had no significant impact on anal continence 6 months after the second delivery in women with asymptomatic obstetric anal sphincter lesions diagnosed by ultrasound. However, in this study 49 of 222 women had OASIs diagnosed and repaired at the time of delivery and the rest were detected by endoanal ultrasound scan subsequently. In addition, the patients did not undergo anal manometry. In effect the RCT by Abramowitz does not fit in to the criteria recommended by the RCOG and difficult to make any recommendations.

A study of 74 women who sustained a 4th degree tear and a review of subsequent deliveries following previous OASIS by Taithongchai [138] concluded that as there are only a few units offer specialist investigations to their OASI cohort, it would be reasonable to offer caesarean section to all women who have sustained a fourth-degree tear and not base this on presence of symptoms alone. However, in centres where EAUS and AM are available, clinicians should offer these investigations for more individualized counselling. The women would need to understand the short- and long-term risks, including the recovery period of each mode of delivery, as well as the fact that a caesarean section would be a recurring indication for all subsequent pregnancies.

Women who have had a successful secondary sphincter repair for FI should be delivered by caesarean section [139]. Some women with FI may choose to complete their family prior to embarking on anal sphincter surgery. It would appear that these women could be allowed a vaginal delivery as the damage to the sphincter has already occurred and risk of further damage is minimal and probably insignificant in terms of outcome of surgery. The risk of worsening or *de novo* neuropathy has not been quantified and in practice, does not appear to be clinically significant.

5. INSTRUMENTAL VAGINAL DELIVERY

Although only 4% of women delivered by forceps sustain a 3rd/4th degree tear, up to 50% of those that do tear have an instrumental delivery [58]. Vacuum extraction is associated with fewer OASIs than forceps and this view is supported by two large, randomized studies [140, 141]. A UK study [140] where mediolateral episiotomy is practised reported severe vaginal lacerations in 17% of forceps compared to 11% of vacuum deliveries and a Canadian study [141] where midline episiotomy is practised reported OASIs in 29% of forceps compared to 12% of vacuum deliveries.

In a Cochrane review [142], forceps were less likely than the vacuum extractor to fail to achieve a vaginal birth (risk ratio 0.65, 95% confidence interval (CI) 0.45 to 0.94). However, with forceps there was a trend to more caesarean sections, and significantly more third- or fourth-degree tears (with or without episiotomy), vaginal trauma, use of general anaesthesia, and flatus incontinence or altered continence. [143]. Compared to vacuum delivery, 'occult' trauma to the anal sphincter has been identified more frequently in forceps delivery occurring in up to 80 percent of women [2, 37, 144]. A small randomized study (n=44) confirmed this by identifying occult anal sphincter defects in 79% of forceps compared to 40% of vacuum deliveries. Trauma occurs more frequently when a second instrument is used to attempt vaginal delivery [144] and therefore if no descent of the head occurs following appropriate cup selection and application technique of vacuum extraction, one should resort to a caesarean section. Metal cups appear to be more suitable for 'occipito-posterior', transverse and difficult 'occipito-anterior' position deliveries [145]. The soft cups seem to be appropriate for straight forward deliveries as they are significantly more likely to fail to achieve vaginal delivery. There was no difference between the two groups in terms of maternal injury. Farrell *et al.* [146] performed a prospective study of 690 primigravid women and found that forceps delivery was associated with a higher incidence of flatal incontinence (RR 2.6) compared to spontaneous vaginal delivery and a higher incidence of both flatal (RR 2.6) and faecal (RR 938.6) incontinence compared to caesarean delivery. Vacuum delivery did not increase the risk of flatus incontinence. MacArthur *et al.* [3] performed the largest questionnaire based multicentre study to establish the prevalence of FI at 3 months post-partum. They reported a prevalence of 9.2%, with 4.2% reporting it more often than rarely. Compared to vacuum extraction, forceps delivery was associated with almost twice the risk of developing FI. Thakar and Eason [147] performed a meta-analysis and demonstrated that one anal sphincter injury is avoided for every 18 women delivered by vacuum extraction instead of forceps. De Leeuw *et al.* [49] have shown that when a mediolateral episiotomy is performed during a forceps delivery, the risk of anal sphincter injury is reduced by almost 80%.

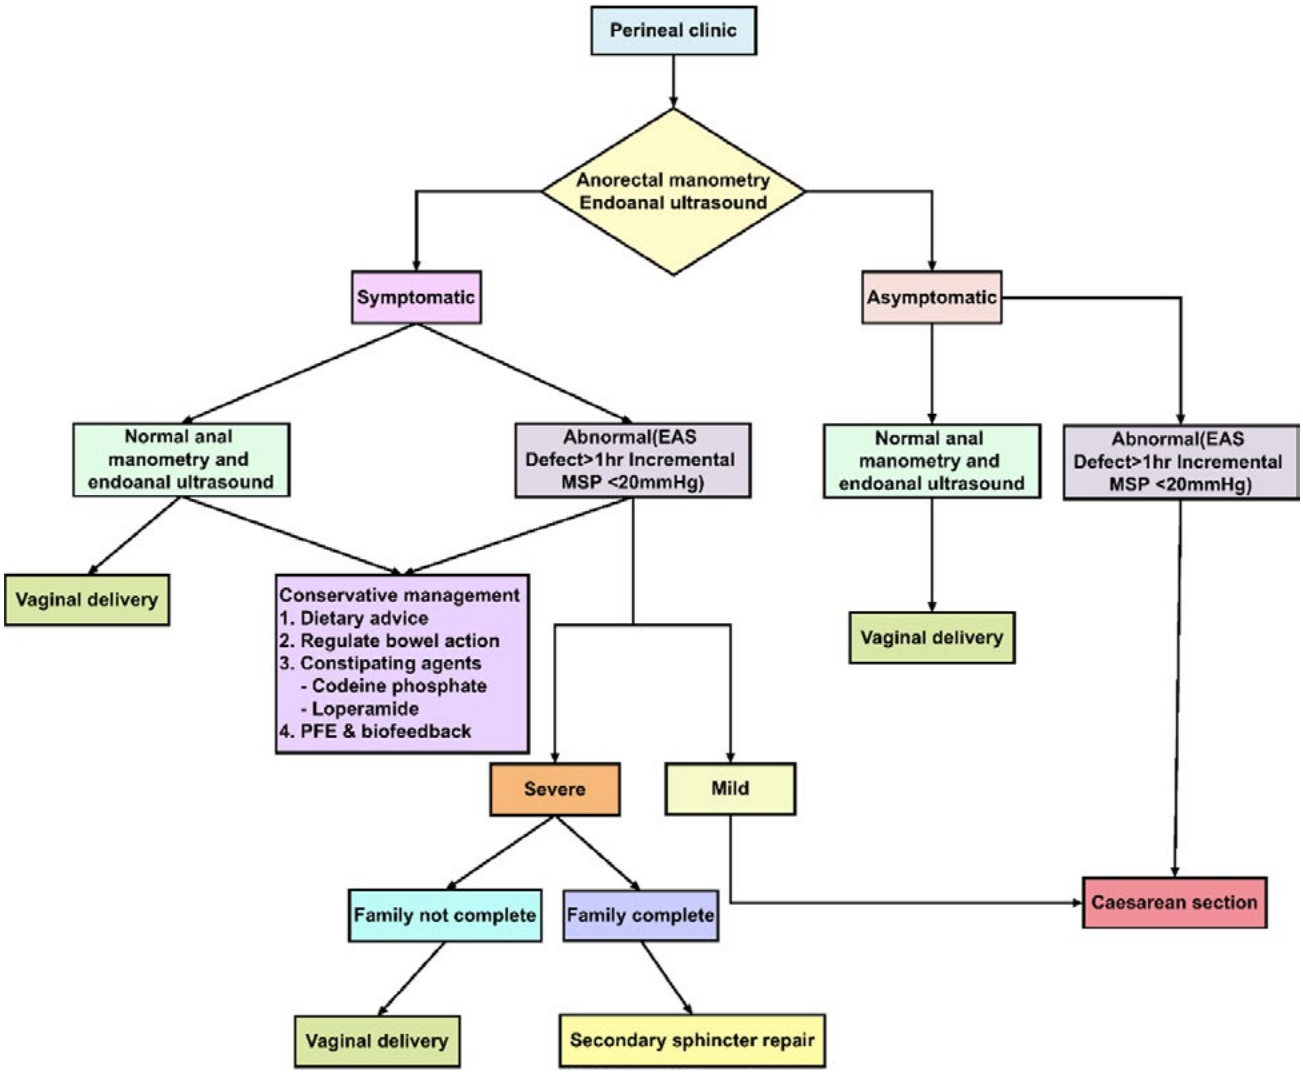

Figure 4. Flow chart demonstrating the Croydon pathway of the management of a subsequent pregnancy following OASIs (EAS = External Anal Pressure; MSP= maximum squeeze pressure)

The occipito-posterior position at delivery is a known risk factor for the development of a third degree tear and the risk of anal sphincter injury doubles with a vacuum delivery but trebles with the forceps [149]. It is strongly recommended that a liberal episiotomy should be performed in the presence of an occipito posterior position. When the baby's head is in the occipito-posterior position the diameter presenting at the outlet is larger than that of an occipito-anterior position. Therefore, it is more likely to cause a delay in progress and also more likely to result in a more extensive perineal tear particularly with an instrumental delivery.

5.1. Episiotomy

Observational data indicate that a reduction in episiotomy rate is not associated with an increase in OASIs. The Cochrane database [150] shows that restricting the use of episiotomy is associated with less posterior trauma. Although there was an increase in anterior perineal trauma it had no effect on the development of urinary incontinence. Henrikssen *et al.* [151, 152] performed an observational study in which they noted that when midwives who previously had a high episiotomy rate reduced their rate, the prevalence of OASIs also reduced. However, this beneficial effect was abolished when midwives with a low rate of episiotomy attempted to reduce it even further. Based on this evidence, it was suggested that the ideal episiotomy rate should lie between 20 to 30% and no more. Midline episiotomies are more popular in North America as it is believed that they are more comfortable, and recovery is less complicated. However, Coats *et al.* [153] performed a quasi-randomised study of 407 primiparae and found 24% of midline episiotomies extended into the anal sphincter (partial or complete tears) compared to 9% of mediolateral episiotomies. Although the perineum was significantly less bruised in the midline group and sexual intercourse commenced earlier, pain and wound breakdown was similar in both groups. Kudish *et al.* (154) performed an observational study in the USA of 46 239 singleton vertex vaginal deliveries and identified two modifiable risk factors for severe perineal trauma, namely, midline episiotomies and forceps delivery. They recommended the use of vacuum extraction and mediolateral episiotomy [154]. However, care needs to be taken to ensure that mediolateral episiotomies are performed correctly as Andrews *et al.* [155] have shown that only 22% of doctors and no midwife made the incision commencing from the posterior fourchette with a 40 to 60 degree angle from the midline. Another study demonstrated that for every six degrees away from the midline there was a 50% reduction in OASIs [156]. It has also been shown that the angle of incision when the head is crowning is underestimated such that a 60-degree angle measures 45 degrees after delivery [157].

Naidu *et al*. have shown that doctors and midwives were poor at cutting at the prompted episiotomy angle of 60° [158]. This highlights the need to develop structured training programmes to improve the visual accuracy of estimating angles or the use of fixed angle devices to help improve the ability to estimate the desired angle. There is evidence that the Episcissors 60 does cut at a 60-degree angle and its introduction in obstetric units is associated with a reduction in OASIs in nulliparous women undergoing spontaneous vaginal deliveries [136].

6. DELIVERY TECHINIQUES

Pirhonen *et al.* [159] compared the frequency of OASIs in low risk deliveries between two Scandinavian countries (26 541 vaginal deliveries) and found the risk to be 13 times higher in Sweden (Malmo) *vs* Finland (Turku). They speculated that the only explanation for this was a difference in manual support given to the baby's head during crowning and pushing the perineum under the chin. Jonsson *et al.* [160] performed a randomised trial between the Ritgen's manoeuvre and standard delivery but found no significant difference in OASIS rates. However, only 50% of the elligible women were assigned and almost 20% of the women randomized to the Ritgen's manoeuvre did not have this method of delivery. Hals *et al.* [161] provided the best available evidence, showing how an interventional programme in four Norwegian hospitals can reduce the frequency of OASIs. The programme involved a 2-3 day course at the delivery suite of each hospital that included training on delivery with perineal support and delivery of the neonate's chin. In addition, restrictive mediolateral/ lateral episiotomy was recommended. OASIs rates reduced from 4.16-5.25% before intervention to 1.73% during the last year of intervention. The following interventions with randomized controlled trials evidence regarding effectiveness demonstrated no effect on OASI: antenatal perineal massage, pelvic floor exercises in pregnancy, water births, positions during labour and birth, epidural analgesia, early vs delayed pushing with epidural and second stage pushing advice [1056]. Although one small randomized trial showed otherwise [5] other large observational studies, have shown that duration of the second stage of labour is an independent risk factor for the occurrence of OASIS [28, 31, 55, 161, 162].

6.1. Training

McLennan *et al.* [163] surveyed 1177 fourth year residents and found that the majority had received no formal training in pelvic floor anatomy, episiotomy or perineal repair and that supervision during perineal repair was limited. Stepp *et al*. found that textbooks used in American practice offered little in terms of prevention and repair of perineal trauma. [164] There is evidence from one study that perineal anatomy is poorly understood by midwives and trainee doctors, who perform the bulk of deliveries in the UK. [48] In this study, 41% of trainees and 16% of midwives incorrectly classified a partial or complete tear of the EAS as 'second degree'. Inconsistency in classification of tears would allow many injuries to pass unrecognised. In another USA study, the majority of residents demonstrated substandard skill in repairing OASIs [164]. It has been shown that hands-on workshops on perineal repair, such as that at (www.perineum.net) can change practice [165-168]. Intensive and focused training in perineal anatomy and repair should therefore become an essential module in the programme for trainees and midwives.

6.2. Inflammatory bowel disease (IBD)

The inflammatory bowel diseases (IBD), ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory diseases that commonly affect people of childbearing age [169] .The prevalence of IBD appears to be increasing worldwide, although the prevalence varies according to country and ethnicity.

A prospective study of 57 women, 17 (29.8 %) with ulcerative colitis, 23 (40.4 %) with Crohn's disease, and 17 (29.8 %) healthy controls showed that the incidence of postpartum anal incontinence is comparable across all groups; there was no statistically significant difference between the IBD and control groups. Postpartum anal incontinence was strongly correlated with the extent of perineal injury ($r = 0.80$; $p < 0.0001$). [170]

Donnelly *et al.* [171] recruited 312 primiparous women and reported that 11% of young primiparous women (n= 34 of 208) suffered from pre-existing IBS prior to their first pregnancy. Twenty four percent reported symptoms of impaired faecal con-

tinence in the puerperium but symptoms were found significantly more frequently in those with IBS compared to those with normal bowel habit (71% vs 18%). Women suffering from IBS were no more likely to incur mechanical or neurological injury to the anal sphincter. Women with IBS delivered by caesarean section did not have altered continence postpartum. However, 6 months postpartum there were no symptomatic differences between those with IBS and those without but only 90 of the 107 women who had either impaired faecal continence or abnormal anal manometry were studied. Treatment is directed towards the predominant symptom and although antispasmodics such as hyoscine, mebeverine and dicyclomine are used widely to relax intestinal smooth muscle, they should be avoided during pregnancy. Robinson *et al.* used validated questionnaires and bowel symptom diaries and found that the symptoms of urgency and diarrhoea in women with irritable bowel syndrome amplify the risk of anal FI in women who have sustained OASIs [172].

6.3. Evidence synthesis

a) Compared to forceps, the vacuum extractor is associated with less perineal and anal sphincter trauma. (LoE 1)

b) Compared to midline episiotomy, mediolateral episiotomy is associated with a significantly lower risk of 3rd/4th degree tears (LoE 1)

c) Liberal use of episiotomy is not beneficial (Level 1) and restricting the rate of episiotomy to about 30% may reduce the risk of trauma to the anal sphincter (LoE 4)

d) A prolonged active second stage of labour is associated with denervation of the pelvic floor and one study has suggested that this also occurs with a prolonged passive second stage of labour with epidural analgesia. In these circumstances, early use of oxytocics in the second stage of labour may be useful. (LoE 4)

e) Selective use of caesarean section may be beneficial, particularly in those who have evidence of compromised anal sphincter function and those who have had previous successful continence or prolapse surgery. (LoE4)

f) Modification in techniques of delivery of the baby, particularly appropriate perineal support ,may reduce anal sphincter injury ompared to midline episiotomy. (LoE 3)

g) A more focused training programme for doctors and midwives needs to implemented. There is a poor understanding of perineal and anal sphincter anatomy and hence identification of anal sphincter trauma, incorrect classification and poor outcome of repair (LoE4)

h) There is increasing evidence supporting the identification and repair of the internal anal sphincter. Outcomes of epair techniques of the external sphincter (overlap versus the end-to-end) for full thickness tears are inconclusive and more long term research is needed (LoE1)

VIII. PATHOPHYSIOLOGY OF FAECAL INCONTINENCE

1. INTRODUCTION

Faecal continence is maintained by a complex, incompletely understood process involving the structural and functional integrity of the anorectal unit, the central and peripheral nervous system and pelvic structures. Continence requires a closed anal canal at rest, sensory function to detect the presence of flatus or stool in the rectum, intact reflex response of the appropriate muscles, cognitive recognition of the sensory signal, adequate storage capacity in the rectum and adequate function of the puborectalis and sphincter muscles. In addition, other factors such as stool consistency and physical mobility play a role. Disruption in the normal anatomy or physiology in any of these areas may lead to incontinence. Most often multiple factors are contributing in patients with significant faecal incontinence.[1-6]

2. STRUCTURE AND FUNCTION OF THE ANORECTUM

The anus is a muscular tube 2 cm to 4 cm long consisting of the internal anal sphincter, conjoined longitudinal muscle, external anal sphincter and puborectalis muscle. [7]

2.1. Muscles

2.1.1. Internal anal sphincter (IAS)

The internal anal sphincter (IAS), an involuntary smooth muscle, is a 0.3 cm to 0.5 cm thick expansion of the circular smooth muscle layer of the rectum. The IAS ends about 10 mm proximal

to the distal end of the external sphincter. It is primarily responsible for closure of the anal canal at rest through both myogenic and sympathetic excitatory activity. Studies disagree about the relative contribution of myogenic and nerve induced activity to the resting tone. [8, 9] The IAS generates slow pressure waves occurring 6-20 times per minute; about 10 % of asymptomatic people also have ultra-slow waves with pressures fluctuating between 20 mmHg and 50 mmHg. [10-12]. The internal anal sphincter contains non-adrenergic, non-cholinergic (NANC) fibres which contribute to contraction of the muscle mediated by nitric oxide. [13-15] Recent research focuses on the role the interstitial cells of Cajal as the generators of the slow waves which result in phasic contraction.[16-23] Other animal studies have focused on the cellular regulation of basal tone in the IAS. Up regulation of RhoA/Rho kinase in the smooth muscle cells of the IAS plays a significant role in the maintenance of the basal tone.[24] The RhoA/Rho kinase components are responsible for the inhibition of myosin light-chain phosphatase of resulting in a high level of myosin regulatory light chain. [25] At present the relative role of pure tonic contraction versus phasic contraction in inducing tone in the IAS is uncertain.

2.1.2. External anal sphincter (EAS)

The external anal sphincter, a 0.6 cm to 1.0 cm thick cylinder of striated muscle, covers the whole length of the internal sphincter and extends more distally into the subcutaneous tissue. The external sphincter contributes to the resting tone. Its primary function, however, is to contract to preserve continence when stool or flatus is present in the rectum or intra-abdominal pressure increases. The contraction may be voluntary or reflexive with increased abdominal pressure from coughing or distension.[26] The muscle also relaxes to facilitate evacuation. The separation of the external sphincter into sections is controversial. [27] Many authors describe three sections termed superficial, subcutaneous and deep but they have also been described as subcutaneous, main body and deep winged portion based upon MRI imaging.[28, 29] On MRI images, the subcutaneous portion is visibly distinct from the other portions with less clear separation between the middle and deeper portions.[28] Others argue the EAS functions as a single muscle unit. [30, 31] The EAS is a predominantly slow-twitch, fatigue resistant muscle with a majority of Type I fibres although there are also Type II rapidly contracting fibres as well. [32, 33] .

2.1.3. Conjoined longitudinal muscle

The outer longitudinal muscle layer of the rectal wall joins with fibres of the levator ani muscle to become the conjoined longitudinal muscle; it is primarily striated muscle with a few fibres of smooth muscle. [34] The muscle extends distally between the internal and external anal sphincter and then splits into extensions that traverse the superficial portion of the external sphincter to attach to the perianal skin and medially through the internal anal sphincter to join the submucosa smooth muscle.[35] Proposed roles for this muscle include provision of supporting meshwork for the anal sphincters and assistance in maintaining anal closure. The functional role is suggested by the differential response of the longitudinal muscle to neurotransmitters when compared to the internal anal sphincter. [15] Another possible role is that contraction of the muscle flattens the anal cushions and shortens the anal canal. [36]

2.1.4. Puborectalis muscle (PR)

The puborectalis muscle, the most medial portion of the levator ani muscle, is a U-shaped loop of striated muscle that encircles the anorectal junction and attaches to the posterior aspect of the pubis. The puborectalis muscle is a mixture of Type I and Type II fibres but has fewer Type II fibres than the EAS. [37] It functions to close the upper anal canal.[38, 39] It is situated immediately cephalad to the external sphincter. The configuration of the puborectalis muscle results in the anorectal angle between the distal rectum and anal canal. At rest, the anal canal forms an angle with the axis of the rectum of approximately 90°; during voluntary squeeze the angle becomes more acute, approximately 70°; during defecation, the angle becomes more obtuse, about 110° to 130°. Some data support the concept that the PR is part of the levator ani muscle (embryology, in vitro stimulation studies, innervation)[40-46] while other information suggests that it is part of the external anal sphincter (anatomic dissection, function during cough and straining [31, 47, 48] The puborectalis muscle responds increased abdominal pressure (coughing or straining) and rectal distension by contraction.

2.1.5. Levator ani

The levator ani muscles are a pair of broad sheets of striated muscle lying below the pelvic organs. There are three major components with different attachments. The iliococcygeus muscle arises from the ischial spine and attaches to the lateral aspect of the lower sacrum and coccyx. The pubococcygeus muscle runs from the posterior aspect of the pubis, mixes with fibres from the contralateral muscle at the anococcygeal raphe and inserts at the distal sacrum and coccyx. The third component is the puborectalis muscle which is described above. The urethra, vagina and rectum pass through an opening between the levator ani muscles called the levator hiatus.

2.2. Nerve structure and sensation

The somatic nerve supply arises from the second, third and fourth sacral spinal segments. The lower motor neuronal cell bodies for those nerves are located in Onuf's nucleus of those sacral spinal segments. The primary nerve is the pudendal nerve which has both motor and sensory functions.[49]. The pudendal nerve divides into three main branches. One branch, the inferior rectal nerve, supplies the external sphincter. The levator muscles including the puborectalis receive innervation directly from those spinal segments.[43, 44, 46, 50] However, ,the puborectalis muscle frequently receives an auxiliary supply from the inferior rectal and perineal branches of the pudendal nerve on its inferior aspect.[51] Both the EAS and levator ani muscles may be controlled voluntarily through corticospinal descending motor pathways.[37] They are also under reflex control through sacral reflex pathways. Pudendal nerve block creates a loss of sensation in the perianal and genital skin and weakness of the anal sphincter muscle, but it does not affect rectal sensation [52] It also abolishes the rectoanal contractile reflexes, suggesting that pudendal neuropathy may affect the rectoanal contractile reflex response.

The anorectum also has a rich nervous supply through enteric, sympathetic, parasympathetic and extrinsic spinal sensory neurons. Enteric motor neurons control most aspects of rectal motility; parasympathetic and sympathetic influence is mediated largely through modulation of the enteric neuronal circuits. [53] Within the myenteric plexuses there are motor, sensory and interneurons. The sympathetic supply of the rectum arises from the first three lumbar spinal segments. The innervation is carried through the preaortic plexus to the upper rectum and through the presacral nerves to the hypogastric plexus and then through the hypogastric nerves to the pelvic plexus. The parasympathetic fibres originate in the sacral parasympathetic nucleus in the sacral spinal cord and emerge through the sacral

foramen as the nervi erigentes. They join the sympathetic fibres at the pelvic plexus and pass-through rectal nerves to the rectal wall. The parasympathetic pathways have a role in propulsive activity of the colon and defaecation.

Extrinsic sensory innervation of the rectum seems to be responsible for sensory perception of rectal distension. Sacral afferents have cell bodies in the dorsal root ganglia of the sacral segments. Specialized sacral afferents have mechano-sensitive transduction sites within the myenteric ganglia of the rectum.[54, 55] These intraganglionic laminar endings are sensitive to distension and contraction of surrounding muscle layers. [56] Both thinly myelinated A fibres and unmyelinated C fibres are present in the rectal mucosa, and the myenteric plexus [57-60] The C fibres are mostly present in the wall of the rectum while the A fibres predominate in the rectal mucosa.[60] These nerves most likely mediate the distension or stretch-induced sensory responses as well as the viscero-visceral, [61] the recto-anal inhibitory, and the recto-anal contractile reflexes [59]. The sensation of rectal distension is most likely transmitted along the S2, S3, and S4 parasympathetic nerves [59] Clinical studies confirm that balloon distension is perceived in the rectum and that such perception plays a role in maintaining continence. [62, 63] Furthermore, sensory conditioning can improve hyposensitivity [64, 65] of the rectum.

Distal rectal and upper anal canal sensation is carried in the inferior rectal branch of the pudendal nerve. The upper anal canal particularly has a rich mixture of free and organized nerve endings such as the Krause end-bulbs,(cold) Goigi-Mazzoni bodies (pressure), genital corpuscles (friction), and the sparse Meissner's corpuscles (touch) [59, 66, 67] Specialized afferent nerves may exist that transmit the sensations of touch, temperature, tension, and friction, but are incompletely understood. [59] The role of anorectal temperature sensation is subject to debate. [68-72] The likely role of anal sensation is to facilitate discrimination between flatus and faeces and reflex maintenance of continence.

All of the sensory nerves reach the spinal cord through the mesorectum and then the brain to achieve perception. [73]The pudendal nerves run below the pelvic floor muscles and the remaining nerves above. The nerves are vulnerable to compression and stretching of the pelvic floor at that location.

2.3. Cerebral cortex

Rectal distension produces activation bilaterally in the secondary somatosensory cortex, sensory association cortex, the anterior cingulate cortex and insular cortex, as well as bilateral activation in the prefrontal cortex and extending from the peri-orbital cortex to the anterior temporal lobe. [74-78] Studies have identified activation in multiple areas of the cortex including those involved in spatial discrimination (secondary somatosensory cortex, sensory association cortex) and those that process affective and cognitive aspects of sensation (the anterior cingulate cortex, insula and prefrontal cortex.). While rectal and anorectal stimulation activated similar regions of the brain the locations within the regions varied. [79] Anal musculature is represented bilaterally on the superior motor cortex (Brodmann area 4); the degree of symmetry varies.[80]

2.4. Reflexes

Distension of the rectum results in contraction of the rectum, relaxation of the internal anal sphincter and contraction of the external anal sphincter.

2.4.1. Rectoanal inhibitory reflex (RAIR)

Rectal distension is associated with a fall in anal resting pressure known as the rectoanal inhibitory reflex. The amplitude and duration of this relaxation increases with the volume of rectal distension. [81] It has been suggested that bowel contents are periodically sensed by anorectal "sampling," [82-84] the process by which transient relaxation of the IAS allows the rectal contents from the rectum to come into contact with specialized sensory organs. This process allows discrimination between flatus and stool.

2.4.2. Cough reflex

Abrupt increases in intra-abdominal pressure, such as those caused by coughing or laughing, are associated with increases in anal sphincter pressure. [26, 85-88] The increased pressure may be achieved through multiple mechanisms, including reflex contraction of the puborectalis. [89] The response is relative to the intensity of the cough.[85]. It is unclear whether the response is a polysynaptic spinal reflex [26, 86] since it is preserved after spinal cord transection [90] or also requires central integrative centres. [87]

2.4.3. Rectoanal contractile reflex (sensori-motor response)

The rectoanal contractile reflex (or rectal anal excitatory reflex or inflation reflex) is the contraction of the EAS in response to rectal distension.[91-93] The amplitude and duration of the rectoanal contractile reflex increases with rectal distension up to a maximum volume of 30 ml [81]. This reflex persists despite damage to the pudendal nerve and does not change with age. [94]

2.4.4. Puborectal continence reflex

A reflex similar to the rectoanal reflex occurs with the puborectalis muscle. [95] While voluntary contractions of the muscle diminish with pudendal nerve damage, the involuntary contraction reflex does not. [96] Recent evidence suggests that the rectoanal reflex assists in control of both solid and liquid stool but the puborectal reflex contributes to continence of solid stool only. [97]

2.5. Rectum

The rectum is a hollow muscular tube, 12 cm to 15 cm long, composed of a continuous layer of longitudinal muscle that interlaces with the underlying circular muscle. These muscles are a mixture of smooth muscle cells and several types of interstitial cell of Cajal.[53] A network of interstitial cells of Cajal joined by gap junction connections coupled to smooth muscle cells trigger mechanisms that give rise to large, slow repetitive depolarization of the smooth muscle, the slow waves.[98] The proximal end is defined either as the sacral promontory, the third sacral vertebrae or the area where the colonic taenie splay out and end. The distal end is the dentate line or anorectal ring. The rectum serves as a reservoir for storage and a "pump" for evacuation of stool facilitated by several characteristics. The rectal walls are compliant maintaining a relatively low pressure with increasing volumes. Its innervation allows the sensation of increasing volume.[1, 53]

2.6. Rectosigmoid junction

Currently there is no standardized definition of the rectosigmoid junction. The possibility of a functional sphincter at the rectosigmoid junction has been debated for years. [99, 100] Recent manometry studies of healthy volunteers identified an intermittent high-pressure band at the rectosigmoid junction that relaxes or contracts in response to a high-pressure propagating wave

in concert with relaxation or contraction of the anal sphincter. [101] Lin and colleagues reviewed the existing evidence of a "rectosigmoid brake" in 2017.[102]

2.7. Anal endovascular cushions

The submucosa of the anal lining contains blood vessels, connective tissue, smooth muscle and elastic tissue. They typically form three separate complexes of smooth muscle fibres and vascular channels called the anal cushions.[103, 104] A study of women demonstrated the normal variation in size; the size did vary with posture and parity but not age, history of obstetrical trauma or mild haemorrhoid symptoms. [105] Differences between asymptomatic women and incontinent women were identified. Their contribution to continence is poorly studied and controversial.

2.8. Stool consistency

Considerable evidence exists that evacuation of formed stool is more easily deferred than loose stool (discussed in detail under diarrhoea). While theories exist about the reason, physiological proof is not available.

2.9. Physical mobility

The ability to defer evacuation until a socially acceptable time and place requires the physical mobility to reach a bathroom in the required time frame. The contribution of physical mobility to continence is largely inferred from studies identifying lack of physical mobility as a risk factor for incontinence.[106-108] There is limited information about the relative role for mobility in continent patients.

3. CONTINENCE MECHANISM

Complete continence depends upon normal transit of formed stool, anal closure at rest, sufficient reservoir capacity and sensation in the rectum, functional reflexes for sampling and sphincter contraction, adequate cognitive function to recognize the urge to defaecate and physical mobility to reach the bathroom in time.

The anus is normally closed by the tonic activity of the IAS with contribution from the EAS and PR at different levels of the anal canal. [39, 109]. Studies of the relative contribution of the IAS to the resting tone yield results varying from 55-85 % [9, 52] Some of that variation is likely related to the measurement technique utilized but it has also been found that resting pressure varies during the day [110] and with posture, increasing with the upright position. [111] The IAS contribution is also influenced by rectal distension. [52, 112] Some postulate that the anal cushions provide a tight seal based upon studies showing that the sphincter muscles in their circular configuration cannot contract sufficiently to provide complete closure. [113, 114]. An in vitro study showed that even during maximal involuntary contraction, the internal sphincter ring was unable to close the anal orifice completely and a gap of approximately 7 mm was left open. This gap was filled by the anal cushions.[115] Anal cushions may exert pressures of up to 9 mmHg and thereby may contribute 10% to 20% of resting anal pressure. [116] These barriers are further augmented by the puborectalis muscle, which pulls the anal canal forward forming the anorectal angle. The extent to which the anorectal angle contributes to continence is controversial.[109, 117-121] One study suggests that it is important to the control of semi-solid material more than the control of liquid.[122]

With rectal distension or increased intra-abdominal pressure, this barrier is reinforced by reflex or voluntary contraction of the EAS and PR. The contraction requires functional peripheral, spinal and cerebral function to sense and recognize the distension, as well as activate the reflex and voluntary responses. In addition, adequate muscular contraction to increase the anal pressure is required. The rectal wall must distend to allow accommodation to the increased pressure. Finally, the mobility to reach an appropriate setting before the muscle fatigues is required.

4. DEVELOPMENT OF INCONTINENCE

Faecal incontinence occurs when one or more mechanisms that maintain continence is disrupted to an extent that other mechanisms are unable to compensate. Hence, faecal incontinence is often multi-factorial.[1-5] In a prospective study, 80% of patients with faecal incontinence had more than one pathogenic abnormality. [2] The interaction of those factors and timing of the development of clinical incontinence is poorly understood.

Clinically, patients may have urgency, passive or mixed incontinence. A recent systematic review found that urgency incontinence was more frequent than passive.[123] However, the authors noted a lack of homogeneity in the definition of each type and lack of availability of validated instruments for research and limited studies of the mixed group. In most studies, the squeeze pressures were higher in the passive incontinence group but other testing results were discordant or the same. A retrospective study published since that review reported on the finding of dynamic ultrasounds in 145 patients with either urgency, mixed or passive faecal incontinence.[124] Sphincter defects were equally present in all groups. The urgency dominant group had a higher rate of loss of rectal support on Valsalva as measured by the dynamic ultrasound. Other investigators studied the role of postprandial and fasting retrograde colonic activity and found differences in patients with urgency incontinence compared to normal controls.[125, 126]

4.1. Passive incontinence

Compromise of anal closure and loss of sensation may result in soiling or incontinence without awareness. Prolapsing tissue (either mucosal or full thickness rectal prolapse, rectal lesions) prevents closure of the anus. Some believe that resection of the anal cushions may result in passive incontinence. [114] Injury secondary to trauma, surgery or childbirth and weakness of the IAS are other causes. IAS atrophy occurs in systemic sclerosis and likely contributes to faecal incontinence [127, 128] although neuropathy also appears to be a contributing factor. [129]. Loss of sensation occurs from peripheral neuropathy, spinal cord and cerebral cortex events or after transection of the nerve supply by surgical or other trauma. Increasing evidence suggests that rectal hyposensitivity significantly contributes to passive incontinence.[130-134] Interestingly faecal seepage in men occurs despite normal anorectal physiology testing. [130, 135, 136]

4.2. Urgency incontinence

Incontinence occurs when the ability to hold stool or flatus is overwhelmed. If the rectum cannot distend to hold stool or the muscles do not contract adequately incontinence results. Changes in the reservoir function of the rectum from disease processes, radiation therapy or surgical resection limit the abil-

ity of the rectum to distend to hold stool. Pelvic floor muscle dysfunction may result from direct injury causing a defect or weakness. Obstetric trauma is the most common cause of injury to internal and external sphincter muscles. The puborectalis and levator ani muscles may also be injured and the presence of defects appears to correlate with poor contractility and symptoms in several studies. [137-141] Major levator ani muscle injuries are more frequent in women with EAS obstetric injuries and those with combined injures are more likely to be symptomatic.[139] However, other investigators found no relationship between the presence of levator ani injuries and faecal incontinence. [142, 143]. Weakness of intact sphincter muscles may develop secondary to aging or neurological dysfunction.

Rectal hypersensitivity, a lower threshold for the urge to defecate, also contributes to urgency incontinence. [3, 4, 125, 144-147] Complex, poorly understood mechanisms mediate rectal hypersensitivity. Variables include decreased compliance, increased sensitivity of extrinsic peripheral pathways or central afferent mechanisms.[145]

5. RISK FACTORS FOR FAECAL INCONTINENCE

Many events and conditions impact the mechanisms of continence often in multiple ways. The next section covers the conditions that most frequently contribute to incontinence.

5.1. Aging

Multiple studies document the increasing incidence of faecal incontinence in association with with age in both men and women. [5, 148-154] One study of community dwelling women found that 70% of incontinence developed after the age of 40. [155] Another study of women in the United States documented an initial 15% prevalence of incontinence in women over 50 years old and onset rate of 7% over the next 10 years. [156]

While the rising incidence is well documented, understanding of the physiological impact of aging is less clear. Conflicting evidence exists about the effect of aging on anal resting pressure. While a number of studies report decreased anal resting pressures in older continent and incontinent adults [146, 157-160], some found lower pressures in patients with incontinence but not asymptomatic older adults.[161, 162] Increased thickness of the internal anal sphincter is associated with aging [146, 163-166]; the finding is thought to represent increased fibrosis although that hypothesis is not proven. Animal studies of smooth muscle contraction demonstrate decreased contractility with aging. [167] Studies of the internal sphincters of aging animals found changes in translocation of signaling molecules as well association and phosphorylation of contractile proteins. [167] Other investigators focus on the role of aging related oxidative stress through the RhoA/Rock pathway as a cause of decreased tone. [168]
